Most minor facial injuries do not interfere with sports participation. However, certain eye conditions preclude participation in contact sports. These conditions include having only one functional eye, severe myopia, Marfan syndrome, and previous retinal detachment. Some eye injuries, such as a hyphema (blood in the eye), require bed rest for several days. For any eye injury, the eye should be painfree and have adequate recovery of vision prior to resumption of sport.

Any facial injury requiring surgery requires appropriate recovery time prior to return to sport. Appropriate facial safety equipment should be worn on return to sport.

Family Doctor

The family doctor, formerly referred to as the *general practitioner,* has the unique role of caring for patients of both sexes over their entire life span, from the cradle to the grave. As a generalist, the family doctor comes equipped with a broad medical knowledge base and skill set that grants him or her the tools to provide comprehensive medical care, both acute and chronic. Included among these tools is training in preventive care, pediatrics, geriatrics, psychiatry, and the nonsurgical treatment of musculoskeletal injury. The possession of this training background helps explain why the family doctor is well suited to care for the athlete well beyond primary treatment of acute injury, in the distinctive role of comprehensive care sports medicine physician.

Defining the Family Physician

To best understand why the modern family doctor is well positioned to care for the athlete, it is helpful to first examine the official definition of family physician. The American Academy of Family Physicians (AAFP) defines *family physician* as

> a physician who is educated and trained in family medicine—a broadly encompassing medical specialty. Family physicians possess unique attitudes, skills, and knowledge, which qualify them to provide continuing and comprehensive medical care, health maintenance and preventive services to each member of the family regardless of sex, age, or type of problem, be it biological, behavioral, or social. These specialists, because of their background and interactions with the family, are best qualified to serve as each patient's advocate in all health-related matters, including the appropriate use of consultants, health services, and community resources.

Simply translated, the family doctor is trained to care for the whole person throughout his or her life, both physically and emotionally, in the context of the patient's medical history, family dynamics, and social standing in the community.

Further defined, the family doctor has a primary role as the patient's health care coordinator. This role begins with the first contact, when the physician is in a unique position to form a bond with the patient. Thereafter, in the event that a medical condition is beyond the treatment capabilities of the family doctor, he or she will function as the patient's means of entry into the health care system through referral to the appropriate specialist. Beyond this action, the family doctor continues as the health care coordinator in an effort to prevent fragmentation of care along the continuum. Acting on the desire to always optimize patient health, the family doctor serves a vital role as the patient's advocate in dealing with other entities including insurance companies, employers, teachers, and, in the patient who is an athlete, coaches and trainers.

Family doctors are often referred to as primary care physicians. It is important to understand, however, that while "primary care" encompasses the type of services most often provided by family doctors, the terms *primary care* and *family medicine* are not interchangeable. In light of the preceding description and the discussion to follow, it will become evident that "primary care" is but one of the services provided by family doctors.

Comprehensive Care of the Athlete: An Illustration

As an example designed to illustrate the unique role the family doctor serves in providing comprehensive, multidimensional care to the athlete, consider the following scenario.

Patient *X* is a high school senior and captain of the football team. A star linebacker, *X* has sustained three concussions to date, the last of which had occurred midseason in the junior year and was severe enough to ultimately end his season. His family doctor, Dr. *S,* possesses additional training in sports medicine and concussion management and has a mutually respectful relationship with the team physician. Dr. *S* was the initial examiner after all *X*'s concussions, coordinating emergency diagnostics and arranging office follow-up in each case. Trusted implicitly by *A*'s parents, who are also his patients, Dr. *S* applied the latest standard in concussion care, including adherence to strict return-to-play guidelines. When Dr. *S* informed *X*'s coach last season that *X* should sit out or risk serious sequelae in the event of a repeat concussion, the coach stated that he must have his star player back in the lineup to better their chances of getting to the play-offs. Acting in the interest of his patient's health and well-being, Dr. *S* refused to grant return-to-play, which in turn led to the coach's insistence on a second opinion. Dr. *S,* knowing both that the coach would request referral to the local neurologist and that this neurologist did not embrace neurocognitive testing, which is an inherent part of current evidence-based concussion care standards, advised *X*'s parents against the referral. At the same time, readily acknowledging his limitations and that he was not a brain injury expert, Dr. *S* suggested a neurologist from another hospital whom he knew to be up on concussion care standards. Dr. *S,* who also serves as the school health adviser, arranged education sessions on concussion for all athletic staff, parents, and students while also ensuring that all district high schools had neurocognitive testing capabilities.

Subsequent to the junior year concussion, *X* endured significant academic difficulties, prompting Dr. *S* to talk with his teachers, advocating on his behalf for necessary classroom accommodations. Among the postconcussion symptoms demonstrated by *X* were difficulty concentrating, chronic headache, insomnia, and severe depression. Despite good compliance with the indicated medications, *X* turned to drugs and alcohol in an effort to "better cope" with his distressing circumstances. The situation became even bleaker after it was determined through further evaluation just prior to the start of the senior year that *X* still exhibited significant cognitive deficits. Playing football again would prove very risky, and Dr. *S* advised against it. *X,* who not long before was being recruited by Division 1 football teams, began expressing suicidal thoughts, prompting Dr. *S* to arrange inpatient psychiatric care.

X overcame the crisis and has since established regular care with a therapist. Dr. *S* sat with *X* and his parents and had a frank discussion about his future. He made it a point to discuss the way concussion and its sequelae can profoundly affect every aspect of an individual's conscious existence. Dr. *S* encouraged *X* and his family to discuss the situation with their pastor, and he referred them to a psychologist as well as directing them to community support groups and online traumatic brain injury resources. Dr. *S* continued to see *X* regularly, following his concussion to resolution. *X*'s insurance company initially refused to pay for much of the concussion care but overturned their decision following a comprehensive letter from Dr. *S*.

Vital Functions

Among the many key points of this illustration, two stand out: (1) the family doctor's indispensable role as "comprehensive care coordinator" and (2) the realization that athletic injury, when significant, may have consequences well beyond mere tissue trauma. The family doctor is eminently equipped to both recognize and manage these consequences. The process begins with the initial patient contact, which in the case of the athlete is typically the preparticipation exam (PPE). Beyond the requisite physical information gained during a PPE, a well-trained family doctor determines the psychosocial setting in which the patient exists. For example, understanding the patient's family dynamics, support system, and academic ability may prove helpful during subsequent visits in understanding what contributes to disease states above and beyond acute musculoskeletal injury.

At the core of family medicine, and a key component of comprehensive care of the athlete, is health promotion and injury/illness prevention. These practices are driven by the family doctor's sworn duty to optimize health status while simultaneously minimizing injury risk. Apart from instruction in proper conditioning and safe exercise practices, general health promotion/preventive care measures include exercise prescription, nutrition counseling, screening for mental illness, and risk factor management. The latter practice generally refers to the identification and management of those factors that contribute to the development of coronary artery disease. In the case of the young athlete having a PPE, the family doctor strives to identify risky health behaviors over a broad spectrum of categories. These include drug, alcohol, and tobacco abuse; high-risk sexual practices; pathogenic weight control behaviors; and use of performance enhancement drugs. It becomes important for physician and athlete to work together in not allowing the focus to fall exclusively on acute issues surrounding a specific sport at the cost of losing sight of these preventive care measures.

Finally, looking beyond care of the school-age athlete, the family doctor is exceptionally well equipped to manage the vast array of general medical problems found in athletes of any age or sex, ranging from diabetes to exercise-induced asthma to headache. Likewise, the family doctor is prepared to diagnose and treat the medical problems of athletes in "special" populations. For example, in the mature athlete an understanding of the physiologic changes of aging is important when adjusting an exercise prescription. Among female athletes, counseling the pregnant athlete or treating the female triad poses another challenge for which the family doctor is well prepared. Knowledge may be further enhanced through the option of fellowship training in sports medicine available to doctors in any branch of primary care medicine but most often pursued by the family doctor.

Fat in the Athlete's Diet

Fat is an important energy substrate for athletes. It provides 9 kilocalories of energy per gram (kcal/g). It is body fuel for low-intensity, longer-duration exercise. About half of the total energy expenditure is derived from free fatty acid metabolism in moderate-intensity, long-duration exercise greater than 1 hour in length. Fat may contribute as much as 75% of the energy demand during prolonged aerobic work in the endurance-trained athlete. Fat is also essential for the absorption of certain vitamins. The most important role of dietary fat is to spare the use of carbohydrates during low-intensity, longer-duration exercise. In general, the true role of fats in exercise has not been well studied and is not well understood; therefore, further research is necessary.

Dietary Content

A diet with inadequate fat content can decrease muscle mass from lowered serum testosterone levels. Conversely, a diet high in fat can cause gastrointestinal discomfort before or during exercise as well as increasing fat stores despite exercise. Over time, too much fat can lead to heart disease, obesity, cancer, and other health problems. Fat intake for athletes, as well as healthy adults and children, should make up less than 30% of the total calories ingested. Fats in the diet may be of animal or vegetable origin. Selecting lean meats and nonfat or low-fat dairy products and limiting added fats such as butter, margarine, salad dressing, cream sauces, gravies, and fried foods will help achieve this goal.

Trained athletes use fat for energy more efficiently than untrained athletes because of their higher fat oxidative capacity due to increased enzyme levels, fatty acid transport, and beta oxidation, which spares the use of glycogen during endurance sports. Therefore, even endurance athletes generally do not require excess fat in the diet because they are metabolically more efficient. Even lean athletes generally have sufficient endogenous body fat stores to meet the metabolic demands of endurance and strenuous exercise. Consuming fat in a precompetition meal 2 hours or less before exercise should be generally avoided. There is evidence that the rate of fat metabolism may be accelerated by ingesting caffeine prior to and during endurance performance.

Types of Dietary Fat

Saturated fats are found primarily in animal sources such as meat, egg yolks, yogurt, cheese, butter, and milk. This type of fat is characterized by being solid at room temperature. Health problems such as heart disease, high cholesterol, and obesity have been linked to excessive dietary intake of saturated fats. Because of this, saturated fat should be limited to no more than 10% of total daily calorie intake.

Unsaturated fats include monounsaturated and polyunsaturated fats, which are typically found in plant food sources. This type of fat is characterized by being liquid at room temperature. Unsaturated fats have health benefits such as lowering cholesterol and reducing the risk of heart disease. Common food sources include olive and canola oil, fish, nuts, avocados, soybeans, and flaxseed.

Trans fats are created (naturally or artificially) when an unsaturated fat is made into a solid. Consumption of trans fats, like saturated fat, should be limited because they increase cholesterol levels and the risk of heart disease. The product content of trans fats has recently been added to many products' nutrition labels, thus allowing the consumer to make better dietary choices with regard to fat intake (Table 1).

Weight Loss

If an athlete desires to lose weight, it is reasonable to make sure that there is a reasonably low intake of dietary fat. If there is too much fat in the diet, then lowering fat intake may be beneficial in weight loss as the overall caloric intake will decrease readily. However, for athletes who pursue or achieve rapid weight loss, frequently this reflects mostly fluid weight loss despite dietary restriction of fat. Rapid weight loss issues are often found in weight class sports such as wrestling. Concerns about fluid weight loss include increased risks of dehydration and heat illness. Truly rapid fat weight loss is usually only achieved through excessive caloric restriction, which also can have negative consequences on an athlete's health and sports performance. Weight loss that will effectively decrease total body fat in an athlete must be achieved over time and with careful attention to overall dietary habits.

Weight Gain

There are some athletes who desire weight gain, usually those who would benefit from being stronger to compete in their sport or who need to gain weight to meet a desired weight class requirement. Usually, the desired weight gain is associated with gains in lean body mass, not fat mass, although this can be challenging. Gains in lean body mass can be advantageous for sports as improvements in strength and power are achieved. Gaining muscle weight can affect the body's resting metabolic rate and may adversely affect endurance performance. Gains in fat mass are universally unhelpful for an athlete. Fat mass decreases strength-to-weight ratios and does not improve strength or power. Agility performance, jump height, and endurance performance can also be adversely affected.

Some suggested techniques for gaining weight that emphasize a gain in lean body mass include the following: eat a healthy breakfast, eat frequently (every 2–3 hours), eat high-density foods such as dried fruits and cereals, and drink or cook with milk regularly. A gain of approximately 1.5% of total body weight per week is ideal. Add moderate- to high-intensity resistance exercise workouts 2 to 3 days a week. Make sure that there is adequate protein in the diet (1.5–1.8 g protein per kilogram

Table 1 Getting to Know Your Fats

	Properties	*Effects on Blood Cholesterol*	*Food Sources*
Saturated Fats	• Solids at room temperature • High melting point • Less likely to become rancid	• Increased harmful LDL cholesterol • Increased total cholesterol	• Animal sources—butter, whole milk, cream, cheese, ice cream, and other full fat dairy products; animal meats, lard, poultry skin • Plant sources—coconut oil, palm oils, cocoa butter • Trans fats are created when unsaturated fats are saturated through the process of hydrogenation—stick margarine, shortening, hydrogenated oils
Monounsaturated Fats	• Soft or liquid at room temperature • Lower melting points than saturated fats • May become rancid when exposed to light and oxygen for extended periods of time	• Decreased harmful LDL cholesterol • Minimal change in beneficial HDL cholesterol • Decreased total cholesterol	*(Plants)* • Olive, canola and peanut oils • Olives, peanut butter, nuts • Avocados
Polyunsaturated Fats	• Soft or liquid at room temperature • Lower melting points than saturated fats • May become rancid when exposed to light and oxygen for extended periods of time	• Decreased harmful LDL cholesterol • May decreased beneficial HDL cholesterol • Decreased total cholesterol	*(Types)* • Omega-6 ○ Linolenic acid—vegetable oils (corn, sunflower, safflower, soybean, cottonseed), poultry fat ○ Arachidonic acid—meats (or made from linoleic acid) • Omega-3 ○ Linolenic acid – Oils (flaxseed, canola, walnut, wheat germ, soybean) – Nuts and seeds (butternuts, walnuts, soybean kernels) – Vegetables (soybeans) ○ EPA and DHA—related to the prevention and treatment of heart disease, high blood pressure, arthritis and cancer – Human milk – Shellfish and fish (mackerel, salmon, anchovy, herring, lake trout, sardines, tuna) – Made in the body from linolenic acid

body weight per day). Genetic factors, sex, physiologic maturity, and endogenous anabolic hormone production all affect an athlete's ability to effectively gain lean body mass. Interestingly, children and adolescents generally have higher levels of glycerol in their blood, which results in increased use of free fatty acids during exercise.

Conclusion

Further research and education is needed to fully understand the role of fat in an athlete's diet. At present, it is important to educate athletes with regard to dietary needs, metabolism of fat, and healthy food choices. For those athletes who require additional calories to maintain a healthy energy balance, it is recommended that those calories come from increases primarily in carbohydrates in their diet and less from protein. It is also essential for athletes to maintain adequate fat (approximately 30%) in their diet to maintain overall health and well-being and optimize sports performance.

Female Athlete

Women have made important advancements in sports and athletics over the past half-century. While females did participate in some sporting events, it was not until 1972, with the passing of Title IX of the Educational Assistance Act, that girls and young women in the United States became a strong force in the sports and health fitness arena. In the 2008 Beijing Olympics, more than 42% of the 11,028 participants were women. The International Olympic Committee expects this number to continue to rise. From young girls playing on recreational teams to women's professional leagues, females have proven themselves as capable athletes.

Female participation in athletic activities promotes exercise and a healthy lifestyle, with benefits that extend beyond the playing field. For women, playing sports leads to higher self-esteem, a positive body image, higher rates of both high school and college graduation, decreased drug use, and decreased sexual risk-taking behavior. While the female athlete has shown that she can be an equal competitor to her male counterpart, there are some sports medicine concerns unique to women and girls.

Females do differ from males in skeletal structure, body composition, physiology, and training effects. These differences lead to unique health and injury concerns for the female athlete. Skeletally, males and females are similar until adolescence, when girls begin their growth spurt an average of 2 years earlier than boys. As males and females reach their full height potential, bony differences are apparent between the sexes. These differences include females being smaller and shorter, with a lower peak bone mass, a wider pelvis, femurs that slant inward toward the knees, less bowing in the lower leg, narrower shoulders with more slope, and a wider "carrying angle" of the elbows. The differences in body composition include higher body fat percentage, lower lean body mass, and greater concentration of subcutaneous fat tissue, particularly in the hip and thigh area, in females than in males. Physiologically, women tend to have lower blood volume, less hemoglobin, a smaller heart, lower maximum cardiac output, a smaller thorax, less lung tissue, and less muscle mass, which all effectively lead to increased workload of the cardiovascular and pulmonary systems to perform the same level of exercise as their male counterparts. This can lead to differences in training effects, since women tend to lag behind men in endurance sports performance and tend to be weaker secondary to less muscle mass.

While the injury profile in males and females tends to be similar for acute injuries (fractures, dislocations, contusions, etc.), overuse injuries seem to be more commonly seen in female athletes. Often these types of injuries occur as a result of a lack of conditioning prior to participation in sports. From a young age, females are often less active than males, and when they do start sports activities, it is often at the height of their growth spurt (between ages 11 and 13). For this reason, it is important that females enter sports gradually and with proper conditioning if they have not been particularly active in their younger years (see the entry Strength Training for the Female Athlete).

Two overuse injuries that are commonly seen in females are stress fractures and patellofemoral pain syndrome. Stress fractures are the result of repetitive trauma to the bone causing a series of microfractures. Stress fractures commonly occur in places where bones are more susceptible to repetitive trauma, such as the tibias and feet of runners. While athletes of any skill level may develop stress fractures, they commonly occur in those who have suddenly increased the frequency or intensity of their training. Females are more commonly affected than males due to the hormonal influences of estrogen on bone. Estrogen helps stimulate the hormones that promote bone formation. Therefore, women who are not menstruating regularly may be at increased risk for stress fractures. (For more on the relationship between menstrual irregularities and stress fractures, refer to the entry Female Athlete Triad.)

Patellofemoral pain syndrome is about three times more common in females than in males. Symptoms of this include pain around the patella (kneecap) while walking or climbing stairs and increased pain or stiffness in the knees after periods of prolonged sitting. While no single biomechanical risk factor has been shown to be associated with this pain, there are a number of factors that might contribute to it. Muscle-tendon imbalances across the knee, such as tightness on the lateral thigh (iliotibial band) and weakness on the medial thigh (vastus medialis muscle), may cause the patella to shift with exercise. In addition, women often have a wider pelvis, which can increase the Q angle (the angle at which the femur meets the tibia), causing increased strain on the patellar tendon. Other factors such as inward rotation of the femurs, overly flat or arched feet with pronation while walking or running, and joint laxity can all contribute to this pain. For female athletes who may be predisposed to this condition, it is especially important to maintain proper strength and flexibility to prevent it.

One acute injury that occurs more often in women is a tear of the anterior cruciate ligament (ACL). This is due to a number of factors, including landing dynamics, training insufficiencies, increased laxity with possible hormonal influences, and anatomic differences. ACL injuries are often the result of either a straight knee landing or a sharp change in direction when the foot is planted. Female soccer players are twice as likely to sustain an ACL injury as male soccer players, and female basketball players are as much as five times more likely to sustain an ACL injury as male players.

Females seem to be more susceptible to ACL injuries for a few reasons. Females have less knee and hip flexion with landing, which places more body weight forward and the knee in a more angulated position. Additionally, women often have insufficient conditioning in the stabilizing muscles around the knee, with increased reliance on the ACL and less on the hamstring secondary to quadriceps dominance. While the literature views are mixed on the subject, some research suggests that there is also a hormonal component to ACL injuries, with increased laxity in the ovulatory phase of menstruation leading to an increased risk of injury. Furthermore, female ACLs tend to be smaller in length, cross-sectional area, volume, and mass, which makes them less likely to handle major increases in load.

Prevention programs have focused on increasing the ratio of hamstring to quadriceps strength through traditional stretching and strengthening, incorporating more agility and balance training in workouts, and using plyometrics to enhance joint stability and decrease landing force. Prospective outcome studies of such interventions are under way. It is hoped that as understanding about the causes and prevention of ACL injuries improves, the rates of ACL injuries in females will decrease.

In addition to inherent differences in build and injury profile, hormonal changes with menstruation may affect female athletes. The effect of the menstrual cycle on performance is highly individual. Approximately one third of all female athletes believe that the timing of their menses do affect their performance. However, Olympic gold medals have been won in all phases of the menstrual cycle. (See the entry Menstrual Cycle and Sports Performance.)

Another unique concern in female athletes is the relationship between exercise and pregnancy. Increases in maternal plasma volume that lead to mild anemia, amplification of maternal gas exchange in the fetus, and increased risk of falls due to increased joint laxity and a changed center of gravity all contribute to the importance of modifying activity for the sake of the woman's and baby's health. Women can often exercise safely throughout their pregnancy, as long as they are aware of the warning signs for ceasing activity and do not have any absolute contraindications. Regular aerobic exercising is good for muscle tone, control of body weight, and general well-being throughout pregnancy. In addition, regular moderate activity has no known significant outcome on birth weight or the time of delivery. (See the entry Exercise During Pregnancy and Postpartum.)

Female athletes have come a long way in the sports arena. There are unique considerations for female sports participation and the health of the female athlete. But as girls begin sports activity at an earlier age, with improved conditioning and technique, it is hoped that they will continue to break performance barriers and records while suffering from fewer injuries. We continue to become more knowledgeable about conditions unique to the female athlete, which will only enhance her success.

Female Athlete Triad

Since the passage of Title IX in 1972, female participation in high school athletics has increased by 800%. While such participation has had a remarkably positive impact on girls, women, and sports, some pressures of athletics and training have placed athletic females at risk for overtraining, undereating, menstrual irregularity, low bone mass, and other adverse health consequences. In 1993, the American College of Sports Medicine coined a term, the *female athlete triad* (triad), to refer to a syndrome commonly seen in athletic women. It involves disordered eating, irregular menstrual cycles, and low bone mass. Athletic women with the most extreme form of this disorder have severe eating disorders (e.g., anorexia or bulimia), amenorrhea (absence of menstrual periods), and osteoporosis (low bone density with increased risk of fractures). However, the syndrome is a continuum, and athletes may have one, two, or all three parts of the triad.

Prevalence

Prevalence of the triad in a population of young women athletes is difficult to ascertain as most statistics are obtained from surveys and self-reporting. Women may not want to admit that they have menstrual irregularities or eating disorders. Underreporting is common in such surveys.

The prevalence of amenorrhea in the general population is 3% to 6%. In specific female athlete populations, amenorrhea has ranged from 3.4% to 69%. The prevalence of disordered eating is 5.5% to 9% in the general population, while surveys have shown a prevalence of 15% to 62% in female college athletes and 25% to 31% in female elite athletes.

Disordered Eating

Female athletes may try to lose weight or maintain a low body weight to improve their athletic performance. For example, a runner may try to lose weight to enhance her speed. A dancer may strive to be thin to improve her jumps and to achieve a certain ideal appearance on stage. Athletes are pressured by coaches, teammates, parents, and/or friends to lose a "few extra pounds" to enhance their performance. This can lead to poor body image and unhealthy eating behaviors.

Disordered eating as part of the triad includes restricting the intake of calories and/or certain types of food (e.g., fat). Some athletes have unintentional nutritional deficits because the calories burned during exercise consistently exceed the calories ingested, but the athlete is not aware of this imbalance. In other instances, athletes engage in very distinctive behaviors signifying the severe eating disorders, anorexia nervosa or bulimia nervosa. Athletes may fast, use diet pills, use laxatives or enemas, purge, try fatfree dieting, or even try excessive sweating through layering clothes in hot weather or sitting in saunas. At-risk athletes include those who restrict dietary intake, exercise for prolonged periods of time, or are vegetarian. Regardless of the type of disordered eating or weight control behavior, the nutritional deficit disrupts many hormonal processes in the body.

Amenorrhea

Rapid changes in weight, loss of specific nutrients, and prolonged nutritional deficits can lead to significant menstrual irregularities. Studies in animals and humans show that reduction of energy availability to less than 30 kilocalories/kilogram of fatfree mass (FFM) per day causes dramatic changes in the normal patterns of hormone secretion. Energy availability is calculated using caloric intake, exercise energy expenditure, and FFM. Low energy availability alters the levels of numerous hormones that can affect the menstrual cycle, including luteinizing hormone (LH), insulin, cortisol, growth hormone, insulin-like growth factor 1 (IGF-1), thyroid hormone, leptin, and ghrelin.

Menstrual irregularities in female athletes are caused by disruptions in the normal hormonal signaling between the hypothalamus, pituitary gland, and ovaries. A variety of menstrual abnormalities may occur, including luteal suppression (shortened luteal phase of the menstrual cycle), anovulation (impairment of follicular development), oligomenorrhea (>35 days between cycles), primary amenorrhea (delayed menarche or the absence of menses by age 15 in girls with secondary sex characteristics such as breast development and pubic hair), and secondary amenorrhea (absence of at least three consecutive menstrual cycles after menarche has occurred).

Osteoporosis

Severe nutritional deficits due to disordered eating (including inadequate calcium and vitamin D), low sex hormone levels (including estrogen, progesterone, and testosterone) due to amenorrhea, and high cortisol levels due to stress can all lead to low bone mineral density (BMD). In women, 90% of adult bone mass is acquired by age 16, and peak bone mass is achieved by around age 30. Thus, disruptions in the menstrual cycle during adolescence and early adulthood have a profound effect on bone health and may result in a lost opportunity to attain peak bone mass. Women with low BMD can fracture more easily with minimal trauma. Initially, this may present in a female athlete as repetitive stress fractures. Later in life, debilitating spine and hip fractures may occur.

Diagnosis

In general, screening for the triad should be done in preparticipation exams, in annual health visits, and whenever an athlete seems to exhibit some of the characteristics or consequences of the triad (weight loss, abnormal eating behaviors, stress fractures, etc.).

Information about dietary habits, weight fluctuations, workout routines, menstrual patterns, body image, stresses, and history of fractures should all be obtained. As mentioned previously, athletes may exhibit all or parts of the triad, so when one abnormality is noted, screening for the other two components should be performed.

Some health professionals rely on BMD scans, such as dual-energy X-ray absorptiometry (DXA), to diagnose low BMD. However, these should be interpreted with caution in both adolescents and athletes. Adolescents may not have attained their total peak bone mass, so the results need to be compared with those of adolescents of comparable developmental age—which is based on both chronological age and age at menarche. In general, athletes have higher BMDs than the sedentary controls used as the reference populations for BMD guidelines. Much of the activity athletes engage in involves weight bearing, which can increase bone remodeling and BMD. Thus, if an athlete has a BMD result on the low end of normal compared with the reference population, this may indicate a lower than expected value and is a matter of concern.

In addition, menstrual irregularity in a female athlete should not automatically be assumed to be the result of her exercise and/or dietary habits. An athlete with amenorrhea should always be referred to a physician who is comfortable investigating the cause of the menstrual disorder. Absence of menses may be caused by energy and nutritional deficits in an athlete, but other causes such as pregnancy, pituitary tumors, polycystic ovarian syndrome, and other endocrine abnormalities should be considered.

Treatment

Unfortunately, there are no universal guidelines for management of women with the female athlete triad. Treatment of amenorrheic women with estrogen and progesterone replacement has not been effective in improving BMD. Instead, correction of the energy deficit has proven much more successful in restoring BMD. Estrogen is only part of the bone-building equation, as other hormones affected by caloric restriction (insulin, cortisol, growth hormone, IGF-1, thyroid hormone, leptin, and ghrelin) all play critical roles in skeletal health. Improving the energy deficit to allow weight gain and resumption of the normal menstrual cycle has shown the greatest benefit.

Achievement of optimal health for the female athlete with the triad requires a team approach. Some athletes improve with help from a nutritionist and a physician. The nutritionist may help target nutritional deficits, estimate caloric needs, and give suggestions for increasing the intake of various vitamins and macronutrients. Physicians can help manage bone healing, rule out other causes of menstrual irregularity, and possibly add medications to treat comorbidities such as depression. Other athletes need the services of these two professionals, along with a psychologist/psychiatrist, an exercise specialist, and other resources.

Addressing the causes of disordered eating, focusing on maximizing training benefits for performance and health, and finding other ways to assist the athlete in her recovery are keys to improving the female athlete's condition. With a multidisciplinary approach involving coaches, trainers, friends, family members, and health professionals, female athletes at risk for the triad, as well as those already affected by it, can receive the help they need to remain physically active and healthy for the rest of their lives.

Femoral Anteversion (Turned-In Hips)

The femur is the long bone in the leg that extends from the hip to the knee; the word *anteversion* means leaning forward. *Femoral anteversion* is defined as the leaning forward of the femoral neck with respect to the rest of the femur. This causes the leg on the affected side to rotate internally or twist inward toward the midline of the body.

Normal Anatomy

All children are born with some degree of femoral anteversion, which decreases naturally as the child grows. The angle between the plane of the femoral neck and the plane of the knee is approximately 40° at birth and declines to 15° by age 10. Because the femur normally has some degree of anteversion as children grow, it is only considered abnormal if it is significantly different from the average value for children of the same age.

Prevalence

Femoral anteversion occurs in up to 10% of children. It is more common in females than in males and is usually noticed between the ages of 3 and 6 years.

Diagnosis

Parents usually notice that their child is walking with his or her toes pointed inward. A child with femoral anteversion might appear more clumsy than his or her peers and tend to trip or fall more often. Parents usually worry most about the appearance of the child's leg or legs while walking or running. In addition, children with femoral anteversion usually prefer to sit in a "W" position because it is more comfortable for them. A child with femoral anteversion is rarely in pain.

The physician will observe the child walking and running and standing straight. In a patient with femoral anterversion, in-toeing will be evident, and the patient will have kneecaps that also turn in toward the middle of the body. Femoral anteversion is an inherited trait, and thus the doctor may ask if anyone else in the family had a similar problem. X-rays are usually not helpful in making the diagnosis.

Etiology

The exact mechanism that causes femoral anteversion is not known. It is considered to be an abnormality of development. As a baby grows inside mom's uterus, the femur may grow with abnormal rotation based on its position in utero and genetic factors.

Treatment

A normal baby is born with approximately 40° of femoral anteversion. This angle naturally decreases as children grow; thus, no treatment is necessary if the anteversion is within the normal range. If the anteversion is greater than the normal values, doctors will generally take the "watch and wait" approach and monitor the children closely as they grow. Studies have shown that night splints and special shoes do not help this condition.

Is Surgery Ever Needed for Correction?

Surgery is only indicated if the child is at least 8 years of age and if the angle of anteversion is greater than 50°. Anteversion naturally resolves as the child grows in 99% of the cases.

The only surgical treatment currently used for older children who still have severe anterversion is called *femoral derotational osteotomy*. A pediatric orthopedic surgeon will intentionally cut the femur, rotate it away from the midline, and then fix or secure it in a more correct anatomical position.

Prognosis

Since the anteversion usually naturally resolves by early adolescence, the prognosis is generally good. Children who have natural resolution of the anteversion are not thought to be at increased risk for hip or knee arthritis or athletic difficulty later in life.

Femoral Anteversion and Athletic Performance

Children with femoral anteversion have more inward rotation of their legs than children who do not have anteversion. As a result, children with femoral anteversion may have inward-pointing feet and a more difficult time running, depending on the degree of anteversion present. They may tend to be more "clumsy" than their peers and can be more prone to tripping over their own feet. As the child grows and the anteversion naturally resolves, these issues also tend to resolve. Children with more prominent anteversion that requires medical intervention are likely to have even more difficulty with running and sports until the anteversion is corrected.

Furthermore, while the child has anteversion, the biomechanical forces transmitted throughout the leg are suboptimal and may cause more strain on the knee than usual by changing the Q angle.

Femoral Neck Stress Fracture

Stress fracture or fatigue fracture of the femoral neck is an uncommon problem. Typically, these injuries arise from repetitive overuse and are most often seen in athletes and military recruits. Unlike stress fractures in other parts of the skeleton, however, the potential for serious long-term consequences from femoral neck stress fractures is high. Anyone involved in the treatment of these groups of patients must always consider femoral neck stress fracture as a potential diagnosis, as early diagnosis and treatment are essential.

Anatomy

The femoral neck represents a bridge between the ball of the femoral head and the shaft of the femur. Significant forces are transmitted through the femoral neck during normal gait. Even higher stress can be seen with athletic activity. Constant stress through the femoral neck produces a phenomenon whereby bone density is higher at the medial part of the femoral neck, known as the *calcar*. The stress in this area is mostly compressive in nature. The opposite side of the femoral neck is less dense, and the forces are mostly in tension. Continual stress through these regions of the femoral neck allows the bone to maintain its integrity by adjusting itself to compensate for activity level.

The blood supply to the femoral head proceeds in a retrograde or backward fashion. Any fracture of the femoral neck can compromise this blood supply. The greater the displacement of the femoral neck fracture, the higher the chance of injury to this extremely important vasculature. If the femoral head loses its blood supply, the bone may die in a process known as avascular necrosis. This has significant long-term, deleterious consequences.

Causes

Bone is living tissue that is constantly changing. Bone density is increased in areas of the skeleton where stress is great and decreased in areas of less stress. Fracture of bone occurs when the force applied exceeds its mechanical strength. Unlike dramatic fractures caused by violent trauma, where the injury force quickly overwhelms the bone's strength, stress fractures arise from repetitive overuse. The skeleton can compensate for increased, repetitive activity by increasing the amount of bone in the area to reinforce itself. However, when inadequate time is allowed for rest and bone remodeling, a stress fracture occurs. Typically, stress fractures occur when athletes suddenly increase the intensity and/or duration of their workouts. Many other factors contribute to stress fracture, including overall patient health, medications, nutrition, activity type and level, and bone strength. Additionally, athletes with significant muscle fatigue are more susceptible to femoral neck stress fractures. Fatigue of the strong stabilizing muscles around the hip joint transmits more force to the femoral neck.

Epidemiology

In general, femoral neck stress fractures occur in two groups stratified by age: young and old. Because this injury is caused by constant and repetitive overuse, the younger groups that suffer it are commonly endurance athletes and military recruits. The second group that develops this condition is made up of older, less active people whose bone quality is poor. However, this condition can occur in any age-group and at any activity level.

Symptoms

The most common symptom of a femoral neck stress fracture is pain. This pain usually starts slowly and worsens over a period of time. Pain is usually located in the groin but can also present anywhere around the hip joint. Activity will typically make the pain worse, and rest will relieve it. Range of motion and loading of the hip joint will reproduce the pain. Other local symptoms such as swelling and tenderness will normally be absent given that the femoral neck is relatively deep and surrounded by large muscles. The patient will usually present a history of a sudden increase in activity intensity or duration or a new type of activity.

Diagnosis

Rapid and accurate diagnosis of femoral neck stress fractures is important to minimize the risk of complications. A high index of suspicion must be maintained in the athletic population presenting with groin pain of unknown cause. Various imaging studies can be used to confirm the diagnosis that is suggested from the history and the physical exam. Radiographs are usually the first step; however, they can often be normal, especially in the early stages of stress fracture formation. Usually, some form of advanced skeletal imaging is necessary to confirm the diagnosis. Bone scan is very helpful in confirming the diagnosis. It will show increased uptake at the area of stress fracture. Magnetic resonance imaging (MRI) is also able to show the fracture and gives a clearer picture of the fracture pattern.

Classification

Classification of femoral neck stress fractures helps in selecting the correct method of treatment. The most commonly used system divides fractures into three types: compression side, tension side, and displaced. Compression-side fractures are those that arise on the medial side of the femoral neck. The forces in this area are compressive in nature. Tension-side fractures arise laterally on the femoral neck, where the forces are mostly tensive in nature. Displaced fractures are those that occur completely across the femoral neck and in which the alignment of the femoral neck is disrupted.

Treatment

The overall goal in the treatment of femoral neck stress fractures is twofold. The first is to provide the optimal environment for the fracture to heal. The second is to minimize the chance that the fracture will displace. The consequences of displacement are dire and are discussed below. These goals are achieved by a combination of modalities. The addition of cross-training exercises will help prevent future recurrences.

Nonoperative Treatment

The first step in creating a good fracture-healing environment is to correct as much as possible those factors predisposing the stress fracture. This includes metabolic, medical, nutritional, and mechanical factors. Often, this requires a multidisciplinary team approach with the input of several different specialists.

Compression-side stress fractures that involve a small portion of the entire femoral neck have a low risk of displacement. This type of fracture is treated nonoperatively. Restricting and modifying the patient's activity is essential. The bone must be given enough rest and relief from the inciting activity so that it can heal itself. The patient is not only restricted from athletic activity but also restricted from putting any weight on the affected limb at all. Non–weight bearing is achieved with the use of crutches. The duration of this treatment should be a period of 4 to 6 weeks, during which the injured bone has a chance to remodel. Radiographs are used to follow the healing of the fracture. Unrestricted return to sports is usually held off for an additional 4 to 6 weeks.

Operative Treatment

Tension-side fractures have a high rate of displacement and are therefore treated more aggressively. Surgical stabilization of these fractures, with the use of several large screws placed across the femoral neck, is usually recommended. Once the screws are in place, the chances of the fracture displacing are rare. After surgery, full weight bearing is allowed; however, unrestricted return to sports is delayed until the fracture is healed and asymptomatic. Radiographs are again used to follow the fracture healing.

Displaced femoral neck stress fractures require urgent surgical management. Once the fracture displaces, the blood supply to the femoral head is compromised. The fracture must be realigned and stabilized with several large screws to decrease the risk of avascular necrosis of the femoral head. This complication can occur nonetheless despite urgent and appropriate surgical treatment; the disruption of the blood supply to the femoral head occurs at the time of fracture displacement. Postoperative management of displaced femoral neck fractures is similar to management of the tension-side fractures but often is individualized.

Complications

Most stress fractures of the femoral neck go on to heal with proper treatment. Others, however, can result in complications. The most serious and dreaded complication of a femoral neck stress fracture is avascular necrosis (AVN) of the femoral head. Interruption of the blood supply to the femoral head from a variety of causes (not always from fracture) causes the bone and cartilage to die. This leads to degeneration of the hip joint in varying degrees depending on how much of the femoral head is involved. Destruction of the joint surfaces, termed *arthritis,* ensues. Such events in young athletes have dire and long-term consequences.

Other, less common complications include failure of the bone to heal or for the fracture to heal in a poor position. Any of the above conditions can predispose the hip joint to early degeneration and arthritis. No good options exist for the successful treatment of advanced joint degeneration or arthritis in the younger population.

Femoroacetabular Impingement

Femoroacetabular impingement (FAI) is a musculoskeletal disorder of the hip, referring to the repetitive contact of the femoral neck and the lateral rim of the acetabulum, and the subsequent trauma and injury that result. The symptoms may be mild, but FAI can progress, lead to other mechanical dysfunctions, and potentially create osteoarthritis significant enough to require hip replacement surgery.

Mechanism

Hip impingement occurs because of two primary mechanisms: (1) cam impingement and (2) pincer impingement. This can be visualized easier as a problem with the ball-and-socket joint.

- *Cam impingement* is caused by problems with the ball, or shape, of the femoral head that is trying to fit into the acetabulum. In many cases, the femoral neck is too thick or has extra bony thickening or spurring at the head-neck junction. Some femoral heads are ovoid and cause more impingement than the normal, spherical head.
- *Pincer impingement* is caused by problems with the socket, or *acetabulum*. The rim of the acetabulum comes into contact with the femoral head-neck junction. With repetitive use, pincer impingement stresses the bone and injures the soft tissue structures, specifically the acetabular labrum. This often occurs because of a socket

that is too prominent or deep (coxa profunda) or turned backward (retroversion) so that the front wall covers the femoral head more than the back.

Whichever mechanism causes the problem, identifying the causative factors for each is important. Legg-Calvé-Perthes disease is a juvenile disorder that affects the physis of the femoral head, but it can cause subtle bone thickening that can lead to impingement years later. Heredity plays some role in passing along hip anatomy that is set up for impingement, but no research has definitively found a marker or gene associated with impingement.

Many athletes can get an FAI, but those who are just nominally active can have symptoms as well. Activities that are correlated with increased incidence of FAI include ice hockey, horseback riding, yoga, football (American), soccer, ballet, dance, acrobatics, golf, tennis, baseball, lacrosse, field hockey, rugby, bike riding, cycling, martial arts, deep squatting activities such as power lifting, rowing sports (kayaking, sculling/rowing), and even car riding (in a deep-seated position).

Other Conditions

Because the hip and pelvis region is so complicated and the symptoms are not always straightforward, many conditions can be confused with FAI.

In some cases, patients may be told that they have hip dysplasia, either instead of or along with FAI. This can be confusing, and the conditions need to be differentiated. A hip with dysplasia typically suffers from a socket that is too shallow, that does not cover enough of the femoral head to support weight bearing. This increases the load on the lateral acetabulum and soft tissue structures, causing labral tears, instability, and premature osteoarthritis.

A hip can have dysplasia as well as FAI, and both can contribute to the patient's pain. However, surgical correction for each condition is different, so an accurate diagnosis is even more important when surgery is considered.

History

A patient will typically complain about pain in the front or lateral side of the hip, toward the level of the greater trochanter. Many patients will use their index finger and thumb to form the letter "C" and place their hand against their side and describe their pain as following their fingers. This symptom is relatively sensitive for the presence of hip pathology.

Pain can radiate down the sacroiliac joint and buttocks. Patients will complain of specific activities causing their pain, even things such as sitting and driving in a car for a while. Sitting cross-legged or on a short chair or stool can cause trouble when standing up again.

Catching or snapping in the hip region, stiffness, and loss of motion are also common complaints.

Often, symptoms are improved but not resolved with conservative therapy, and many patients will recall pain in the hip region for many years before seeking care.

Physical Exam

Clinical exam involves basic palpation, range of motion, and strength testing, which is cursory for

Conditions With Symptoms That Can Mimic FAI

- Hip dysplasia (adult form)
- Lumbar spine pain
- Lumbar radiculopathy (sciatica)
- Sacroiliitis
- Greater trochanteric bursitis
- Piriformis syndrome
- Iliopsoas tendinitis/tendonitis/tendinosis (hip flex or inflammation)
- Groin pull
- Sports hernia
- Iliac apophysitis (inflammation of a frontal hip growth plate)
- Quadriceps hernia/strain
- Chronic pain syndromes
- Psychosomatic pain disorder

Source: Adapted in part from Ganz R, Parvizi J, Beck M, Leunig M, Notzli H, Siebenrock KA. Femoroacetabular impingement: a cause for osteoarthritis of the hip. *Clin Orthop Relat Res.* 2003;(417):112–120.

orthopedic examinations. The hip exam involves two specific maneuvers, (1) the Scour test and (2) the Patrick or fabere test, both done with patients lying on their back:

Scour test: The thigh is flexed, internally rotated, and adducted. The clinician moves the thigh around the edge of the socket in somewhat of a semicircle. A normal hip would not hurt with this maneuver, so pain or catching in the front hip is considered positive.

fabere test: The leg is moved into a figure-four position, with the ankle resting on the opposite thigh, just above or at the knee. The clinician gently pushes down on the knee that is bent while holding the opposite side of the pelvis down. Pain in the front of the hip indicates hip pathology, while pain elicited in the lower back suggests sacroiliitis.

Trigger points are commonly found on the tensor fascia lata and gluteus medius muscles, the proximal hamstring tendon, the sacrotuberous and sacroiliac ligaments, and the anterior hip and hip flexor tendon region.

Hip impingement causes inflammation of the hip capsule, or synovitis, and that reaction can lead to weakened gluteal and hip rotator muscles (e.g., the piriformis and obturator muscles). This can lead to chronic pelvic malalignment, core instability, leg length discrepancies, and chronic lumbosacral dysfunctions. This is important to remember in patients with long-standing complaints of pain or problems in one area that do not improve with time or treatment. The source of those problems may be the hip joint.

Diagnostics

History and physical exam are usually enough to diagnose FAI, and imaging procedures help clinicians by confirming diagnoses and establishing prognosis and treatment options.

X-rays should include a frontal standing PA (posterior anterior) view of the pelvis and "frog-leg" views of the hip joints. Early degenerative changes, depth and position of the acetabulum, and bony irregularities of the femoral head and neck should be evaluated.

Computed tomography (CT) *scan* is a computerized radiographic exam that shows the bony anatomy better than any other imaging modality, especially thin-slice CT scans with three-dimensional image rendering. It benefits the surgeon who is contemplating surgery, but it is not essential or necessary for diagnosing FAI.

Magnetic resonance imaging (MRI) uses a powerful magnetic field to differentiate soft tissue on images, something that CT scans cannot do well. Therefore, it is used consistently to aid in the diagnosis and prognostic staging of FAI. Most physicians order an MR arthrogram, where a specialist injects a contrast agent into the hip joint to enhance the view of the labrum and articular cartilage. A normal MRI scan taken under normal circumstances is insufficient to diagnose subtle changes and small areas of damage. However, a few programs in the United States, most notably at the Hospital for Special Surgery in New York, run an MRI protocol without contrast that is clear and effective enough for physicians to make a diagnosis.

Treatment

Since FAI is a relatively new condition, little research exists to support specific treatments in treating it. Conservative therapy is always the first approach, but many patients will need to modify their activities to accommodate this treatment. A rigorous core-strengthening program should be started, but it should not involve high ranges of hip motion, particularly in flexion and abduction. Improving flexibility and correcting dysfunctions and alignment problems can help relieve the symptoms.

Surgical intervention should be considered right away if the hip shows degenerative arthritis, labral tears, or anatomical factors that lead to FAI or dysplasia. The goal is to preserve the hip joint and prevent permanent degenerative changes of the articular cartilage; once degenerative changes occur, the only effective corrective options are hip resurfacing or replacement.

If the articular cartilage is intact and the condition is identified early, then procedures can be done that preserve the hip. These include the following:

Hip arthroscopy: to repair a torn labrum, remove loose bodies

Surgical hip dislocation/osteoplasty: to reshape the acetabular rim, shave down thickening or spurring of the femoral head-neck junction

Microfracture technique: to stimulate new cartilage growth in an arthritic area of the acetabulum (usually done during arthroscopy)

Periacetabular osteotomy: to reorient a dysplastic acetabulum in order to absorb load over a broader area.

Fever

Fever is an elevation of core body temperature; in medical terms, fever is a temperature over 38 °C (100.4 °F). Fever is involved in the body's immune response and most often occurs as a result of an infection. Participation in sports while the athlete is febrile is a controversial topic in sports medicine.

Regulation of Body Temperature

Normal body temperature is 37 °C (98.6 °F) when taken orally. However, variability exists between people, and temperature may fluctuate depending on the time of day, weather, exercise, menstrual cycle in women, and age; therefore, an individual's baseline temperature may deviate slightly from 37 °C. For about 99% of the population, normal oral temperature ranges from 36.0 to 37.7 °C (96.8–99.86 °F).

An individual's body temperature is set by the hypothalamus, an area in the base of the brain that acts like a thermostat, maintaining normal temperature through heating and cooling mechanisms. The main heating mechanism is the constriction of blood vessels in the periphery of the body, which decreases heat loss from the skin; another is shivering, which causes a release of heat from the muscles. Sweating acts as the body's chief cooling mechanism by causing the loss of heat through evaporation.

Pyrogens

Fever is the result of the hypothalamus raising the body's temperature set point in response to a stimulus (termed a *pyrogen*). In the cascade that leads to fever, pyrogens cause specific white blood cells called phagocytes to produce a number of proteins, including interleukins, interferons, and tumor necrosis factor alpha. These proteins then induce the production of prostaglandins, which subsequently leads to a resetting of the body's temperature set point.

In response to the elevation of the set point, the hypothalamus activates the heating mechanisms illustrated above, and the body's core temperature rises until the new set point is reached.

Most commonly, the inciting pyrogen comes from outside the body and, thus, is termed *exogenous*. Infectious agents (viruses or bacteria), medications, and drugs can all act as exogenous pyrogens. Occasionally, fever may be caused by a stimulus from within the body (an endogenous pyrogen); examples of conditions that produce these pyrogens are autoimmune and other inflammatory diseases, brain injury, and some forms of cancer.

Overall, infectious agents are by far the most common cause of fever. Examples of common viral and bacterial illnesses that cause fever are colds, the flu, and gastroenteritis. Additionally, some serious infections are known to cause fever, including meningitis, endocarditis, and sepsis; however, these conditions are relatively rare and usually have associated symptoms that indicate a significant underlying illness.

Typically, the pyrogen can be determined by a thorough history, physical exam, and laboratory testing as necessary.

Fever and the Immune System

Fever acts as a part of the body's defense system against infection. Most bacteria and viruses have evolved to function best with a surrounding temperature of around 37 °C (98.6 °F); therefore, the increase in ambient temperature that occurs with fever directly decreases the ability of those organisms to survive. Furthermore, fever activates the body's immune system, causing increased production of white blood cells, which in turn fight the infection that initiated the fever; in the presence of fever, these white blood cells also become more mobile, multiply faster, and are better able to destroy the invading microorganisms.

Treatment

In the vast majority of cases, treatment of the fever itself is not necessary, especially as it aids in the immune response. However, a temperature above 41 °C (105.8 °F) may lead to neurological damage and possible death if persistent. In these instances, the fever should be treated with antipyretic medications, such as acetaminophen or ibuprofen, until the underlying cause can be elicited and treated.

At this time, no clear principle exists for the treatment of fever in cases where temperature is below this level, as scientific studies in this area are conflicting. The decision is therefore left to the patient and the treating physician.

Fever in Sports Medicine

Fever has a number of effects on the body's physiology that may influence athletic performance. It increases cardiopulmonary effort and decreases peak exercise capacity and endurance. It may also decrease muscle strength, coordination, and concentration, so athletes who participate in their sport while febrile may be at a greater risk of injury, although no studies have been done to document this. Additionally, fever puts an athlete at greater risk for heat illness.

Due to the effects of fever on physiology and its hypothetical effects on performance and safety, the American Academy of Pediatrics recommends that febrile pediatric athletes should not participate in sports. The policy with adult athletes is somewhat more controversial, and no clear consensus exists. A similar strategy is suggested by the journals *Evidence Based Sports Medicine* and *The Physician and Sportsmedicine:* Allow athletes with cold symptoms (confined to their head and neck area) to participate in a limited fashion, while disqualifying athletes with symptoms below the neck, as these may indicate a more serious infection. However, the suitability of this approach has not been clinically studied. Therefore, as no specific and tested policy exists, sports participation with fever is often based on the specific characteristics of each case and the preferences of the health care provider making the decision.

Field Hockey, Injuries in

Field hockey is a team sport comprising 11 players, 10 field players and one goalkeeper. Worldwide, it is second only to soccer in popularity among team sports. Players use a one-sided, curve-toed stick that is approximately 36 inches (in.; 36 in. = 91.4 centimeters) long to move a hard plastic ball down the field in an attempt to score within the goal area. The left hand is at the top of the stick, and the right hand is below this in variable positions depending on whether the player is dribbling, hitting, or playing defense. Most injuries arise as a result of being struck by a hard-hit ball or accidentally by the hockey stick, primarily on the hand, lower legs, and head or face. Other injuries are overtraining injuries, acute muscle strains (hamstring and quadriceps), or ligamentous injuries such as ankle sprains or ACL (anterior cruciate ligament) tears, which one might find in any sport that involves changing direction quickly and playing in close proximity to other players. Although field hockey is a noncontact sport, incidental contact occurs frequently.

Types of Injury

The box below lists some of the injuries that field hockey players may be prone to.

Contusions/lacerations/ fractures	Fingers and hand
	Face and head
	Lower leg and feet
Ligamentous	Ankle sprain
	ACL (anterior cruciate ligament) tear
Muscle strains	Hamstring
	Quadriceps
	Groin
Overuse	Shin splints
	Stress fractures
	Patellofemoral syndrome
	Low back pain
Head injury	Facial fractures
	Lacerations
	Concussion
Eye injury	Infrequent but can be serious

Protective Equipment

Players wear mouthguards and plastic or foam shin guards that protect the lower leg and ankle. Many states require high school students to wear a goggle-type eye protection, but this is optional at the college and international levels. The use of close-fitting gloves, with padding over the top of the fingers, can help reduce both finger and hand injuries. The goalkeeper is protected from head to toe with a helmet, a throat protector, a chest protector, padded pants, arm and hand pads, sturdy leg guards, and "kickers," which go over the feet to provide protection as well as a way to clear the ball away from the goal area. Despite facial injuries being fairly common in field hockey, helmets are not currently part of the equipment for field players. Controversy remains over the introduction of such equipment that might lead to more aggressive play and thus make the game more dangerous rather than less. Face masks are temporarily worn by field players on the penalty corner, a situation where the ball is hit sharply toward the goal from 16 yards (yd; 1 yard = 36 in.) away. Deflections by the goalkeeper or other players may dangerously redirect the ball toward the defender's head.

Field Hockey Surfaces

Field hockey is played on a variety of surfaces, most commonly grass at lower levels and some sort of artificial surface at the collegiate and international levels. Hand injuries tend to be more frequent on artificial surfaces, likely due to the higher speeds and different stopping techniques that move the hand closer to the ground and closer to danger. Artificial surfaces include products such as AstroTurf, which is basically a short, fiber carpet that is rolled over a concrete surface. "Field turf" is a longer, blade carpet that is interspersed with rubber pellets or sand. Field turf is a softer surface for landing and is felt to be less of a risk for concussion, turf toe, and joint injuries than the synthetic carpet over concrete. However, field turf tends to be slower and less "true" for a rolling ball than AstroTurf, the preferred surface at higher levels of play. Artificial surfaces should be watered prior to use to prevent athletic shoes from catching and locking and thus leading to injuries such as ACL tears. Water also helps keep the ball on the field surface to prevent bouncing and helps reduce abrasions when sliding or falling on the surface. Abrasions can be quite severe when falling on a dry turf. Because the artificial surfaces are significantly hotter than grass fields in the summer months, applying water can also temporarily cool the surface. Watering is generally done before the game and at half-time.

Preventing Injury

Rule enforcement is important for preventing dangerous play that might lead to unnecessary injury. Using the stick or undercutting the ball in a dangerous manner or hitting the ball intentionally or recklessly into other players is a serious foul. Supervision by competent coaches and teaching of proper hitting and tackling techniques can help reduce injuries. Safe field conditions are critical. Uneven surfaces from holes or ruts need to be corrected and loose objects, such as rocks, removed. Artificial surfaces have generally eliminated this problem. Proper footwear for the surface being played on is important in preventing catching or slipping of the foot.

Management of Injuries

Use of braces or taping may help get an athlete back to sport or help prevent injury in susceptible players. Athletes with stable finger fractures may be allowed to return to play with buddy taping. Tight-fitting face masks may be used by players who have suffered nasal fractures or other stable facial fractures. Padding of the injured area may help prevent recurrent injury to the same area.

Fieldside Assessment and Triage

Fieldside assessment and triage of an injured athlete are essential skills for any sports medicine specialist. The initial assessment is crucial to direct the provider toward the best course of action. The decision-making process can often be challenging. If a serious injury is found, one must be prepared to manage the athlete until transfer to a medical facility can be arranged. If the injury is a minor one, the practitioner can assess and test the athlete before sending him or her back to the field. In between these extremes, the physician must make a decision as to whether to observe the athlete for a short while or to refer the injury for further investigation or management. The process of triage and assessment described in this entry allows physicians to quickly recognize those with severe injuries and transfer them to an appropriate medical facility quickly.

Early planning and rehearsal are the best methods of preparation, preventing delay in transfer and medical care in the event of an emergency. Perhaps the most important point to remember is that anything can happen and seemingly innocuous problems can rapidly become life threatening if not considered in a structured manner. This entry is intended to be a rough guide for general readers, students, and professionals with an interest in sports medicine. It will describe what happens when an experienced physician examines an injured athlete on the field. The "ABCDE" approach to assessment is discussed to introduce a standard plan for the primary and secondary survey. The ABCDE survey is designed to detect life-threatening injuries, such as those caused by airway, cervical spine (C spine), breathing, circulation, circulatory, and environmental stressors. The most common cause of nontraumatic sudden death in an athlete is cardiovascular, with dehydration, drug use, and elevated or decreased core temperatures being medical risk factors to consider. This entry provides the basic principles to decide whether an athlete can return to the field of play or not. Many of the elements of the secondary survey are discussed elsewhere in this volume, but issues relevant to triage and assessment are also discussed here.

Preparation and Planning

The most important feature of providing good medical triage and assessment at any sporting event is good preparation. The medical team should fully understand both the sporting demands of the event as well as the dangers that can arise from competing. The team should have a good idea of their roles, and a consistent plan should be followed in the event of serious injury. Outside health facilities will have their own emergency medical protocols, which should be reviewed prior to making any preparations. Planning starts with organizing a staff that can deal with a number of competitors, with the risk level being understood and taken account of. The medical team should not only consider the common emergencies that can occur but also be aware that natural disasters or sudden weather changes can put athletes at risk. Ambulance routes should be planned in advance, and pre-event practice should be standard among the team. Only by rehearsing will the team gain familiarity with communication systems as well as emergency protocols. This should be done through regular workshops and training exercises. Ideally, members of the medical staff should be certified in first aid and cardiopulmonary resuscitation.

A well-stocked medical bag, good communications, and accurate weather assessment will go a long way in dealing with any athlete's injuries. Preparation of equipment is vital and should be tailored to the event being covered. A sample list of common equipment is outlined in Table 1.

Communication is a vital part of assessment and triage as the physician must be able to activate emergency protocols and contact emergency services for rapid transfer of acutely ill athletes. In mass participation events, a main means of communication is recommended with a secondary

Table 1 Suggested Equipment List for a Medical Bag

Airway and Ventilatory Supplies	*Circulatory Supplies*	*Transport*	*Medications*	*Miscellaneous*
Rigid cervical spine collar	Intravenous catheters	Spine board + head blocks and tape	Adrenalin (epinephrine), 1 in 10,000 solution	Sterile gloves
Bag valve mask	Intravenous fluids	Stretcher	Oral/sublingual nitrates	Alcohol swabs
Oropharyngeal airway	Intravenous line tubing	Crutches	Aspirin	Athletic tape
Nasopharyngeal airway	Tourniquet		Beta-agonist inhaler	Splints
Intubation equipment	Automatic external defibrillator		Aerochamber	Ice
Laryngoscope			Analgesia	Gauze and bandages
Crycothyroidotomy kit			Oral anti-inflammatory drugs	Suture kit
14-gauge cannula for tension pneumothorax			Antibiotics	Stethoscope
Oxygen tank and reservoir			Oral glucose tablets	

method of contact as backup. Radios or cellular phones are often used as means of communication. Simple procedures such as having sufficient spare batteries and good radio protocol can eliminate failures of this network. At a minimum, the physician should also carry a fully charged cell phone for emergency use. The numbers of local emergency services and any other important local resources should be kept close at hand and distributed among the team.

Anticipation of weather hazards is important for all outdoor events. Heat illness is a common concern in sports events in hot, humid environments, particularly if the athletes are exposed to direct sun for prolonged periods of time. Ambient temperature above 28 °C (82 °F) can lead to heat-related injury, so particular attention should be paid to keeping athletes well hydrated. In cases of extreme heat, it is better to practice indoors, increase water breaks, and shorten high-intensity workouts as necessary. Games may need to be rescheduled to cooler times, such as the morning or evening, or, more rarely, cancelled in the event of high temperatures. Conversely, one should consider hypothermia in cool weather with any fall in temperature or increased windchill. Athletes are at risk in water sports when the water temperature is below 10 °C. If the athletes are ill prepared, this can become a problem even in relatively mild conditions. Rain, snow, and sleet can be dangerous in events of long duration as they can further reduce the temperature of athletes and make transfer or rescue much more challenging. Athletes and coaches should be made aware of this, allowing them to either be prepared by wearing warm clothing or consider postponing the meet.

Primary Survey

In the case of an athlete who has had a fall, a primary survey should be sequentially performed. This involves assessment of vital signs and ensuring that the life of the patient is not immediately in danger.

A suggested approach, formulated by the American College of Surgeons, is as follows:

A = *A*irway and cervical spine

B = *B*reathing

C = Circulation

D = *D*isability

E = *E*xposure and environment

This algorithm is a method for carrying out the primary survey in a fieldside assessment in a systematic and simple framework. The goal of the primary survey is to identify and manage reversible life-threatening problems. Each letter of the algorithm is approached and cleared before moving on to the next, and the entire algorithm should be completed before moving the athlete from the field of play. In this way, dangerous situations such as airway compromise or cardiorespiratory emergency can be detected and addressed by even those without great clinical experience. The athlete should not be moved off the field until the primary survey is completed. Body substance precautions include avoidance of contact with bodily fluids and wearing gloves at all times to prevent disease transmission during the resuscitation process.

A: *Airway (and Cervical Spine)*

Airway: What to Look Out For

When an athlete has fallen on the field of play, the assessment should begin by looking at his airway. Lack of oxygen to the brain can lead to irreversible damage within 4 minutes, so any airway blockage needs to be immediately reversed. An athlete struggling for air will often be agitated. Abnormal sounds such as gurgling or gasping suggest a partial obstruction.

How to Assess the Airway

1. A good start can be to ask the athlete's name. If the athlete can respond, then the airway is secure and breathing is occurring.
2. Listen for abnormal breathing sounds; gurgling and whistling suggest partial airway obstruction.
3. Purple discoloration around the lips is called *cyanosis*. This is a sign that the patient does not have enough oxygen in the bloodstream. However, this should be treated with caution as the sign can be misleading in the cold or in individuals with dark skin.

4. Observe for use of muscles around the neck and shoulders for breathing. These accessory muscles may need to be used to assist in the inspiratory effort.
5. Keeping the neck immobile, as described below, the mouth should be inspected for foreign bodies such as teeth or a mouthguard and tongue occlusion of the airway.

How to Manage the Airway

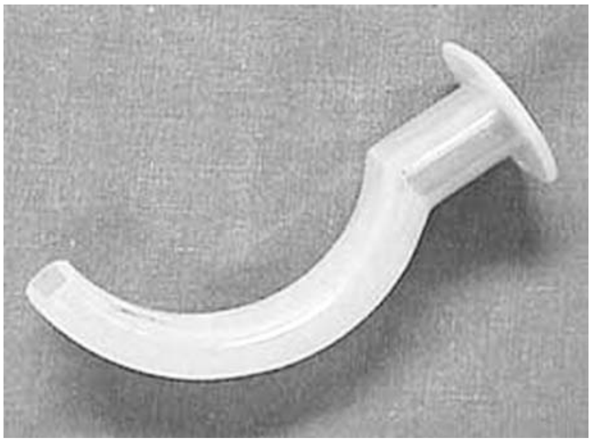
If airway obstruction is suspected, the primary concern is to reestablish a secure and patent airway. The C spine must be protected, especially in an unconscious patient, until serious injury to the neck has been excluded. A maneuver called *in-line manual immobilization* can be used to prevent rotation or sudden movement of the neck, with a medical team member holding the patient's head still with both hands (see image a, this page).

If the tongue is suspected to be causing obstruction, the "chin lift" maneuver can be tried, in which the fingers are placed under the chin and thumbs placed on the lower lip, pulling the chin down and opening the mouth to look in. This technique places the neck at risk of movement and should be performed by those with at least some experience. With the neck immobilized, a "jaw thrust" can also be used, by placing one's fingers behind the angle of the jaw and pulling the whole jaw forward to draw the tongue forward.

If aspiration becomes a problem, then the patient should be turned onto his or her side and suction given. In emergencies, a supportive airway can be inserted, such as an oropharyngeal airway (see image b, this page). This is a rigid plastic tube that can be placed in the mouth, over and behind the tongue, to secure the airway. A nasopharyngeal airway is illustrated in photo (c) below.

If an airway cannot be quickly established, it must be managed by a specialist. In rare cases, a surgical area may need to be created to allow breathing to take place.

(b)

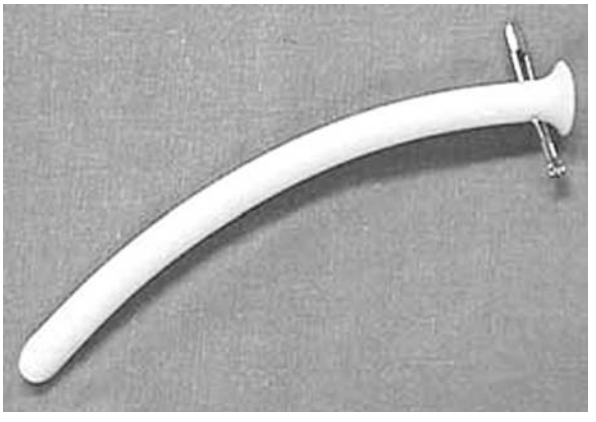


Oropharyngeal airway. It is useful for unconscious patients who lack the gag reflex. A nasopharyngeal tube can be used in awake patients. The long flexible tube is inserted into the nose into the back of the patient's throat, bypassing the tongue.

(a)

In-line manual immobilization of the neck (manual fixation of the neck to prevent further injury)

(c)



Nasopharyngeal airway, used in awake patients with breathing difficulties

Cervical Spine: What to Look Out For

A C-spine injury can have severe consequences, including spinal cord injuries leading to limb paralysis. Unfortunately, it is easy to overlook an injury to the C spine in an emergency situation. Anyone who is found unconscious or is complaining of neck pain following heavy trauma to the head and neck should be considered to have C-spine injury until proven otherwise.

How to Assess the C Spine

Neck immobilization should be carried out routinely at the beginning of any primary survey examination, as part of the assessment of the airway, and throughout the rest of the assessment (see image a, page 512). Serious consequences can follow improper mobilization, however. Helmets and protective equipment should not be removed unless absolutely necessary—for example, to manage medical problems such as protecting the airway. An experienced sports medicine practitioner is needed to gently palpate the spine and safely assess motion in order to rule out C-spine injury.

How to Manage C-Spine Injuries

The C spine should remain immobilized throughout the fieldside assessment to avoid extension, flexion, or rotation of the neck. Manual in-line immobilization of the C spine should be maintained until rigid fixation with a C-spine collar (image d) has been achieved or the neck has been assessed and cleared by an experienced specialist. The athlete may feel that he or she can move but must be prevented from doing so until it is made sure that the athlete has no pain in the neck and that medications or secondary injuries are not distracting the athlete from the pain. Fieldside assistants should avoid using smelling salts to revive players as these can cause a sudden jerking of the head and possible C-spine damage.

The cervical spine is often cleared at the hospital since radiographic imaging of the neck may be required to rule out a fracture.

A maneuver called *logrolling* is sometimes necessary to shift a prone patient into a more practical position on his or her back (see images e, f, and g, p. 514). Logrolling must be performed with a minimum of four people. Three people prepare to move the patient on one side, while the leader takes control of the neck. This lead person must coordinate the logroll and at all times maintain the stability of the neck. Logrolling can be used to move the patient onto a spine board ready for either transportation or further assessment.

(d)

A stiff cervical spine collar maintains in-line immobilization and is often combined with sandbags on either side for transportation.

B: *Breathing*

What to Look Out For

In any sports injury, once the airway is clear and maintained, the breathing must be checked. There are some dangerous conditions to watch out for during sports that cause reduced breathing. A tension pneumothorax is where there is a leak into the lung cavity, enabling air to fill inappropriately around the lung, preventing efficient breathing, and possibly leading to a collapsed lung. Similarly, a hemothorax is due to a penetrating injury to the chest wall, leading to bleeding into the lung cavity. Chest wall trauma, such as rib fractures and/or muscle strains, can also occur, making breathing painful and difficult. Finally, medical conditions can lead to respiratory distress. For example, asthma is a chronic inflammatory disorder of the airways, characterized by airway hyperresponsiveness and reversible airflow limitation. In some athletes, exercise can exacerbate symptoms of shortness of breath, cough, and/or wheezing. *Exercise-induced bronchospasm* (EIB) is a more appropriate term to describe the condition, which is commonly found in asthma

(e)

(g)

(f)

Logrolling. Four people are required for this, one leader and three assistants. The leader's role is to control the head and neck and direct the assistants as to when they should turn the patient. The assistants position themselves at the torso, pelvis, and legs. The leader counts to 3, and the assistants roll the patient up to 90°. The cervical spine can be checked at this stage with the neck collar removed. The roll is completed and the patient placed in a supine position.

patients and in individuals with environmental allergies. It can also be found in those with no history of allergies and is thought to be highly prevalent among high school athletes.

How to Assess Breathing

A simple way to first assess breathing is to lean over the athlete and listen for breath sounds while observing for symmetric chest movements. Asymmetry would suggest that the chest wall is damaged and breathing is impaired. A stethoscope can then be used to auscultate over each field. If sounds are not heard, a pneumothorax (air blocking breathing) or hemothorax (blood blocking breathing) should be suspected. Deviation of the trachea from the midline should then be checked. A tension pneumothorax should be suspected if there are decreased breath sounds, tracheal deviation away from the injured side, and evidence of a chest trauma.

How to Manage Breathing Difficulties

If the athlete is found to have a clear airway but is unable to breathe spontaneously, a bag-valve-mask device is used to give supplementary oxygen. The appropriate mask size is selected, and then one or two people work together to produce a seal over the mouth and nose of the athlete. A good method for creating a good seal when only one person is available is to draw the lower jaw (mandible) forward toward the mask with the third and fourth fingers while pressing down with the first and second on the mask. If no ventilation is achieved with this method, it is important to check the airway again for signs of obstruction and to check the equipment for failure. When two caregivers are present, one person can maintain the seal while another squeezes the bag. This should be done at a rate of approximately once every 5 seconds or twice for every 30 chest compressions if they are being performed.

When trying to achieve ventilation, a bag-valve-mask device may not always be available and mouth-to-mouth resuscitation must sometimes be performed. A face shield device is useful to avoid direct contact between the caregiver and the athlete, decreasing the risk of exposure to bodily fluids.

Treatment of tension pneumothorax is urgent and requires skilled management. A large-bore needle must be inserted through the second intercostal space into the chest cavity, to allow relief of the positive pressure built up inside the pleural space. The athlete must be transferred immediately for placement of a chest tube. It should always be remembered that a tension pneumothorax can be fatal.

C: *Circulation*

What to Look Out For

When circulation fails, an athlete may go into "shock." This is a state where the blood flow from the heart cannot match the needs of the body. A patient in shock is in a critical condition, and prompt diagnosis and emergent transfer to a medical facility are imperative. When an athlete is exhibiting signs of shock, the immediate suspicion should be cardiac arrest or arrhythmia. The physical signs to be mindful of are high heart rate (tachycardia), low blood pressure, cold peripheries (indicating vasoconstriction), and a decreased level of consciousness. What makes it more challenging to pick up these signs in an athlete is the naturally reduced resting heart rate and compensation mechanisms that are better than average. This can lead to late diagnosis of imminent shock. Other causes of shock can be dehydration or bleeding into bodily spaces in trauma.

How to Assess Circulation

Feeling the carotid pulse is a good way to start assessing for cardiac arrest or failure. This can be found under the line of the jaw, and if it is absent, a complex cardiac cause or extremely low blood pressure should be suspected. If this is coupled with the signs of shock described above, cardiac arrest or arrhythmia should be assumed and cardiopulmonary resuscitation (CPR) commenced immediately. In young athletes, the most important intervention in a cardiac arrest has been shown to be use of the automated external defibrillator (AED), as it can convert life-threatening cardiac arrhythmias such as ventricular tachycardia and ventricular fibrillation back into a stable rhythm. If a defibrillator is not present, chest compressions should be carried out, with the usual rate being 30 compressions for every two breaths. If a pulse is detected, then heart rate and rhythm should be assessed, and there should be no skipped or extra beats. The resting heart rate should be approximately 60 to 100 beats per minute (bpm) in an adult, but children can have resting pulses up to 140 bpm when younger than 5 years. Trained athletes can have pulses as low as 40 bpm at rest.

How to Manage Circulatory Difficulties

Management of the athlete who shows no pulse first involves starting CPR and immediately activating the emergency system for help. While immediate transfer to specialist care is ideal, if a rhythm can be found to defibrillate, early defibrillation can be lifesaving. In the case of a traumatic wound causing bleeding, pressure with sterile dressings should be applied to the wound to try to stop the bleeding. If possible, the legs should be elevated if signs of shock are present. Intravenous fluids should be administered as soon as possible. Normal (0.9%) saline or Ringer's lactate solution is most commonly used to replace losses. Vital signs should be regularly checked to assess for response to the resuscitation. If no response occurs, the cause of shock has been misdiagnosed and blood loss is not to blame. All cases of shock require immediate transfer to a medical facility for further management.

D: *Disability*

What to Look Out For

Clearing airway, breathing, and circulation constitutes the most important life-saving steps of the primary survey. In the assessment of the disability stage, there are fewer immediate causes of death; however, there are still dangers such as head injuries that can lead to a rapid deterioration in the patient's status. Therefore, the ABCs should continually be reassessed. If bleeding or clear fluid is observed from the ears, nose, or mouth, it may suggest a head injury. Swelling or local tenderness over the skull can suggest an underlying fracture.

Tenderness over the temporal area is particularly worrisome as rapid bleeding in the skull can occur should the underlying artery be torn.

How to Assess Disability

The AVPU is a good method of describing the level of consciousness at the fieldside.

A = *A*lert

V = Responding to *V*oice

P = Responding to *P*ain

U = *U*nresponsive

If the athlete is unable to answer questions coherently, head injury should be suspected. Trauma to the head should be noted by any bruising or bleeding, and immediate medical care should be sought if the athlete is drowsy with a clear head injury. Neurological deficits can be screened for with a brief neurological exam and if the patient is unconscious. Assessments of spontaneous eye movements, speech, and motor function are parts of the Glasgow Coma Scale, which can be used to evaluate responses (Table 2).

A pen torch should be used to check for symmetrical reactivity to light, spontaneous eye movements, pupil size, and symmetrical eyelid movements. A sluggish light response or dilation might mean intracranial injury on the side of the enlarged pupil, while impaired eye closure and blinking may mean damage to a cranial nerve. While the eyes are examined, it is useful to check the athlete's verbal responses and level of concussion by asking simple questions such as "What is your name?" More testing questions such as "What team are you playing?" will test short-term memory and also understanding. Formal assessment tools such as a Maddocks score (Table 3) and the Standardized Assessment of Concussion (SAC) can be used to elicit information about suspected concussion. A quick check of finger and toe movements will show if there is a deficit of motor function.

Neck injuries should be further assessed at this stage and a decision made about whether they require specialist medical care. A good rule to follow is that any athlete who is unwilling to spontaneously move his or her neck should be suspected of having a serious neck injury. If the athlete reports no pain and the suspicion of a serious neck injury is low, a screen for neck injury is to ask the athlete to very slowly raise his or her head off the ground voluntarily to touch the chin to the chest. If the index of suspicion for head and neck injury is high, then any movement should be avoided until the head and neck are cleared in an appropriate medical facility.

Table 2 Glasgow Coma Scale: A Tool for Assessment of a Patient With Reduced Consciousness

Eye opening	
Spontaneous	4
To voice	3
To pain	2
None	1
Verbal responses

Flexion to painful stimulus	3
Extension to painful stimulus	2
None	1

Examination of the peripheral limbs for fractures and any other abnormalities forms part of the secondary survey. An examination of light touch and distal pulses can usually identify a serious problem early on the field.

How to Manage Disability

The most worrisome type of disability is head and neck injury, and if one is noted, it is important

Source: McCrory P, Meeuwisse W, Johnston K, et al. Consensus Statement on Concussion in Sport. Third International Conference on Concussion in Sport held in Zurich, November 2008. *Clin J Sport Med.* 2009;19(3):185–200.

Notes: Ask the patient to answer the following questions to the best of their ability. Give one point for each correct answer. This tool is validated for sideline diagnosis of concussion only.

to be on the lookout for the other. If there is any suspicion of these injuries, the patient should be immobilized and transferred to a spine board for further evaluation. Logrolling may need to be performed as discussed earlier (see pages 513–514). Extremity fractures may be splinted in a painless position to reduce tension as part of the primary survey, but reduction of fracture should only be undertaken by an experienced physician. Similarly, an obvious dislocation should be reduced only by a practitioner experienced in the procedure, as improper reduction can lead to nerve and vessel damage. Most problems identified during the disability step require urgent medical attention and further investigations.

E: *Exposure and Environment*

What to Look Out For

This step consists of making sure that any injuries have not been missed and planning on moving the athlete to a safe environment if he or she is stable. Any environmental dangers should also be looked for in terms of both the other athletes and the patient. If one athlete has succumbed to the environmental problem, then it is highly likely that others will too. The two major conditions to watch out for are hypothermia (low body temperature) and heat illnesses. Heat injuries are often underdiagnosed. Humidity can also play a part in causing heat-related illness. Athletes competing in particularly hot, humid climates are more susceptible to dehydration. Other environmental problems to watch for are lightning and rain. Lightning, although very rare, carries the threat of burns, mechanical damage from the high voltages passing through the body, and blunt trauma injuries from falling or propelled objects. A wet athlete can become cold rapidly and, if appropriate, should be covered when carrying out the primary survey.

How to Assess Exposure and Environment

An accurate measure of core body temperature can be difficult to obtain, as oral, external, and tympanic thermometers are not very reliable. Rectal temperature is still the best estimate of core temperature, though it is not always practical to measure on the field of play. Obvious signs of heat stroke are confusion, a decreased level of consciousness, and hot, dry skin. Dehydration may further complicate the picture, and the athlete will be acutely unwell. Early signs of this are decreased skin turgor (loss of skin elasticity) and dry mucous membranes, most noticeably in the mouth. Hypothermia can also occur along with dehydration but is most recognizable from a decreased level of consciousness combined with a cold, pale, cyanotic skin.

How to Manage Exposure and Environment

Heat- and cold-related injuries are covered in more detail elsewhere in the encyclopedia, but controlling the athlete's environment is still an important part of a primary survey. Obvious signs of heat- or cold-related injury should precipitate immediate transfer to a medical facility. While the primary survey is being carried out, it is not unreasonable to cover the athlete to keep him or her warm; however, care should be taken not to move the patient. In the case of a heat injury, any heavy clothing should be removed. The athlete should be cooled with water and ice, preferably in the shade. Ice water immersion appears to be the most practical means of reducing core temperature during a sports event. Dehydration can exacerbate both heat and cold injuries, and so fluid balance is an important part of treatment. Intravenous or oral fluids should be given to correct this and aid in temperature regulation. Dehydration can be a major contributory factor to hyperthermia, and though it is possible for heat injury to occur in well-hydrated athletes, this is unlikely. If a cold injury is suspected, then the patient's wet clothing should be removed and replaced with dry clothing and warm blankets. In the event of severe hypothermia, the athlete must be rewarmed slowly at a medical facility to avoid metabolic disorders, referred to as reperfusion injury.

Once the primary survey is completed and the athlete's immediate condition has been assessed, he or she can be triaged. Any abnormality found on primary survey usually requires emergency transfer. Otherwise, the secondary survey can be performed on the sidelines.

Emergency Transfer

Following the primary survey, the decision must be made about whether to activate the emergency protocols. If the athlete's condition is of concern, a call to activate the emergency services (911) should be made immediately for hospital transfer. Similarly, if the primary survey did not reveal an immediate life-threatening issue but the secondary survey reveals a serious problem, emergency transfer is needed. Ideally, patients will be assessed as soon as possible, and the level of transfer urgency is often determined by the emergency medical services. Suggestions for stabilizing the athlete and best options regarding the method of transfer, whether by ambulance or by air transport in a helicopter, should be considered if the athlete's arrival at an emergency center may be delayed. It is best to call the emergency center and provide as much information as possible to help them prepare for the injured athlete. Once the ambulance crew arrives, they often take the lead in preparing the athlete unless there are other individuals on site with more experience.

Prior to departure from the field, the patient's airway, breathing, and circulation should be stabilized as well as possible, and an attempt should be made to control hemorrhage. All face masks and obstructions to the airway should be removed before transfer, except the headgear, which causes no obstruction. A secure airway should be established before transfer commences.

If vertebral column or spinal cord injury is suspected, the patient should be transported to an appropriate trauma center. When moving the patient with a suspected spinal injury, the most important thing to remember is that the head and the spine must be moved as one. Generally, this will involve the head being repositioned to the neutral position for in-line immobilization. Using the technique described earlier in the entry, the patient should be logrolled and a spine board placed underneath. The neck can be secured to the spine board using either a rigid neck collar or, if needed, padded towels and sandbags. This should be done by paramedics if waiting is possible, unless there is a need to move the athlete immediately or provide resuscitation measures. Transfer of athletes with suspected spinal injuries should not be done in a private vehicle and should always be carried out by emergency medical staff with the assistance of athletic trainers and team medical staff.

Secondary Survey

The secondary survey ideally should be carried out in a comfortable, controlled environment away from any further exposure, preferably indoors. It usually involves a detailed, systematic assessment from head to toe to find any non–life-threatening conditions that were not detected immediately.

History

The history should include specific details regarding any concerning conditions. More general information regarding the athlete's overall health should be elicited, for example, age, medication use, allergies, past medical history/pregnancy, last meal, and the events preceding the injury. A thorough history of the injury can help the practitioner make decisions about the athlete's management plan as well as return to play, withdrawal from play, or transfer to a medical facility.

Examination

The patient should then be examined from top to toe, starting at the head, looking for obvious lacerations or deformity and signs of underlying injury.

Moving methodically down the spine and neck to the chest, abdomen, and limbs, the examining physician should look at each organ system, including the respiratory, cardiac, abdominal, renal, and neurologic systems, thoroughly before any decision about return to play is made. The detailed examination of any affected joints or limbs and organ systems is explained in other entries of this encyclopedia.

First Aid

The approach to first aid should be dictated by both the outcome of the primary and secondary surveys and common sense. It is vital that the physician recognize his or her limitations with regard to skills and resources, but if appropriate, the physician may decide to manage problems on site at the event. This should be accompanied by early follow-up and notification of relevant support services. A good understanding among all members of the medical team will help direct the care of the athlete more cohesively and allow good agreement over return-to-play decisions.

Procedures that the physician may consider performing on site are taping injured joints, splinting fractured limbs or joints, applying pressure bandages, and simple measures such as applying ice to bruises and new injuries. The physician should be comfortable with basic therapies in early treatment of sports injuries, such as massaging, stretching, ice application, and rehabilitation exercises for injuries such as sprains and strains.

Immobilization and Splinting

If a fracture is suspected or there is considerable damage to a joint or bone, splinting must be considered to protect the area and prevent further damage. For the lower extremity, a splint or leg immobilizer can be applied, while a sling or splint is used to immobilize the upper extremity.

Joint Dislocation and Reduction

A dislocated joint is often more easily relocated immediately after an injury, before any soft tissue swelling occurs and muscle spasm tightens around the joint itself. The shoulder is the most commonly dislocated large joint, with dislocation of the fingers, hips, elbows, and knees also possible. Many techniques have been described to relocate a dislocated shoulder, mainly dealing with the common anterior dislocation. In the right hand, an immediate reduction maneuver is a highly effective treatment. There are significant dangers in poorly conducted relocation, such as displacement of fractures and neurovascular injury. Reduction should only be undertaken by experienced professionals and should not be attempted repeatedly as complications can occur, such as soft tissues catching in the joint. Prompt medical evaluation is still needed even following a successful reduction of the joint to properly assess for any underlying damage. Dislocations are often accompanied by ligament injury and fracture.

Wound Care

It is valuable for the sports practitioner to know the basics of proper wound care. The well-prepared fieldside physician will bring supplies to clean, sterilize, and close wounds. Oftentimes, normal saline or water can clean most wounds, though many antiseptic cleansing solutions are available. Before any attempt at closure is made, the wound must be thoroughly cleaned and debrided of all tissue at the edges of the wound. All foreign objects should be removed, and the wound should be thoroughly irrigated with normal saline. Very dirty wounds should be left open until they can be treated at a medical facility, as closure can carry a high risk of infection. Immunization status is another area where mistakes can be made as an out-of-date tetanus status can make small lacerations much more serious.

A local anesthetic can be used on the skin to reduce sensation in a painful wound. Sutures, staples or sterile adhesive strips, and/or proper wound dressing and bandaging techniques can be used to close small wounds effectively. Large lacerations should receive firm pressure and wound dressing to stop or at least slow any bleeding and usually require transfer to a medical facility for closure. Care should be taken to avoid bandaging a wound too tightly to avoid any compromise of distal blood flow to a limb, in case transfer will be delayed by more than 2 hours.

Eye, Teeth, and Facial Injuries

Particular care should be taken with these types of injuries as players can be tempted to continue to play when it is really not advisable to do so. Eye injuries generally fall into the categories of blunt trauma, corneal abrasions, and penetrating wounds. All these can produce lasting damage, and it is highly recommended to seek expert help at the earliest. While emergency transfer is not warranted, removal from play and referral to an ophthalmologist are recommended in all but the most minor of injuries.

Return to Sports

Effective management of minor problems can take place after major problems are ruled out in the primary and secondary surveys. If the athlete has been through these stages and the injury seems minor, the player can be assessed for return to play. It is perhaps the most challenging decision to make for sports physicians, as their own clinical intuition and caution must be tempered against the will of athletes and coaches to carry on. All members of the medical team should communicate their input regarding the athlete's status to the lead individual to make a decision for safe return to play.

For immediate return to play in the case of minor injury, the physician decides whether the athlete will be safe from further injury. If so, the return to play can be discussed with the coaches, athletes, and other involved parties as to whether the player is able to compete effectively and be painfree. Risk of reinjury will be an absolute contraindication to continuing play, and this must be assessed based on the physician's knowledge of the condition. If the athlete can safely play with his or her injury and there is no risk of reinjury, this must be balanced against how effective the athlete will be on return to play. To gain further insight into the effectiveness of the player, it is common to put the athlete through a series of drills specific to his or her sport. If the athlete experiences pain, then it is common to withdraw him or her from play. However, if the athlete completes the tasks well, then play can be recommenced at the physician's and coach's discretion.

Figure Skating, Injuries in

From its historical origins as a mode of transportation, ice skating has developed into figure skating, a popular sport that combines the highest levels of artistry and athleticism. Mastery of figure skating requires years of practice and continual repetition of skills. Injuries in figure skating are most commonly of the overuse type, largely due to this constant repetition. Acute injuries are less common but certainly do occur as a result of falls, collisions, and errors in the execution of skills.

There are four disciplines in figure skating that the athlete may pursue once the basic skating skills have been developed. First, singles skaters perform multirevolution jumps, spins, step sequences, and edge moves. The second group, pair teams,

Professional figure skaters performing at a "Stars on Ice" show

Source: Can Stock Photo.

consists of a male and a female skater performing all the same moves as the singles skater with additional high-risk skills of overhead lifts and throw jumps. In the third group, male and female skaters can join to form a dance couple. The required skating skills performed in ice dance emphasize quality edges in intricate step sequences and precise body positions to a specific dance rhythm with limitations on spins, lifts, and jumps. Synchronized skating is the fourth and fastest-growing discipline in figure skating. Teams of 16 skaters perform together and are required to do quality edges in intricate step sequences, creating specified formations on the ice. The skaters connect through various arm holds and may also intersect the formations with one another. At the advanced levels, teams perform spins, single-revolution jumps, and lifts under specified limitations.

Contributing Factors for Injuries

More than half of all skating injuries are the result of overuse. The ankle and foot are often involved, with increasing hip, pelvis, and spine injuries occurring as the level of difficulty in skating moves increases at younger ages. Injuries to skaters occur frequently because of their equipment, the boot and blade. Evaluating the fit of the boot and alignment of the foot in the skate can be important in assessing the cause of injury.

Overuse injuries in sports typically result at least in part from lack of flexibility and asymmetry of strength, and skaters are no exception. Additionally, the skater must have correct spinal and body alignment to properly balance on the ice. Issues of flexibility and strength therefore are crucial to the skater maintaining proper alignment and, thus, balance while skating.

Foot

Malleolar bursitis develops with excessive pressure and shear force stress between either the medial or lateral malleous and the boot, creating inflammation and at times significant swelling. This condition often occurs if the boots are breaking down and not providing adequate support. It may also develop as a skater is breaking in a new pair of boots. The goal of treatment is accommodating the boot to the skater's foot. The boot can be stretched or punched out over the malleoli. Doughnut padding with a compressible foam material can also be useful. Aspiration and cortisone injection are typically not beneficial. In rare instances, surgery may be necessary.

"Pump bump," or the Haglund deformity of the calcaneal tuberosity, results from improper fit of the skater's heel in the boot. A loose fit causes the heel to slide up and down in the skate, creating friction, whereas a fit too tight can cause compression. Padding and heel lifts can usually help achieve proper heel fit.

The anterior aspect of the ankle is subject to excessive compression from the tightened laces and creases in the tongue of the boot, causing what is commonly referred to as "lace bite." Tendinitis over the front of the ankle can occur from these boot factors combined with the repetitive bending at the ankle and pointing of the foot. Skin irritation can also develop, and skaters commonly develop a protective callus over the anterior ankle. Proper positioning of the boot tongue and protective padding can alleviate these issues.

Repetitive stress due to bending of the ankle in the boots, along with the loading of jumps and landings, subjects the posterior ankle to potential overuse as well. Achilles tendinitis can result from chronic compression if the boot is too high at the back of the ankle. The boot may be modified by creating a cutout area for the Achilles tendon. Poor flexibility in the Achilles combined with the repetitive plantarflexion during skating push-offs may also contribute to Achilles tendinitis. The posterior tibialis medially and the peroneal muscles laterally work to maintain balance, which may subject them to boot compression or overuse including shin splints. Ongoing and repetitive stress to these structures of the foot, ankle, and lower leg has the potential to lead to stress fractures as well. A thorough assessment of the strength and flexibility of muscle/tendon structures about the ankle is imperative. Careful examination of the boot, blade position, and the skater's foot position in the boot should be done for their contribution to abnormal stress production.

Knee Injuries

Knee injuries in skaters are also typically due to overuse. Acute ligament or meniscus injuries do occur, but less frequently. Since the blade is not fixed to the ice, the characteristic mechanism of an ACL (anterior cruciate ligament) injury of planting the foot and then rotating is more difficult to accomplish on the ice.

Anterior knee pain occurs frequently in the skater as a result of the physical demand on the extensor mechanism of the knee. Jump takeoffs and landings produce significant forces on the quadriceps muscle and extensor structures. Falls may produce contusions to the patella, but fracture is rare. Patellar tendonitis is common and again related to the stress placed on the patellofemoral extensor mechanism. Skaters frequently demonstrate tightness of the quadriceps, hamstrings, and hip flexor muscle groups, along with asymmetry of muscle strength of the hip and thigh from one side to the other or anterior to posterior.

Hip and Groin Injuries

The issue of flexibility and strength of the hip and thigh musculature also increases the risk of groin and hip flexor injuries in the skater. The focus on mastering triple and quadruple multirevolution jumps at younger ages has led to an estimated 25% increase in these injuries among elite skating competitors. Skaters may perform 50 or 60 repetitions of a given jump during a day's practice in an attempt to perfect the execution of the jump. Clearly, overuse strains are a potential problem. Many falls and fumbled attempts occur in the practice of jumps, which can produce more acute injuries such as an avulsion fracture of the ischium or iliac crest. The skeletally immature skater in a growth spurt is especially vulnerable to such an injury. As in other sports, these injuries can be difficult to manage and slow to heal. Focus on proper flexibility, strength, and avoiding excessive repetition plays a critical role in preventing these injuries.

Spine

The spine sustains significant stress during jump landings and several extension moves performed in figure skating. Stress on the posterior elements of the spine is further increased if correct spinal alignment is not achieved and maintained during execution of these moves. Tightness of the hip flexors along with weakness of the lower abdominal core muscles necessitates a hyperlordotic ("sway back") posture to maintain balance. This creates compression and stress on the posterior elements during the hyperextension of the layback spin (extending or leaning backward) or the Bielman position (extending backward while pulling one leg over the head in a U shape). Jump landings occur onto a backward skating edge and can generate a quick hyperextension as the skater regains contact with the ice. If the skater is in a more lordotic posture with weakness in the lower abdominal muscles, he or she will land the jump with the body forward of the center of gravity. To remain upright, the skater must quickly extend the back to regain balance.

Causes of back pain in the skater may include lumbar muscle strains, facet joint sprains, apophysitis (inflammation of tendon attachments to bone), or spondylolysis (stress fractures) of the spine. The development of spondylolysis in skaters is common. Any skater with persistent back pain, especially with extension, should be tested for spondylolysis. X-rays are not very sensitive in identifying this problem; therefore, evaluation with a bone scan is recommended. Further exam with computed tomography (CT) scan or magnetic resonance imaging (MRI) may be necessary. Treatment for spondylolysis includes rest, physical therapy for core strengthening, and possibly bracing.

Upper Body

Injuries of the upper extremities usually occur in paired, dance, and synchronized skaters. Acute injuries such as ligament sprains or shoulder dislocations can develop from missed lifts and falls or errors in partner positions and holds. With synchronized skaters, the repetitive holds may lead to overuse injuries, typically of the rotator cuff and wrist.

Skaters are also at risk for head injuries. Falls, especially from lifts and collisions on the ice, are typically responsible. In synchronized skating, with 16 skaters on the ice and skating closely together, even small errors in position could result in collision and "pileups" on the ice, with risk of head injuries and also lacerations from skate blades.

Finger Dislocation

A *finger dislocation* is an abnormal alignment of the bones of a finger. Due to injury, the bones separate, and one of them moves out from its normal position in the joint. Therefore, the joint's articulating surfaces no longer touch each other, whereas finger subluxation occurs when the loss of continuity between the joint's articulating surfaces is only partial: The bones lose their normal relationship but still touch each other.

Finger dislocation is a common hand injury in athletes. Several sports have been associated with finger dislocations: American and Canadian football, basketball, lacrosse, ice hockey, water polo, cheerleading, rodeo, handball, and volleyball are some among them. Among martial sports, whose practitioners are particularly exposed to finger dislocations, can be cited judo, jujitsu, aikido, wrestling, boxing, tae kwon do, kickboxing, karate, kung fu, and mixed martial arts.

Anatomy

In each finger, there are three bones, called *phalanges*: (1) the *distal phalanx,* which is located furthest from the wrist; (2) the *middle phalanx;* and (3) the *proximal phalanx*. The thumb contains only two phalanges: the proximal and the distal phalanx. Each proximal phalanx is joined to a specific metacarpal bone, one of the five bones that compose the middle part of the hand. Bones are linked to each other in joints: Finger dislocation may involve either the joint between two phalanges, which is called the *interphalangeal joint,* or the joint between the proximal phalanx and the metacarpal bone, which is called the *metacarpophalangeal joint* (see Figure 1).

Around the joints, there are ligaments and tendons. These structures stabilize the joint, holding the bones together, and allow the muscles to perform their movements. Ligaments are bundles of

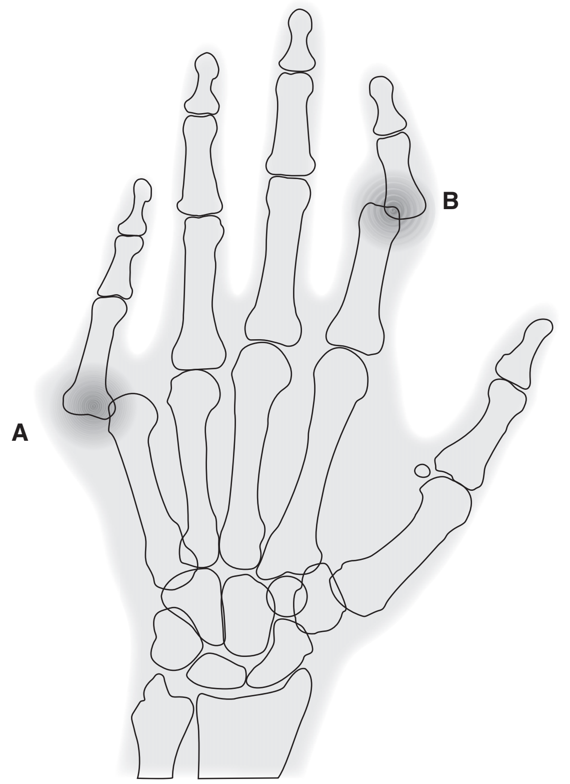

Figure 1 Finger Dislocations: A = Metacarpophalangeal Joint; B = Interphalangeal Joint

fibrous tissue that connect the extremities of different bones. In the hand, each interphalangeal and metacarpophalangeal joint is supported by the volar plate, which forms the floor of the joint, and two collateral ligaments. Tendons are ropelike structures that attach the muscle to the ends of one or more bones. Also, tendons lend further support to joints.

Injuries that cause bone misalignment can also provoke damage to ligaments and tendons. In fact, when bones lose their normal joint position, ligaments may disconnect from their attachment or tear, and tendons may suffer strains and tears. These injuries can cause further joint instability. Moreover, other soft tissues that surround the dislocation site may suffer damage, among them the muscles, periosteum (the tissue that covers the bones), nerves, blood vessels, and connective tissues.

Causes

Sports are among the most common causes of dislocations. A finger dislocation can result from falls and all accidents in which fingers are trapped between objects (e.g., equipment, such as helmets and pads), twisted sideways, and/or forced to hyperextension or hyperflexion. *Hyperextension* is a movement that extends the angle between the bones of a joint, so that this angle becomes greater than normal. For instance, this may occur when an athlete tries to catch a ball with his or her fingertips. On the contrary, *hyperflexion* is a movement that decreases the angle between the bones of a joint, so that this angle becomes smaller than normal. These events occur frequently in sports and especially in martial sports. Dislocations may occur in predisposed athletes even in the absence of severe trauma: Such a predisposition is shown by participants whose ligaments are looser than normal—for instance, those who suffer from congenital ligamentous laxity.

Symptoms

The patient experiences intense pain immediately, at the time of injury, and later, when he or she attempts to move the injured finger. Within a short time following the injury, the dislocated finger swells: Blood flows from the torn blood vessels into the dislocated joint and accumulates. Usually, the dislocated finger appears misaligned or awkwardly bent, but in some cases the deformity may be obscured by the swelling. The injured joint may suffer a loss of function (which results in a limited range of motion of the affected finger) and/or a loss of stability (which results in an abnormal range of motion of the affected finger). If nerves are pressed, pinched, or cut, numbness, tingling, hypoesthesia, or dysesthesia may result in the involved finger below the dislocation.

Diagnostic Tests

To diagnose a finger dislocation, the physician requests information about the history of the injury and makes an initial physical examination. After musculoskeletal and neurovascular evaluation, the physician may order X-ray films from different angles to confirm the dislocation hypothesis and/or detect possible fractures. Imaging studies are repeated after reduction to assess the repositioning of the dislocated bone. After 2 weeks, magnetic resonance imaging (MRI) and/or ultrasound imaging may be required to evaluate the healing process. After some weeks, stress tests will be performed to evaluate joint stability.

Treatment

On-Field Treatment

During on-field evaluation and management, the finger should be elevated at or above heart level, and an ice compress should be applied to reduce swelling and pain. If there are skin lacerations, irrigation must be performed to clean the wounds. Rings should be removed immediately. Medical care should be sought as soon as possible, because delaying treatment increases the risk of permanent damage to the affected joint.

Nonsurgical Treatment

In many cases, a closed reduction can correct the dislocation. This occurs when the physician moves the misaligned bones to put them back in proper position. After evaluating joint stability/instability, the doctor wraps loosely a dry gauze around the injured finger to improve grip. Then, he or she grasps the dislocated finger and makes appropriate motions with the aim of removing the bone extremity from the wrong position and gradually pushing the displaced phalanx into its correct anatomical position. All the motions made for reduction are accomplished gradually and gently, because violent maneuvers may cause permanent injury. After reduction, the physician examines the neurovascular status, the tendon function, the phalanges' range of motion, and the joint's stability. Then, he or she immobilizes the joint with a splint to prevent instability or redislocation. As a general rule, the splint can be removed after 2 to 3 weeks; thereafter, the dislocated finger can be "buddy taped" for 3 to 4 weeks. This technique, in which the injured finger is taped to an adjacent finger above and below the dislocated joint, prevents hyperextension but allows, however, active range of motion (see Appendix A for further information on buddy taping).

Surgery

In some cases, finger dislocations require surgery, for instance, if there is a severe injury to ligaments or tendons, so that these structures need to be repaired. Moreover, it may be necessary to perform an open (surgical) reduction if the injury has caused a dislocation of the volar plate, ligaments, and/or tendons, which could prevent the correct repositioning of the joint bones. If the finger dislocation is an old one, it may be necessary to remove the scar tissue that could have formed after the injury. Finally, operative reduction may be necessary if the joint, though restored to its normal position by a closed reduction, is nonetheless not yet stable. As a general rule, the hand surgeon will expose the joint by means of one or more incisions; then, he or she will reduce the joint and repair the damaged structures. Finally, the surgeon will close the incisions by suture.

Medications

A finger dislocation and the following reduction may be very painful; therefore, the physician may prescribe drugs to relieve the pain, such as analgesics or even narcotic pain relievers. Anesthesia is usually given: local anesthesia in the case of a closed reduction and general anesthesia if surgery is necessary. If there are open wounds and/or a surgical reduction has been performed, antibiotics are prescribed to prevent/fight infections.

Prognosis

The long-term prognosis for finger dislocation is good. However, pain and/or swelling may persist for some months. There is a high risk of recurrent dislocations of the affected joint. This can be due to the damage to the ligament and/or inadequate immobilization of the affected joint after reduction. Delayed reduction may cause loss of joint motion and, thus, limitation of hand function.

Rehabilitation and Return to Sports

When the supportive wrapping can be removed, rehabilitation can begin. The injured area should be massaged with ice before and after a workout. Rehabilitation exercises should be individualized; yet simple activities, aimed at improving the active and passive motions of the injured finger (such as slowly squeezing a tennis ball or extending the fingers), are generally recommended. The athlete can return to sports when the injured finger has regained its full range of motion; however, rehabilitation exercises should be performed even after that date. For several weeks, use of taping during sports may be recommended.

Prevention

Primary prevention involves using protective devices or tapes. Secondary prevention can be carried out by stretching and strengthening the muscles that surround the injured joint.

Finger Fractures: Bennett Fracture, Boxer's Fracture

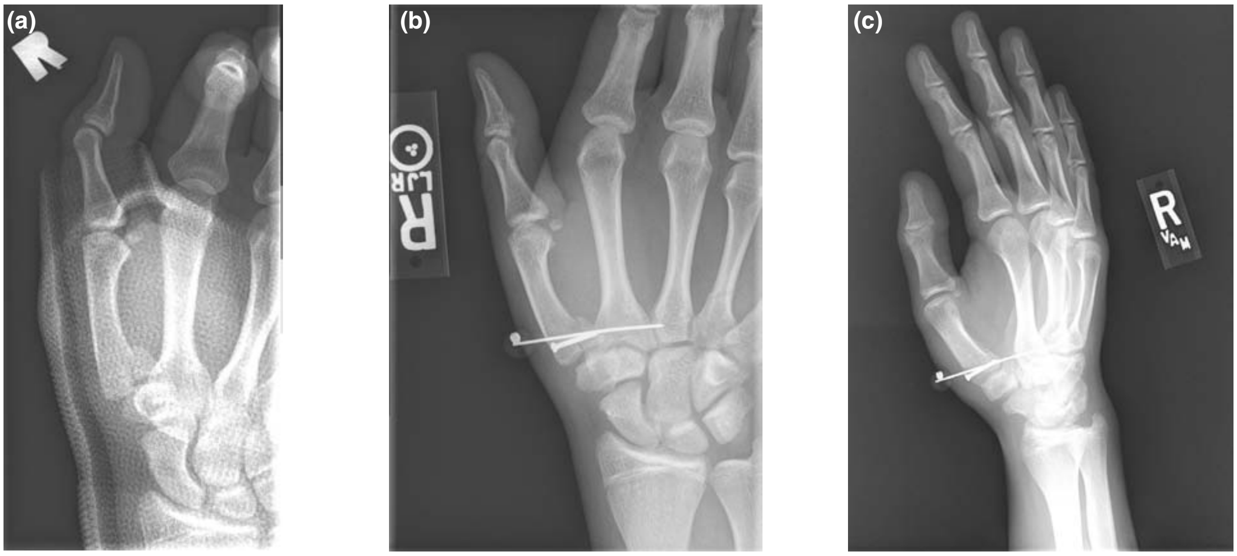
Bennett Fracture

The Bennett fracture, first described by Edward Hallaran Bennett in 1882, is a two-part fracture/subluxation (or dislocation) of the base of the thumb metacarpal involving the volar (palmar) articular surface. This fracture type represents approximately 30% of all thumb metacarpal fractures and occurs when the thumb metacarpal is partially flexed and axially loaded. These are relatively common sports injuries.

Although the fracture fragment can vary in size, it always consists of the volar ulnar aspect of the metacarpal base. The abductor pollicis longus (APL) acts as a deforming force and may displace the metacarpal base proximally, dorsally, and radially and tends to supinate the metacarpal shaft. The adductor pollicis, in contrast, may adduct the metacarpal shaft. The intraarticular volar ulnar fragment is held in a constant position via its attachment to the anterior oblique ("beak") ligament that inserts onto the trapezium. The base of the thumb metacarpal articulates with the trapezium, forming the basilar joint or thumb carpometacarpal (CMC) joint. Axial rotation of the joint is limited by the joint capsule, the ligaments, the extrinsic tendons, and the geometry of the articular surface. The articulation of the thumb metacarpal and the trapezium resemble two interlocking saddles, allowing motion in both flexion-extension and abduction-adduction planes. If Bennett fractures go on to a malunion, posttraumatic thumb CMC joint arthritis will likely develop. The goal of treatment, therefore, be it nonoperative or operative, is to achieve the best articular congruity and stability possible at the thumb CMC joint.

Closed reduction of a displaced Bennett fracture/dislocation should be attempted by applying longitudinal traction on the end of the thumb, coupled with abduction, extension, and pronation of the metacarpal shaft. Manual pressure on the base of the metacarpal may prove to be helpful. If adequate reduction is unobtainable via closed means or is obtainable but is unable to be held over the course of several weeks, surgery may be necessary to ensure articular congruity. Cast immobilization of this fracture pattern has the benefit of avoiding surgical infection risk but is sometimes problematic as it can be difficult to maintain adequate three-point fixation over the thumb metacarpal and to maintain this contact pressure once swelling has subsided. The literature demonstrates poor outcomes if these fractures are treated 4 or more days after injury with cast immobilization. Long-term studies of patients treated nonoperatively for Bennett fractures reveal a high incidence of symptomatic arthritis, with impaired mobility and decreased strength.

Acceptable surgical treatment options include closed-reduction percutaneous pinning (CRPP), open-reduction internal fixation (ORIF), and external fixation. Two percutaneous pinning methods are commonly used for treatment of this fracture pattern. The first is intermetacarpal pinning, where two Kirschner wires are used to hold the thumb metacarpal to the index finger metacarpal. The second pinning option involves placement of a Kirschner wire down the shaft of the thumb metacarpal and through the first CMC joint. If open reduction is required to obtain articular alignment, fixation can be achieved in a number of ways. If the Bennett fragment is large enough, a screw can be used to obtain compression across the fracture site. Similarly, a plate and screws can be used to hold the Bennett fragment to the metacarpal shaft. Instead of using internal fixation, two Kirschner wires can be used to secure the metacarpal shaft to the constant fragment. The wires can be buried under the skin or left exposed and then removed at a later date. If pins are used for fixation, the thumb is immobilized in a thumb spica cast. Trans-CMC joint pins are usually removed 4 weeks after surgery, and fracture fragment pins are usually



(a) Posteroanterior (PA) radiograph of a displaced Bennett fracture that presented to the office 4 weeks after injury. There was a notable intraarticular step-off at the thumb CMC joint. (b) Posteroanterior (PA) view. (c) Oblique radiographs of this fracture postoperatively treated with an interfragmentary compression screw and a Kirschner wire traversing the first and second metacarpal bases.

removed 4 to 6 weeks after surgery. Active range of motion can be started relatively sooner postoperatively if screw fixation is used than if pins are used. Image (a) above demonstrates a radiograph of a displaced Bennett fracture that was presented to the office of one of the authors (C.R.) 4 weeks after injury. Images (b) and (c) show the postoperative radiographs of this fracture after an ORIF using both interfragmentary compression and a temporary Kirschner wire traversing the first and second metacarpal bases.

Although nonunion of a Bennett fracture is exceedingly rare, malunion of these fractures is not uncommon and can result in persistent thumb CMC subluxation. A closing-wedge osteotomy at the base of the thumb metacarpal has been described to correct instability following malunion of a Bennett fracture more than 6 weeks postinjury. Patients with long-standing instability and/or arthritis following a Bennett fracture/subluxation malunion may benefit from a salvage procedure such as arthroplasty or arthrodesis of the thumb CMC joint.

Boxer's Fracture

The term *boxer's fracture* typically describes a fracture through the metacarpal neck of the small finger, but in fact, it can be used to describe a metacarpal neck fracture of any digit. A boxer's fracture of the small finger is really a misnomer, because boxers rarely suffer from this type of injury. A small finger metacarpal neck fracture is more commonly seen in brawlers and in people who hit solid objects such as walls.

The metacarpal neck represents the weakest portion of the metacarpal and commonly is fractured when a clenched metacarpophalangeal (MCP) joint strikes a solid object. The volar aspect of the fracture is affected because the impact occurs on the dorsum of the metacarpal head. As such, the fracture typically has an apex dorsal deformity because the pull of the intrinsic muscles lies volar to the axis of rotation and maintains the flexed metacarpal head posture (see image d, page 528). The metacarpal head tends to displace volarly and proximally. Excess volar proximal displacement leads to an imbalance of the extrinsic tendons and results in a claw deformity. Nonunion of boxer's fractures virtually never occurs, but malunion is a relatively common occurrence. Patients may complain of loss of prominence of the metacarpal head, decreased range of motion, a palpable metacarpal head in the palm, and possible rotatory malalignment.

Several factors help determine the treatment algorithm for these fractures. First, it is necessary to focus on which metacarpal is involved and, second, to assess the degree of angulation. Third, it is important to determine if there is any rotational deformity present. An acceptable volar angulation for these fractures is approximately 40° to 50° for the small finger, 30° to 40° for the ring finger, 20° for the middle finger, and 10° for the index finger. The ring and small fingers have approximately 20° to 30° of laxity in the sagittal plane, and therefore, more angulation may be tolerated in these digits. The index and middle finger CMC joints have less mobility in the sagittal plane, so rotation cannot be compensated for as well.

When performing a closed reduction of a boxer's fracture, the Jahss maneuver can be used. This maneuver involves flexing the affected digit to 90° at the MCP joint, which causes the intrinsic muscles to relax and the collateral ligaments to tighten. An upward dorsal force is then applied to the head of the proximal phalanx at the proximal interphalangeal (PIP) joint, and a downward volar force is applied to the metacarpal proximal to the fracture site. Once the metacarpal neck is reduced, the fracture can be splinted in an intrinsic plus position (wrist extension, MCP flexion) with an ulnar gutter splint for approximately 2 to 3 weeks. If the small finger is the affected digit, it should never be immobilized in the Jahss position (MCP and PIP joints flexed at 90°) following closed reduction. Several prospective studies have been performed comparing splinting, functional bracing, and elastic bandaging after closed reduction. Although there was no difference with regard to patient satisfaction among the three treatment groups, those patients who underwent functional bracing became mobile faster and experienced less pain.

Source: Photos courtesy of Craig M. Rodner, M.D.

If surgery is necessary for a boxer's fracture, the treatment options are similar to those described for Bennett fracture. If reduction can be achieved by a closed technique, the fracture may be pinned by two intersecting Kirschner wires placed within the shaft of the metacarpal (image (e), page 528), or transversely through the fracture fragment to the adjacent metacparpal. The disadvantage of pinning these fractures is that Kirschner wires do not provide rigid fixation and some form of external immobilization is usually necessary. Open reduction of boxer's fractures is indicated when closed manipulation fails to restore an acceptable angulation or rotational alignment. Once the fracture site is opened and the metacarpal neck reduced, the fracture can be secured with Kirschner wires or a plate and screws (image (f), page 528).

If a patient presents with a malunion of a boxer's fracture, an osteotomy can be considered to correct the malalignment if the patient desires.

Finger Fractures: Overview

Phalangeal fractures are common causes of sports-related morbidity. Ball-handling sports, particularly football and basketball, pose the greatest risk. A study of all sports-related hand injuries showed that 71% were fractures and 4% were dislocations. In a recent U.K. study surveying hand fractures sustained during sport activities, 54.1% of fractures were to the phalanges, most commonly the fourth and fifth digits. Young athletes are particularly susceptible to these injuries, with 22.4% of all finger injuries being sports related. The 10- to 19-year-old age-group is the most affected group. Historically, nearly a third of high school football injuries are sustained in the hand.

Clinical Evaluation

As with other injuries, a basic history of the incident provides essential information for diagnosis, treatment, and prognosis. The mechanism of injury will suggest not only the location of injury but also an approximation of the amount of force applied. For example, if a substantial amount of axial force is responsible, simultaneous injury to more proximal structures, such as the carpus or elbow, should be suspected.

General physical examination of the area will likely reveal edema (swelling), ecchymosis (bruising), and tenderness of the affected area. Range of motion and sensation of the affected digit may be decreased. Examining for associated soft tissue injury to collateral ligaments, tendons, blood vessels, and nerves is essential. Stability and stress testing are important for functional assessment immediately after the injury, postreduction if necessary, and throughout the treatment process.

Initial radiographic evaluation of any hand injury should include a minimum of three views. The most revealing radiographs for suspected phalangeal injuries are postero-anterior (PA) and lateral views of the specific digit, centered on the proximal interphalangeal (PIP) joint. If an open wound is present, radiographs can also be used to identify a foreign body, but further imaging, such as ultrasound (US), computed tomography (CT), or magnetic resonance imaging (MRI), may be necessary.

While the orthopedic trauma association provides a detailed classification scheme, fractures can generally be described in terms of location (head, neck, shaft, base physeal) and direction (transverse, spiral, and oblique, comminuted). They should also be classified as open or closed and stable or unstable. Determining these fracture characteristics will guide treatment and prognosis.

Basic Treatment

Most fractures do not require surgery and can be treated with closed reduction and splinting. "Buddy taping" is ideal for nondisplaced and impacted transverse fractures because it involves using an unaffected, adjacent finger as a splint (see Appendix A for further information). Closed reduction of phalanx fractures can be done by anesthetizing with a digital nerve block and approximating the proximal and distal fragments. Reduction is followed by splinting with the metacarpophalangeal (MCP) joint flexed to 90° and the interphalangeal (IP) joint fully extended. Postreduction assessment should evaluate rotation, stability, and strength. Two ways to assess for malrotation are to view all the digits in an end-on position for parallel nail plates and when fully flexed into the palm for signs of overlap. Fractures that are not stable after closed reduction have to be surgically corrected.

Surgery is indicated for phalanx fractures that are unstable, have severe injury to soft tissue structures, are rotationally deformed, or have intra-articular displacement. The following are specific evaluation and treatment considerations for individual phalangeal segments.

Proximal Phalanx

Shaft fractures are more common in adults, and subcondylar and neck fractures occur more often in children. Comminuted or transverse fractures generally result from direct trauma to the proximal phalanx, while spiral or oblique fractures arise from twisting injuries. It is essential to examine both the patient and the radiographs for signs of malrotation and angulation, as both can lead to significant morbidity.

The pull of intrinsic muscles usually pull transverse and short oblique fractures apex volar. However, long oblique and spiral fractures tend to rotate and shorten. Generally, the proximal fragment is held in a flexed position by intrinsic muscles, and the distal fragment becomes extended secondary to extrinsic forces.

Addressing treatment options for each type of fracture depends on its inherent stability and potential complications. Nondisplaced shaft fractures can be treated with immobilization alone. Most minimally displaced stable fractures and reducible stable fractures can be treated nonoperatively. Treatment involves splinting or buddy taping, with some fractures requiring up to 6 weeks to attain full healing.

Generally, a fracture that is not in satisfactory alignment after a closed reduction requires surgery. There are several types of fractures that always require surgery. Spiral-oblique fractures are always considered unstable and require internal fixation. Because even minimally displaced condylar fractures can lead to incongruity, angular displacement, or malrotation, they must be treated surgically. Variants of the subcondylar fractures that involve volar plate entrapment in the joint also require surgical treatment. Fracture dislocations involving greater than 40% of the articular surface often require surgical intervention. Finally, base fractures are most likely to be associated with soft tissue injuries such as extensor tendon, collateral ligament, and volar plate damage, which may require surgical correction.

Middle Phalanx

The middle phalanx is structurally unique because the central slip inserts dorsally and the flexor digitorum superficialis (FDS) inserts volarly. They exert deforming forces onto the fractured middle phalanx fragments. As a result of the pull of the FDS, the proximal fragment of a neck fracture often becomes flexed and creates volar angulation. In comparison, base fractures are affected by central slip extension forces on the proximal fragment and FDS flexion forces on the distal fragment, which create dorsal angulation.

Base fractures require special attention as they can be most functionally devastating. Volar base fractures can result in subluxations in the sagittal plane. The amount of articular surface involved determines the inherent stability of the fracture. Fractures with greater than 40% articular involvement usually require surgical intervention. Otherwise, they can be treated with extension block splinting. Dorsal base fractures can disrupt the integrity of the central slip and result in boutonniere deformity. They can also be accompanied by PIP dislocations. If the fracture is displaced, surgical fixation may be necessary.

Pilon fractures refer to a comminuted metaphyseal and articular surface that causes inherent instability. These fractures have been treated with open reduction and internal fixation, and now, alternatively, are treated with dynamic traction. Anatomic restoration of PIP articular contour is often not achieved, regardless of technique. Open reduction should be approached cautiously and may result in significant complications. Dynamic traction has become the treatment of choice. Complications of pilon fractures include arthrofibrosis or posttraumatic arthritis.

Distal Phalanx

The distal phalanx is anatomically distinct because it contains a tuft region and supports the nail apparatus. Crushing injuries to this region often result in nail bed injuries that can vary from a subungal hematoma to a nail avulsion and entrapment in the fracture site. These soft tissue injuries must be addressed to avoid deformity or nonunion.

The base of the distal phalanx is also the site of insertion for flexor and extensor tendons. While fractures to the volar and dorsal base are less common than fractures in other regions, they are the most unstable and may be associated with tendon avulsions. Most tuft and nondisplaced fractures can be treated nonoperatively.

Physical Therapy

Relying on radiographs alone can delay treatment progression, as clinical improvement often precedes radiographic union. Although the duration of splinting can be determined by patient symptoms, immobilization for longer than 3 weeks is associated with a poor outcome. Range-of-motion exercises for all unaffected digits should commence immediately after the injury and for the affected digit, once it is clinically healed.

Complications

The most common complication of phalangeal fractures is stiffness, and the most effective prevention is with early, protected motion. Stiffness occurs most often when a joint is involved and in post–open reduction internal fixation (ORIF) patients with comminuted and open fractures. While malunion of the fracture fragments may lead to deformity, stable and asymptomatic cases may be treated conservatively. Early judicious use of osteotomy and acceptance of further surgical risks should be considered when there are significant symptoms and loss of function secondary to malunion. Nonunion, though rare, occurs more frequently in open fractures.

Finger Sprain

Ligament injuries of the finger—commonly referred to as *sprains*—are frequently sustained during sports participation, largely due to the hand's role in absorbing the initial contact with players, playing equipment, and playing surfaces. Although many injuries are minor in nature, the potential for misdiagnosis of finger injuries as "jammed" or "sprained" remains high. Proper diagnosis and treatment of finger injuries require a fundamental understanding of the complex anatomy of the finger and its associated tendons and ligaments. Because a comprehensive discussion is beyond the scope of this entry, we will focus on the most common ligament injuries of the hand—those involving the proximal interphalangeal joints and the metacarpophalangeal joints.

Anatomy

The joints of the hand include the carpometacarpal joints, the metacarpophalangeal (MCP) joints, and the interphalangeal (IP) joints. Each finger has two IP joints: a proximal interphalangeal (PIP) joint and a distal interphalangeal (DIP) joint. The thumb has one IP joint.

The collateral ligaments of the MCP joints provide significant sideways (or lateral) movement when the fingers are extended. However, when the fingers are flexed, the collateral ligaments become tight, restricting lateral movement in this position.

The IP joints are strong, hinge-type joints and allow only flexion and extension. Ligaments create a three-sided box around each of these joints. Both MCP and IP joints have thick volar plates on the palmar surface, and the radial- and ulnar-positioned collateral ligaments provide stability while allowing up to 100° of flexion and some joint hyperextension.

PIP Joint Injuries

"Jammed" Finger

The PIP joint is most commonly involved. While most athletes report such injuries from catching or deflecting a ball or catching their finger in a jersey or face mask, this injury can occur in any sport involving a moving ball or player. Axial (downward) loading with hyperextension or valgus (inward) or varus (outward) stress on the joint provides the mechanism of injury in most cases. The radial collateral ligament is the most frequently injured, usually from its proximal attachment. Partial ligament tears predominate.

Volar (palm side) plate injuries usually involve hyperextension mechanisms. Rupture of the volar plate at its distal insertion is most common and manifests as point tenderness over the volar aspect of the base of the middle phalanx (finger bone). Volar plate injuries are often associated with collateral ligament injuries.

Injured athletes typically describe pain and swelling rather than instability. Evaluation should include inspection, palpation, and active flexion and extension of the PIP joint in isolation, which may reveal some instability. Additionally, valgus and varus stress should be applied with the PIP joint in 30° of flexion and the MCP joint in 90° of flexion. Laxity of the injured finger should be compared with that of an unaffected finger. If stress testing results in >20° of deviation, the collateral ligament is completely ruptured.

X-rays (anteroposterior, lateral, and oblique views) of the injured finger will assist in differentiating a sprain from a fracture or dislocation. Treatment depends on the ligament involved. For partial tears of the collateral ligaments, buddy taping (i.e., taping the injured finger above and below the joint) or splinting in full extension is recommended. If the ring finger is injured, it should be taped to the little finger to reduce the likelihood of injury to the little finger, which is naturally extended in the hand's rest position. The duration of treatment is dictated by pain during physical activity, but treatment is typically continued for 2 to 4 weeks.

For volar plate injuries without associated fracture, a progressive extension block splint should be used, starting at 30° of flexion for 1 to 2 weeks. PIP motion should begin following this initial period of immobilization, but significant extension or hyperextension should be avoided as these positions could compromise healing. A total of 4 to 6 weeks of extension block splinting should be completed, increasing the extension weekly to permit increased range of motion. Less severe volar plate injuries can alternatively be buddy taped.

Dislocated Finger

The PIP joint is also susceptible to dislocation resulting from a hyperextension injury. Dorsal dislocation is the most common, although lateral or rotary dislocations also occur. Rupture of the volar plate distally and the associated avulsion fracture commonly accompany this injury.

Reduction is accomplished by using steady traction on the distal phalanx, with slight hyperextension while applying direct pressure over the distal base. This allows the base of the middle phalanx to be gently manipulated over the articular condyles of the proximal phalanx. Once reduced, the PIP joint is continued through flexion. Neurovascular status should be assessed before and after the reduction attempts.

Dorsal and lateral dislocations without associated fractures should be managed in a dorsal splint in 30° of flexion for 3 to 5 days, followed by range-of-motion exercises with buddy taping for 3 to 4 weeks during sports participation. Preventing hyperextension, which may compromise healing of the volar plate, is a key treatment principle.

Thumb MCP Joint Injuries

Gamekeeper's or Skier's Thumb

Ligament injuries to the thumb most commonly involve the ulnar collateral ligament (UCL). Traditionally referred to as "gamekeeper's" or "skier's" thumb (the former being a reference to Scottish gamekeepers who forcefully applied pressure to the back of small animals' heads, thereby breaking their necks, as a means of instantly killing them), this injury typically results from forceful abduction and extension of the thumb, as occurs when a skier falls while holding a ski pole.

The UCL is usually disrupted near its insertion on the proximal phalanx. This injury may involve an isolated ligament tear, an avulsion fracture, or a combination of the two. Occasionally, the UCL becomes trapped outside the adductor aponeurosis, resulting in a Stener lesion. Stener lesions present with a mass over the ulnar side of the MCP and lack an end point when ulnar stress of the MCP joint is performed in both extension and 30° of flexion. Up to one third of UCL injuries involve Stener lesions.

Examination yields pain, swelling, and/or bruising over the ulnar aspect of the MCP joint. X-rays may show a small avulsion fracture involving the ulnar side of the first MCP base. Stress radiographs, performed with the MCP joint maximally flexed and with radially directed stress, are helpful in assessing stability. Greater than 35° of laxity implies instability.

Thumb spica splint immobilization for 6 weeks is the initial treatment for stable UCL injuries without fracture or with nondisplaced fracture. Surgery is the treatment of choice for Stener lesions or displaced avulsion fractures.

Athletes may return to play protected in a splint if comfortable and if their sport allows for thumb immobilization. Otherwise, return to play is allowable only when the joint is stable and healing has occurred.

Finger MCP Joint Injuries

The MCP joint of the finger is relatively resistant to ligamentous injury. When injury occurs, hyperextension is the typical mechanism, and partial ligament tears occur.

Dislocation of the MCP joint can accompany hyperextension injuries to the ligaments; most commonly, the index finger is involved, followed by the little finger. Dislocations are almost exclusively dorsal, resulting from volar plate rupture.

X-rays should be obtained to differentiate between a ligament sprain, dislocation, and fracture. Stress X-rays can be helpful in assessing for joint instability but should not be obtained in the case of nondisplaced avulsion fractures.

Partial MCP collateral ligament tears with or without minimally displaced or nondisplaced avulsion fractures are often treated with splinting for 3 weeks and with protective splinting during sports participation for an additional 3 weeks. The MCP joint should be splinted in 30° of flexion to prevent extension contracture. For the middle finger, buddy taping to an adjacent finger is an alternative to splinting. For the other fingers, buddy taping may be used after an initial course of splinting. Strengthening exercises should begin 6 weeks after injury.

If symptoms continue beyond 1 month despite conservative management or if instability develops, surgical treatment should be sought.

Fitness Testing

The importance of exercise in maintaining good health is becoming increasingly evident. This is highlighted by the American College of Sports Medicine's recent "Exercise is Medicine" campaign. It is recommended, however, that before beginning an exercise program, one should undergo an evaluation by one's primary physician, so as to determine if there are any contraindications or risks to exercise, to delineate any disabilities that require treatment and/or activity adjustments, and to elucidate one's current fitness level and specific exercise needs. Such fitness testing can also be used to monitor an individual's progress within an exercise program as well as to motivate that individual within his or her program. This entry discusses the importance and components of fitness testing.

What Is the Purpose of Fitness Testing?

One of the primary focuses of fitness testing is to highlight individuals at risk for exercise-related sudden death. This risk stratification involves several general categories, including the individual's age, medical conditions, coronary artery disease risk factors, and signs and/or symptoms of cardiovascular or pulmonary disease. Older age, greater than 45 years in men and greater than 55 years in women, is associated with increased risk. Women younger than 55 years, who have undergone menopause without hormone replacement therapy, are also at increased risk. Having an existing diagnosis of a cardiovascular, pulmonary, or metabolic disease can also increase one's risk of exercise-related sudden death. Pertinent cardiovascular diseases include heart disease, peripheral vascular disease, and coronary artery disease. Cystic fibrosis, chronic obstructive pulmonary disease (COPD), and asthma are among the pulmonary diseases associated with exercise-related sudden death. Common metabolic disorders associated with exercise-related sudden death include diabetes mellitus and thyroid disease.

Coronary artery disease risk factors are many. One coronary artery disease risk factor includes hypertension, either having a blood pressure >140/90 millimeters of mercury (mmHg) or taking an antihypertensive medication. Hypercholesterolemia, also a coronary artery disease risk factor, can consist of low-density lipoprotein (LDL) levels >130, high-density lipoprotein (HDL) levels <40, total cholesterol >200, or taking a lipid-lowering medication. An elevated HDL level (>60) is considered a negative risk factor. Another coronary artery disease risk factor is obesity, which can be defined as a body mass index (BMI) >30, a waist-to-hip ratio >0.95 in men and >0.86 in women, and a waist circumference >102 centimeters (cm) in men and >88 cm in women. A fasting blood glucose level of 100 or greater is a coronary artery disease risk factor, as is having a family history that includes acute myocardial infarction (MI) and sudden death in men <55 years old and in women <65 years old. The last two coronary artery disease risk factors are purely related to behavior—a sedentary lifestyle and smoking—currently or within the past 6 months.

Cardiovascular and pulmonary disease can also present with a variety of signs and symptoms. Cardiac symptoms include palpitations, heart murmur, chest pain, and other signs of myocardial infarction, such as jaw or arm pain. Shortness of breath with activity or at rest and unexplained fatigue can be symptoms of cardiac or pulmonary disease. Dizziness can be a symptom of cardiovascular insufficiency (i.e., inadequate blood flow), as can claudication (pain in the legs, associated with walking) and ankle edema (swelling in the ankles, related to poor blood return to the heart). Orthopnea, immediate difficulty breathing while lying flat, and paroxysmal nocturnal dyspnea, delayed difficulty breathing after lying flat, both relieved by sitting up, are also symptoms of cardiovascular disease, as the inadequate blood flow from the heart can cause fluid congestion in the lungs.

Components of Fitness Testing

Having an understanding of the purpose of fitness testing provides a foundation for the application of the components of fitness testing. There are five major parts of a fitness test, including (1) general health measurements, (2) body composition measurements, (3) cardiovascular assessments, (4) flexibility testing, and (5) muscular strength testing (i.e., the force generated by muscle or muscle group) and muscle endurance testing (i.e., the ability of a muscle or muscle group to contract repeatedly over a period of time). The most commonly used general health measurements include height, weight, resting heart rate, and resting blood pressure. The body composition measurements most commonly performed include skin fold testing, approximating total body fat based on caliper measurements at the abdomen, ilium, triceps, and thigh; BMI, the ratio of one's weight (in kilograms) to the square of one's height (in meters); waist circumference; waist-to-hip ratio; and bioelectrical impedance analysis. Less commonly used body composition measures include hydrostatic weighing for body fat and bone density testing (via dual-energy X-ray absorptiometry [DEXA] or total body electrical conductivity [TOBEC]).

Cardiovascular components of fitness testing are many and may vary in their use based on the individual's fitness level and capabilities, as well as on the exact purpose of the test. If feasible, the individual may be tested with field tests outside, such as a 12-minute run, a 1.5-mile (mi; 2.41-kilometer [km]) run, or a 1-minute walk. If outside testing is unavailable or unfeasible, step testing can be performed. Treadmill testing is another viable indoor option and includes tests such as the 1-mi (1.61-km) walk and the Bruce and Balke-Ware protocols, which gradually increase the metabolic equivalents (METs, representing the physiologic intensity level of exercise) that apply to the individual. The Bruce protocol, with its relatively rapid and large rise in METs per stage, is most commonly used for young and athletic individuals. The Balke-Ware protocol, with its smaller escalation in METs per stage, is more suited to older and less fit individuals.

The last two components of fitness testing include flexibility and muscle strength and endurance testing. The most common flexibility test is the sit-and-reach test, which measures how far one can reach beyond one's toes from a seated-forward bend. Additional flexibility testing involves measuring individual joint angles. Muscle testing involves testing both the strength of muscles, with heavy resistance and fewer repetitions, and the endurance of muscles, with light resistance and more repetitions. Commonly used muscle tests include the grip test, the dynamometer, chin-ups, push-ups, sit-ups, curl-ups, and the bench press.

Should an individual be at moderate or high risk of exercise-related sudden death (see Table 1), he or she may benefit from graded cardiovascular exercise testing with a monitored physiologic response. The individual would participate in indoor treadmill testing, using either the Bruce or the Balke-Ware protocol mentioned earlier, for example, while the evaluator monitors the individual's heart rate and blood pressure response, electrocardiogram (EKG),

Table 1 Risk Level of Exercise-Related Sudden Death

Risk Level	*Age (years)*	*Symptoms*	/	*Risk Factors*
Low	Men: <45 Women: <55	None	or	≤1
Moderate	Men: >45 Women: >55	None	or	≥2
High	Men: >45 Women: >55	≥1	or	cardiac, pulmonary, or metabolic disease

rate of perceived exertion (RPE), METs, and/or $\dot{V}O_2max$. A monitored exercise test may be stopped if the individual requests that the test be stopped, the clinician monitoring the test requests that the test be stopped, the individual develops symptoms of physiologic stress, the maximum limit for the test has been reached, or the ACSM (American College of Sports Medicine) conditions for stopping have been met.

Who Performs Fitness Testing and Under What Conditions?

After understanding how fitness testing is performed, it is important to understand who performs fitness testing and under what conditions it should be performed. Fitness testing should be performed in a safe environment of low stress to the individual. This includes providing sufficient patient education as to the various components of the test as well as providing a quiet and comfortable environment with a relaxed, confident, and competent staff. Generally considered safe, exercise testing can be performed by exercise physiologists, physical therapists, nurses, physician's assistants, and medical technologists. As the rates of cardiovascular complications during exercise testing in the presence of paramedical personnel and in the presence of physicians are similar, it is considered appropriate to have paramedical personnel present during the test or to have the test conducted under the direct supervision of a physician in the immediate vicinity. A physician must directly supervise an exercise test if the patient has recently undergone a cardiac event or if the patient requires graded exercise testing. Supervising physicians must have knowledge and understanding of the following: basic exercise physiology, cardiovascular and hemodynamic responses to exercise, and the effects of aging disease, and medication on exercise; the indications for, contraindications to, methods of, appropriate and necessary modifications to, and reasons for termination of exercise testing; and the American Heart Association–approved cardiopulmonary resuscitation and advanced cardiac life support training.

Conclusion

Fitness testing, involving general health and body composition measurements, cardiovascular and flexibility assessments, and muscular strength and endurance testing, can be used as a tool to determine an individual's physiologic readiness to participate in exercise. The results of an individual's fitness test can be used to create an exercise prescription, as well as to monitor that individual's fitness level in the future.

Flat Feet (Pes Planus)

Pes planus (flat feet), sometimes referred to as "fallen arches," is a condition where the long arch of the foot collapses or never develops. It is a condition that can have a serious effect on an athlete's performance, as well as predispose the athlete to injury.

At birth, infants usually appear to have no arch due to the amount of fat they have in this area as well as the loose ligaments that are common in infancy. The arch will develop in most children by the time they are 2 to 3 years old. In adults, pes planus can develop over time from mechanical stress that occurs as the result of anatomical problems, prolonged stress on the foot, the aging process, diseases such as diabetes, or faulty biomechanics.

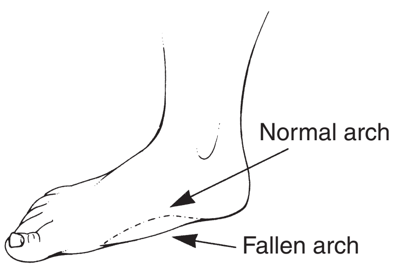
There are generally two types of flat feet, rigid and flexible. Another way to look at the condition is to see whether the foot is structurally flat or whether it flattens out. People can also develop flat feet over time.

It is important to diagnose what factors contribute to the individual's condition so that treatment is appropriate.

The Rigid Flat Foot

A rigid flat foot can be associated with a fusion of two or more bones in the foot, called a coalition. A coalition will limit motion in the foot, often leading to pain and deformity. This condition can be usually diagnosed with X-rays or computed tomography (CT). The condition will stop motion at the site of the joined bones. Depending on the bones joined, symptoms can vary from localized pain to painful muscle spasms that greatly limit activity. Treatment can consist of orthotics and physical therapy, but sometimes surgery is needed if conservative care fails to give the patient relief.

A rigid flat foot can also result from the progressive collapse of the arch over time with associated arthritis. The causes of this collapse can vary among structural variants in the foot, bad biomechanics that put stress on the feet, diabetes, injury, and improper footwear.



Flexible Flat Feet

A child or adult with a flexible flat foot will usually have a normal-looking arch when he or she is not bearing weight, such as when on an examining table. However, when the individual stands, the arch will collapse, sometimes causing the bones of the foot to contact the ground. Usually, the individual can stand on his or her toes and re-create the arch. These individuals will lack the "rigid-lever" effect of the foot at toe-off. This can lead to poor performance, improper biomechanics, and injury in both the foot and the legs. Some examples of injuries that can occur are shin splints, stress fractures in the feet and legs, and patellofemoral syndrome.

Conditions That Can Lead to Flat Feet

Some structural variants that can lead to flat foot are an accessory navicular, an extra bone that can get in the way of the supporting structures of the foot; a bony blockage in the front of the ankle that over time leads to mechanical stress on the bones of the foot, leading to collapse of the arch; and even a high arch. In individuals with a high arch, osteoarthritis can develop in the midfoot area, leading to damage to the bones and support structure, which can eventually lead to collapse of the arch.

Biomechanics and the Development of Flat Feet

Poor biomechanics can result in forces that cause the foot to flatten when the individual stands or flat foot to develop slowly over time. This can arise from conditions such as leg length inequality, genu varum (bowlegs), lack of or excessive tibial torsion (the "twist" of the lower leg from the knee to the ankle), genu valgum (knocked knee), or tight calf muscles. By identifying the cause of the deforming force, treatment can be properly focused on the cause rather than the result. This can also help the athlete identify a biomechanical problem that may be interfering in performance in other areas—for example, a figure skater who cannot get an inside edge and who is bowlegged.

Treatment

Some doctors advocate no treatment unless symptoms arise. However, if deforming forces are present that are affecting the athlete's performance or have the potential of causing irreversible damage later in life, early treatment is warranted. If an injury is present, it is important to determine the role of the foot's mechanics in the athlete's problem.

Again, treatment should be directed at the causative factor(s). Something as simple as a heel lift in an individual with an anterior ankle block or a lift in an athlete with leg length inequality can be all that is needed. In cases with injuries resulting from the flat or flattening foot, a team approach may be more appropriate. For example, a treatment regiment here could run the spectrum from orthotics to control the foot mechanics to surgery on a knee to repair a torn meniscus.

The athletic coach should be made aware of any findings; these could help contribute to the athlete's performance and overall well-being.

Foot and Ankle Injuries, Surgery for

The ankle and foot play a major role in virtually all types of athletic competition. Any sport that requires running, jumping, or rapid change of direction places significant demands and high-energy stress on the bones, tendons, and ligaments of the foot and ankle. Sports such as football, basketball, baseball, soccer, and track-and-field events are just a few examples of high-impact activities that commonly result in foot and ankle injury. A clear diagnosis is imperative to initiate appropriate treatment and optimize rehabilitation. In some cases, surgery is indicated as the primary mode of treatment, but in most cases, initial management most often consists of the RICE mnemonic: *r*est, *i*ce, *c*ompression, and *e*levation. Surgery is often required for fractures, repeated injury, or joint instability or if initial attempts at conservative treatment fail.

Ankle and Foot Anatomy

The *ankle joint* and the *subtalar joint* complex (subtalar, talonavicular, and calcanoecuboid joints) are the key to hindfoot function. The ankle joint is a *mortise and tenon* joint connecting the lower leg and the foot. It is formed by the *talus* (ankle bone), which fits into a socket formed by the lower ends of the *tibia* (shinbone) and the *fibula* (a thin bone on the outside of the leg). The tibia and fibula form a sturdy unit (or mortise) that cups the talus (or tenon). The ends of the tibia and fibula have bony prominences called *malleoli,* which help hold the talus in the correct position during movement. The surfaces of the talus, tibia, and fibula that articulate (rub) during ankle motion are covered by smooth cartilage (e.g., gristle on a chicken bone) to minimize friction. Below the ankle joint is the subtalar joint, which is formed by the bottom of the talus and the top of the *calcaneus* (heel bone).The talus is mostly cartilage surface contributing to the ankle joint, the subtalar joint, and the talonavicular joint. The three joints of the subtalar complex, the talonavicular, subtalar, and calcanoecuboid, all work together, and if there is abnormality in one of them, it will affect overall subtalar movement and function.

The rest of the foot is very complex, as there are 28 bones and more than 30 joints in the foot. The *tarsal* bones of the foot connect to the talus and calcaneus at the back and the *metatarsals,* the five long bones of the foot, in front. Each of the five metatarsal bones connects to one of the five toes (the first metatarsal connects to the big toe).

The muscles of the ankle and foot can be divided into *intrinsic* and *extrinsic* muscles. Intrinsic muscles (within the foot) serve mainly to move the toes and support the arch of the foot. Extrinsic (outside) muscles arise on the lower part of the leg. Each of the extrinsic muscles has a tendon that crosses the ankle joint. Tendons are strong fibrous bands of tissue that connect muscles to bone and provide the force needed for movement. Tendons arising from the extrinsic muscles of the lower leg assist in movement of the ankle, foot, and toes. Ligaments are strong fibrous bands of tissue that connect bone to bone for stability. Three important sets of ligaments hold the bones of the ankle in correct alignment, providing further stability.

Ankle Joint Function

The mortise and tenon nature of the ankle joint mainly allows the foot to move upward (*dorsiflexion*) and downward (*plantarflexion*) during running and walking while providing a great degree of stability to the joint. The side-to-side motion generally attributed to the "ankle" actually comes from the subtalar joint, which is not as constrained.

The strength and power needed for movement at the ankle comes from four groups, or *compartments,* of muscles in the lower leg. Two compartments are behind (posterior to) the tibia. The calf muscles are in the more *superficial* (surface) posterior compartment and are connected by the Achilles tendon to the heel bone. This connection provides the strength used to push off the ground when running or jumping. Under the calf muscles is the *deep* posterior compartment of muscles, which allows for rotation of the foot inward toward the body (inversion). There is one muscle compartment in the front (anterior) of the leg that provides force for upward movement of the foot. Overuse of the muscles in the *anterior* or deep posterior compartment can be a cause of "shin splints" (discussed in a separate entry). There is one muscle compartment outside (*lateral*) the leg that mainly provides force for rotation of the foot outward, away from the body (eversion).

Foot and Ankle Injuries

Both the professional athlete and the "weekend warrior" place enormous amounts of strain on the ligaments, tendons, and bones of the foot and ankle during competition. When the demands of an activity are too great, the result can be tearing, inflammation, or fracture of these structures. For the majority of sports-related foot and ankle injuries, initial attempts at treatment are conservative. Treatment consisting of rest and immobilization, ice, anti-inflammatory medications, and a course of physical therapy is usually quite successful. In severe injuries, or when these methods fail to produce satisfactory results, surgery may be necessary to help the athlete get back to competition. Decreased stability as assessed by the surgeon on physical exam and confirmed by X-rays of the ankle joint is the most important factor guiding the need for surgery. Ligament *sprains,* chronic *tendinitis,* tendon *rupture,* and *fractures* often result in instability or dysfunction and often require surgery. It is important to understand that all surgeries carry the risk of infection, bleeding, pain, and possible damage to the surrounding nerves or vessels. Additionally, after any operation involving the foot and ankle, a course of immobilization is usually required during the initial period of healing. This can involve a cast or a splint and may require the athlete to be non–weight bearing on the affected leg for a period of time. A course of physical therapy to achieve normal muscle strength and range of motion is also essential to the success of any operation and will help facilitate a much quicker return to competition.

Sprains

Sprains are the most commonly encountered sports-related foot or ankle injury, especially in sports that require quick changes of direction. About 25,000 people experience an ankle sprain each day. Sprains arise when the ligaments connecting two bones together are stretched more than normal. The classic example is when an athlete "rolls" an ankle. There are three degrees of ligament sprain. Grade I sprains are the most common, and in this case, the ligaments are often not actually torn but have been stretched to the point where they are microscopically damaged. There is no instability, and these mild sprains require less treatment and time to heal. A Grade II sprain is more severe, with the ligaments having been partially torn. A Grade III sprain indicates that the ligament has been significantly damaged or completely torn to the point where there is instability of the joint. With all degrees of sprain, there is associated swelling, pain, and bruising.

Acute (sudden) sprains are treated conservatively and usually heal well on their own with proper rest and rehabilitation. Multiple acute sprains or the failure of the ligaments to heal properly can lead to *chronic instability*. With severe sprains, there may be an associated fracture of any of the bones that make up the ankle joint, most commonly one of the malleoli. With chronic instability, damage can result in abnormal motion of the joint and loss of stability. This level of injury often requires surgery to repair ligaments or fix broken bones in position to allow for proper healing and stability.

Surgery for Ankle Fractures

Severe sprains are often associated with fractures, commonly malleolar fractures. Because it is the function of the malleoli to hold the ankle joint in place, malleolar fracture can result in instability. A lateral (outside) malleolar fracture is a fracture of the end of the fibula. Surgery is not always required, but if the bone is out of place or the ankle is unstable, the bone pieces can be “fixed” together with either a plate and screws on the side of the bone or a rod on the inside of the bone to keep the fragments in place as they heal. A medial (inside) malleolar fracture is a fracture of the shinbone. Similar techniques are used in surgery to treat medial fractures. Sometimes medial fractures are treated with surgery even if the ankle is not unstable to decrease the risk of *nonunion* (not healing). Postoperatively, immobilization is usually required until healing occurs, and then, motion and strengthening exercises are initiated. Weight bearing is also increased as healing progresses and is confirmed with X-rays; healing usually takes approximately 4 to 6 weeks.

Surgery for Severe Sprains and Instability

The *lateral* (outside) *ligaments* are the most commonly sprained. This occurs during an injury in which the foot “rolls” inward (inversion), putting stress on the outside of the ankle. Surgery for an acute sprain is rare but mainly involves *arthroscopy,* during which small cameras are placed inside the joint to visualize and remove loose fragments of bone or cartilage. Multiple sprains can lead to *lateral ligament instability,* a chronic condition in which the ankle tends to roll into inversion during routine activity because the ligaments no longer provide enough support on the outside of the ankle.

There are two categories of surgery for lateral instability. *Anatomic repair* is preferred because it is a smaller surgery and maintains normal motion of the joint. It involves direct repair and tightening of the torn lateral ligaments with sutures. In cases where the ligaments are too badly damaged for anatomic repair, the ligament is replaced with a piece of one of the healthy tendons from the patient’s ankle. In this procedure, holes are drilled into the fibula and talus to anchor the tendon to its new location. This procedure, *tenodesis* or tendon transfer, provides a great deal of stability at the cost of decreased ankle and subtalar motion and a bigger incision. After surgery, 3 to 6 weeks of cast immobilization, followed by a course of strengthening and rehabilitation, is required.

The *syndesmotic ligaments* connect the tibia and the fibula together to form the upper part of the ankle joint. Syndesmotic sprains are commonly referred to as “high ankle” sprains and tend to take longer to heal than the more common lateral sprains. Syndesmotic sprains are most often treated with a non–weight-bearing cast for 6 weeks. If a bone fracture at the ankle is also seen, syndesmotic sprains are frequently unstable. For unstable sprains, surgery may be necessary for placement of a screw(s) to hold the tibia and fibula together while the ligaments heal.

The *deltoid ligament complex* on the inside of the ankle is injured when the foot is rolled toward the outside of the body, putting stress on the inside of the ankle. These sprains are seldom seen without a simultaneous fracture or syndesmotic sprain. Surgery is only required when deltoid sprains are associated with ankle fracture or syndesmotic sprains, leading to instability, but it consists of the same techniques discussed previously.

Another injury seen in athletes is the *Lisfranc sprain,* occurring at one or more of the joints connecting the small *tarsal* bones in the middle of the foot and the longer *metatarsal* bones in the front of the foot. A simple ligament sprain at the Lisfranc joint will cause dislocation of the small bones of the foot. A more severe Lisfranc sprain may be associated with fracture of the metatarsals. Surgery consists of percutaneous (through small puncture holes in the skin) placement of screws or wires across the Lisfranc ligament to fix the bones in the correct anatomic position. With severe displacement of the site of injury, an incision or multiple incisions may be required to put the injured bones back in place and stabilize with screws. After surgery, patients are non–weight bearing for at least 6 weeks, and screws are kept in place for 6 to 12 weeks.

Tendon Problems

Tendon problems of the foot and ankle are common in athletes. Tendinitis represents overuse injury that causes the muscle tendon to become irritated and inflamed. This inflammation, if not properly treated with rest and anti-inflammatory medications, can lead to degeneration of the tendon, which then predisposes to rupture or tearing of the tendon. Rupture can be either partial or complete and is an important cause of pain and instability of the joint that may require surgery. Management of tendon problems is initially conservative, with rest, ice, anti-inflammatory medications, and physical therapy. Tendinitis and even tendon ruptures are often able to heal on their own without surgery. The most commonly injured tendon in the ankle is the Achilles tendon, which connects the calf muscles to the heel bone. Normal function is essential for jumping, running, and other sporting activities. Partial and complete Achilles tears can be treated nonoperatively with immobilization; however, it is reasonable to suggest operative treatment when the patient is active and healthy in order to hasten recovery and return to sport.

Surgery for Tendinitis and Tendon Rupture

Surgery for tendon problems is used to treat inflammation and tendon damage before degeneration occurs and to repair partially or completely torn tendons. Inflammation of the sheath surrounding a tendon, or of the tendon itself, can be treated with debridement (removal of damaged tissue), done through incisions or alternatively through small holes with cameras, called *tendoscopy.*

Surgery for an Achilles rupture involves *approximating* the two ends of the torn tendon close together with sutures to allow healing. This is the best option for acute tears when there are sufficient healthy tendons available. Reconstruction of the tendon with a graft (healthy tendon harvested from another part of the body) is a better choice for more chronic cases with a long history of tendinitis because the tendon is not as healthy and is more likely to rerupture. Surgery to repair other ruptured tendons in the ankle is less common but can also involve using graft or tendon transfer. Rehabilitation in these cases often involves walking in a walking boot with a heel lift for the first few weeks to reduce tension on the repair site. The heel lift can be reduced every 2 weeks and discontinued 6 weeks after surgery. At 6 weeks, strengthening and gradual return toward activity can begin.

Stress Fractures

Stress fractures of the smaller bones of the foot are seen in athletes, most commonly in the fifth metatarsal (outside the foot) and the navicular bone. With repetitive activity, overload of these bones can occur, and the repetitive stresses can cause a stress fracture or crack in the bone. Most stress fractures can heal with rest and protective braces or inserts for 2 to 4 weeks. Stress fractures may require surgery to ensure adequate immobilization and to promote timely healing.

Surgery for Stress Fractures

Surgery for stress fractures is often important to ensure that the injury heals properly. In athletes, surgery is also a consideration because it may speed return to sport. Surgery for navicular fractures involves placing a screw across the fracture line to fix pieces firmly together. For fifth metacarpal fractures, a screw is placed inside the bone (intramedullary) to allow for healing. Postoperatively, weight bearing and return to activity depend on healing of the fracture as seen clinically, on X-rays, and on special scans such as magnetic resonance imaging (MRI) or computed tomography (CT).

Foot Fracture

Foot fractures require special attention in the world of sport. Whether it is the basketball player cutting to the basket, the ballet dancer en pointe, or the snowboarder losing the edge, the foot is vulnerable to fracture in many different ways. The human foot is placed under an extraordinary amount of stress during sports. Injury to the foot can mean pain and loss of productivity for the weekend warrior or the end of a career for the elite athlete. Injuries to the foot are common. Acute fractures occur less frequently than stress fractures but are important to recognize as diagnosis can sometimes be difficult. This entry first outlines general principles and then goes on to discuss specific fractures.

General Principles in Fracture Management

The human foot is essential for mobilization, and as such, delay in the diagnosis and treatment of fractures can result in long-term consequences such as chronic pain, immobility, stiffness, loss of balance or position sense (proprioception), decreased range of motion, and loss of strength.

To diagnose a fracture, a thorough history and physical exam are essential. Knowing exactly how the injury occurred provides clues to diagnosis. During a physical exam, point tenderness is the best indicator of injury. It is crucial to understand the anatomy. Physicians consider the Ottawa Ankle/Foot Rules when deciding to X-ray the foot (see the entry Ankle Injuries). X-rays should be obtained if there is

- bone pain in the foot,
- tenderness at the base of the fifth metatarsal bone, or
- tenderness over the navicular bone or
- if the patient cannot take four steps bearing weight on the foot.

Suggested views are anterior-posterior, oblique, and lateral, to best visualize the complex architecture in the foot. Once the fracture is identified, it should be reduced (realigned) as quickly as possible to minimize the swelling that comes with the injury. Sometimes surgery may be required to achieve the best alignment.

It is important, while dealing with a fracture in the foot, to recognize the important role of therapy and rehabilitation early in an effort to prevent long-term complications. Immobilization should be limited to as short a time as possible, though sometimes it is essential to proper healing. Work to restore motion early, and when immobilizing the foot or ankle, allow motion in the toes to prevent stiffness and future complications in rehabilitation.

Proximal Fifth Metatarsal Fracture

The proximal fifth metatarsal is vulnerable to fracture in sports. The location of the fracture depends on the mechanism of the injury. You can recognize the base of this bone as the "bump" along the outside (lateral) portion of the foot. There are essentially two types of acute fracture.

The most proximal (closest to the heel) is an avulsion fracture. This occurs with an extreme inversion of the ankle (the sole of the foot folds inward). Avulsion literally means that the muscle tendon that attaches at this location (peroneus brevis) tears off the end portion of the bone. This causes a fracture, usually diagonally, through the base of the metatarsal. The fracture is usually easy to see on an X-ray. So long as the fractured portion is not severely displaced, it can heal well by treating the foot one would treat a severe lateral ankle sprain. Immobilization can help reduce the pain but is not necessary for healing. With initial weight bearing as tolerated in a hard-soled shoe, this fracture can heal in as few as 6 weeks. If it is significantly displaced, it may require surgery with a screw or pin to hold it in place while it heals.

The next fracture to the proximal fifth metatarsal happens slightly more distal than the avulsion (further toward the toe) and occurs by a different mechanism. The Jones fracture occurs with medial to lateral force, similar to the cutting maneuver common in soccer or basketball. The pressure placed on the proximal fifth metatarsal (outside the planted foot) is so severe that a fracture occurs. This fracture is notoriously more difficult to heal and is seen as a more horizontal fracture on X-ray, generally. Its healing process involves non–weight-bearing immobilization for 6 to 8 weeks and then slow reintroduction of weight while in a postoperative shoe for several more weeks. In high-performing athletes, this extended time off is often detrimental, and so surgical screw fixation hastens return to sport. In this case, non–weight bearing 1 week after surgery, then 2 to 3 weeks in a postop shoe is suggested. Full return to the sport can occur within 6 to 10 weeks.

Lisfranc Fracture/Dislocation

The tarsometatarsal joint is the junction between the metatarsal and the tarsal bones. It can be approximated by finding the highest point of the arch on the dorsal (top) surface of the foot just before the foot slopes down to the toes. This joint constitutes the junction between the midfoot and the forefoot.

Fractures can occur anywhere along the joint lines. Common injury mechanisms in sports come from extreme force being applied to the heel of a planted forefoot. This is most common in contact sports and in ballet, if the dancer's weight shifts too far forward, buckling the joint. With this fracture, the ligaments holding the bones in place are often damaged, causing a dislocation or separation of the bones. Hence, the resulting injury, often called a Lisfranc fracture (after Napoleon's surgeon, who first noticed the pattern of the fracture), is termed a *fracture dislocation.*

Diagnosis is often difficult but important, because if missed and left untreated, Lisfranc injury can cause chronic foot pain and disability. Most often, swelling is seen on top of the foot and bruising at the bottom. There is pain while pressing along the joint line and with passive movement. Stressing the joint with weight-bearing X-rays will reveal the dislocation if present.

Treatment is based on the stability of the joint and the severity of the fracture. A stable joint responds to the conservative treatment of initial non–weight bearing in a molded cast with progression to full weight bearing. Repeat X-rays are done to ensure proper alignment while in the cast. For an unstable joint or severe fracture, surgery may be necessary. The goal of surgery is to obtain proper anatomic alignment, often with the use of wire or screws to secure the bones. Postoperative care is similar to postoperative care for proximal fifth metatarsal fracture in that it involves non–weight bearing for an initial amount of time followed by progressive weight bearing. If treated appropriately, this injury can heal well after proper rehabilitation.

Lateral Process of the Talus Fracture

The talus, located above the calcaneus (heel bone), is involved in rotation and hinging movements and creates the ankle joint with the distal tibia and fibula. The lateral process can be felt as the bony prominence just inferior to (below) the lateral malleolus. Fracture to this lateral process is seen almost exclusively in snowboarding, earning it the name "snowboarder's fracture." During a fall while tethered to a snowboard, the ankle is inverted with extreme dorsiflexion (flexed up) and external rotation, leading to a fracture and pain directly at the site of this process. The pain is very similar to a severe lateral ankle sprain, but a fracture should be considered in snowboarders. If left undiagnosed, it can lead to chronic pain, arthritis, and long-term disability in an otherwise healthy young athlete. When this injury is suspected, it is often difficult to confirm. A special "mortise"-view X-ray or a computed tomography (CT) scan is best. Fractures that are minimally displaced can respond to 4 to 6 weeks' non–weight bearing with a short leg cast, followed by another 4 to 6 weeks in a walking boot with protected weight bearing. If the fracture is more severely displaced, it may require surgical fixation or removal of the fracture fragments. It is important to start rehabilitation soon after cast removal to prevent the common complication of chronic pain.

Toe Fractures

Toe fractures may be the most common foot fractures in sports. These fractures are usually from crush or stubbing injuries. Pain is focused at the fracture site. These fractures can usually be managed with "buddy taping" to the adjacent toe until the pain resolves. If the fracture is open (breaks through the skin), if blood flow is impaired, or if the fracture involves a joint, it should be seen by a surgeon. If the first (big) toe is fractured, the patient should also wear a hard-soled shoe during the healing process because this helps redistribute the weight and reduce the stress on the toe. Surgery is uncommon but is necessary for severe fractures.

Foot Injuries

Foot injuries are fairly common in sports and can present as both acute and chronic problems. They are particularly common in running, jumping, and kicking sports such as football, basketball, and soccer, as well as in dance and gymnastics. Acute injuries include fractures, ligament and tendon injuries, and more minor injuries such as blisters and contusions. Chronic or overuse injuries include stress fractures and tendon injuries.

Anatomy

The foot can be divided into three distinct regions: (1) the rear foot or hindfoot, consisting of the calcaneus and talus; (2) the midfoot, consisting of the three cuneiform bones, the navicular medially, and the cuboid laterally; and (3) the forefoot, consisting of the five metatarsals and corresponding phalanges. The calcaneus is the biggest and strongest bone in the foot and serves as the attachment for the Achilles tendon as well as the origin of the plantar fascia. The calcaneus and talus form three articulations. The subtalar or talocalcaneal joint allows inversion and eversion of the foot. The navicular serves as the attachment for the posterior tibialis tendon. The great toe has a proximal and distal phalanx, whereas the other four toes have proximal, middle, and distal phalanges. On the plantar aspect of the first metatarsal-phalangeal joint (MTP), there are two pea-sized bones called sesamoids in the substance of the flexor hallicus brevis tendons. The sesamoids help increase the mechanical advantage of the flexor tendons and disperse forces with gait and stance.

In children, there are areas of new bone growth called apophyses. In the foot, there is an apophysis in the calcaneus and at the base of the fifth metatarsal. The apophyses are attachment points for tendons. The Achilles tendon attaches to the calcaneal apophysis; the peroneal tendon attaches to the base of the fifth metatarsal. Traction of the tendons can cause inflammation of the apophyses, resulting in traction apophysitis. The base of the fifth metatarsal is also subject to avulsion fractures in children.

Two important ligaments in the foot are the spring ligament and the Lisfranc ligament. The spring or calcaneonavicular ligament prevents talar head sag and medial migration of the talus, thereby stabilizing the medial arch of the foot. The Lisfranc joint divides the foot into the midfoot and forefoot and comprises the five MTP joints. The Lisfranc or tarsometatarsal (TMT) ligament is the main stabilizer of the Lisfranc complex. It originates on the lateral aspect of the medial cuneiform and inserts on the medial aspect of the second metatarsal base dorsally and plantarly.

The muscular anatomy of the foot comprises three compartments: (1) the anterior, (2) the lateral, and (3) the posterior. The boundaries of these compartments are formed by the interosseous membrane and anterior crest of the tibia. The anterior compartment is made up of the extensor hallucis longus, extensor digitorum longus, and anterior tibialis and primarily dorsiflexes the ankle. The anterior tibialis attaches to the first cuneiform and metatarsal and inverts the foot. The peroneus longus and brevis constitute the lateral compartment and evert the foot. The peroneal brevis attaches to the base of the fifth metatarsal; the longus crosses the sole of the foot and attaches to the first cuneiform and base of the first metatarsal. The posterior muscle compartment has superficial and deep groups. The superficial group is the triceps surae, comprising the gastrocnemius, soleus, and plantaris. The deep group includes the flexor hallucis longus, flexor digitorum longus, and tibialis posterior muscles, which function to flex the ankle and toes and invert the foot. There are many intrinsic muscles in the foot. The plantar fascia runs from the inferior aspect of the calcaneus to the forefoot and helps support the arch of the foot.

The sciatic nerve provides primary innervation of the foot. The dorsiflexors of the foot and ankle are innervated by the common peroneal nerve. The tibial nerve innervates the intrinsic muscles of the foot, except for the extensor digitorum brevis. The peroneal muscles are innervated by the deep peroneal nerve.

Evaluation of Injuries

Details of Injury

As with any injury, the mechanism can help determine the nature of the injury. Injuries may be acute, resulting from a fall or twist, or chronic, where pain develops over time. In acute injuries, the athlete may be unable to bear weight after the injury. There may be swelling or bruising at the site of injury. The athlete may have heard or felt a "pop" or "snap" at the time of injury. There may have been previous injuries to the same or opposite foot.

With chronic or overuse injuries, there may be mechanical symptoms, such as snapping, clicking, or locking. Intermittent swelling is also possible with chronic injuries. The athlete may also have weakness or decreased balance. Activities that aggravate the athlete's pain may help point to possible causes. Details of treatment to date, including medications, investigations, braces/orthoses, and physiotherapy, can help guide further management.

Other details that can help in management of a foot injury include athlete-specific questions, such as what sport(s) they play, what level of competition, what position, where they are in their season, and any changes in training (intensity, duration, frequency). "Red-flag" symptoms, such as fevers, weight loss, chills, night sweats, rashes, or localized warmth and redness, as well as a family history of juvenile idiopathic arthritis, tarsal coalition, multijoint laxity, or other chronic health problems can indicate other causes of foot pain, such as infection or arthritis.

Physical Findings

Athletes may be predisposed to foot injuries because of their body type and stage of development. Heavier athletes may have more chronic foot pain. Athletes with poor lower extremity alignment, such as flat feet or bowlegs, may have foot pain. An athlete with a foot injury may walk differently or be unable to bear weight at all. The gait may be antalgic (shortened stance phase), flat footed (no movement at the ankle), or "deweighted" (walking on the foot in an area that is not painful, for instance, walking on the heel if the toe is sore).

There may be an obvious deformity, swelling, redness, or bruising of the foot. Range of motion of the injured foot may be decreased compared with the noninjured side. Subtalar motion can be assessed by observing the heel move to varus with toe raise and the ability to walk on the lateral border of the foot; it can also be assessed by "rocking" the mid- and forefoot in and out.

Palpation of the foot can determine the area of maximal tenderness. Tenderness along the bones may indicate a fracture or stress injury. Tenderness along the Achilles tendon may indicate tendinitis. Tenderness along the ligaments indicates a sprain. Sesamoiditis usually causes tenderness to palpation of the sesamoid bones.

Injuries to the foot may result in neurological abnormalities, such as decreases in the tone, strength, sensation, and deep tendon reflexes. There may be impairment of the blood supply to the foot, as well as abrasions, lacerations, redness of the skin, or rashes.

Table 1 Foot Injuries

Foot Region	*Common*	*Less Common*
Rear foot	Plantar fasciitis	Calcaneal fractures
	Fat pad contusion	Calcaneal stress fracture
	Sever disease (calcaneal apophysitis)	Talar stress fracture
		Retrocalcaneal bursitis
		Osteochondritis dissecans of the talus
		Reflex sympathetic dystrophy (RSD)
Midfoot	Navicular stress fracture	Stress fractures
	Tibialis posterior tendinopathy	Peroneal tendinopathy
	Extensor tendinopathy	Cuboid syndrome
		Tarsal coalition
		Kohler disease
		Accessory navicular bone
		Lisfranc joint injury
		RSD
Forefoot	Corns, calluses	Freiberg osteochondritis
	Hammertoe	Islen disease
	First metatarsophalangeal joint sprain (MTP) joint sprain (turf toe)	Sesamoid stress fracture
	Subungal hematoma	Stress fracture of base of second metatarsal

Investigations

X-rays are helpful to look for acute fractures, healing stress fractures, or the presence of bony abnormalities, such as tarsal coalition, bone spurs, or bony tumors. Weight-bearing X-rays should be ordered to maintain the foot in its usual functional position. Stress fractures usually require isotopic bone scan for diagnosis, followed by computed tomography (CT) or magnetic resonance imaging (MRI). Ultrasound can be helpful for soft tissue injuries such as tendinopathies, plantar fasciitis, or Morton neuroma.

Types of Injury

For a list of sports-related foot injuries, see Table 1.

Prevention of Injury

One of the key ways to prevent foot injuries is to ensure overall fitness level and good conditioning. Maintaining an appropriate weight with proper nutrition and healthy lifestyle behaviors is essential for overall good health.

Prior to the start of an athlete's season, a preparticipation exam can help identify any injuries or

Perform exercises as instructed below, stopping with any sharp pain.

1. Toe raises, both legs together: 1–3 sets of 15 repetitions
2. Toe raises, injured leg alone: 1–3 sets of 15 repetitions
3. Balance on the injured leg: 1–3 sets, 30 seconds in duration
4. Walk at fast pace: 1–3 times, 50 yards each
5. Jumping on both legs: 1–3 sets of 10 repetitions
6. Jumping on injured leg: 1–3 sets of 10 repetitions
7. Easy pace straight line jog: 1–3 times, 50 yards each
8. Sprint (half speed, quarter speed, and full speed): 1–3 times each, 50 yards each
9. Jog straight and gradual curves: 2–3 laps around field, court, or track

Cross-country, track, and running can gradually advance to desired distance at this point. More demanding sports (football, soccer, basketball, baseball, tennis) need to advance to more sport-specific drills, such as the following:

1. Running figure-8s (half speed, quarter speed, and full speed): 1–3 times each
2. Crossovers, 40 yards: 1–3 times to the right and left each
3. Backward running (backpeddling): 1–3 times, 40 yards each
4. Cutting (half speed, quarter speed, and full speed): 1–3 times
5. Sport-specific drills
6. Return to sport

Figure 1 Functional Return-to-Sports Protocol

muscle imbalances that may predispose the athlete to injury during the season and allow for targeted efforts to correct imbalances and rehabilitate injuries in the preseason. Athletes should wear the proper protective equipment for their sport and ensure that the equipment is appropriately maintained and replaced as necessary. Taping or supportive bracing should be employed for athletes who are injured. At the start of practice sessions and games, participants should "walk the field" to identify any potential hazards, including debris on the playing surface or uneven playing surfaces. In practice sessions, emphasis should be laid on appropriate warm-ups and skill drills to improve strength, flexibility, and neuromuscular control. Such drills could include jumping, landing, cutting, and balance training.

Return to Sports

Return to sports after an injury is somewhat injury specific. In general, however, the athlete should be able to walk, run, hop, jump, and do everything necessary for his or her sport without pain. Depending on the injury, the athlete may have to be non–weight bearing for a period of time to allow healing to occur. During this time, the athlete can participate in non–weight-bearing aerobic activity, such as swimming and stationary biking, to maintain cardiovascular conditioning and increase blood flow to the extremity. Physical therapy can help improve swelling, range of motion, strength, and balance.

When pain has resolved and the athlete is able to fully bear weight, he or she can then proceed through a functional return-to-sport protocol (Figure 1). This protocol should be supervised by an athletic trainer, physiotherapist, or physician. As long as the athlete does not experience any sharp pain with activity, he or she can progress to more advanced tasks. To prevent reinjury once the athlete returns to sport, athletic taping or a foot orthosis may be necessary for the remainder of the sport season. The athlete may be able to return to a less demanding player position sooner than to his or her typical position.

Foot Stress Fracture

A *stress fracture* can occur when a particular bone is subjected to repeated stresses (such as stretching or compressing forces). Stress fractures are most commonly seen among athletes and military recruits. The reported incidence of stress fractures is less than 1% in the general population, but it may be as high as 20% in runners.

The pathophysiology of a stress fracture has been well described in the literature. The repetitive stresses on normal bone result in microfractures that need to remodel, but the bone is unable to keep pace with the remodeling of the microfractures, and thus, multiple microfractures consolidate into a larger stress fracture.

There are multiple factors that may increase the risk of a stress fracture. The more common intrinsic risk factors include low bone mineral density (weaker bones), pathologic bone states (abnormal starting bone), hormonal imbalances (which influence the ability to remodel), and muscle fatigue (which increases the load on the bone). Extrinsic risk factors associated with stress fractures include excessive volume or intensity of training over time, change in the training surface, training shoes that have lost cushioning, inadequate nutrition, and cigarette smoking.

Stress fractures are classified into low risk and high risk by their risk of complications, such as nonunion, and are commonly distinguished by the fracture site. Low-risk sites are generally amenable to nonoperative management, compared with high-risk stress fractures, which are often managed with internal fixation.

Weight-bearing bones are at greater risk for stress fracture. In one study, tibial stress fractures accounted for 49.1% of all stress fractures seen in athletes, followed in frequency by tarsal (25.3%), metatarsal (8.8%), and sesamoid (0.9%).

Low-risk stress fractures of the foot include fractures of the second through fourth metatarsal shafts and the calcaneus. The sites at high risk of complications include the medial malleolus, the talus, the navicular, the proximal fifth metatarsal, the base of the second metatarsal bone, and the great toe sesamoids.

History

Obtaining a complete and detailed history is essential when suspecting a stress fracture. Initially, the foot pain is mild, and it occurs at the end of a training session. Cessation of the aggravating activity may alleviate the pain. If ignored, the pain usually worsens and will start to occur during activity and eventually constantly.

Assessing for the presence of intrinsic and extrinsic risk factors is important. In female athletes, the menstrual history should be obtained. A training history and previous history of lower extremity injuries are helpful in the diagnosis.

Metatarsal Stress Fractures

Metatarsal stress fractures had been termed *march fractures* since they were commonly found in military recruits. In athletes, the incidence of metatarsal stress fractures is second only to the incidence of tibial stress fractures. Of all metatarsal stress fractures, 90% occur in the second, third, and fourth metatarsals. Several weeks after an abrupt increase in activity or with chronic overload and pes planus, the risk of metatarsal stress fracture is increased.

There are multiple factors that increase weight-bearing loads or decrease the ability to handle loads on a particular metatarsal, predisposing individuals to metatarsal stress fractures. Anatomic abnormalities such as dorsal- or plantarflexed metatarsals, a long second metatarsal, or excessively tight gastrocnemius muscles are factors that have been associated with metatarsal stress fractures. Other associated factors include obesity or osteopenia associated with amenorrhea and external factors such as poorly fitting shoes.

A disproportionate number of stress fractures occur in the second metatarsal shaft, especially at the neck. This is possibly due to its increased rigidity, being more firmly fixed at the tarsal-metatarsal joint.

History and Physical Examination

The proposed mechanism of injury is a repetitive stress to the forefoot, usually from running, jumping, dancing, and other repetitive weight-bearing activities. Patients with a metatarsal stress fracture commonly describe a history of gradually worsening pain in the forefoot that is initially intermittent and occurs only with use. Patients may present with poorly defined forefoot pain or point tenderness over a metatarsal shaft.

Examination will reveal pain at the fracture site with gentle axial loading of the metatarsal head. This maneuver should not produce pain in patients with only soft tissue injury. Weight bearing is often possible but usually produces pain.

Imaging

Anteroposterior (AP)/lateral radiographic films are important as the initial imaging study and may reveal evidence of a stress fracture. In patients, evidence of stress fracture can usually be seen no earlier than 2 to 6 weeks after the onset of symptoms. Distinct, well-organized callus is usually seen after several months. Bone scan or magnetic resonance imaging (MRI) is very helpful when X-rays are negative and there is clinical suspicion of stress fracture. Some recent reports of diagnostic ultrasound to diagnose stress fracture are promising.

Treatment

Considered a low-risk stress fracture, most metatarsal shaft stress fractures do not require casting or immobilization. Nonoperative management consists of cessation of the causative activity for 4 to 8 weeks. Crutches and partial weight bearing for several weeks should be used in patients who have pain with walking. A short leg cast and non–weight bearing can be used for short periods of time in patients with severe pain. Higher-impact activities can be resumed gradually after 4 to 8 weeks if there is no pain with normal activities.

Nonsteroidal anti-inflammatory drugs (NSAIDs), theoretically, may impair bone healing. It would be prudent to avoid or limit usage during recovery, especially if pain is hindering return to play.

Sesamoid Stress Fractures

The two sesamoid bones beneath the first metatarsophalangeal (MTP) joint sustain 12% of injuries to the great toe complex. These sesamoids are embedded within the tendon of the flexor hallucis brevis, and they provide a mechanical advantage for the MTP joint. The medial sesamoid bears greater force during the normal gait cycle and is more commonly fractured from either direct force or cumulative stress.

History and Physical Examination

The proposed mechanism of injury in sesamoid stress fractures is described as sports that require rapid acceleration and deceleration, such as tennis, racquetball, football, soccer, and volleyball. Patients with a sesamoid stress fracture usually complain of poorly localized pain around the first MTP joint for several weeks. Swelling is not generally seen until the injury has progressed, and erythema is typically absent.

Examination consists of direct palpation over the injured sesamoid that is causing pain. The tender spot will move with flexion and extension of the first ray. Passive dorsiflexion of the first MTP can elicit pain in sesamoid fractures. Holding the MTP in maximal dorsiflexion and deeply palpating the suspected area while the patient tries to plantarflex the great toe is another useful test.

Imaging

Standard radiographs (AP, oblique, and lateral views) of the foot are generally sufficient to demonstrate sesamoid fractures (these may not show initially). Special views such as lateral oblique (which shows the fibular sesamoid), medial oblique (which shows the tibial sesamoid), and sesamoid can be obtained if standard X-rays are negative and there remains a high index of suspicion.

Like scaphoid fractures, sesamoid fractures may not be apparent on initial radiographs. X-rays should be repeated after 2 weeks of presumptive therapy. If a fracture is strongly suspected but initial films are negative or when the diagnosis is unclear (such as a partite sesamoid), a bone scan or MRI can be helpful.

Treatment

The majority of these fractures can be managed nonsurgically. Treatment is controversial. Abstaining from the activity thought to have caused the fracture is common to all approaches. In addition, some type of padding or bracing footwear is used, including C- or O-shaped padding around the sesamoid to unload it, molded orthosis, wooden-soled shoes, or short leg walking boots. Padding, use of a firm-soled shoe, or immobilization should be continued for 6 to 8 weeks. Initial follow-up is done 1 to 2 weeks after diagnosis and monthly thereafter.

Open or displaced sesamoid fractures, which are rare, should be treated operatively. If healing of nondisplaced fractures has not occurred by 4 to 6 months (nonunion) or if symptoms are still bothersome after 4 to 6 months, sesamoidectomy may be necessary. After the initial 6- to 8-week treatment period, patients may return to activities as their symptoms permit.

Navicular Stress Fractures

Navicular stress fractures can be difficult to diagnose and treat because of their often vague clinical presentation and the poor correlation between radiographic and clinical presentations. Although these fractures were previously thought to be less common, more recent studies have reported their incidence to be as high as 35% of all stress fractures.

Both the kinematics of the navicular joint and its blood supply contribute to the characteristic location of stress fractures in this bone. During heel strike, the navicular is compressed between the talus and cuneiforms, and this places force on the central third of the bone. This part of the navicular also has decreased vascularity compared with the medial and lateral portions, thus making it more vulnerable to stress fractures.

History and Physical Examination

A high index of suspicion for navicular stress fracture is necessary in the approach to treating an active patient who complains of foot pain. In other words, if a weight-bearing athlete experiences an insidious onset of midfoot pain, a stress fracture of the navicular must be ruled out, even if radiographs are normal. Patients often complain of pain with an insidious onset that worsens during and following physical activity. Sprinting, jumping, and pushing off are movements that particularly aggravate the condition. A vague pain along the longitudinal arch on the dorsomedial aspect of the foot may be the initial complaint, but as the condition progresses, the pain is often localized to the dorsum of the navicular bone. Patients also may report a recent increase in the intensity or duration of physical activity or a change in equipment or technique.

Physical examination should include palpation of the foot to identify areas of tenderness and swelling. Navicular stress fractures typically are tender over the "N" spot, which is defined as the proximal dorsal portion of the navicular. Symptoms may also be reproduced by hopping on the affected leg with the foot in an equinus position.

Imaging

Conventional radiographs of the weight-bearing foot should be obtained for patients in whom navicular stress fractures are suspected. The fracture is usually in the middle third of the bone and oriented in the sagittal plane. However, radiographic results may be normal in the acute phase and may not demonstrate changes until 3 to 6 weeks after the injury.

If the initial radiographic evidence is normal, additional studies may include computed tomography (CT), MRI, or bone scan. Bone scan is a sensitive modality for evaluating a possible navicular stress fracture. A negative result reliably rules out a stress fracture; however, a positive result is nonspecific and requires clinical correlation and further imaging.

Treatment

These are high-risk fractures; aggressive nonoperative treatment can be considered for fractures involving less than 50% of the navicular. Nonoperative treatment should begin with a non–weight-bearing cast for a period of at least 6 weeks, by which time the fracture would have healed. If tenderness has resolved after the period of casting, then weight bearing can resume, and functional rehabilitation can be started. If pain persists, then the patient can be allowed to bear weight in a boot until the pain resolves. Patients may require up to 8 months before return to full activity. Operative treatment consists of percutaneous screw fixation. Generally, bone grafting is reserved for chronic fractures and delayed union or nonunion.

Fifth Metatarsal Stress Fractures

Background

A fifth metatarsal fracture is considered a high-risk fracture. Fractures of the fifth metatarsal are separated into three zones. Zone 1 is the most proximal and includes the metatarso-cuboid articulation, the insertion of the peroneus brevis, and the lateral plantar aponeurosis. Zone 2 fractures start at the metaphyseal-diaphyseal junction and are usually transverse in nature. Zone 3 fractures include the proximal 1.5 centimeters of the diaphysis. Zone 1 fractures are usually the result of an acute indirect injury and are typically avulsion-type fractures. Zone 2 fractures are usually the result of a large adduction force to the forefoot with plantarflexion. Zone 3 fractures usually are associated with repeated stress beneath the fifth metatarsal head.

Stress fractures of the fifth metatarsal are usually Zone 3 fractures and occur less frequently than the acute types. The prognosis and treatment differ substantially among the zones. The most difficult distinction to be made is between acute fractures and stress fractures of the proximal diaphysis. Despite their infrequency, they deserve special attention because of their marked propensity for delayed union and nonunion as compared with other proximal fifth metatarsal fractures and stress fractures of other metatarsals.

History and Physical Examination

Patients usually experience a prodrome of pain up to several months prior to presentation that is characteristically more intense during exercise or other weight-bearing activity. Tenderness is present over the fracture site. Occasionally, edema and/or ecchymosis may be present over the site.

Physical examination should include inspection, palpation for the point of maximal tenderness, and neurovascular assessment. The clinician should briefly evaluate adjacent structures, including the other metatarsals, the tarsals, and the ankle.

Imaging

Standard X-rays of the foot (AP, oblique, and lateral) should be obtained. Stress fractures are most commonly seen just distal to the intermetatarsal articulation (between the bases of the fourth and fifth metatarsals). However, stress fractures may also occur more proximally, where they can be confused with an acute fracture. Radiographic findings vary depending on the stage of the stress fracture.

MRI or bone scan should be considered for patients in whom clinical suspicion remains high but follow-up X-rays at 2 weeks fail to reveal any evidence of fracture.

Treatment

Stress fractures of the proximal diaphysis of the fifth metatarsal have high rates of nonunion. A classification system for predicting outcome and planning treatment has been developed. In contrast to acute fractures, where the fracture line is sharp and the surrounding bone appears normal, the bone surrounding stress fractures appears abnormal. An early stress fracture will demonstrate cortical thickening (Torg Type I). An older stress fracture will demonstrate a widened fracture line and partial (Torg Type II) or complete (Torg Type III) obliteration of the medullary canal. Misclassification can lead to inappropriate treatment, potentially causing delayed healing.

The ideal candidate for nonoperative management is a patient with a Type I fracture who can tolerate prolonged non–weight-bearing immobilization in a short leg cast for 6 to 12 weeks, even up to 20 weeks if necessary. Rest, ice, compression, and elevation with acetaminophen help reduce symptoms. As with other stress fractures, the use of NSAIDs is best avoided. Nonunion may still occur, and early operative fixation is a viable option, especially for athletes or extremely active patients. In athletes, early surgical fixation is generally preferred to minimize deconditioning and enable a quicker return to competition. While Torg Type II fracture may occasionally be a candidate for nonoperative management, surgical fixation should be considered in Torg Type II and all Torg Type III fractures. Bone stimulators may help decrease healing time, but a definitive reduction in healing time has not been reported.

Surgery consists of intramedullary screw fixation. Portland and colleagues recommend surgical fixation for Torg Type I fracture, since it might facilitate quicker fracture union rates and return to activity. It is suggested that following intramedullary screw fixation, the aftercare involves non–weight bearing for 2 weeks, then placement in a cam walker boot as tolerated. Radiographs should be repeated every 2 weeks until full union is achieved. Patients may return to full activities within 6 to 8 weeks.

For both nonoperative and operative care of the fracture, once healing is clearly present, as evidenced by callus formation and/or resolution of tenderness, the cast may be discontinued, and the patient may begin gradual, progressive weight-bearing and range-of-motion exercises. Physical therapy is helpful when immobilization exceeds 2 to 3 months. Cross-training with cycling and swimming can help the patient regain cardiovascular fitness while minimizing the impact on the foot. High-impact and high-stress activities, such as jumping and pivoting, should be reserved for the final stages of rehabilitation.

Football, Injuries in

The game of football is one of the most popular sports in the United States, with an estimated 1.5 million participants yearly. A variety of medical and musculoskeletal issues need to be considered at all competitive levels. In fact, it was safety concerns about the early game of football, and its notorious "flying wedge" formation, that led to the establishment of the National Collegiate Athletic Association (NCAA) at the urging of President Theodore Roosevelt, when colleges banded together with the goal of reforming football to limit the injuries (and fatalities). Football is the leading cause of sports-related injuries, with an injury rate almost twice that of basketball, the second most popular sport. Between 300,000 and 1.2 million high school athletes are estimated to sustain football-related injuries annually.

Common Injuries in Football

Sprains and strains account for approximately 40% of injuries, with contusions 25%, fractures 10%, dislocations 5%, and concussions 5%. More than 50% of injuries occur in the lower extremity, while upper extremity injuries account for approximately 30%. The most frequently injured are the knee (medial collateral ligament [MCL], followed by meniscus and anterior cruciate ligament [ACL]), ankle, shoulder, and upper leg. Patterns of football injuries vary by type of exposure and level of play. A recent NCAA study demonstrated that injury rates are greater in games than in practice, football injury rates in spring are greater than in the regular season, and preseason rate of injury is higher than both regular-season and postseason rates. Running plays were the leading cause of injury, with running backs and linebackers being the positions most commonly injured. Approximately 50% of players at all levels will be injured to some extent during each season.

Cardiopulmonary disease (including arrhythmias, hypertrophic cardiomyopathy, and myocarditis) and asthma account for most of the nontraumatic deaths in football players. Heat illness and blood dyscrasia, such as sickle cell hemoglobinopathies, are important entities to identify as they are often precipitators of nontraumatic deaths.

When the Player Has "the Wind Knocked Out"

A blow to the abdomen may cause a sudden contraction of the abdominal muscles, forcing the diaphragm upward. This results in a reflex contraction of the intercostal and serrati muscles to stabilize the rib cage and causes a forceful expiration that is maintained for a few seconds due to the muscle spasm. The athlete becomes acutely aware of the inability to breathe until muscle relaxation occurs, which allows for spontaneous recoil of the displaced structures and inspiration.

Concussion Management

Concussion is the most common head injury in football. Approximately 250,000 such concussions occur yearly. Common symptoms are dizziness, headache, visual disturbance, and nausea, often with confusion, disorientation, or an altered level of consciousness. Accumulative damage can occur from repeated concussions, resulting in the increasing severity and duration of each subsequent concussion, and catastrophic brain hemorrhage and swelling can occur rarely (second-impact syndrome) if return to play is allowed while still symptomatic. Long-term complications in athletes who have suffered multiple concussions show a greater decline in cognitive dysfunction than in the general population.

Sports medicine staff should be trained in the recognition and management of concussion. Many classification systems exist in the literature, but there is no universal agreement regarding the grading systems, and they should only act as a guide for sideline management. If the athlete has had his or her "bell rung," serial examinations should be performed every 15 minutes. Athletes who have symptoms for only a brief period of time can return to competition if symptoms completely resolve and they are appropriately stress exercised on the sideline before returning to competition. Athletes exhibiting amnesia, those who have sustained a documented loss of consciousness, and those with persistent symptoms should not be allowed to return to participation on the day of injury. Return to play should not be permitted unless the athlete has completely recovered from the concussion. Postconcussive symptoms such as persistent headache, irritability, fatigue, visual difficulties, dizziness, behavioral problems, school difficulties, and/or inability to concentrate may persist, and athletes should be banned from competition until the problems resolve. Return to competition guidelines for multiple concussions are even more subjective. The length of time before return to contact sports depends on the number of concussions as well as the timing and severity of each episode. In the 2004 Prague consensus guidelines, concussions are graded as either simple or complex, depending on the symptoms, timeline, and level of consciousness. Each athlete needs to be individually counseled about return to play, and factors such as level of play, importance of play to the athlete, and potential health risks and consequences should be involved in the decision-making process. Neuropsychological testing and brain imaging may be used in the evaluation and monitoring.

Injuries Common in Football

"Burners" or Stingers

"Burners" or stingers are believed to be traction or compression injuries of the brachial plexus causing traumatic neuropraxia of the involved nerve roots (C5-C6). The athlete complains of unilateral burning/stinging, numbness, and tingling radiating into the upper extremity, frequently with weakness, in the absence of neck pain. The most common motor deficit is deltoid weakness, so shoulder abduction should be routinely checked in all athletes with burners. Symptoms usually resolve within minutes, and if there is no pain or motor weakness on examination, the athlete may return to competition. Athletes should be counseled regarding neck and upper extremity strengthening and range-of-motion (ROM) exercises, the proper tackling technique, and protective measures such as a neck roll and proper fitting equipment. Bilateral symptoms should be immobilized with appropriate workup for cervical spine injury or transient quadriplegia.

Turf Toe

The injury known as *turf toe* is a sprain of the plantar capsular-ligament complex, occurring most often from a hyperextension injury at the large toe metatarsal-phalangeal (MTP) joint as another player falls on the elevated heel. It often occurs in football linemen pushing off on the artificial turf, and examination demonstrates pain at the MTP joint beginning several hours after the initial injury, with ecchymosis, swelling, and plantar tenderness beneath the metatarsal head. X-rays are negative, and initial treatment includes *r*est, *i*ce, *c*ompression, and *e*levation (RICE), nonsteroidal anti-inflammatory drugs (NSAIDs), and anti-inflammatory physical therapy modalities. Doughnut padding and special taping techniques stabilize the joint during motion, with orthosis and properly fitted shoes with a rigid forefoot to facilitate return to play. Full participation can begin as soon as the player can tolerate full weight bearing.

"Hip Pointers"

"Hip pointers" result from either a contusion to the iliac crest or separation of muscle fibers pulled from the crest, resulting in marked local pain, swelling, and considerable disability in the athlete. Tenderness and lameness may persist for days or weeks following this injury. An X-ray may be taken to rule out iliac crest fracture, especially in the high school athlete who may avulse the iliac crest apophysis. Early treatment with compression dressings, ice, rest, and NSAIDs should be instituted. Contrast thermal modalities, ultrasound, and steroid injection may speed recovery. Return to play with protective hip padding is allowed when the pain is tolerated and gait has returned to normal.

Blocker's or Tackler's Exostosis

This is an area of painful bony prominence occurring as a result of direct blows to the anterolateral humerus distal to the edge of the shoulder pads. This bone forms in continuity with the cortex, grows by accretion, and results from periosteal damage at the insertion of the deltoid or at the brachialis origin. Early recognition and treatment are important as the localized pain and swelling can be disabling. Initial treatment consists of ice, rest, compression dressing, and hematoma aspiration if necessary. Local padding is usually sufficient to allow play, and surgical excision is required only if the area remains painful despite conservative management.

Jersey Finger

The injury commonly known as "jersey finger" is an avulsion of the flexor digitorum profundus. It is commonly seen in a player who attempts to tackle an opponent by grabbing his or her jersey. It presents as an inability to flex the distal interphalangeal (DIP) joints independently. Appropriate diagnosis and early surgical reattachment are the treatment of choice.

Thigh Contusions

Thigh contusions from direct blows are treated with pain relievers, ice, massage, and ultrasound to prevent progression to myositis ossificans.

Management of Cervical Spine Injuries

Axial loading of the spine is the suspected mechanism of cervical spine injury in football. When a player lowers the head to ram an opponent, the cervical spine is straightened, converting a normally lordotic cervical spine into a segmented column. At the time of collision, the head stops, but the trunk keeps moving, compressing the cervical spine. When the compressive force from an axial load cannot be dissipated by controlled motion in the spinal segments, a cervical spine injury may occur.

If cervical spine injury is suspected, helmet and shoulder pad removal on the field should be delayed until the injured athlete can be transported to a location where more definitive management can take place. If necessary, helmet and shoulder pads should be removed simultaneously. Athletic trainers and/or prehospital staff should be equipped with the knowledge and proper equipment to remove the face mask if airway access is required.

Equipment removal on the field should only be considered in the event of a cardiorespiratory emergency.

Forearm Fracture

The upper extremity is involved in approximately one half of all fractures seen in adults and children. Most upper extremity injuries, whether sports related or not, typically occur after direct trauma or a fall on an outstretched hand (FOOSH). Forearm fractures most commonly occur in children, accounting for 10% to 45% of all pediatric fractures. Treatment options vary depending on the patient's age, type of fracture, degree of displacement or instability, and level of sports participation. Younger patients have a greater potential for bone remodeling and better chances of obtaining good functional outcome without surgery. However, return-to-play decisions, particularly for contact sports, are difficult due to the potential for refracture during the weeks that follow the period of initial immobilization. Bracing and other protective devices may be used, but they often have a limited role for sports participation and may not fully protect against the risk of refracture or subsequent injury.

Anatomy and Clinical Evaluation

Normal range of motion (ROM): elbow flexion/extension 0° to 150°, wrist flexion 80°, and wrist extension 45°. With forearm rotation, the ulna lies in a relatively straight and fixed position, while the radius rotates about the ulna. The neutral position, or 0°, is when the palm faces medially and the thumb is directed up. *Normal ROM:* forearm pronation +90° and supination −90°. With forearm fractures, proper restoration of the normal anatomic alignment is essential for good functional outcomes.

Neurovascular structures run across the forearm and are at risk for injury. The radial nerve courses over the lateral epicondyle and radial head, traveling along the length of the radius. Radial nerve function is tested with thumb extension and sensation over the dorsal aspect of the thumb. The ulnar nerve sits within the ulnar groove between the medial epicondyle and olecranon, running through the forearm along the ulna. Ulnar nerve function is tested with finger abduction/adduction and sensation over the small finger of the hand. The median nerve travels over the anteriormedial aspect of the distal humerus and elbow joint and continues along the interosseous membrane. Decreased sensation at the tips of the index or middle finger and diminished pinch strength with the thumb and the index finger are an indication of median nerve injury.

Physical examination includes a careful inspection for deformities and characterizes areas of tenderness, particularly olecranon, if at the radial head, and physes (growth plates) if skeletally immature. An open fracture should be suspected if there are any lacerations. If there is an obvious deformity, ROM evaluation of the joints can be temporarily deferred. Every exam must include a thorough neurovascular evaluation distally before and after any manipulation or splinting. If there is a concern for a neurovascular deficit, an emergency referral should be made to an orthopedic surgeon. Although uncommon, swelling from injuries can increase forearm compartment pressures, resulting in an acute compartment syndrome.

Diagnostic Imaging

Plain radiographs (anteroposterior and lateral) of the forearm should be obtained for every suspected forearm fracture. It is essential to adequately image the elbow and wrist; therefore, frequently additional radiographs specific to the elbow and wrist are obtained in patients suspected of fracture. Comparison views are often obtained in skeletally immature patients as they can increase the likelihood of detecting subtle fractures or physeal injuries.

Radius Fractures

With a FOOSH injury, most of the axial loading force from the fall will be transferred to the distal radius rather than the ulna. Therefore, distal radius fractures are more common than midshaft or proximal radius fractures. Overlying muscles protect the radial shaft; therefore, injuries severe enough to cause radial shaft fractures will typically also involve ulna fractures or joint dislocations. Unlike distal radius fractures, it is uncommon to have an isolated radial shaft fracture; therefore, examiners should be suspicious for associated injuries. Nondisplaced fractures can be treated with splinting and then cast immobilization. Displaced fractures typically require a closed reduction followed by immobilization in a long arm cast or splint.

A *Galeazzi fracture* is a radius fracture, typically at the junction between the middle and distal third, with a distal radioulnar joint (DRUJ) dislocation. Signs and symptoms that suggest an injury to the DRUJ include widening of the DRUJ on radiographs, fracture of the ulnar styloid, or pain with stressing or "piano keying" of the DRUJ. A Galeazzi fracture should be splinted and immediately referred to an orthopedic surgeon for definitive treatment. A "reverse Galeazzi" fracture is a distal ulna fracture with a DRUJ dislocation. These fractures tend to heal poorly if treated nonoperatively.

Ulna Fractures

A "nightstick" or isolated ulna fracture is typically caused by a direct blow, such as when using the forearm to protect oneself from a blow to the head or trunk. This can occur in sports that use blocking techniques, such as martial arts, lacrosse, and football. The ulna acts as the main strut of the forearm; therefore, displaced, angulated, or comminuted fractures should be referred for orthopedic evaluation and possible surgical fixation. A long arm posterior splint at 90° of elbow flexion and neutral forearm and wrist position can be used initially until reevaluation within 7 to 10 days. Athletes with stable, well-aligned forearm fractures are often transitioned to a forearm plaster sleeve or functional brace for 4 to 6 weeks. A sleeve or brace will allow for elbow and wrist function without compromising ulna healing and may shorten the rehabilitation time needed to regain the strength and motion required for safe return to sports. Patients are seen frequently, with radiographs obtained weekly initially to ensure that alignment is maintained and to monitor healing through the appearance of bony callus. A failure to maintain adequate alignment, despite adequate immobilization, is always an indication for prompt surgical referral.

A *Monteggia fracture* is a fracture of the ulna with an associated radial head dislocation. A dedicated radiocapitellar view may identify subtle radial head injuries. On any radiograph of the radiocapitellar articulation, a line drawn down the center of the radial shaft through to the radial head should always bisect the capitellum. If this does not occur, one can suspect a radial head injury. With Monteggia fractures, an urgent referral to an orthopedist for surgical repair is necessary.

Both-Bone Forearm Fracture

Fractures involving both the radius and the ulna are FOOSH-type injuries, typically resulting from high-energy mechanisms such as tackling, takedowns, and collisions that occur during participation in contact sports. When both the radius and the ulna are injured, the fractures are inherently more unstable and there is a greater likelihood of extensive soft tissue injury. The presence of any neurovascular compromise is an indication for immediate fracture reduction in an emergency room or operative setting with adequate analgesia. Even after closed reduction, a majority of these fractures will still require surgical fixation to achieve better functional outcomes.

Displaced both-bone forearm fractures requiring a closed reduction and immobilization or an open reduction/internal fixation are more common than nondisplaced both-bone fractures. Stable fractures are frequently treated in a long arm cast with the elbow flexed at 90°, forearm in neutral rotation, and wrist slightly extended. Close follow-up within 7 to 10 days for repeat radiographs is essential to monitor for any loss of alignment, which requires urgent orthopedic referral. For displaced fractures, the classic "dinner fork" angular deformity (see images a and b) is most noticeable laterally and is indicative of the severity of the injury. Often, relatively good anatomic alignment is preserved in the anteroposterior (AP) plane; nevertheless, a prompt closed reduction is usually indicated to improve functional outcomes (images c–f). The most common complication of both-bone forearm fractures is loss of pronation and supination, which requires patients to adapt motion at the elbow and the wrist to compensate and can adversely affect an athlete's ability to successfully return to sports participation, particularly in overhead sports requiring full ROM of the elbow and wrist in the dominant arm.

Complications

Complications of forearm fractures may occur at rates of up to 30%. Typical complications include malunion or nonunion, synostosis, reflex sympathetic dystrophy (complex regional pain syndrome), nerve injury, compartment syndrome,

stiffness or decreased ROM, posttraumatic arthritis, musculotendinous injuries, heterotopic ossification, and/or refracture. All these are serious complications for athletes as weeks to months of rehabilitation may be required prior to any attempt to successfully resume sports participation.

Fractures

Fractures are breaks in bones. They are caused by trauma or overuse. This entry reviews the basic types of fractures, fracture healing, fracture treatment methods, and general outcomes.

Fracture Types

Fractures are described by their location, the degree of displacement, and whether or not the bone has broken through the skin. In lay terms, it is sometimes assumed that a break is more serious than a fracture; to a physician, both refer to the same thing. A fracture that is incomplete or not fully through the bone may be a stress fracture, which often results from overuse in the foot, leg, or hip of a runner, for example. A complete fracture that is fully through the bone may be described as either *nondisplaced* (hairline crack) or displaced (the two parts not aligned), ranging from minimally displaced to widely displaced. If a bone is broken into many pieces rather than cleanly, it is referred to as a *comminuted fracture*. The former term for a broken bone that has gone through the skin was *compound fracture*; now this is described as an *open fracture*. A fracture where the bone does not pierce the skin is a *closed fracture*. Thus, a person with an open, widely displaced, comminuted tibia fracture has a shinbone that is broken into many pieces, is badly out of place, and has gone through the skin.

Fracture Healing

Fracture healing varies by age, location, severity of the fracture, and treatment method. In general, children's bones heal much faster than those of adults. In a baby a long bone may heal in a few weeks, whereas in a 6-year-old child the same bone may take 6 weeks and in an adult 6 months to fully heal. When a bone fractures, first a blood clot forms, much like a scab forms on cut skin. Next, the cells in the blood clot recruit bone-forming cells (*osteoblasts*), which begin making new bone. At first, this bone is poorly organized and looks cloudy on an X-ray. This is called *callus*. Usually, enough callus is present to allow weight bearing by 6 weeks after the fracture. Over time, this new bone solidifies and reorganizes into a strong new bone. This is called *remodeling*. The process of remodeling takes from several months to several years after the injury. Images (a)–(d) on page 560 depicts a displaced tibia (shinbone) fracture treated with a cast and its progressive healing over the next 6 months in an 11-year-old boy. In children particularly, bones have wonderful remodeling properties. It is possible in a child to have a bone heal very crookedly and straighten itself out without help over time. It should be mentioned that good nutrition, in particular 400 international units

(IU)/day of vitamin D and 1,000 milligrams (mg)/day of calcium, is very important for fracture healing.

Fracture Treatment Methods

Fracture treatment varies widely by the age of the patient and the severity of the injury. For some fractures, crutches or a sling may be all that is needed. For more severe fractures, surgery with a rod or plate and screw fixation may be needed. The following are the guidelines for fracture treatment.

Initial Treatment

The initial treatment when someone is injured should be to assess the injury and to stabilize the injured part, straightening it gently if it is bent or twisted. A removable stabilizing device called a splint is applied. If an open fracture is present, the bone should not be put back through the skin. Instead, a clean dressing should be applied as well as a splint and urgent transport to a medical center arranged. The limb below the fracture should be assessed for vascularity and nerve function by checking that the fingers and toes can move and are pink and warm. After initial immobilization, the patient should be assessed by a physician. Generally, X-rays are obtained, and sometimes, other studies such as computed tomography (CT) scans and magnetic resonance imaging (MRI) are done to find out what kind of fracture is present. Once the fracture has been properly diagnosed, treatment can proceed.

Definitive Treatment

Stress Fractures and Nondisplaced Fractures

These are generally treated nonoperatively with rest, protected weight bearing, and time. For example, a stress fracture (not out of place) in the foot usually needs a walking boot and crutches for 4 to 6 weeks. A complete but nondisplaced fracture in the leg may need a cast and no weight on it for 6 weeks or until healing callus is seen on the X-ray. A collarbone fracture that is nondisplaced would typically be treated with a sling and no lifting with that arm for 6 weeks.

Displaced Fractures

Fractures that are out of place generally need to be straightened (this is called *reduction*) and may need surgery. In children, displaced fractures can often be treated successfully with reduction and casting for 6 to 12 weeks depending on the child's age and the type of bone. In adults, many displaced fractures need surgical fixation for treatment. Fixation may range from pins (image e, page 561) to external fixators, where external pins attached to rings or a bar hold the bone in place (image f), to plates and screws (image g) to medullary rods, inserted down the medullary canal of long bones (image h).

Open Fractures

Fractures that come through the skin always need surgery to clean them. This is because they

are at high risk of infection. After the surgical cleaning, the bones are fixed in the method most appropriate for the type of fracture.

Rehabilitation

On average, many fractures are healed enough by 6 weeks to allow weight bearing. However, it takes just as long to rehabilitate the fractured limb back to full function. Often, the rehab process takes at least as long as the bone-healing time. Usually, this involves physical therapy. A physical therapist is a person trained to guide a patient through exercising an injured part according to the physician's orders and aiding return of full strength and function.

Source: Photo courtesy of Children's Orthopaedic Surgery Foundation.

Outcomes

After the fracture is healed, most patients return to a high functional level. Thus, most athletes who have sustained a fracture can expect to return to their sport. However, except for minor fractures, such as a toe fracture, it often takes 3 to 6 months to fully heal and rehabilitate a fracture.

Friction Injuries to the Skin

Dermatologic injures are the most frequently encountered injuries in sports, with friction injuries accounting for the majority of skin problems in athletes. Friction injuries, such as abrasions, blisters, chafing, and calluses, occur when the skin is destroyed by physical shearing forces. Because sporting equipment is usually the primary cause of skin trauma, different sports cause friction injuries on various areas of the body. This entry discusses the most common friction injuries encountered in athletics and touches on the specific friction injuries seen in different sports.

Causes

Friction injuries occur from shearing forces applied to the superficial layers of the skin. The mechanical forces eventually lead to cellular damage and breakdown of the outermost layer of skin, the epidermis. These injuries can occur from acute traumatic forces applied to the skin or from chronic, repeated low-intensity forces. The feet and hands are the most commonly affected, but friction injuries can occur anywhere on the body. Improperly fitted sporting equipment, clothes, and shoes increase the risk for friction injuries.

Blisters

Blisters are very common among athletes. Repetitive shear forces lead to damage and separation of the internal layers of the epidermis, sparing the most superficial layer. This allows for fluid to collect and be contained between epidermal layers. Blisters usually occur on the hands and feet, where the thick skin can withstand repeated forces without sustaining significant damage to the outermost layer. Risk factors for blister formation include a moist environment, poor-fitting shoes or gloves, and sports requiring frequent changes of direction. Excessive moisture increases the frictional forces transmitted to the skin. Also, the frequent cutting or changes in direction that occur in sports such as soccer, basketball, and tennis place the skin of the soles in repeated shearing situations.

Blisters in uncommon areas such as the trunk or upper arms or legs should raise the question of an underlying connective tissue disorder such as pemphigus vulgaris or bullous pemphigus. These conditions are autoimmune disorders, where the body attacks itself within the layers of the skin, causing fluid collection and blister formation. Little friction is needed in this case to cause the blisters, and these can be debilitating diseases.

Treatment of blisters involves removing the enclosed fluid and protecting the outermost epidermal layer. Draining the fluid will allow the layers of the skin to heal more quickly. It is important not to damage the roof layer of the blister when removing the fluid as this layer is an excellent biological protective dressing. Then, covering the blister with a nonocclusive dressing that can protect it from recurrent frictional forces is also helpful. Prevention of blister formation involves wearing properly fitted shoes to limit excess friction and limiting excessive moisture buildup.

Calluses

Calluses are areas of thickened skin that develop in response to recurrent frictional forces. Unlike blisters, calluses are a more chronic condition, where the body responds to excessive friction by increasing the thickness of the superficial skin layers for protection. Calluses frequently occur in areas of prior blisters, and again the hands and feet are the most common areas for callus formation. Calluses are common on the soles of the feet of runners and on the palms of tennis players and rowers. Some athletes feel that calluses give them a competitive advantage because the thickened area of skin gives them increased protection from the more painful blisters that can occur.

Treatment of calluses involves paring down the thickened layers of skin with either a surgical blade or a chemical agent (salicylic acid). During this process, there should be no evidence of bleeding as blood vessels do not grow into the thickened skin layers, unlike in warts. Preventive measures to limit callus formation include limiting repetitive friction or protecting the area of skin with a barrier such as moleskin.

Chafing

Chafing refers to skin abrasions or erosions caused by repeated frictional forces either between two opposing layers of skin or between skin and clothing. Chafing occurs most commonly around the groin, underarms, and nipples but can also occur anywhere on the body. As with blister, chafing is exacerbated by moisture. Frequent friction between the inner thighs or between the chest wall and inner arms during running motions can lead to chafing. Also, a moist shirt repeatedly rubbing on a runner's nipples (jogger's nipples) can cause significant chafing in this area. The symptoms of chafing include pain, burning, bleeding, and scab formation.

Treatment of chafing is similar to care of open wounds. This includes avoiding repetitive frictional forces, limiting infection risk with antiseptics, and covering the area with a protective, breathable barrier. Decreasing friction can be done by applying a lubricant to the commonly affected areas of the body with either petroleum jelly or other commercially available lubricating products. Staying hydrated is also helpful as this allows the body to maintain sweat production and prevents salt crystals from forming on the skin that can increase frictional forces. Avoiding loose-fitting clothing, which can cause excessive rubbing over prominent skin areas, will decrease the risk of chafing as well.

Hemorrhages

Besides blisters and calluses, repeated trauma or friction from sports with frequent stopping and starting can cause toenail damage. With repeated contact between the great toe and the front inside surface of a shoe, the nail can be dislodged from the nail bed, and bleeding under the nail can occur. This is called a subungual hematoma and is commonly seen in tennis, soccer, basketball, skiing, and running. Over time, chronic disruption of the nail from the nail bed can lead to a dystrophic and thickened nail. Wearing shoes that have a wide toe box while fitting tightly around the midfoot can be preventive. Although this process is benign, subungual hematomas can be painful enough to limit participation in sports.

Another hemorrhage problem that can occur in the foot is on the lateral aspect of the heel. Repeated shearing of the epidermis on the underlying dermis can lead to small areas of bleeding between these two layers. This is referred to as "talon noir" or "black dot heel." Differentiating this entity from other more serious pigmented skin lesions such as melanoma is important. In talon noir, the small hemorrhagic areas can easily be removed by paring away the superficial layer of skin, whereas a melanoma cannot be removed this way. This lesion is benign and should not limit athletic participation.

Sport-Specific Injuries

Jogger's Nipples

Repeated rubbing of loose-fitting clothing can cause chafing and fissuring of a runner's nipples. This can occur in both males and females and can be quite dramatic if the rubbing erodes down into superficial blood vessels, leading to bleeding. Prevention involves wearing a well-fit jogging bra or soft shirt or by covering the nipples with a protective bandage.

Tennis Toe

Common in tennis but not limited to this sport, tennis toe refers to a painful subungual hematoma that usually affects the first or second toe.

Mogul Skier's Palm

This is another hemorrhagic condition where repeated planting of a ski pole leads to hemorrhage in the area just below the thumb. This is a self-limiting condition, and avoidance of continued palmar friction is the treatment, which usually occurs at the end of the ski season.

Pulling Boat Hands

This refers to blister and callus formation in the palms of rowing athletes due to repetitive frictional forces applied to the hands from oar handles. Over time, however, the callus formation may become beneficial.

Swimmer's Shoulder

This is an abraded area of the upper shoulder caused by repeated friction trauma in male swimmers. The cause is abrasive forces between an unshaven face and the skin over the shoulder. Regular shaving eliminates this irritation.

Runner's Rump

Frictional forces at the top of the gluteal cleft sustained during long-distance running can cause a localized area of bleeding. This is usually minimally painful and does not lead to any long-term complications. It is also self-resolving.

Rower's Rump

This condition is experienced by rowing athletes and involves an area of skin over the buttocks where the athletes sit on the boat seat for prolonged periods of time. This chronic irritation can lead to itchiness and thickening of the skin. Treatment involves changing to a padded seat.

Frostbite and Frost Nip

Outdoor athletes are faced with many challenges. In addition to dealing with the physical demands of their individual sports, outdoor athletes are also faced with the challenge of dealing with environmental conditions that can not only affect performance but also cause significant health issues. Exercising in the cold poses many such problems, and the skin, the largest organ in the body, can be seriously affected by cold exposure.

Frostbite is the most common dermatologic injury caused by cold exposure and will affect many athletes participating in outdoor winter sports. It is difficult to accurately estimate the frequency of frostbite or frost nip in the athletic population as many of the cases go unreported to coaches and trainers. Studies have reported that frostbite is seen most commonly in the 30- to 49-year-old age-group and is most common in the exposed areas, such as hands, feet, and face.

Frost nip is very common and is the precursor to frostbite. Frost nip involves freezing of the very top layers of the skin. Most athletes will become aware of this when someone else alerts them to the fact that their skin is slightly discolored, usually a bluish white color. Typically, there is a slight change in sensation in the skin, with some people complaining of mild numbness.

Deeper frostbite involves progressive freezing of the deeper layers of the skin. Typically at skin temperatures in the range of 37 to 50 °F (3–10 °C), the top layers of the skin begin to freeze, causing a decrease in sensation and slight swelling of the skin. If cooling continues, usually to temperatures of 5 to 21 °F (–15 to –6 °C), there will be deeper freezing of the skin tissue, leading to the formation of ice crystals inside and outside cells, with eventual cell destruction. This phase is usually accompanied by tingling of the affected area. As cooling progresses, the blood vessels become very leaky, and eventually the area of tissue will begin to die as the blood flow is essentially cut off. Frostbite of this severity is very rare but is seen with more frequency in high-altitude climbers. Deep frostbite is usually painful initially but then becomes painfree as the affected tissue becomes numb. The skin is pale, cold, firm, and rigid to touch.

The severity of deeper frostbite is usually not apparent until the thawing process begins. First-degree frostbite demonstrates mild numbness, redness, and swelling on exam. Blisters are not present. Second-degree frostbite results in clear blister formation along with redness and swelling. Third-degree frostbite has blood-filled blisters. Fourth-degree frostbite involves freezing down to the muscle and bone and will eventually result in loss of the affected tissue. It may take several days after the initial exposure to get a true sense of the severity of deeper frostbite.

Treatment

Treatment involves warming of the affected area, but this should not be done until the risk of refreezing has been eliminated. Repeated cycles of freezing and rewarming can actually cause more inflammation and tissue damage than leaving the affected area cool until definitive warming can be achieved. The affected area should be protected with splinting and elevation whenever possible, and the person should be transported to a warm environment immediately. As with any injury that occurs in the cold, care must be taken to not overlook the symptoms of hypothermia.

Definitive treatment involves removing cold and wet clothing and placing the patient in a sheltered warm environment. Frost nip can usually be treated adequately by removing the athlete from the cold and warming the affected body part with direct skin contact. Deeper frostbite is best treated with submersion of the affected body part in a warm bath, usually between 102 and 108 °F (39 and 42 °C), for 15 to 30 minutes. With severe frostbite, athletes may require pain medication as the affected area can become very painful with warming and the return of sensation. Blisters should be treated in a medical facility. Clear blisters are typically drained and covered with a clean dressing along with aloe vera. Blood-filled blisters are left intact and covered with a clean aloe vera dressing. Patients with severe deeper frostbite usually require antibiotic treatment to prevent infection. Most patients with significant deep frostbite should receive a dose of a nonsteroidal anti-inflammatory drug as soon as possible to decrease the amount of inflammation and the resultant tissue injury. There are other treatments that have been proposed for severe frostbite, including hyperbaric oxygen, tissue plasminogen activator, prostaglandin analogs, nifedipine, and other drugs; however, none of these have shown consistent benefit.

Prognosis

The long-term outcomes of frostbite depend on the severity of the initial injury. Frost nip has no long-term complications. With deeper frostbite, if the area has intact sensation and the color looks good, the likelihood of any long-term complications is very low. Skin that has blood-filled blisters, severe discoloration, and frozen tissue has a much higher rate of long-term sequela including decreased sensation, cold sensitivity, skin discoloration, and excessive sweating. In extreme cases, deep frostbite can cause nail abnormalities, early closure of growth plates in young children, and eventual loss of the affected digit.

Return to Sports

Return-to-play guidelines for athletes with frost nip or frostbite again depend on the severity of the exposure. Frost nip does not preclude returning to play, but any level of injury worse than this necessitates removal from competition or training. For frost nip, once the affected area regains normal color and sensation, the athlete may return to play with close observation. If symptoms recur, the athlete should be removed from play. With deeper frostbite, the athlete should be removed from play and treated as described earlier. As stated earlier, care should be taken to avoid repeated freeze and rewarming cycles, and as a result, athletes with deeper frostbite should not be allowed to return to play that day. Return to full play is subsequently guided by clinical healing. The affected part should have normal sensation and range of motion, and the skin should be healed of all blisters. Athletes need to be warned that they are twice as likely to get frostbite once they have had an initial frostbite injury.

Prevention

The prevention of frostbite involves protecting the skin from the cold and keeping the core warm. It is important to remember that heat loss is exacerbated by contact with metal, water/moisture exposure, and windy conditions. As a result, removing metal jewelry is recommended. Layering with good wicking materials will help pull moisture away from the skin and thus prevent excessive cooling. Keeping the core of the body warm and keeping the head covered will reduce rapid heat loss, allowing the extremities to stay warmer for longer. An external wind barrier can also assist in staying warm. Finally, paying attention to environmental conditions can also help prevent frostbite injuries. Athletes need to be aware that on cool, wet, windy days, they can still get frostbite even if the temperatures are not below freezing.

Athletes are faced with many challenges as they try to improve their abilities in various sports. Outdoor athletes need to take into account how the environment will affect not only their performance but also their physical health. Frostbite and frost nip are frequent ailments that outdoor athletes will run into, especially in the colder climates. With a little preparation and awareness of their surroundings, athletes should be able to recognize the early signs and symptoms of frost nip and, thus, prevent the more severe cases of deeper frostbite.

Frozen Shoulder

Frozen shoulder is a descriptive diagnosis for a shoulder that has lost substantial range of motion. Usually, the term refers to an abnormality of the glenohumeral joint capsule where the capsule has lost its normal distensibility or to adhesions that have formed between the joint capsule and the head of the humerus. Typically, other structural reasons for loss of shoulder range of motion (e.g., glenohumeral arthritis, fractures, or loss of function of shoulder muscles) are not considered to be frozen shoulder. However, there can be substantial overlap between rotator cuff tendinopathy and frozen shoulder symptoms, especially early in the course of the disease, and it is common to confuse the two diagnoses.

Anatomy

The shoulder is a ball-and-socket joint with great freedom of movement. The head of the humerus is a relatively large ball, and the glenoid is a relatively small socket. The relationship between the two is commonly compared to a golf ball sitting on a golf tee. Because there are few bony restrictions on the motion of the humerus at the shoulder, the joint is typically very free moving, with approximately 180° of forward flexion and abduction and 90° of internal and external rotation. However, this freedom of movement also causes instability in the shoulder. Several redundant anatomic structures provide the shoulder with stability. The glenoid labrum is a ring of cartilage that extends from the rim of the glenoid and wraps around the head of the humerus. Outside the labrum is the shoulder capsule, a loose bag of synovium that defines the joint space and prevents extremes of motion. The glenohumeral ligaments are fibrous thickenings of the interior capsule wall that attach the glenoid to the humerus and provide the majority of the stabilizing properties of the capsule. Fifteen individual muscles and tendons cross the shoulder joint. Of these, four short muscles, collectively called the rotator cuff, contribute significant stability to the shoulder joint. When the rotator cuff muscles contract, they pull the humeral head onto the glenoid. In addition, they contribute to internal and external rotation and abduction of the shoulder.

Causes

Frozen shoulder is an idiopathic illness. It occurs most commonly among women between the ages of 30 and 60 years. Apart from age and sex, having diabetes mellitus is the strongest risk factor for frozen shoulder. Occasionally, it occurs in patients who have had shoulder pain or loss of function due to other pathology, such as rotator cuff strains or tendinosis, fracture, paralytic stroke, or seemingly minor trauma. Whether or not these ailments contribute to the development of frozen shoulder is controversial. Rarely, thyroid disease, Parkinsonism, or antiretroviral medications (e.g., for human immunodeficiency virus [HIV] infection) can be associated with the development of frozen shoulder. Some authors have argued that patients with low pain thresholds or poor compliance with physical therapy exercises seem to be at higher risk, but this is not well established. Using a shoulder or arm sling can also lead to frozen shoulder if it is used for too long. Typically, 1 to 3 days of shoulder immobilization following injury is safe. More prolonged shoulder immobilization should be accompanied by at least daily shoulder range of motion or pendulum stretch exercises if they can be safely performed.

Symptoms

Frozen shoulder typically follows a three-phase progression. The "freezing" phase is marked by significant shoulder discomfort and progressive loss of range of motion. This phase is also sometimes called the "painful" phase. The pain may be due to coincident shoulder pathology, such as rotator cuff tendinopathy, but is usually intrinsic to idiopathic frozen shoulder. The freezing phase typically lasts 3 to 9 months. The "painless frozen" phase consists of continued restricted range of motion but markedly reduced pain. Patients are often quite satisfied with their progress during this phase despite continuing to have poor range of motion. The painless frozen phase typically lasts for 3 to 6 months. The final phase is commonly called the "thawing" phase as improved range of motion spontaneously returns to the shoulder. This phase typically lasts for 3 to 9 months. The entire course of frozen shoulder can last for 15 to 24 months.

Diagnosis

The diagnosis of frozen shoulder is made based on history and physical examination. The hallmark feature of the condition is a palpable block to range of motion that is not due to a bony abnormality or pain. Patients have at least a 50% reduction in shoulder range of motion, with loss of both active and passive motion. Close inspection is required to ensure isolation of the glenohumeral joint when evaluating range of motion. The examiner can be fooled into thinking that the patient has near-normal motion if he or she is able to compensate for his or her tight glenohumeral joint with scapulothroacic movement. No diagnostic imaging is needed to make the diagnosis of frozen shoulder, but it is common practice for medical providers to order X-rays to assess for bony abnormalities and/or magnetic resonance imaging (MRI) to assess the integrity of the rotator cuff muscles and glenoid labrum. Thickening of the capsule and synovium can be seen on the MRI scan in both idiopathic frozen shoulder and frozen shoulder due to other pathology. If an arthrogram of the shoulder joint is performed, it is common to see a decrease in volume of the glenohumeral joint. This represents contracture and loss of elasticity of the joint capsule.

Treatment

If a patient's frozen shoulder is due to an underlying abnormality (e.g., a complete rotator cuff tear, fracture, or nerve injury), this cause must be addressed first. It can be very difficult for a patient to recover shoulder range of motion in the face of other significant shoulder pathology. For idiopathic frozen shoulder and frozen shoulder due to abnormalities not amenable to surgical correction, the most commonly prescribed treatment is physical therapy. The goals of therapy during the painful phase are to protect the shoulder joint and slow loss of function. During the painless and thawing phases, therapy consists of progressive stretching to increase range of motion and restore function. There are few data to support this practice, but most medical providers think that it is unlikely to do harm, and there are clearly some patients who respond well to physical therapy. Also, a well-trained and thorough physical therapist may pick up on other shoulder abnormalities that were not noticed during the initial medical evaluation.

Other commonly prescribed treatments during the painful phase include a course of nonsteroidal anti-inflammatory drugs (NSAIDs) or oral corticosteroids, such as prednisone. These medications do provide some short-term relief of the symptoms but do not seem to affect the overall course of the condition, and relief generally does not last more than 6 weeks.

Corticosteroid injection of the subacromial space does provide relief and may decrease the duration of symptoms in patients who have underlying rotator cuff or biceps tendinosis. In the absence of these conditions, corticosteroid injection may improve shoulder pain and mobility for several months following the injection, especially if combined with supervised physical therapy. However, there seem to be no long-term benefits of corticosteroid injection for the treatment of frozen shoulder.

Intraarticular dilation (hydroplasty) is a procedure that can be performed in the primary care setting for patients with frozen shoulder. It involves placing a needle or catheter in the shoulder joint and using saline and a small amount of corticosteroid to distend the shoulder capsule. The procedure is often done with radiographic verification of needle placement and injection of contrast material to confirm intraarticular injection. Initial studies of this technique have provided encouraging results. Patients with severe and persistent symptoms who undergo hydrotherapy report decreased pain and improved range of motion as early as 3 weeks after the procedure, and benefits seem to persist for the duration of the illness.

Shoulder surgery is reserved for patients who have had prolonged and severe symptoms and have not had improvement with more conservative measures. Surgery should never be considered as first-line therapy, because it can aggravate the symptoms, prolong the course of the illness, or precipitate a bout of reflex sympathetic dystrophy in some patients. Surgical therapy is aimed at stretching or releasing the contracted joint capsule. There are two techniques that are commonly used. Sometimes, they are both done at the same time. The most common surgical technique for frozen shoulder is manipulation under anesthesia. The patient undergoes general anesthesia and paralysis to relax the muscles of the shoulder. The surgeon forces the shoulder joint through an increased range of motion, stretching or tearing the tight capsule. Arthroscopy may be performed at the time of manipulation or separately. The surgeon will insert a small camera and instruments through small incisions in the skin and shoulder. Small cuts are placed in the joint capsule to allow it to distend. Following surgery, it is important for the patient to continue with physical therapy in order to preserve any gains in motion obtained with surgery.

Functionally One-Eyed Athlete

Eye injuries are common in athletes, and they often can be very devastating injuries. In the

United States, eye injuries occur most commonly in baseball and basketball. Any sport with a ball or a striking object increases the risk for a possible sports-related eye injury. Eye injuries are easily preventable so long as the proper protective equipment is used.

In the United States, sports-related eye injuries are second only to occupation-related eye injuries. Eye injuries are the leading cause of blindness in children in the United States, and many of these injuries are sports related. According to the National Eye Institute, these injuries account for an estimated 100,000 physician visits per year at a cost of more than $175 million.

Classification and Mechanisms

Eye injuries can be classified as blunt trauma, penetrating trauma, or radiation injury. Blunt trauma can be further classified by the anatomic location in which the injury occurs (anterior chamber, posterior chamber, and orbit and adnexa).

The type of injury that occurs depends on the equipment used in the sport, the playing field/court, and the rules of the game. For example, the injuries to the face and eye from a small, hard ball (e.g., a golf ball) are different from those imparted by a larger, deformable ball (e.g., a soccer ball). Also, the nature of soccer, with the ball often coming from the ground up to the face, will lead to different injuries than if a ball were to come from a higher elevation down toward the eye, because the forehead and the bony orbit are better able to protect the eye in the latter scenario.

Different injuries can also result from the different playing venues. Racquetball and tennis are both racquet sports, but in racquetball the athletes share the same playing space, whereas in tennis the net divides the playing surface. Therefore, the risk of hitting your opponent with the racquet is much higher in racquetball than in tennis.

Definition

Severe eye injuries can lead to permanent impairment of vision. If an athlete has an underlying severe visual impairment, an injury to his or her good eye could lead to a permanent visual disability. This type of athlete is considered functionally one eyed. If there is an injury to the initially unaffected eye, the person can be severely impaired for the rest of his or her life, and the injury could leave the athlete permanently blind. Some ophthalmologists use a cutoff of best-corrected vision in the poorer eye of 20/40 or 20/60 to determine if someone is functionally one eyed. This means that the "bad eye" can only be corrected to 20/40 or 20/60 at the very best. This leaves the athlete with only one "good eye." If this good eye were to be injured, it could leave the person permanently disabled.

Clearance to Play

The functionally one-eyed athlete should consult an ophthalmologist prior to playing any sport. The athlete will be counseled to use protective eyewear at all practices and all games. This includes sports with other protective equipment. For example, acceptable eyewear should be worn under a standard football helmet. These athletes also should be made aware that even recreational "pickup" games are not immune from possible injury and that protective eyewear must always be used.

Certain sports do not have proper protective eyewear available (e.g., martial arts, boxing, wrestling); therefore, the athlete should not compete in these events.

Eyewear

Acceptable protective eyewear is usually molded frames of a single piece with at least a 2.5-millimeter polycarbonate lens. Ordinary eyeglasses do not offer adequate protection to the eye, often because the lens is not shatterproof and also because the frames are not strong enough to withstand the forces of sports. They should pass the ASTM (American Safety Testing of Materials) guidelines for use in sports.

Fungal Skin Infections and Parasitic Infestations

Fungal skin infections and parasitic infestations are common among athletes who participate in sports requiring close physical contact. These infections are quite contagious, and widespread outbreaks can occur if athletes continue to participate in sports without proper treatment. Most of these infections can be treated with topical medications, although some may require oral medication. Athletes who participate in sports at the high school and collegiate levels may be restricted from returning to activity until they complete a minimum period of treatment.

Fungal Infections

The organisms responsible for causing fungal skin infections are called *dermatophytes*. These organisms are found in soil, on animals, and on humans. Dermatophytes are spread by direct contact with an infected person or animal or by contaminated soil. Fungal infections are typically named based on the location of the infection rather than using the name of the causative organism. Fungal skin infections affecting the scalp and hair are called *tinea capitis*. *Tinea corporis,* also known as "ringworm," refers to fungal infection of the skin of the body. *Tinea cruris* or "jock-itch" is a fungal skin infection in the groin. The term *tinea pedis,* or "athlete's foot," is used for fungal infections of the feet.

Clinical Manifestations

The appearance of fungal infections depends on the location on the body. Tinea capitis often appears as a round patch on the scalp, with hair loss and a gray scale on the lesion. Ringworm on the body also has a round appearance, with a red raised border and a flat central area that may be scaly or flaky. Tinea cruris is characterized by bright red scaly lesions on the inner thighs and groin area. The appearance of athlete's foot may vary, but a common presentation is redness and scaling on the soles of the feet or between the toes. The red scaly skin of athlete's foot may also appear moist or weepy. Itching is a common complaint with fungal skin infections.

Diagnostic Testing

The diagnosis of a cutaneous fungal infection is often made by clinical appearance alone. However, cutaneous fungal infections can often be mistaken for other skin conditions such as psoriasis, impetigo, lichen planus, and seborrheic dermatitis. A simple, office-based diagnostic test with a potassium hydroxide (KOH) preparation can be done to confirm the diagnosis of fungal infection. Additionally, a fungal culture can be performed to confirm the diagnosis. The potassium hydroxide preparation is made by taking a small amount of scale from the lesion and placing it onto a microscope slide. The potassium hydroxide solution is then added to the scale, and it is examined under the microscope. If there is indeed fungus present, then characteristic hyphae will be observed.

Treatment and Side Effects

Athletes with cutaneous fungal infections can be treated with a variety of topical or oral medications. Many of these products are available over the counter, but some are available only by prescription. Oral treatment regimens are often associated with more side effects than topical regimens.

Topical regimens for tinea corporis and tinea cruris typically call for the application of a fungicidal cream such as terbinafine, ketoconazole, or clotrimazole once or twice daily for 2 to 4 weeks. Oral treatment regimens for tinea corporis and tinea cruris using griseofulvin, itraconazole, or fluconazole involve once-daily medications for 2 to 4 weeks. Relapses or recurrences of fungal infections are common, particularly if the athlete failed to complete the full treatment regimen.

Certain fungal infections require either longer topical treatment courses or treatment with oral agents. Tinea pedis requires longer topical treatment regimens than are used for tinea corporis or tinea cruris. Terbinafine, tolnaftate, and clotrimazole are commonly used over-the-counter agents for tinea pedis. These topical treatments are effective but require treatment courses of 4 to 6 weeks. Treatment of tinea capitis requires an oral regimen as topical treatment is ineffective. Most clinicians prescribe a 6-week course of griseofulvin to treat tinea capitis. Shorter treatment regimens are possible if itraconazole or fluconazole is prescribed.

Most of the topical agents used to treat fungal skin infections do not induce many adverse effects. However, the oral agents used to treat tinea capitis and tinea pedis do commonly cause side effects. Griseofulvin commonly causes mild side effects such as headache, photosensitivity, and rash. More serious effects such as liver damage, numbness and tingling, and reduction of white blood cell counts can occur in patients treated with oral griseofulvin. Doctors may order blood tests to monitor patients being treated with oral antifungal medications.

Return to Sports

Athletes who participate in high school and collegiate sports are commonly held from practice and competition until they have received adequate treatment for their infection. The National Federation of State High School Associations (NFHS) recommends that athletes with tinea corporis complete 1 week of treatment with an oral or topical agent before being allowed to return to sports. The National Collegiate Athletic Association (NCAA) recommends a minimum of 3 days of treatment before returning to play. Additionally, the NCAA requires that all lesions be covered with an occlusive bandage once the athlete returns to competition.

Parasitic Infestations

Parasitic infestations are not as common among athletes but are problematic when they arise. The two most common forms of parasitic infestation are *pediculosis capitis,* commonly referred to as head lice, and *pediculosis corporis,* commonly termed scabies. Both head lice and scabies are most commonly transmitted via direct contact with an infected individual. Head lice can be transmitted via shared combs, hats, and brushes. It is possible to contract scabies from infested bedding, but this is uncommon. Both conditions are common problems among people living in overcrowded conditions.

Clinical Manifestations

Head lice may produce itching of the scalp in the infected individual. Other symptoms associated with head lice are uncommon. Signs of head lice include the presence of nits and live lice visualized on the scalp. Scabies typically produces a very itchy reaction, with red linear burrows present on the skin. The burrows of scabies are often found between the fingers, at the wrists, in the armpits, and in the groin. The itching associated with scabies is most intense at night.

Diagnostic Testing

The diagnosis of head lice is typically made by directly observing lice and nits on the head. Nits are typically found at the base of the hair shaft, close to the scalp. Microscopic evaluation of lice and nits are typically not necessary. Similarly, the diagnosis of scabies is most commonly made based on the typical clinical appearance of the burrows and the patient's history. A scabies preparation can confirm the diagnosis through microscopic analysis of scrapings taken from the burrows, revealing lice, eggs, and fecal matter.

Treatment and Side Effects

Medications and local environmental controls are keys to effectively treating head lice and scabies. The treatment of choice for head lice is permethrin, available over the counter as a 1%-cream rinse. It is applied to hair that has been shampooed and towel dried and is left in place for 10 minutes before rinsing. The treatment can be repeated in 1 week if live head lice are still observed. Lindane 1% is a prescription shampoo that can be used in a similar fashion. Malathion is available as a 0.5% lotion, which is applied to the hair and left on for 8 to 12 hours before rinsing. In addition, most physicians recommend removing nits from the scalp by using a fine-toothed nit comb on wet hair. Bed linens, pillows, and hats should all be washed as well. Most clinicians recommend treating family members who share a bed or otherwise have close contact with the affected person.

Scabies is typically treated in a similar fashion. Topical treatment with lindane, malathion, or permethrin creams or lotions can be effective. The creams are applied from neck to toes in affected patients, generally at night, and rinsed off the next morning. Oral treatment with ivermectin can be used for recalcitrant or widespread cases. Most medical providers treat all household contacts of patients presenting with scabies.

Lindane has been linked to adverse events, including neurotoxicity, seizures, and, rarely, death. These adverse events are more commonly observed in children. As a result, many practitioners do not regularly prescribe lindane. The use of lindane was banned in California in 2002 due to concerns over water contamination with lindane.

Return to Sports

NCAA requires that athletes, particularly wrestlers, be free of parasites prior to competition. They require patients with head lice to be appropriately treated and reexamined for effectiveness of therapy prior to returning to competition. Athletes with scabies must be treated and must have a negative scabies preparation on the day of competition. The NFHS allows athletes to return to competition 24 hours after an appropriate course of treatment for head lice and scabies.

Future Directions in Sports Medicine

The future of sports medicine holds more promise for radically improving the lives of patients than perhaps any other field of orthopedic surgery or primary care. Sports medicine focuses on the prevention, diagnosis, and treatment of athletes, predominantly for injuries involving the soft tissues (ligaments, tendons, menisci, and cartilage). Sports medicine has already clearly demonstrated the major benefits of a team approach to the care of patients—a team that includes players from the daily environment of the patient to the most complex medical care. These teams of patient, family, coach, certified athletic trainer, physical therapist, surgeon, and physician have long been a successful example of why continuity of care is so critical to a successful outcome—a principle that is only now being recognized by other fields of orthopedics and medicine. This team approach will continue to be a cornerstone of sports medicine in the future.

The future of sports medicine will also be one in which many injuries commonly seen today will be prevented, and when they do occur, diagnosis will be accurate and rapid and treatment even more successful than with the excellent options already available today. Possible key improvements in each of the areas are outlined in the paragraphs that follow. Undoubtedly, other advances that we cannot even imagine today will also contribute to the ongoing and continual advancement of sports medicine.

Injury Prevention

A 1999 estimate of injury rates in the United States indicated that each year approximately 550,000 patients rupture their anterior cruciate ligament (ACL; a major stabilizer of the knee), 400,000 tear a rotator cuff, 600,000 have injuries to the meniscus, and 600,000 damage their articular cartilage. The numbers of these injuries are believed to have increased since that time in proportion to increased participation in sports and exercise activities. It has also been estimated that the number of patients suffering from overuse injuries (e.g., tendinitis, plantar fasciitis, and epicondylitis) is more than 10 times greater than those numbers. Among the major advances in sports medicine will be the prevention of many of these injuries—both acute and overuse injuries. This will be the result of the increased understanding of injury mechanisms and the relationship between injury occurrence and epidemiologic factors such as gender, age, and body mass index. In addition, a more individualized approach, where both alterable and intrinsic factors are assessed, will also likely become routine practice. Assessment of intrinsic individual factors, including improved understanding of the effects of physical parameters (e.g., ligamentous laxity, knee valgus, lumbar lordosis), will be combined with the risk of injury in certain sports (e.g., ligamentous laxity with swimmer's shoulder; knee valgus with ACL injuries, lumbar lordosis, and spondylolysis) to create an athlete risk profile for activity in general, with additional sport-specific information. These risk profiles will be enhanced with the use of genetic markers for traits such as wound-healing capabilities, subtle collagenous defects, neuromuscular coordination, bone mass, and even tendon or ligament strength. In addition to these intrinsic, or unchangeable, factors, an even more exciting development will be the improved understanding of how factors that are variable and changeable can be enhanced to decrease risk for individuals. These alterable factors will become of paramount importance and will include learning and applying the knowledge gained for an individual during a gait analysis (hyperpronation as a simple example), with an assessment of the individual's muscle flexibility, and combining these pieces of information with the information on injury avoidance for a specific sport to design an individualized training regimen that will help athletes minimize the risk of injury. For example, a sprinter could have a gait analysis and physical exam in the off-season that might identify hyperpronation, decreased quadriceps strength, and decreased hamstring flexibility. The athlete could then be counseled to hold off on a full sprint until hamstring flexibility is improved in order to minimize the risk of a hamstring pull or to minimize stair training until the inner quadriceps is strengthened enough to allow for this without aggravating the patellofemoral joint.

For each athlete, all this will evolve into an individualized approach, whereby an individual deciding on which sport to pursue will be able to "test" for sports with performance of simple tasks (running, jumping, and physical demonstration of flexibility and laxity), a genetic screen for known associated factors, and quantified observation of sport-specific skill performance (landing a jump) and will be able to have an "athletic aptitude profile" that details the current state of the athlete's strengths and weaknesses and his or her overall aptitude for a given sport or a selection of sports. This would be similar to a career aptitude test administered to high school students considering a career choice. Athletes would thus not only have information that might allow them to make choices between a less risky and a more risky sport but also, most important, be able to determine which alterable factors they could improve to lessen their chances of injury. Clinics designed to address the common alterable factors, similar to the neuromuscular training programs designed to decrease the risk of ACL injuries in women, will become more widespread and begin to address common problems such as shoulder instability, rotator cuff injury, and even osteoarthritis. Web-based information will enable individualized analyses to be made accessible to all, and subsequent teaching of skills to lessen risk will also be available to the individual through the web, as well as with physicians or certified athletic trainers (ATCs) or physical therapists.

Prevention of overuse injuries will follow a similar trend, with children playing baseball having a screening of their throwing technique, and correction of technique will be possible in real time before the joints are stressed to the point of injury. This, in combination with an increased knowledge of the effect of training on the individual's body, will allow coaches and ATCs on the field to assess when an athlete is at risk of developing an overuse injury and will make this possible much before the onset of pain in the player.

Overall physical screening for all athletes from middle school onward will help identify any problem areas and perhaps use individualized training to help avert both acute and overuse injuries. In an ideal case, this screening will become part of the physical education program in our school system, but an interim step may be the conduct of these screenings in local sports medicine and physical therapy settings.

To realize the potential of these individualized injury prevention programs, much research into the influence of gait, kinesiology, strength, flexibility, fatigue, and training methods must be successfully conducted. Additional work in the long term on the influence of genetic factors on injury risk will further refine and improve these programs.

Diagnosis

In the future, the diagnosis of musculoskeletal injuries will be faster, easier, and more reliable. Current methods of diagnosis hinge on careful history taking and physical examination. This will continue, but additional tools will be available to make both these analyses even more accurate and informative. Cohort studies and research into identifying risk factors for injury will provide great input and value to the history taking by the physician, ATC, or physical therapist. For example, cohort studies that identify history factors for ACL injury may include the patient hearing a "pop" or the timing of swelling, which will help the clinician determine whether the risk of an ACL tear is particularly high in a particular patient. Physical examination findings will also be assisted by similar studies; the predictive values of special tests for shoulder injuries, labral tears, and meniscal injuries will have greater clarification in the future. Gait labs will be more common and generally available to provide information on gait changes with early osteoarthritis or meniscal or labral tears. These data would assist with more rapid diagnosis of these and other entities.

Supplemental tests to the physical exam and patient history will include additional noninvasive measures. Handheld imaging devices will be available for office use. Office-based ultrasound is already being used to confirm diagnoses of tendinopathies and acute injuries. Additional handheld noninvasive imaging instruments that will provide even clearer pictures of structures below the skin will be developed. This will allow for speedier diagnosis of common problems such as stress fractures (and will assist with differentiating these from periostitis or shin splints). The resolution of both handheld and larger imaging devices will be improved as well, allowing clinicians to detect injuries on a microscopic level, as opposed to only being able to diagnose complete tendon or ligament disruption. Imaging techniques will also allow for functional assessment of living or dead cells within tissues, providing information about the extent of damage for tendinopathies and to help direct therapies for these entities. Currently, we have imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI). These techniques are useful in defining the anatomical features of the knee in a noninvasive way, and the resolution of these scans continues to increase and will likely continue to do so. The future likely holds use of these noninvasive measures to predict outcome and, more important, function—for example, the use of MRI or a similar modality to measure the strength of an ACL graft, the use of delayed gadolinium-enhanced magnetic resonance imaging of cartilage (dGEMRIC) or other special techniques to evaluate the status of the cartilage at the time of injury as well as after injury. High-resolution MRI and dGEMRIC or other techniques to help assess the functionality and viability of tissues such as cartilage, ligament, meniscus, and bone will become excellent adjunct tools for the clinician in diagnosing and treating injuries of these types.

The use of handheld imaging devices in the physician's office will also be extremely helpful in guiding injections into joints or injured tissues. With imaging assistance, smaller needles can be used and drug delivery to specific areas of injury can be performed. With the addition of monitoring for cell viability, the efficacy of treatments can also be monitored.

In addition to local imaging of pathology, there will be improved systemic markers for diseases including osteoarthritis, septic arthritis, stress fractures, and overuse injuries. These markers will be identified in the blood initially. Noninvasive methods for detecting the blood levels of these markers (e.g., light-scattering techniques) will be developed. In addition, these markers will also be detected in the urine, which would provide another noninvasive way of detecting disease and following its progression.

Evidence-Based Medicine

The future of sports medicine starts at the "bedside," with an improved understanding of how effective the current treatments of sports medicine problems are and what factors influence the likelihood of having a positive response to a treatment. For example, ACL reconstructive surgery in general is a very successful procedure—there is an excellent chance of patients getting back to their sports activities. However, some patients have more trouble than others. Determining the risk factors for a good or poor outcome is thus important to help advise patients about treatment options. One can imagine that the risk factors that might influence the outcome of a surgery could include body weight, activity level preoperatively, gender, or age. Not only is learning how these factors may affect outcome critical to predicting outcomes, but if the risk factors are modifiable (e.g., smoking), then patients can also be counseled as to what changes in lifestyle they could make to improve their outcomes of treatment.

To define the risk factors for a good or poor outcome, cohort studies are the most useful study design. Cohort studies are those that follow a group of patients after an injury or treatment. At the beginning of the study, data on the patients are collected—their age, gender, activity level, knee symptoms, and weight, among other informational items. Then, the group is followed, and outcomes are assessed at different time points. For example, patients with an ACL injury have the preoperative information, and then data on outcomes are collected at 1, 2, 5, and 10 years after surgery. Scores for how well patients are doing are correlated with the preoperative data, and the investigators can see which preoperative factors influence the outcomes. The Multicenter Orthopaedic Outcomes Network (MOON) is one such study looking at ACL reconstruction outcomes. Additional studies of revision ACL reconstruction (the Multicenter ACL Reconstruction Study, or MARS) and meniscal tear are also under way. The results of studies such as these will help orthopedists determine how to counsel their patients about risk factors and modifiable behaviors.

In addition, understanding how patients recover after a procedure should guide research in sports medicine. For example, some types of rotator cuff repair fail at a relatively high rate. This makes it an important clinical problem and should stimulate research into determining why these repairs fail and what can be done about it.

Treatment of Injury

While there are a lot of areas that will certainly grow and develop in sports medicine over the next decade, one of the most exciting areas will be stimulating tissues to heal better and faster. This revolution will be grounded in the science that is currently improving our understanding of many of the key musculoskeletal tissues involved in sports medicine injuries—ligament, tendon, meniscus, and cartilage. Improved understanding of how these tissues respond to injury and surgical treatment will lead to newer and more effective strategies for caring for patients with these injuries. A few examples are presented here.

Anterior Cruciate Ligament Injuries

Recent work has demonstrated that the ACL, which is located inside the knee joint, may have trouble healing after injury due to the synovial fluid environment breaking down the repair tissue between the two ends almost before it can form. This new understanding is leading to multiple investigators around the world working on ways to stabilize the wound site of the ACL with a scaffold that can stimulate healing of this important ligament after injury. Research is still preliminary, but the importance of stimulating healing of the ACL, and other tissues inside joints, such as the meniscus, is being recognized, and additional resources are being applied to find a solution to this very important problem. In the future, patients with an ACL tear may have the option of having their ligament repaired by using a biologic, injectable scaffold to stimulate healing—a procedure that could be less invasive than the current procedure used to treat these injuries.

Rotator Cuff Tears

Rotator cuff tears also often require surgical treatment for healing. Work currently being conducted on the biology of the tendon and the accompanying muscle atrophy that can occur after a rotator cuff tear will likely guide development of new strategies to improve the effectiveness and success rate of rotator cuff repair. For a long period of time, there has been no animal model available where the rotator cuff will not heal after injury (as occurs in the human condition). Recently, progress has been made on developing an animal model that has a similar ineffective healing response after a rotator cuff tear, and the successful completion of the development and validation of this model will greatly facilitate testing and speed development of new candidate procedures and biologic scaffolds purported to enhance healing in an animal model.

Thus, the development of this model is of paramount importance to moving the quest for improved rotator cuff repair ahead.

Meniscal Repair

Today, only a select group of meniscal tears can be repaired, and most meniscal tears are treated by removing the injured tissue (called a partial meniscectomy). Patients who have to have their whole meniscus removed due to symptomatic meniscal damage have an increased risk of osteoarthritis. It is not known if partial meniscectomy will have the same effect or how much meniscus can be safely removed without the patient having an increased risk for osteoarthritis. Future work on scaffolds that can be implanted to serve as a template for meniscal regeneration (replacement implants) and adhesive materials that can facilitate healing of tears that are currently thought to be irreparable (e.g., tears in the inner third of the meniscus or radial tears) may enable surgeons to preserve more meniscal tissue, and in turn, it is hoped that it may help avoid the accelerated osteoarthritis associated with complete meniscal loss. Research on enhancing meniscal repair and regeneration is currently hampered significantly by the lack of a validated animal model for meniscal tears. Without animal testing, it is difficult to test new candidate materials and techniques, and thus, even new techniques that look promising in the test tube can't be tested to learn more about how they might behave in a human knee.

Cartilage Repair

Currently, most cartilage repair is attempted only for relatively small and well-defined defects; larger defects are treated with replacement of large sections of bone and cartilage with either plugs or pieces of bone and cartilage obtained from a donor (osteochondral allografts) or from another site in the same patient, or by metal and plastic, as is done in a partial or total joint replacement. In the future, new biomaterials that encourage cartilage cell ingrowth from the remaining cartilage may help physicians successfully stimulate repair of larger lesions. In addition, techniques aimed at filling in the fissures seen in chondromalacia, and essentially resurfacing of the cartilage, will continue to be of great interest both on a basic science level and in the treatment of patients.

Summary

In summary, the future of sports medicine is extremely bright. With the continuation of the team approach to patient care, many advances will occur. In the future, the majority of injuries we see today will be prevented. For the injuries that do occur, our ability to diagnose the injuries will be improved in both accuracy and speed. A greater understanding of risk factors for outcomes after injury or surgery will also enhance our ability to advise and counsel patients. New, improved, and less invasive treatments will continue to be developed to make the burden of a sports medicine injury as low as possible for patients. The improvements outlined here, and the many improvements that one cannot even yet anticipate, will ensure that sports medicine continues its vibrant culture of "bedside to bench" research and continual advancement in the care of patients.

G

Gastrointestinal Problems

Gastrointestinal problems are common in the general population, including athletes. Athletes are also at increased risk for traumatic abdominal injuries.

Motility Disorders

Gastrointestinal motility disturbances affect a significant number of recreational and competitive athletes. Runners report symptoms more frequently than other endurance sports athletes; hence, the term *runner's trots* is used to describe the stool changes that have been associated with running. Motility disturbances manifest through a variety of gastrointestinal symptoms, including nausea, vomiting, bloating, cramping, urge to defecate, or change in frequency of bowel movements. Lower gastrointestinal symptoms are noted more frequently than upper gastrointestinal symptoms, especially in female athletes, likely due to hormonal changes of the menstrual cycle. Deconditioning in the untrained athlete also seems to lead to increased symptoms.

The precise etiology of gastrointestinal motility disturbances with exercise is unclear. Some theories suggest that muscle enlargement during exercise causes compression of the colon, while others point to decreased blood flow to the colon during exercise resulting from the greater blood flow to the muscles. Other theories identify mechanical and hormonal changes as causing altered transit time of material through the gastrointestinal system. Most likely, the etiology involves multiple factors that may be influenced by the intensity of exercise and hydration status.

Symptoms typically occur during or immediately following exercise and may involve a range of symptoms from abdominal cramping to severe diarrhea with incontinence. A complete history should review any recent travel or unusual food consumption to evaluate for an infectious cause. Symptoms that are not related to exercise activity should raise suspicion for an underlying disorder such as inflammatory bowel disease or irritable bowel syndrome. Evaluation and testing should be directed based on the history and exam findings as well as on the concern for etiology other than exercise. Treatment should emphasize rest until symptoms resolve, as well as proper hydration. Gradual return to exercise is recommended when the symptoms resolve. Antidiarrheal agents should be used with caution as they may increase the risk of heat injury. Avoidance of substances that may worsen symptoms is recommended. Foods high in fiber and fat as well as milk and fruits should be avoided for a few hours before exercise. Protein and herb supplements have also been associated with increased symptoms. Symptoms may be alleviated with bowel and bladder emptying before exercise.

Gastroesophageal Reflux Disease (GERD)

Gastroesophageal reflux disease (GERD) is a condition where the stomach (gastric) contents move up into the esophagus (the muscular tube from the throat to the stomach). The characteristic symptoms include heartburn and acid indigestion, but patients frequently complain of nausea, belching, bloating, cough, or wheezing. Many factors have been identified that contribute to worsening of GERD symptoms, including increasing age, exercise after eating, smoking, a high-fat diet, and weight gain or obesity. Up to 50% of athletes complain of GERD symptoms during exercise, especially if they have had a previous history of GERD. Treatment of GERD begins with dietary and lifestyle modifications. It is recommended to avoid eating within 3 hours of lying down and to avoid large meals. Foods to avoid include caffeine, chocolate, mint, fatty foods, spicy foods, citrus fruits, and tomatoes. Other behavioral changes that may improve symptoms include discontinuing smoking, reduction of weight, and avoiding exercise for 3 hours after eating. Patients who fail to respond to these changes may require additional treatment with medications. Symptoms that persist despite treatment, especially in older adults, require additional evaluation and testing.

Trauma

Athletes who participate in sports, especially contact sports, are at risk for traumatic abdominal injuries. The muscles of the abdominal wall are vulnerable to strains or contusions. Hollow organs, such as the colon, intestine, or stomach, may suffer contusion or laceration. Solid organs of the abdomen, such as the liver and spleen, are more vulnerable to injury than hollow organs. The spleen, with its rigid capsule and vulnerable location, is susceptible to injury from a direct blow or possibly from an overlying rib fracture. Bleeding from an injured spleen is typically rapid, requiring immediate stabilization and transport to the hospital. Patients with infectious mononucleosis are at particular risk for spleen injury. *Splenomegaly* (enlarged spleen) occurs in about 50% of patients with mononucleosis, and the greatest risk of rupture is during the first 3 to 4 weeks of the infection. Normal impact from contact sports can result in a rupture in the mononucleosis-infected spleen. Spleen ruptures have been noted in the mononucleosis patient during normal physical activity without trauma.

Liver Injuries/Disorders

The liver is the largest solid abdominal organ and plays an essential role in the body's physiology. Severe liver injuries are fortunately rare in athletics but occur more frequently in high-impact sports such as football, wrestling, rugby, and soccer. Blunt liver injuries are less likely to cause severe bleeding; however, contusions and hematomas do develop. Complete evaluation and careful monitoring are necessary before return to sports is permitted.

Liver function tests may be elevated in the asymptomatic athlete, which is thought to result from the decreased blood flow during vigorous exercise. In most instances, these abnormal liver function readings are transient and benign, with return to normal conditions after rest and repeat testing. Persistent liver function elevation requires further evaluation for infections such as hepatitis, cytomegalovirus, or Epstein-Barr virus. Hepatitis A can be easily transmitted among athletes in close contact via the fecal-oral route or possibly through exposure to contaminated food or water, especially during travel. Hepatitis B or C infections are transmitted from blood to blood or via sexual contact. Education regarding proper hygiene, with good hand washing and protected sexual contact, as well as immunization for hepatitis A and B are recommended preventative measures.

"Side Stitch": Abdominal Pain

Athletes frequently experience a sharp side pain with exercise, commonly called a "side stitch." It occurs most often in runners and in those who are deconditioned and starting an exercise program. Activity after eating also seems to be an aggravating factor. The exact etiology is not known, but it is thought to result from a spasm in the diaphragm due to poor oxygen delivery to the diaphragm muscle. Symptoms seem to subside as training continues and conditioning improves. Persistent symptoms may require additional evaluation for other gastrointestinal causes.

Gender and Age Differences in Response to Training

Fitness training, or athletic training, can be defined as a systematic way of improving one's fitness for a desired benefit (e.g., one's health, one's sports performance). Training is typically conducted in two arenas—aerobic fitness and muscle strength and endurance—and operates around several different principles, including the overload-fatigue-recovery-adaptation cycle, reversibility, and specificity. It is important to note, however, that not everyone will have the same response to fitness training. Training response can be affected by one's general health (i.e., current physical fitness and ability levels, psychological readiness to participate, and nutrition status), age, and gender. This entry discusses gender and age differences in response to training.

Training in Children and Adolescents

The unique training needs and responses of children and adolescents center on several key areas, including their physical readiness and abilities, their psychological readiness to participate, their nutritional status and needs, and their injury patterns.

Children's physical state both affects and is affected by their training. Before children can participate in an athletic activity, they must have not only reached the appropriate developmental milestones that will give them the necessary gross and fine motor skills to participate but also attained a certain level of performance for the particular activity. Growth attenuation has been observed in children participating at certain levels of training intensity (e.g., gymnastics). Catch-up growth does occur when the intensity is returned to a more physiologic level. Exercise can also increase a child's bone formation during periods of rapid bone development. When performed under adult supervision, strength training can increase a child's neuromuscular activation, improving contractility as well as facilitating a balance between the agonist and antagonist muscle groups. Overtraining—for example, participating in one sport year-round—can result in overuse injuries, including growth plate injuries (e.g., Little League shoulder) and apophysitis. Return-to-play decisions should be conducted with predetermined, and strictly enforced, guidelines so as to avoid further or additional injury. Injury rates can also be reduced by providing appropriate coach and trainer education; rule, field, and equipment adjustments; and supervision.

Psychology is also an important component of pediatric and adolescent training. Before a child can participate in sporting activities, he or she must be psychologically ready. Preschool children are only ready to participate in activities that display and promote their general skills (e.g., kicking, running, and throwing) and are not quite ready to participate in a sporting event (e.g., baseball, soccer), as they are able to appreciate neither the rules of the game nor the theory of teamwork as grade school children are able to do. Middle school–age children have advanced capacities for teamwork, an increased understanding of competition, and improved skills for play. Pubertal adolescents' skills are further increased, as is their self-evaluation and ability to compare themselves with others in their sport.

Just as the readiness of the child affects his or her training and sport, so does his or her participation in athletics affect his or her psyche. Healthy participation can provide the motivation to continue the activity, confidence in oneself and one's abilities, and general enjoyment. Children and adolescents who participate in athletic activities also display a higher level of social function than their nonathletic peers. One caveat involves children and adolescents who overtrain. These individuals are susceptible to burnout, resulting in depression, fatigue, substance abuse, and eating disorders.

Balanced nutrition and good hydration are essential for good health and athletic participation. Boys and girls have the same energy needs until puberty, after which active males require more calories than active females. Energy needs are also affected by one's general health (e.g., age, height, weight, body composition, and stage of growth), as well as by the frequency, intensity, time, and type of activities performed. Lack of appropriate nutrition can affect not only one's health but also one's training and sports participation.

What would be the optimal training program for children and adolescents? Running is considered a safe and effective aerobic activity for children of all ages. Prepubertal athletes should use free weights and/or resistance bands, as the weight machines used by adolescents and adults are not configured to support younger children's needs. Strength training should be conducted at a low, but gradually increasing, resistance. In addition, power lifting should be reserved for those with closed growth plates. Whatever the program, it should be conducted to conform with the development and skills of the child or adolescent.

Training in Older Adults

On the other end of the spectrum are older adults who participate in training and athletics. Their ability to train effectively and their response to training affect each other. Older individuals typically have lower levels of spontaneous activity, resulting in decreasing athletic performance over time. In addition, older adults might continue to suffer from lingering past injuries, which may hinder their performance. Decreasing hormone levels result in a decreased training response, as well as in an increased training response time. Older individuals may also need increased time for recovery between bouts of activity. The physiologic parameters of older adults can be improved with training. Decreasing muscle function (due to negative alterations in motor unit functioning and enervation), increasing tendon laxity with decreased efficiency of muscle action, and decreasing lean body mass may all be attenuated with resistance training. Aerobic training can help improve the natural decrease in one's $\dot{V}O_2max$ (volume of maximum oxygen, a measure of cardiorespiratory fitness and the functional capacity of the heart). Fitness training has also been shown to decrease older adults' morbidity and mortality when compared with their sedentary peers.

An ideal program for older adults would consider their current health status and their current fitness level. Most exercise and training parameters would be similar to those recommended for young, healthy adults (30 minutes of moderate exercise five times a week and resistance training with 8 to 10 exercises, two times a week). Due to the increased recovery time needed by older adults, the frequency of activities may need to be decreased. Cross-training programs would allow for this recovery while also providing aerobic and muscle strength and endurance training.

Training in Women

The female response to athletic training is similar to that in males. With the same level of training, women can increase their cardiovascular fitness at the same rate as men. In addition, with resistance training, women see similar—if not greater—increases in strength (per body mass) than men; however, they will never reach the same absolute strength as men, due to their lower testosterone levels and the resultant decreased muscle fiber size and reactivity. Active women also have decreased percent body fat when compared with age-matched controls; however, due to their physiologic needs and hormone levels, they will never attain the low percent body fat levels of active men.

A unique female response to training involves the female athlete triad, which includes disordered eating, altered menstruation, and decreased bone density. Disordered eating, unintentional or intentional, can reach varying levels of severity, from low energy availability to anorexia and bulimia. Altered menstruation includes primary and secondary amenorrhea (absence of menstruation), as well as oligomenorrhea (decreased menstrual frequency) and anovulation. Decreased bone density, diagnosed by DEXA (dual-energy X-ray absorptiometry), can present with stress fractures. Girls and women involved in aesthetic and weight category sports are particularly susceptible to this triad.

A unique female training situation is the pregnant athlete, who is both helped and hampered by the many physiologic changes of pregnancy.

Increased cardiac output and cardiac reserve can actually boost exercise tolerance early in pregnancy. Exercise can also help increase her cardiac reserve and avoid hypovolemia (low blood volume), decrease labor time and complications, decrease the need for partum medications, and decrease her return time to activities postpartum. Some caveats to exercise during pregnancy include the increased risk of hypoglycemia (due to fetal use of glucose and increased maternal insulin levels) and the increased risk of sprains (due to increased ligamentous laxity). Any negative effects on fetal health in an uncomplicated pregnancy have not been observed.

Genitourinary Injuries

Genitourinary injuries in sports are relatively uncommon. Injuries, when they do occur, can affect the external genitalia and the internal urinary system.

Anatomy

The kidneys are located behind the 12th rib in the retroperitoneum (the region behind the abdominal cavity). The *ureters* are tubes that begin at the kidneys and carry urine to the bladder. They run along the back of the abdominal cavity and cross the bony edge of the pelvis to attach to the bladder. The bladder, a hollow organ, is located in the pelvis, but it is at risk for injury when it is full. The urethra empties the bladder.

The female reproductive system is situated in the pelvis, except for the external genitals. Internally, the ovaries are connected to the uterus by the fallopian tubes. The vagina extends from the vulva (external genitals) to the uterus.

The male reproductive system is more vulnerable than the female. The penis, urethra, scrotum, and testes are located externally. The internal urethra and prostate are located inside the pelvis.

Renal Physiology

At rest, renal (kidney) blood flow is 20% of the cardiac output. The renal blood flow decreases with activity, with as much as 75% of its capacity at rest. The blood is filtered by the kidney structures called *glomeruli,* which act to prevent loss of protein and blood cells in the urine.

The kidneys help regulate the body's electrolyte and fluid balance. Antidiuretic hormone causes more water to be reabsorbed by the kidneys. It is stimulated by low blood volume, as when the body is in a state of dehydration.

Hematuria

Hematuria, or blood in the urine, is gross (seen by the naked eye) or microscopic (seen only under a microscope and identified with a urine dipstick or urinalysis). It occurs in about 75% of athletes who participate in sports. Hematuria can be caused by serious illness and by trauma to the kidneys and bladder. However, there is also an atraumatic cause called *athletic pseudonephritis*, or *exercise-induced hematuria.*

In athletic pseudonephritis, the decreased blood flow to the kidneys causes increased permeability of the glomerulus, allowing red blood cells to pass into the urine. This is a diagnosis of exclusion, meaning that it is important to rule out traumatic etiology and other medical problems that may cause hematuria, such as kidney stones, infection, tumors, and glomerulonephritis. Athletic pseudonephritis should resolve within 48 to 72 hours.

Athletes with hematuria who have symptoms, such as fever, or other findings on physical examination, including elevated blood pressure, are at high risk and need a more aggressive evaluation.

Athletes over 40 years of age are also at high risk. Low-risk athletes with hematuria should stop exercise completely for 24 to 48 hours and also repeat urinalysis. If the hematuria resolves, it is exercise induced, and they should be given reassurance. If the hematuria persists, they should undergo a more extensive workup with their physician or a nephrologist (a kidney doctor).

Proteinuria

About 70% of athletes have *proteinuria* (elevated protein levels in the urine) after activity. This is found on urinalysis. Unlike hematuria, there is a direct relationship between intensity of exercise and level of proteinuria. Proteinuria will begin within 30 minutes of exercise and clears in 24 to 48 hours.

Proteinuria may be exercise induced, but it may also be related to more serious illnesses (diabetes, glomerulonephritis, nephritic syndrome, etc.). As for hematuria, a complete history and a complete physical exam to identify any concerning signs or symptoms should be taken. If the history and physical exam are normal, the athlete should be counseled to stop activities for 24 to 48 hours and have a repeat urinalysis. If it remains positive, further workup must be considered to rule out more serious disease. If the test is negative, it can be exercise-induced proteinuria.

Urinary Tract Trauma

Renal Trauma

This is the most common genitourinary trauma and is covered more extensively in the renal injury section.

Ureter Trauma

This is unusual in sports and is usually associated with severe renal trauma, pelvic fractures, and lumbar spine fractures. The only treatment is surgical repair.

Bladder Trauma

Usually the bladder is well protected in the pelvis. However, a full bladder extends over the pelvis and is at risk for injury. Athletes will have a history of trauma and pain just above the genitals (suprapubic region). There will be hematuria and pain with urination (dysuria). Contusions can be treated with catheter placement, pain medication, and antibiotics for about 7 to 10 days. A bladder rupture is rare in sports and is associated with a pelvic fracture. This requires emergency surgery.

Reproductive System Trauma

Testicle Injuries

Direct trauma to the testicles may result in pain, nausea, anxiety, bruising, and swelling. All painful and swollen testicles need further evaluation with ultrasound. Ultrasound can help identify testicular rupture or fracture, as well as testicular torsion. If the ultrasound is normal, testicular contusions are treated with pain medications, rest, ice, and elevation of the scrotum.

Testicular torsion is a surgical emergency and must be suspected in any patient with scrotal pain and swelling. This is a twisting injury to the spermatic cord above each testicle. The twisting cuts off the blood supply, causing pain, and it may result in loss of the testicle. On physical exam, a darkening of the scrotum with swelling and a high-riding testicle may be visible; the affected side appears much higher than the other testicle. The elevation of the scrotum on physical exam will increase pain with testicular torsion.

Penis Injuries

The penis can be damaged by direct trauma, particularly if erect. This will cause painful swelling and bruising, and it is a surgical emergency. The penis may also be damaged by frostbite in cold-weather sports.

More commonly, cycling can irritate the pudendal nerve. This nerve can be compressed by riding in the saddle. It may cause increased pain in the penis and possibly priapism (or intractable erection).

Female Genital Injuries

The female reproductive organs are generally quite well protected inside the pelvis. The vulva (external genitalia) may be damaged by direct trauma. This can cause a hematoma (blood collection), which can be very painful. Since the vulva is very vascular, the hematoma may become quite large and may require surgical drainage. Women who fall while water-skiing may sustain a water douche, which is an injury where water is forced into the vagina. This can cause a laceration in the vagina and potentially severe internal bleeding and uterus damage.

Stress Incontinence

This is the involuntary loss of urine during exercise. It is quite common in women (about 30% to 50% of all regularly exercising women), especially after childbirth. This may be due to the shorter urethra and loss of muscular control after delivering an infant. Exercises such as running and jumping are likely to create incontinence. Treatment involves strengthening the pelvic floor muscles and using biofeedback. If that is not beneficial, there are medications (alpha agonists) that may be useful. Surgical intervention is indicated only if exercises and medication fail.

Special Populations

Wheelchair Athletes

Many wheelchair athletes do not have good neurologic control of their urinary tract. These athletes are at higher risk for infections and kidney stones. These injuries can be recurrent, and they can lead to permanent kidney damage. However, wheelchair athletes have a lower risk for these problems than sedentary wheelchair users.

Single-Organ Athletes

There is no clear evidence regarding clearance for athletes with a single kidney, testicle, or ovary. Single-organ concerns are discussed in other entries in this encyclopedia.

Glenoid Labrum Tear

The shoulder has the widest range of motion of the joints in the body. The soft tissue (labrum) surrounding the glenoid cavity of the scapula helps stabilize the head of the humerus within the glenohumeral joint. Injury to the labrum can occur from overuse or as the result of trauma, such as a glenohumeral joint dislocation.

The physical examination of a labral tear involves a complete examination of the shoulder to test the condition of the surrounding muscles, capsule, and ligaments. Magnetic resonance arthrography is an effective way of visualizing a tear of the labrum.

Although small labral tears can be treated nonsurgically, factors such as the athlete's age or activity level may influence the decision to have a labral tear repaired surgically after a first-time dislocation.

Anatomy

The glenohumeral joint is made up of a ball-like humeral head rotating on a shallow dishlike surface, the glenoid. The bony anatomy of the glenohumeral joint is what allows the shoulder its wide range of motion. Because of this wide range of motion, the shoulder is very dependent on soft tissue restraints for stability.

The soft tissue restraints of the shoulder include the glenoid labrum, the surrounding capsule and ligamentous structures, and the rotator cuff musculature.

The glenoid labrum is a border of soft tissue that surrounds the bone of the glenoid and effectively deepens the glenohumeral articulation. The labrum may provide stability against humeral head translation.

The capsule extends from the periphery of the glenoid to the periphery of the articular cartilage of the humeral head. The capsule is thickened in three distinct areas. These thickenings make up the glenohumeral ligaments. The ligaments function to stabilize the shoulder by becoming taut in different positions of shoulder motion.

Increased reliance is placed on the surrounding rotator cuff musculature to maintain proper shoulder mechanics after injury to the labral tissue.

Shearing of the labrum from the anterior inferior glenoid was described by Bankart in 1923 and subsequently was named the *Bankart lesion*. Since that time, others have described avulsions of the labrum from other portions of the glenoid. These include SLAP (superior labrum anterior posterior) tears, ALPSA (anterior labral periosteal sleeve avulsion) lesions, and reverse and bony Bankart lesions.

A *SLAP lesion* refers to a tear of the superior portion of the glenoid labrum, extending from the anterior to the posterior glenoid.

A *bony Bankart* occurs when a shoulder dislocates and the impact of the humeral head on the glenoid breaks a piece of bone off the anterior inferior glenoid. A small piece of bone can often be reattached along with the soft tissue. Any piece larger than 25% of the glenoid needs to be repaired, fixed in place with a screw or heavy suture to prevent recurrent dislocation or subluxation.

A *Hill-Sachs lesion* is a bone bruise or bony defect that is often found in association with a Bankart lesion. When the humeral head is traumatically dislocated from the glenohumeral joint, the posterior superior aspect of the humeral head can strike against the anterior inferior glenoid and bruise or create a bony defect in the humeral head. Although these create an interesting pathology that can be explained by the mechanics of the dislocation, most do not need to be addressed surgically unless they engage the glenoid with shoulder rotation and contribute to shoulder instability. Lesions that involve greater than 30% of the humeral head or are associated with a capsular lesion are at a greater risk of leading to shoulder instability.

An *ALPSA lesion* refers to a tear of the anterior inferior glenoid labrum, where the periosteum remains intact (the periosteum is torn in a Bankart lesion). The intact periosteum pulls the labrum medially on the scapular neck. Untreated periosteal sleeve avulsions may cause the avulsed labrum to heal in an abnormal position, leading to chronic shoulder instability.

A *GLAD lesion* (glenolabral articular disruption) is a superficial tear of the glenoid labrum in combination with injury to the articular cartilage of the anterior inferior glenoid. Because the labrum remains firmly attached to the glenoid, GLAD lesions are not commonly associated with shoulder instability and can usually be treated conservatively (unless associated with a large cartilage defect or loose body).

Symptoms

An athlete who presents with a tear of the glenoid labrum will often complain of positional arm pain or pain that worsens with activities. Other symptoms include restricted range of motion, instability, and/or a catching sensation with shoulder motion.

Shoulder pain often correlates with the location of the labral tear (i.e., posterior shoulder pain with posterior labral lesions). Symptoms are often associated with activities. Patients may complain of a catching sensation, instability, or numbness and a tingling of the affected extremity. Nocturnal pain is variable.

Diagnosis

Physical Examination

Both shoulders should be made visible for the physical exam. This will allow the examiner to compare the symmetry of the injured shoulder with the opposite uninjured shoulder. Muscle bulk and scapular position can also be compared.

A sensory and motor exam should be performed to rule out any nerve injuries that may be contributing to muscle atrophy or a neuropraxia that may have occurred if the labral tear was associated with a shoulder dislocation.

Range of motion is assessed in forward flexion, extension, abduction, and internal and external rotation with the elbow at the side and at 90° of abduction. Internal rotation at the side is measured by having the patient reach up to his or her back as far as possible and recording the level of the most superior vertebral body that he or she is able to reach (Apley scratch test). Any associated pain, catching, subluxation, or apprehension of dislocation with range of motion should be documented.

Rotator cuff strength should also be evaluated. Supraspinatus strength is tested with The Jobe empty can test. This is performed by placing the arm in 90° of abduction and 30° anterior to the coronal plane with the arm internally rotated so that the thumbs are pointing toward the ground. The patient is then asked to resist a downward directed force by the examiner.

The subscapularis muscle can be tested with either the lift-off test or the belly press test. The lift-off test is performed by having patients place the back of their hand on their back and then lifting the hand away from the back. When performing the belly press test, patients place the palm of their hand on their abdomen with the elbow brought anteriorly until it is in line with the hand. Patients are then asked to resist the examiner's attempt to lift their hand off their abdomen. A positive test occurs when a patient drops his or her elbow posteriorly in an attempt to supplement a weak subscapularis muscle by assisting with the posterior deltoid.

The external rotators (infraspinatus and teres minor) are tested with the elbow at the side while the examiner resists attempted external rotation.

Tests specific to evaluate a torn glenoid labrum include the Speed test, the O'Brien test, the anterior apprehension test, the relocation and release tests, the load and shift test, and the jerk test.

The Speed test evaluates the strength of the biceps and the integrity of its attachment. It is performed with the shoulder flexed forward 90° with the arm abducted approximately 30° from the sagittal plane. With the hand supinated, the patient resists the examiner's inferiorly directed force. Resulting shoulder pain is indicative of injury to the biceps tendon attachment at the superior glenoid labrum.

The O'Brien test evaluates the integrity of the glenoid labrum. This is performed by flexing the shoulder to 90°, pronating the arm so that the thumb is pointing toward the ground, and adducting the arm approximately 15° from the sagittal plane. The O'Brien test is positive if there is shoulder pain with a resisted downward force on the arm in this position and if the Speed test is negative.

The anterior apprehension test is the classic provocative test for anterior instability. It is performed by placing the arm in 90° abduction, extension, and external rotation with the elbow flexed to 90°. The examiner then progressively externally rotates the shoulder. A patient with anterior instability will complain of pain in the anterior shoulder or apprehension of impending dislocation.

The relocation test increases the specificity of the anterior apprehension test for cases of subtle instability. It is performed by placing the shoulder in a position of apprehension and then applying a posteriorly directed force over the humeral head. The posteriorly directed force decreases the patient's pain and reduces the apprehension of impending subluxation. When the examiner removes the posterior force, the pain and apprehension return (a release test).

Anterior and posterior labral pathology can also be tested with the load and shift test. This test is performed with the patient lying supine on the examination table. The table serves to stabilize the scapula. The patient's arm is slightly abducted from his or her side. The examiner then stabilizes the patient's shoulder with one hand and grasps the proximal humeral shaft with the other hand. While slightly compressing the humeral head against the glenoid, the examiner attempts to slide the proximal humerus off the anterior and then the posterior glenoid rim. In the stable shoulder, anterior or posterior translation of approximately half the distance of the humeral head will occur.

The jerk test is an additional test for posterior shoulder instability or a posterior labral tear. It is performed by placing the patient's arm in 90° of flexion, adduction, and internal rotation with the elbow flexed to 90°. The examiner then applies a posteriorly directed force at the elbow, attempting to push the humeral head posteriorly off the glenoid. A jerk or clunk is felt as the humerus slips over the edge of the posterior glenoid rim.

Imaging

Imaging of a patient with a suspected labral tear should begin with plain radiographs, including anteroposterior (AP), scapular Y, and axillary views, to rule out any bony pathology. Additional views that may be helpful to evaluate for bony injury include the West Point and Stryker notch views. The West Point view puts the anterior inferior glenoid rim in a better position to detect rim fractures (bony Bankart). The Stryker notch view evaluates the humeral head for an impaction (Hill-Sachs) lesion. The glenoid labrum itself is best visualized with an MRI or MR arthrogram of the shoulder.

An MRI of the shoulder usually includes coronal, axial, and sagittal views. A labral tear is best visualized in the axial plane. In this view, the torn labrum is seen as soft tissue elevated off the surface of the glenoid. When dye has been injected into the shoulder prior to the MRI (MR arthrogram), the dye is seen to extravasate between the soft tissue and the bone, making the tear easier to visualize.

Recent comparisons quantify the sensitivity of an MRI alone in diagnosing a labral tear to be 91% to 93%. The addition of dye in the glenohumeral joint (MR arthrogram) improves the sensitivity of diagnosing a labral tear to 96%.

Treatment

Nonsurgical

Small labral tears that are not associated with instability can sometimes be treated with an initial period of anti-inflammatories and rest, followed by a program of physical therapy, to strengthen the surrounding rotator cuff musculature and the periscapular stabilizers.

Some of the factors that come into consideration in determining whether a labral tear should be fixed surgically or not include the size of the labral tear, the degree of shoulder instability, the age of the patient at the time of dislocation, and whether the athlete participates in contact or collision sports.

Traumatic dislocations that occur in patients who are less than 20 years of age are at a significant risk for redislocation. A youth or adolescent with a first-time dislocation is at a 70% to 100% risk of redislocation.

Risks associated with recurrent dislocation include damaging the articular cartilage and a longer time out of sports (an unsuccessful nonoperative period followed by postoperative treatment and recovery).

Surgical Treatment

Arthroscopy

Some of the benefits of treating a labral tear arthroscopically include reducing the morbidity associated with a large incision and releasing of the subcapularis muscle from its attachment site on the proximal humerus, as required in an open-surgical approach.

Arthroscopy is additionally beneficial because it allows the physician to visualize and probe the entire glenoid labrum for any areas of detachment.

Shoulder arthroscopy is performed through two to three small incisions made around the shoulder joint. These incisions are used for placement of the camera and the instruments used to evaluate and repair the torn labrum. With the camera in the shoulder, the entire glenoid labrum can be seen and evaluated. Other structures that can be visualized include the articular surfaces of the glenoid and the humeral head, the long head of the biceps, the rotator cuff attachments, and the capsule.

A labral tear is repaired by suturing the detached labrum back to the glenoid with suture anchors. Suture anchors are made up of a bioabsorbable or metal anchor that is placed into the bone of the glenoid. The anchor has attached sutures, which are then used to secure the torn labral back to the bone of the glenoid while it heals.

Open Treatment of Shoulder Instability

An open procedure is performed by making a longitudinal incision in the axillary crease. Dissection is carried down through the subcutaneous level to an interval between the pectoralis major and the deltoid muscles. The subcapularis muscle is then identified and released from its attachment on the proximal humerus. The capsule can then be split and the labral tear identified and repaired. The repair can either be performed using suture anchors, similar to an arthroscopic repair, or by suturing the torn labrum back to the glenoid through small drill holes placed in the edge of the glenoid.

After Surgery

The shoulder is usually protected in a sling for 4 to 6 weeks after surgical repair of the glenoid labrum. The sling should be removed several times a day for elbow and wrist range-of-motion exercises.

During the first 2 weeks after surgery, patients may be allowed to perform pendulum-type exercises with their arm hanging independently at their side while they gently swing their arm in small circles.

Formal physical therapy begins at the 2-week postoperative visit. Initially, forward flexion to 90° is allowed. External rotation is limited to neutral for the first 6 weeks. At 6 weeks, the patient is allowed to increase external rotation to 30°. Full external rotation range of motion is allowed at 4 months postoperatively. Progressive strengthening exercises are begun at 6 weeks postoperatively. Return to sports is anticipated to occur approximately 4 months after surgery

Gluteal Strain

Gluteal strain is a trauma to the gluteal muscles, a group of three muscles of the buttocks and upper thigh, the gluteus maximus, gluteus medius, and gluteus minimus. A strained muscle is colloquially known as a *pulled muscle* and involves a tear of the muscle fibers. The tear occurs as a result of overstretching the muscle beyond the amount of tension or stress that it can withstand. The problem can also result from using the gluteal muscles too much on a particular day or due to a blow to them. Suddenly putting stress on the muscles when they are not ready for it also predisposes them to a tear.

Sports activities include complex and coordinated processes that involve the entire body. Sports that require bursts of speed increase the chances of getting a gluteal strain. Especially sports such as running, hurdles, long jump, basketball, soccer, football, rugby, and so on put the players at risk of having a gluteal strain. These are dynamic sports and require explosive movements such as sprinting, jumping, shooting, and so on, with large forces generated by muscles and tendons.

In many running overuse injuries, the upper buttock muscle (gluteus medius) is the culprit. This is because during running the body is always either completely in the air or dynamically balanced on one leg. And in both situations, the gluteus medius is the key muscle. Situated on the upper edge of the hip, the gluteus medius is responsible for lifting the leg away from the body, helping it rotate inward and outward, and essentially keeping the pelvis stable, so that the pelvis doesn't tilt heavily toward the ground.

Symptoms

Pain and tenderness in the buttocks and stiffness and weakness of the gluteal muscles are indicative of a gluteal strain. Bruising also appears around the gluteal muscles.

During physical activity, 70% of the cardiac output is diverted to muscle blood flow. So any injury is likely to lead to significant bruising, which may be intramuscular (i.e., within the muscle sheath) or intermuscular. Intramuscular hematoma is a more serious injury, and the resultant swelling usually persists beyond 48 hours and is accompanied by significant tenderness, pain, and impaired muscle function. Intermuscular hematoma, on the other hand, causes dispersal of blood within the fascial planes, and after an initial period of increased pressure, there is a relatively rapid reduction in pressure and swelling and return to normal muscle function.

Diagnosis

Tenderness and bruising on the buttocks and pain on contracting the gluteal muscles, particularly against resistance, are diagnostic of a gluteal strain. For severe gluteal strains, magnetic resonance imaging (MRI) is used to see the extent of injury and to predict the length of the recovery period. Depending on their degree of severity, the strains could be graded as follows:

Grade I: This is a mild strain with microtearing of fibers. Less than 5% of muscle fibers are involved. This requires 2 to 3 weeks to heal.

Grade II: There is more extensive damage to the gluteal muscle with more fibers involved, but the muscle is not completely ruptured. The rest period required is usually between 3 and 6 weeks.

Grade III: This involves complete rupture of the muscle, but it is rare in gluteal muscles. It is surgically repaired; exploration and apposition of the muscle ends are required. It takes 3 months of rest to heal.

Gluteal strains should be rested and allowed to heal. If the patient continues to play, the condition will worsen. If ignored, a Grade I strain has the potential to become a Grade II strain or even a complete rupture.

Treatment

The treatment should aim to stop the bleeding within the tissue as soon as possible, in order to allow the fibrin scaffold to develop on the damaged capillaries.

The immediate treatment consists of the RICE protocol: *r*est, *i*ce, *c*ompression, and *e*levation.

Rest: Stop all activities that cause pain to avoid the strain becoming more serious. The injured player may be able to continue playing, but the importance of his or her contribution to the current match must be weighed against the increasing damage that is being done with every minute that the player continues in the game.

Ice: Apply ice or a cold pack to the affected buttock for 15 to 20 minutes, four times a day for several days after the injury. Wrap the ice or cold pack in a towel. To avoid freezing the skin, do not apply the ice directly to the skin. A cold bath is a popular treatment of gluteal strains as it offers two distinct improvements. First, it allows controlled and even constriction around all the muscles, effectively closing the microscopic damage and numbing the pain. Saint Andrew's cross-country coach John O'Connell, a 2:48 masters marathoner, recommends to hit the ice baths before the ibuprofen. "Pain relievers can disguise injury," he warns. "Ice baths treat both injury and soreness." The second advantage involves a physiological reaction. Assuming that one has overcome the mind's initial flight response, the body fights back by invoking a *blood rush*. This rapid circulation flushes the damage-inflicting waste from the system while the cold water outside preserves the contraction. The blood rush revitalizes the very areas that demand fresh nutrients.

Compression: Wrapping the gluteal region reduces swelling.

Elevation: The strained gluteal region should be kept close to the level of the heart to keep the blood from pooling into the injured area.

This immediate treatment is usually accompanied by the use of NSAIDs (nonsteroidal anti-inflammatory drugs), such as ibuprofen, which both reduce the immediate inflammation and serve as an analgesic.

The healing process of the gluteal muscles starts with the inflammatory response and consists of three stages. First, new muscle fibers grow from special cells within the muscle. Second, there is bleeding in the gap between the torn muscle ends, and from this blood, a matrix or scaffold is formed to anchor the two ends together. And third, the scar matures, and collagen becomes aligned along the lines of external stress.

Rehabilitation

When the acute pain in the gluteal muscles is gone, the patient should start gentle stretching but stay within pain limits and afterward begin strengthening exercises. Gluteal muscles can be stretched using the following two exercises:

Single knee-to-chest stretch: Lie on your back with your legs straight out in front of you. Bring one knee up to your chest, and grasp the back of your thigh. Pull your knee toward your chest, stretching your buttock muscle. Hold this position for 15 to 30 seconds, and return to the starting position. Repeat three times on each side.

Piriformis stretch: Lying on your back with both knees bent, rest the ankle of your injured leg over the knee of your uninjured leg. Grasp the thigh of your uninjured leg, and pull that knee toward your chest. You will feel a stretch along the buttocks and possibly along the outside of your hip on the injured side. Hold this for 15 to 30 seconds. Repeat three times.

The patient can begin strengthening his or her gluteal muscles as soon as the sharp pain is gone and there is only a dull ache when doing the gluteal isometrics.

Gluteal isometrics: Lie on your stomach with your legs stretched straight out behind you. Squeeze your buttock muscles together, and hold for 5 seconds. Release. Do 3 sets of 10.

After gluteal isometrics become easier, the patient can do the next gluteal-strengthening exercises.

Prone hip extension (*bent leg*)*:* Lie on your stomach with a pillow underneath your hips. Bend your injured knee, tighten up your buttocks muscles, and lift your leg off the floor about 6 inches (15.2 centimeters). Keep your knee straight. Hold for 5 seconds. Then, lower your leg and relax. Do 3 sets of 10.

Resisted hip extension: Stand facing a door with elastic tubing tied around the ankle on your injured side. Knot the other end of the tubing, and shut the knot in the door. Pull your leg straight back, keeping your knee straight. Make sure you do not lean forward. Do 3 sets of 10.

Hip abduction (with elastic tubing): Stand sideways near a doorway with your uninjured side closest to the door. Tie some elastic tubing around the ankle on your injured side. Knot the other end of the tubing, and close the knot in the door. Extend your leg out to the side, keeping your knee straight. Return to the starting position. Do 3 sets of 10.

After the gluteal-strengthening exercises become easy, the patient can strengthen the buttocks by doing lunges.

Lunges: Stand and take a large step forward with your right leg. Dip your left knee down toward the floor, and bend your right leg. Return to the starting position. Repeat the exercise, this time stepping forward with the left leg and dipping the leg on your right side down. Do 3 sets of 10 on each side.

Prevention

For reducing the chances of sustaining a gluteal strain, the player should undertake the following measures.

A warm-up prior to matches and training is thought to decrease gluteal muscle stretch injuries because the muscle is more extensible when the tissue temperature has been increased by 1° to 2°. A good warm-up should last about 20 minutes—starting gently and finishing as a full-pace activity. Recovery after training sessions and matches can be enhanced by performing a cooldown, which is thought to help muscles get rid of their waste products. This is the ideal time to do stretching exercises.

Maintaining good gluteal muscle strength and flexibility allows a player to carry out match activities in a controlled manner and decreases the uncoordinated movements that can lead to injury.

A diet that is high in carbohydrates taken 48 hours before the match can supply the body with adequate energy for muscle contraction. Otherwise, muscles become short of fuels, and fatigue sets in, predisposing a player to injury.

Golf, Injuries in

A sport enjoyed by people of all ages and fitness levels, golf is not known for traumatic injuries. However, many injuries can occur in the golfer, and these can be intrinsic or extrinsic. Intrinsic injuries occur based on the individual traits of the golfer. Variables such as the golf swing, skill level, age, gender, and athletic condition affect the injury patterns of golfers. Most of the intrinsic injuries in a golfer occur as a consequence of overuse of a part of the body. Extrinsic factors that can cause injury occur independently of the individual golfer. Variables such as clothing, environment, course terrain, and other golfers can be a source of injury.

Intrinsic Injuries

Most intrinsic golf injuries are the result of either of two mechanisms: (1) overuse during play or practice or (2) the golf swing mechanics. Certain injury patterns are more common in different subgroups. Discussions of these patterns of injuries are given below.

The Golf Swing

Before discussing the various patterns of injury of golfers, it is important to understand the golf swing. Understanding the mechanics of the golf swing is helpful in understanding the mechanisms of injury. The body coils from side to side using the golf club to swing through 360°, impacting the ball at about the 180° mark.

The golf swing can be divided into four phases:

1. *The back swing:* The dominant arm is maximally abducted and externally rotated; the nondominant arm crosses the body with a straight elbow. The core of the body is coiled away from the target. The weight is shifted onto the inner side of the dominant foot.
2. *The swing phase:* The body begins to uncoil. The head of the club is brought down to strike the ball. The nondominant arm is pulled toward the nondominant side, while the dominant arm guides the club to the position of impact. Weight is shifted from the dominant foot to the nondominant foot.
3. *The impact phase:* This is where the club hits the ball using the body's maximum uncoil velocity. Using iron clubs, the ground is struck slightly under the ball; when teeing off with the wood, the golf club hits the ball suspended by a tee.
4. *The follow-through:* This part of the golf swing occurs after impact, and the remainder of the circle is completed and held in position. The nondominant arm is abducted and externally rotated, and the dominant arm is adducted and flexed. The weight is on the nondominant foot. The pelvis is twisted toward the target.

Back Injuries

Most experts agree that among the most common injuries in golf are those to the back, especially lower back injuries, particularly among amateur male golfers. The back must coil in a twisting and side-bending motion. Inconsistencies of the swing mechanics can cause injury.

The vertebral motion of the back is important in the kinetic chain of the golf swing. The timing and tempo of a golf swing require the fluid motion of all the components of the back to move and to fire in sequence with the coordination. Disruptions in the fluidity of motion can cause injury. There are several areas within the back that can be injured. Often, there are several component areas involved in the same injury—namely, the muscles, joints, ligaments, and bones. The level of pain from an injury can vary.

Muscle Injuries

Misfiring of muscle sequences or overstretching a tight muscle can cause injury in the back. Weak stabilizing or postural muscles require other muscle groups to stabilize the back through the golf swing. This, in turn, predisposes the golfer to injury and decreases the swing power. Reduced swing power reduces the distance of the driven ball owing to inefficiencies of the muscle mechanics. Similarly, a deconditioned muscle fatigues more easily and is more prone to injury. When a muscle is injured, it often shortens; when this happens, the muscles may spasm. This can be very painful.

The voluntary and postural muscles of the back and oblique abdominal muscles require a sequential series of firing and relaxing. Recently, there has emerged a clearer understanding of the transverse abdominis muscle, which provides stabilizing forces to the spine through the golf swing. Strengthening of this muscle can increase the distance of a golfer's swing. The postural muscle most involved in the golf swing is the multifidus.

Spinal Joints

The joints of the spine can also be injured. Spinal motion in the lumbar and thoracic spine follows Fryett's laws: In brief, when a group of vertebrae is rotated to one direction, the same vertebrae side bend to the opposite direction. The golf swing requires the vertebrae to rotate quickly and therefore to side bend quickly. At times, if the rotation is not smooth, a single vertebra or group of vertebrae in motion can become restricted relative to the remainder of the spine. This is known as *somatic dysfunction* and can be treated with osteopathic manipulative treatments. Another joint problem seen in older golfers is osteoarthritis of the spine. The surfaces of the joints become less smooth with advancing arthritis, making the golfer more prone to injury and inflammation of the joints involved.

Ligamentous Back Injuries

These can occur when the bony structure is pushed beyond an anatomic barrier, and they may be seen in a golfer who has increased mobility at a vertebral segment or if the force on the impact phase results in sudden deceleration.

Bony Injuries

Bony injuries of the back occur far less frequently and are uncommon in the vertebrae. Compression fractures can occur in elderly golfers, although this is rare. Stress fractures of the ribs are more common but, overall, less common than the soft tissue injury described above.

Chest Wall Injuries

Chest wall injuries such as rib stress fractures are caused by muscles pulling on the ribs to stabilize the scapula during the golf swing. Muscle strains along the chest wall can also occur. Muscle strains of the chest wall are more common than stress fractures.

Rehabilitation

Rehabilitation of core muscle groups can increase the power of the golf swing as well as prevent injury. The stretching and strengthening of core muscle groups such as the multifidi, the transverse abdominous, and the oblique abdominal muscles play an important role in the prevention and treatment of low back pain in golfers.

Elbow Injuries

Elbow Tendon Injuries

These are another set of very common golf injuries. Female golfers tend to have more elbow injuries than their male counterparts. Medial epicondylitis ("golfer's elbow") and lateral epicondylitis ("tennis elbow") can result from overuse injury with repetitive swings of the golf club. Additionally, these tendon injuries can also occur from a sudden deceleration injury in the impact phase of the golf swing when the club divots in the ground or hits a surface that is immobile, such as a tree stump or a rock. The nondominant side is more prone to injury and more likely to have lateral epicondylar injuries.

Bone Injuries

These injuries, including avulsion fractures where the tendon is stronger than the bone and pulls a part of the bone off with forced contraction, are more common in young golfers. Young golfers, who are still growing, have a risk of injuring their open growth plates and suffering elbow pain; problems with elbow catching should be evaluated by a sports physician.

Rehabilitation and Prevention

Stretching the forearm and changing the grip strength and location can be helpful for prevention of injury. Using an elbow brace and resting the elbow as well as using ice and anti-inflammatory medications when appropriate are measures used to rehabilitate elbow tendon injuries.

Shoulder Injuries

Shoulder injuries are very common among golfers. Injuries to the shoulder are more frequent in professional golfers than in amateurs and are more common in the nondominant side. A high degree of motion is required from the backswing through the follow-through swing. Equal strength is needed in both shoulders for a successful swing. Injuries such as subacromial impingement can occur when the space between the humerus and clavicle is narrowed. When the nondominant arm crosses the body on the backswing, it can enclose this subacromial space and cause inflammation. Rotator cuff strain and acromioclavicular joint strain are overuse injuries seen in golfers. Instability of the shoulder joint can also happen in golfers and predispose the shoulders to other injuries. Pain in the back of the shoulder during the downswing could be a sign of tightness or injury in the rotator cuff. Dominant shoulder pain at the height of the back swing or as the golfer begins the downswing are signs of impingement. Pain in the front of the shoulder could mean an impinged rotator cuff or an acromioclavicular strain.

Rehabilitation and Prevention

The golf swing requires equal strength through both the upper extremities. A stretching and strengthening program that focuses on the latissimus dorsi and the rotator cuff can be helpful. Steroid injections and resting the shoulder can aid in the shoulder rehabilitation process.

Wrist and Hand Injuries

Wrist Tendon Injuries

These are common injuries in golf but chiefly in professional golfers. Through the golf swing, the wrist undergoes a complex series of movements. On impact, the wrist is held straight, and the muscles of the forearm and the tendons of the wrist are held in position, resisting the impact of the ball. As with other sports, overuse of the tendons through practice or playing can predispose them to injury. Ideally, the motions of the wrist in proper swing mechanics are hingelike, from the fifth finger toward the thumb. Amateurs can overgrip or undergrip the club, changing the dynamic of the golf swing and the force of the wrist on impact from the ball. In general, on the dominant hand, the tendons that are more prone to injury are the flexor carpi ulnaris and the extensor carpi ulnaris. These tendons are at the ulnar side of the wrist on the palmar and dorsal side, respectively. Flexor carpi radialis tendinitis can also occur on the dominant side in golfers who use more pronation in their wrist mechanics. This tendon is on the radial palmar side of the wrist and can be tender to the touch. The tendons most involved in injury of the nondominant wrist are the adductor pollicis brevis and the extensor pollicis tendons. When the sheath around these tendons becomes inflamed, it is known as *de Quervain tenosynovitis* or *paratenonitis*.

Bony Wrist Fractures

These are uncommon, but a hook of the hamate fracture can occur in all gripping sports. The golfer would describe a sudden and severe pain after the impact phase of the golf stroke. Pain is at the palmar and ulnar sides of the hand and gets worse when moving the wrist from side to side. These fractures have a high incidence of nonunion; therefore, if a hook of the hamate fracture is suspected, the golfer should seek medical attention without delay.

Hand Injuries

Trigger finger results from irritation of the tendon pulley, where the metacarpal bones connect to the phalanges. The golf club is grasped across the metacarpal bones, compressing the tendon, tendon sheath, and pulley area. The pulley area can get irritated and enlarged, causing the finger to get stuck in a flexed position.

Rehabilitation and Prevention

Wrist injuries in golf are related to grip tightness and the grip size of the golf clubs. Changing the grip width and tightness and minimizing the flexion and extension in the golf swing can help avoid wrist injuries. To prevent further hand and forearm injuries, the golfer should not grip the club as tightly. The golf glove worn on the nondominant hand can also help the golfer grip the club with less shearing force, preventing blisters and calluses. Wider grips could also be added for prevention. Having newer grips on the club can also prevent friction and hand, wrist, and forearm injures. A trigger finger can be injected with steroids to decrease inflammation.

Foot, Ankle, and Knee Injuries

Injuries to the foot, ankle, and knee are less frequent in golf. The dominant foot and the non-dominant foot have very different motions through the golf swing. Shoes that accommodate the side-to-side motion of the foot for the golf swing are not as comfortable for walking.

Plantar Fasciitis

This can occur in walking golfers. The plantar fascia is a thick tissue that spans the sole of the foot. If it gets irritated, it can inflame and cause pain. This condition is most painful on taking the first few steps after resting for a period of time.

Chronic Tendon Injuries

Crowding or shearing forces in the golf shoe over time can cause chronic tendon injuries to the toes and deformities such as hammer and claw toes.

Morton Neuroma

Irritation of the digital nerves, between the metatarsals, can cause Morton neuroma. This is more commonly seen between the third and fourth metatarsal heads. The golfer would experience a sensation of burning in the concerned toes. Chronic irritation of the nerve causes pain and leads to the formation of a fibrous tissue, called a *neuroma*, around the nerve.

Achilles Tendinitis

This condition is most common in middle-aged and older golfers. Irritation caused by a golf shoe on the heel of a golfer who has a tight Achilles tendon can cause it to become inflamed. The area most common is the point of attachment to the calcaneus. Chronic inflammation can cause rupture to this tendon if left untreated. Keeping the Achilles tendon stretched and seeking medical advice with persistent heel pain is important to prevent injury.

Ankle sprain can occur in golf in a twisting injury or fall and is more commonly related to the golf shoes or wet ground.

Knee injuries are less common in golfers and can be related to uneven surfaces.

Rehabilitation and Prevention

The golf shoe should be cleated to prevent falls, cushioned in the heel, and wide enough to allow for weight transfer. Socks should be cotton and should wick the sweat away from the skin. This prevents blisters and fungal infections such as athlete's foot.

Mind-Body Disconnection

Golf is a sport that requires a close mind-body connection. The golfer is mindful of all the areas of the body through the golf swing and the putt. In golf, there is a condition called "Yipes." It can occur during a putt and during shorter-distance swings. The golfer has involuntary movements of the arms when he tries to hit the ball. This is thought to be a mind-body disconnect and has debilitated professional golfers. In this condition, increasing the club length can sometimes help.

Extrinsic Injuries

Extrinsic injuries are injuries that are not inherent to the golfer or the individual's golf swing.

Head Injuries

These are more common in young and inexperienced golfers. The golfer can be hit with the club during a backswing or a practice swing. Head injuries also occur with flying stray balls. A golfer is supposed to yell the word *fore* when a ball is going to land near another golfer.

Sunburn

On an 18-hole course, a golfer could be in direct sunlight for 4 to 5 hours. It is recommended to limit sun exposure with sunblock, hats, and protective clothing. Excessive sun exposure can predispose the golfer to skin cancer.

Dehydration and Heat Injuries

The feeling of thirst occurs when a body's fluid reserve is less than 20%. The thirst drive can decrease in the senior golfer, making this population more prone to heat illnesses; however, these illnesses do affect all age-groups. Being on a golf course for 4 to 5 hours in the warmth, humidity, and sunlight, a golfer can get dehydrated. This can lead to more serious medical conditions—heat exhaustion and heat stroke. Heat exhaustion occurs when the body starts to deregulate its own body temperature. Fainting, exhaustion, dizziness, and a mild temperature increase are signs of heat exhaustion. In heat strokes, the body deregulates its internal heat control. The body can heat to up to 106 °F. The hallmark of a heat stroke is that the athlete stops sweating. This can lead to organ failure. These are serious medical conditions and require medical attention. It is important to cooldown the body by applying bags of ice and removing the golfer from direct sunlight.

Lightning Strike

Lightning is an important environmental hazard that deserves consideration in the game of golf. In 1975, professional golfer Lee Trevino was struck by lightning during a tournament, suffering a spinal injury that required surgery. Though these are not common golf injuries, they can be fatal or can cause severe organ damage. Golfers should seek shelter in the clubhouse during inclement weather.

Golf Cart Injuries

These are relatively uncommon, but the incidence is rising, especially among youthful golfers. Falling from the golf cart and being struck by a cart are common mechanisms of injuries.

Groin Pain

Groin pain in the athlete is one of the most complex diagnostic challenges for sports medicine physicians. Due to the overlapping anatomy of this area, many different injury patterns can produce groin pain. Understanding the anatomy of the groin is the key to determining the pain source. Specific physical exam findings should alert the clinician to the possible diagnoses. Imaging techniques including X-rays, magnetic resonance imaging (MRI), and bone scans can be helpful in identifying or ruling out certain conditions. Physical therapy is a key component of most treatment regimens.

Anatomy

The complex anatomy of the groin area must be understood to properly diagnose the conditions that are causing pain in the athlete's groin. The hip joint is located directly in the groin area. The hip is a ball-and-socket joint made up of the head of the femur bone (ball) and the acetabulum (socket). The femoral head connects to the femoral neck, which then attaches to the shaft of the femur. The hip joint is lined with cartilages, which provides a smooth, low-friction surface to allow for free movement. Surrounding the acetabulum is a rubbery ring of cartilage that attaches to its outer rim, called the *acetabular labrum*. The labrum functions like an O-ring to help hold the femoral head in the socket of the acetabulum. The outer hip has tough strong ligaments that surround and reinforce the joint and prevent the femoral head from dislocating out of the acetabulum.

Problems intrinsic to the hip joint can cause groin pain in athletes. Some common causes include stress fractures of the femoral neck, impingement of the femoral head on the acetabulum, tears of the acetabular labrum, and cartilage injuries to the femoral head or acetabulum.

Surrounding the hip joint are many different muscles and tendons that control movement of the abdomen, hip, and leg. A tendon is a taut, thin, ropelike portion of a muscle that attaches to a bone. The psoas muscle is responsible for hip flexion (bending the hip upward toward the chest). The psoas muscle tendon lies directly in front of the hip joint and attaches to the shaft of the femur. The adductor muscles are responsible for hip adduction (moving the hip toward the opposite hip). These muscles run just below the groin on the upper, inner portion of the thigh. The adductor muscles become tendons that attach to the lower portion of the pubic bone, above the genitalia. The rectus abdominus is the major abdominal muscle. It also attaches to the upper portion of the pubic bone. A bursa is a fluid-filled sac that lies between the tendons and the bone to allow the tendons to slide without much friction. There is a large bursa where the psoas muscle tendon lies over the acetabulum and another bursa near the adductor tendons and the pubic bone.

Problems with the muscles, tendons, and bursas can cause groin pain in the athlete. Muscle injuries include sprains, strains, and tears. Tendons and bursas can become irritated and inflamed, leading to tendinitis or bursitis. Avulsion injuries occur when a strong muscle contraction causes a tendon to pull off a small piece of bone where it attaches. Imbalances of muscle forces may be responsible for osteitis pubis and sports hernia.

History

A detailed history should be obtained from the athlete with groin pain. How long has the pain been going on? Was there an actual injury? Is the pain constant or episodic? Which specific activities exacerbate the pain? Does the groin hurt with weight bearing? Is the pain nearer to the groin or to the pubic area? Groin pain following a traumatic injury suggests a hip labral tear, a cartilage injury, an avulsion fracture, or a muscle strain. A slow-onset pain near the pubis may be caused by osteitis pubis or sports hernia. Groin pain with weight bearing that develops over time might represent a femoral neck stress fracture. Certain sports produce characteristic injury patterns. Dancers who constantly strain the motion limitations of their hip joints have a higher incidence of psoas tendinitis, snapping hip, labral tears, and hip impingement. Osteitis pubis, adductor strains, and sports hernia are common in kicking sports such as soccer and rugby. Female long-distance runners have a high incidence of stress fractures of the femoral neck.

Physical Examination

The physical exam attempts to differentiate between muscle/tendon/bursa pain, pubic pain, and hip joint pain. Initially, the muscles, tendons, and bursas near the groin are individually examined for tightness or point tenderness. Comparison with the other hip may be necessary to determine if a particular muscle is tight. The pubic bone and groin are separately palpated, looking for tender areas. The hip joint is then provocatively stressed to see what movements cause pain. The hip impingement test is done by having the athlete lie on his or her back while the examiner flexes and internally rotates the hip (bends the hip and knee up toward the chest while rotating the foot away from the body). This maneuver causes the hip joint to compress, and if pain is produced, it is likely that the hip joint is the source of pain.

Imaging

X-rays of the hip and pelvis can show changes consistent with hip impingement and bony avulsion fractures. Stress fractures of the femoral neck may or may not be visible on X-rays. When a stress fracture is suspected, an MRI is necessary for diagnosis. Tears of the acetabular labrum are best seen on an MRI after the dye has been injected into the hip joint. This test is called an *MR arthrogram*. A *bone scan* is a special type of X-ray that is done after dye injection. It is less commonly used, but it may also show increased activity in the pubic bone (which suggests osteitis pubis or pelvic stress fracture) or the femoral neck (which suggests stress fracture).

Differential Diagnosis

The following is a partial list of some of the more important and common causes of groin pain in athletes.

Groin Pull

A groin pull occurs when there has been a strain or microtear of the adductor muscle tendon, which attaches to the pubic bone. These injuries are common in kicking sports such as soccer and rugby. Pain is located over the adductor tendon, which is located on the upper inner thigh or the psoas tendon, which runs in front of the hip joint. On physical exam, the adductor tendon is tender to the touch, and moving the hip away from the body causes pain (by stretching the tendon). No imaging is necessary to make the diagnosis. Treatment includes rest, anti-inflammatory medications such as ibuprofen for pain, and physical therapy directed at stretching and strengthening the adductor muscle.

Pelvic Avulsion

An avulsion occurs when a strong muscle contraction causes the tendon to partially tear off a piece of bone of the pelvis or femur where it attaches. These injuries commonly occur in younger athletes who are still growing. The psoas, adductor, hamstring, and quadriceps tendons can all pull away from the bone where they attach. These injuries cause a sharp pain and an audible pop. An X-ray may show that a piece of bone has pulled off of the pelvis or femur. An avulsion might not be seen on X-ray if the portion of the bone that pulled off was mostly made up of cartilage. Most of these injuries heal on their own without surgery as the area surrounding the tendon scars back into the bone. Crutches are recommended for a period of time as the avulsion fracture heals. Avulsions that involve large bony fragments that have been pulled far away from the bone may need to be surgically reattached.

"Snapping Hip"

An internal *snapping hip* occurs when a tight psoas muscle tendon snaps over the hip joint or over the inner part of the pelvis. This snap is usually audible and reproducible by the athlete, but it does not always cause pain. Snapping hip is commonly seen in dancers, gymnasts, and long-distance runners. If the snapping does not cause pain, no treatment is necessary. If the snapping becomes painful, it is likely that the psoas tendon or the bursa underneath has become inflamed. In these cases, the athlete is treated with rest, anti-inflammatory medications, physical therapy to stretch the psoas tendon, and, occasionally, corticosteroid injections into the psoas bursa. Surgery is rarely necessary.

Osteitis Pubis

Osteitis pubis is inflammation, irritation, or strain at the pubic bone, where the hip adductor tendon and rectus abdominal muscle attach. It is a repetitive trauma overuse injury commonly seen in soccer, hockey, and rugby players. Pain occurs at the pubic bone and is associated with kicking or jumping. It is thought to be related to an imbalance between the adductor and the rectus abdominus muscles. On physical exam, the patient reports tenderness over the pubic bone. Hip abduction (moving one leg away from the other) may exacerbate the pain. X-rays can show some bony changes at the pubic joint, but an MRI will more reliably show a swelling of the pubic bone. A bone scan that shows high uptake at the pubic bone is also used to make the diagnosis. Treatment includes rest; avoiding kicking, running, or jumping; anti-inflammatory medications; and physical therapy to correct the muscle imbalance.

Hip Stress Fracture

A stress fracture of the hip most commonly occurs in the neck of the femur bone. It is a repetitive, overuse injury that is often seen in female long-distance runners. Femoral neck stress fractures present with groin pain during weight-bearing or running activities. Diagnosis is usually made by MRI as X-rays may be negative. Athletes are usually treated with crutches and non–weight bearing for a period of time. No running is allowed until the stress fracture heals. Rarely, the stress fracture does not heal with time, and surgery is necessary to fix the fracture with screws and/or a metal plate.

Hip Impingement and Labral Tear

The hip, as noted, is a ball-and-socket joint. When the acetabulum (socket) or the femoral neck is large, they can bump into each other with extreme hip movements. Hip impingement can occur in athletes who move their hip to the end range of its motion. For example, as a ballet dancer kicks the leg above the head, the femoral neck can bump into the front of the acetabular socket. This impingement occurs at the location of the acetabular labrum. Over time, after repetitive episodes of hip impingement, a bony spur can form on the acetabulum or femoral neck. In addition, the increased stress on the labrum can cause the labrum to tear.

Athletes with hip impingement or labral tears present with groin pain made worse with flexing the hip and turning it inward. Physical exam shows a positive hip impingement test. While bony spurs may be seen on X-ray, an MR arthrogram is necessary to diagnose a hip labral tear. Initial treatment usually consists of physical therapy to stretch and strengthen the hip while avoiding activities that cause hip impingement. Surgery may be necessary if the groin pain continues after a few months of conservative management. Surgical treatment options include hip arthroscopy and open hip surgery, which attempt to repair the labral tears and remove the bony spurs.

Sports Hernia

Sports hernia is a relatively new and poorly understood cause of groin pain. It is seen commonly in hockey and soccer players. Similar to osteitis pubis, it is thought to be related to an imbalance between the abdominal and the adductor muscles. This imbalance places a shearing force on the pelvis and causes pain. On physical exam, there is often no hernia seen. The athlete usually has groin pain while doing a sit-up. In addition, pain is noted with resisted hip adduction and with coughing. X-rays, MRI, and bone scan are often completely normal. Physical therapy aimed at correcting the muscle imbalance may help, but pain often recurs. Many athletes require surgery, although recommended surgical treatments vary.

Groin Strain

In athletics, one often hears the terms *groin pull* and *groin strain. Groin* is the word usually used for the crease or hollow at the junction of the inner part of each thigh with the trunk and the adjacent region. *Groin pull* usually refers to minor tears of some muscle fibers without a major effect on the main muscle. *Strain* means stretching the muscle too far: A severe strain can often lead to the tearing of the muscle fibers (sometimes even the entire muscle separates from its bony attachment). A groin strain is a serious setback to a professional athlete and can potentially threaten his or her career if not handled properly.

Anatomy

Essentially, groin pull or strain denotes a strain or perhaps the tearing of the upper or proximal attachments or the fibers of the anteromedial thigh muscles or inner thigh (usually involving the adductor group—six muscles that stretch from the anteroinferior part of the pelvis bone to the linea aspera of the femur or, put simply, the muscles that run from the groin area down the inner thigh to the inner side of the knee; see Figure 1). The adductor muscles comprise the adductor magnus, adductor longus, adductor brevis, obturator externus, and gracilus. The most common muscle to be involved is the adductor longus. As is obvious from the name of the group, the main action of these muscles is to adduct the thigh, or to bring the legs together.

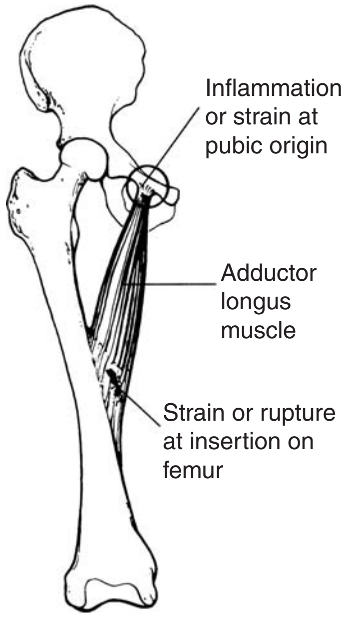

Figure 1 Groin Strain

Note: Groin strain commonly affects the adductor longus muscle, usually where the muscle tendon attaches to the thigh and sometimes where it attaches to the pubic bone.

Cause

Groin strain is usually the effect of one of the following on muscles that are weak or tight, or basically unconditioned:

- Resisted forceful abduction of the hip (outward movement of the thigh) or stretching of the adductors excessively (e.g., kicking a football)
- Putting sudden stress on the adductors, for example, a sudden change in direction
- Excessive overuse of the adductors at a given time
- A direct blow (kick or getting hit with a ball) in the groin

This condition is mostly seen in sports requiring sudden starts or bursts of speed, as in sprinters (due to the fast start), hurdlers, fast bowlers in cricket, footballers, and ice hockey players.

Predisposing/Risk Factors

Weak and tight adductor muscles, usually due to lack of proper conditioning in the prematch period, predispose to the development of the condition. Other factors include fatigue, overexertion, cold weather, and lack of proper warm-up.

Symptoms

Pain is the dominant symptom in this condition. It can take the following forms:

- A sudden sharp pain, which is felt during the exercise
- Tight or sore groin muscles (this symptom could be delayed till the next day)
- Pain on walking or movement of the thigh
- Pain and inability to bring the legs together (adduction)
- Pain on stretching the adductors
- Pain on resisted adduction (bringing the thigh to the midline from the side)
- Pain on resisted hip flexion (bringing the thigh upward toward the trunk)
- Bruising in the groin area (the area joining the abdomen to the thigh; this symptom could be delayed for a day or two)
- Swelling in the affected area (this too can be delayed by a couple of days)

- Sometimes a gap or swelling in the adductor muscles, indicating a tear

Grading of Severity

The condition is graded according to the severity of the pain and associated symptoms:

Grade I: There is discomfort, usually with the absence of any disability. There is no swelling. Recovery usually takes 2 weeks in this case.

Grade II: There is discomfort associated with inability to perform strenuous activities such as running. Some swelling or bruising may be evident. About 1 to 2 months may be required for recovery.

Grade III: Severe pain on walking. In severe cases, there may be pain at rest also. Significant swelling and bruising are often present. The patient may also experience muscle spasms. Recovery may take 3 months or more.

Diagnosis

Clinical Examination

- The presenting or main complaint is pain in the adductor area.
- Palpation or touching reveals tenderness or pain of the adductor muscles.
- *Provocative test:* Resisted adduction or inward movement of the thigh causes pain; sometimes a hip flexion or a bending thigh is also painful.

Imaging Studies

An imaging/radiograph of the hip joint should be taken to rule out avulsion or snapping of the muscle at the adductor tubercle. Magnetic resonance imaging (MRI) may be needed for exact diagnosis and grading of severity.

Treatment

First Aid

Athletes should be trained to recognize the symptoms and apply the RICE protocol: *r*est, *i*ce, *c*ompression, and *e*levation.

Injured athletes should be careful not to strain the muscle further, even if they have to use crutches or a stretcher. They can wear an elastic compression bandage on the upper thigh for compression, but they should be careful not to wrap the bandage too tight. The leg should be kept elevated above the level of the heart for the first 24 hours to prevent swelling.

A sports injury specialist should be consulted as soon as possible.

Professional Treatment

Treatment varies with the severity of injury. One or all of the following may be considered.

Initial Treatment

Rest. This is the cardinal principle in any groin injury. Adequate rest is often followed by complete healing of the muscle. The patient should be advised to avoid all activities that are likely to cause pain and even to shorten the stride or use support while walking.

Local cold pack/ice. Using ice or cold packs on the injury during the first 2 days is often very helpful in easing the pain and swelling. Ice should be applied for 15 to 20 minutes four times a day and should be wrapped in a towel to avoid direct application. Ice application can be extended for several days if necessary, and the process can be repeated after activity involving the affected area.

Medication. Oral nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen, should be taken as prescribed by the doctor.

Subsequent Treatment

Stretching. Stretches are employed in both prevention and treatment. Gentle stretching is advisable, although care must be taken not to overdo it as excessive stretching may be counterproductive. A gentle pulling sensation is the aim, but the stretch should not be painful. Stretching should be done in the recovery period and can be done several times a day. Stretches include the following:

- *Squatting adductor stretch:* The patient squats with the arms between the legs; the knees should be moved outward by pushing apart with the elbows.
- *Butterfly stretch:* The patient sits with the knees bent and feet together, grasping the feet with the hands and stretching the knees toward the ground.

- *Adductor stretch:* The patient stands with leg out to the side, bending the knee of the leg under the body to stretch the muscles of the inner thigh of the opposite leg.
- *Cross-legged stretch:* The patient sits in a chair with one leg crossed over the other, pressing the knee of the crossed leg toward the ground.

Local application of heat. While a cold compress is helpful after activity, a hot compress is of benefit before any activity is undertaken (e.g., stretching), to soften the area and reduce any chance of further aggravation of the injury. However, use of heat should be started in the recovery period, not in the period immediately following the injury.

Physiotherapy. Ultrasound treatment, infrared treatment, specific exercises, and massage by trained physiotherapists under the supervision and guidance of sports injury specialists or rehabilitation specialists are often of value in speeding up the recovery period and preventing complications.

Strengthening exercises. These are added gradually when a fair amount of recovery has taken place, but they must be done under supervision. These include adductor and abductor strengthening as well as pelvic stabilization exercises, including lunges, squats, extensions, and so on, and also core strengthening exercises that target muscles that are hard to get to, including abdominal and lumbar stretching. These are usually done with a large exercise ball.

Surgery. Conservative treatment usually works even in the most severe cases, but in rare cases, one may have to resort to surgery to reattach the torn ends of the muscle.

Prevention

The most important factor in the prevention of this injury is the proper conditioning of athletes, especially those who participate in sports where groin injury is more likely. To ensure hip strength, athletes should warm up properly before any exercise. It is also important to incorporate stretches and strengthening exercises into the preseason training routine.

Groin Tendinitis

Injuries to the soft tissue around the hip and pelvis are among the most common athletic injuries, and the majority of these cases involve musculotendinous strains and inflammation. Hip, pelvic, and groin injuries can present with similar symptoms, so it is often challenging to differentiate between problems that occur within the hip joint, such as labral tears and femoroacetabular impingement, and those that occur outside the hip joint, such as iliopsoas tendinitis, iliotibial band syndrome, femoral neck stress fractures, and adductor strains. *Groin tendinitis* refers primarily to an inflammation of the iliopsoas tendon as it crosses in front of the hip joint and inserts on the femur.

Common causes of iliopsoas or groin tendinitis include acute trauma and overuse from repetitive hip flexion. Groin tendinitis occurs most frequently in dancers, gymnasts, runners, rowers, and soccer players.

Anatomy

The iliopsoas is actually made up of two muscles, the iliacus and the psoas major, which are separate near their points of origin in the abdomen but converge and form a single tendon, known as the *iliopsoas tendon*, as they pass out of the abdomen under the inguinal ligament and across the anterior aspect of the hip joint. The iliacus muscle originates on the iliac fossa on the inside of the pelvis as well as on the anterior inferior iliac spine (AIIS). Conversely, the psoas major originates on the lumbar vertebrae, and together, the combined iliopsoas tendon inserts onto the lesser trochanter of the femur. About 40% to 50% of the population also has a psoas minor muscle, which also originates on the lumbar vertebrae but inserts on the iliopectineal arch and, thus, does not form part of the iliopsoas tendon. All three muscles are innervated by nerves that come off the lumbar plexus. The main purpose of the iliopsoas is to act as a hip flexor, but it can also aid in trunk flexion and lateral rotation of the hip. It is prone to shortening and tightening if it is not regularly stretched, which can in turn lead to increased lumbar lordosis and anterior pelvic tilt.

There is also a small sac of fluid, called a *bursa*, that lies under the iliopsoas tendon and acts as a cushion to reduce friction as the tendon moves over the bones. When the tendon is inflamed, the bursa often becomes inflamed too, but the symptoms and treatment are the same.

History

The two main mechanisms of injury in groin tendinitis are acute injury and overuse injury. Acute injuries often occur when the iliopsoas undergoes rapid flexion against resistance (eccentric contraction) or, less commonly, from direct trauma to the muscle or tendon. Conversely, overuse injuries typically occur with activities that require repeated hip flexion or outward rotation of the thigh, such as ballet, rowing, soccer, gymnastics, and running (especially uphill), and even training with weights. Overuse of the iliopsoas can lead to inflammation of the tendon, and the risk of painful inflammation is increased if the iliopsoas is tight. It is not uncommon for adolescents, especially during a time of rapid growth, to develop tight hip flexors as their bones grow faster than their muscles and tendons do. However, adults are still at risk for tightness in their iliopsoas too, especially those with an anterior pelvic tilt or increased lumbar lordosis (an increased curve in their lower back) and athletes who do not regularly stretch the iliopsoas.

Dancers are especially at high risk of developing a related problem known as "snapping hip" syndrome, which can be due to poor technique. In snapping hip syndrome, an audible pop or snap can be heard as the iliopsoas tendon literally snaps over the iliopectinial eminence or femoral neck. Most cases of snapping hip are not painful, but they may become painful if the muscle is not stretched or with continued use without correction of the poor technique that may be causing the snapping. Snapping hip secondary to the iliopsoas is also referred to as "anterior" or "internal" snapping hip, which should be differentiated from "lateral" or "external" snapping hip, which is due to the iliotibial band snapping across the greater trochanter on the outside of the hip.

The pain associated with groin tendinitis is usually in the front of the hip and typically is only present when flexing or outwardly rotating the hip, but over time, it may progress to the point where it occurs during daily activities and then even at rest. Patients may complain of pain with sports-related activities, such as running and kicking, as well as non-sports-related activities, such as putting on socks and shoes, rising from a chair, and walking up stairs or on inclines. Sometimes the pain may even radiate down the front of the thigh toward the knee.

Physical Examination

Since there is such a broad array of potential causes of groin pain, physical examination of the athlete who presents with this symptom should always include a thorough examination of the abdomen, hip, and groin.

Inspection may often be normal, but it may occasionally yield an increased anterior pelvic tilt, a slightly flexed and externally rotated hip. During normal walking, stride length may be shortened on the affected side as well, and in severe cases, a limp may be noted.

There may be tenderness to palpation in the groin area over the iliopsoas itself and at its insertion at the lesser trochanter of the femur.

There are several maneuvers to elicit pain in the hip that would suggest that the pain is due to iliopsoas tendinitis. One way is to stretch the iliopsoas, and the other is to make it contract and flex against some resistance.

The best way to perform a stretch test of the iliopsoas is to have the patient lie on his or her back and drop the leg on the affected side over the side of the table, effectively extending the hip backward. This sometimes causes pain in the groin, but the iliopsoas can be targeted and stretched even more if the foot is slowly brought away from the table, which rotates the hip inward.

There are two ways to stress the iliopsoas by actively making it contract against resistance. One way is to have the patient lie on his or her back with the unaffected leg straightened out and the affected leg crossed over it so that the outside of the foot on the affected side lies on top of the knee on the unaffected side. This is sometimes referred to as a "frog position" or a "figure-four position." Then, the examiner should place his or her hand on the knee of the affected leg and ask the patient to bring the knee up and toward the midline while keeping the foot resting on the knee of the unaffected side. If this causes pain, it is suggestive of iliopsoas tendinitis. The other way to test for iliopsoas is to have the patient either seated with the legs straight or lying down, again with the knees straight, and to ask the patient to raise his or her leg on the affected side. If the patient experiences pain with the leg about 15° off the table, it is suggestive of iliopsoas tendinditis. This test is commonly referred to as the Ludloff sign.

Last, a patient with groin tendinitis may also experience groin pain when his or her hip is moved by the examiner to a point of maximum flexion such that the knee is over the abdomen or chest. This maneuver is referred to as passive hyperflexion of the hip, and the patient should be relaxed and not assisting the examiner with this movement.

Diagnostic Imaging

Although tendons cannot be seen on plain radiographs (X-rays), X-rays are usually the first imaging study obtained to rule out other, more serious causes of groin pain. they can show problems with the bones of the pelvis, hip, and upper leg, and they would be normal in cases of isolated iliopsoas tendinitis.

Magnetic resonance imaging (MRI) is generally considered to be the best test for evaluating hip pain because it can examine both bone and soft tissue structures that may be the source of pain. An MRI scan can show swelling and thickening of the tendon, inflammation, and tendon tears.

Ultrasound can also be used to evaluate the iliopsoas tendon, which may appear thickened and surrounded by fluid in cases of tendinitis. However, this technique is highly user dependent and requires a very knowledgeable and experienced technician to make an accurate diagnosis.

Treatment

Once iliopsoas tendinitis has been diagnosed, the preferred initial treatment includes "relative rest," anti-inflammatory medications, and physical therapy.

Relative rest implies avoidance of the sports and activities that cause pain and usually needs to be adhered to for 2 or 3 weeks. During this time, nonsteroidal anti-inflammatory drugs, or NSAIDs, should also be taken on a scheduled basis, either two or three times a day with meals for 5 to 14 days, provided the patient can tolerate this group of medications. When taken on this type of schedule, NSAIDs can act to both decrease pain as well as to decrease inflammation. Physical therapy should address the stretching of the hip flexors and external rotators and also the strengthening of these muscles and the adductors and internal rotators of the hip. Core and peripelvic strengthening to reduce excessive lumbar lordosis or increased curvature in the lower back should also be addressed, because the psoas muscle originates on the lumbar spine before traveling through the pelvis and across the hip joint. A physical therapist may also massage and apply heat to the iliopsoas, which may decrease pain and assist in recovery. As pain and inflammation subside, the patient can gradually begin increasing his or her physical activity, with progression to sport-specific activities and eventually to full, painfree participation. To prevent recurrence, care must be taken to correct poor technique or the biomechanical issues that may have initially led to the groin tendinitis. Furthermore, continued compliance with a maintenance strengthening and stretching program is also of paramount importance to prevent reinjury.

Most cases of groin tendinitis resolve with the aforementioned interventions; however, some chronic cases of tendinitis that fail to respond to these more conservative measures may require either a steroid injection or, rarely, surgery. Corticosteroid injections into the iliopsoas tendon sheath under fluoroscopic guidance may provide significant relief in these recalcitrant cases. These injections may be given up to three times and in the setting of relative rest and stretching. These injections usually bring about resolution of symptoms, but in the rare cases that they do not, surgery—with either complete or partial release of the iliopsoas tendon—is indicated. Both approaches have produced good results with regard to pain relief with minimal weakness postoperatively, such that the majority of patients are able to return to their previous athletic activities.

Groin/Inguinal Hernia

A *hernia* occurs when a structure or organ contained in one body cavity passes through the wall of tissue that normally separates it from another cavity. Hernias are described and classified according to where the structures pass through the weakened body wall. The most common areas of the body to have a hernia are the groin—the site of inguinal hernia—and the abdominal regions. The condition known as "sports hernia" manifests as pain in the groin area, but it is actually not a true hernia, as described below.

There are a few common types of hernias. An inguinal hernia occurs in the groin region; the inguinal canal is a small opening in between the layers of the abdominal muscles. These hernias can be further classified into indirect and direct hernias. An *indirect inguinal hernia* develops at the internal ring, where the spermatic cord in males or the round ligament in females leaves the abdomen. Indirect hernias originate lateral to the inferior epigastric artery. Most inguinal hernias are thought to be congenital; that is, they were formed during abnormalities in fetal development. The hernia may have been there since birth and then may have risen with instances of increased abdominal pressure.

A *direct inguinal hernia* originates at the Hesselbach triangle, formed by the inferior epigastric vessels laterally, the rectus abdominus muscle superiorly, and the inguinal ligament inferiorly. Many of these hernias are also congenital, but some are thought to arise from weakness in the floor of the inguinal canal. Weakness in the floor of the canal may be caused by heavy lifting; however, studies indicate that the relationship between heavy lifting and hernias is not clear.

Inguinal Hernia

Symptoms

Groin hernias may present with a range of manifestations, from no symptoms at all to very severe pain. The most common symptom is mild pain or a heavy, pressure-like sensation when lifting or straining, causing an increase in abdominal pressure. These sensations are caused by the contents of the hernia trying to move through the opening or weakened body wall. The pain is usually resolved by lying down or by stopping the straining activity. People who stay on their feet for prolonged periods of time or do repetitive lifting may notice that their symptoms are worse at the end of the day. Some hernias present as a bulge in the groin, thigh, or abdominal areas. The most common complaints by the athlete and the patient are pain and mass in the groin area.

Diagnosis

Physical Exam Findings

The easiest way to demonstrate a hernia is to examine the patient while he or she is standing. Using one or two fingers, the external ring is palpated while the patient is asked to cough or strain. In women, the femoral canal should be examined as well. This area is found at the midpoint of the inguinal canal by locating the femoral artery. If a hernia is demonstrated, the examiner will feel a small pressure or bulge against the fingertips, sometimes described as a silky sensation against the fingers.

Imaging

Hernias may be demonstrated by a variety of imaging techniques. A herniography involves injecting a contrast medium or dye into the lower abdominal region to visualize the hernia. However, this technique is invasive and involves exposing the patient to a needle puncture and radioactive material. Ultrasound and magnetic resonance imaging (MRI) have been shown to be fairly sensitive and specific in detecting groin hernias as well.

Treatment

The definitive treatment of groin hernias is surgical repair. The reason for this is primarily to prevent the main serious complications of hernias, strangulation and incarceration. An *incarcerated hernia* is when the contents of the hernia are trapped and cannot be pushed back into the inguinal canal or reduced. A *strangulated hernia* is a condition in which the blood supply to the contents of the hernia is reduced. This condition is an emergency; without blood flow, the hernia contents lack oxygen and may become necrotic; in other words, the tissue may die. Surgery within hours of this condition usually has a favorable outcome. There are many surgical techniques available to repair a hernia. They include open repair through an incision and laparoscopic repair.

Recovery/Return to Sports

Opting to have surgery for a groin hernia allows the patient to return to previous activity fairly rapidly. In general, people in sedentary professions may return in 10 days. Heavy lifting (more than 25 pounds [34 kilograms]) is not recommended for approximately 6 weeks.

Sports Hernia

A *sports hernia*, so called, is defined as any condition causing groin area pain. This common term can be misleading, as there is no actual hernia on physical exam. Some define the sports hernia classically as weakening of the posterior inguinal wall. This condition is also known as *Gilmore groin*, *sportsman's hernia*, *hockey groin*, and *athletic pubalgia*.

Causes

Sports hernias appear to be more common in men. They occur more often in sports where the athlete leans forward in an "athletic stance"—that is, in football, soccer, hockey, and rugby. Any sport where there is high-speed twisting, turning, or torquing of the groin likely contributes to this condition. One proposed mechanism is that hip abduction, adduction, and flexion-extension with associated pelvic motion place a shearing force across the pubic symphysis. This leads to stress on inguinal wall musculature perpendicular to the fibers of the fascia and muscle.

Numerous pathologic abnormalities have been reported, including tears of the external oblique aponeurosis with injury to the inguinal nerve and its branches. Other reported injuries include abnormalities at the insertion of the rectus abdominus muscle, avulsions of the internal oblique muscle fibers at the pubic tubercle, and tears of the conjoined tendon or transversalis fascia. There has also been an association with osteitis pubis, a degenerative condition of pubis symphysis and surrounding muscle insertions.

Symptoms

The diagnosis of a sports hernia is primarily clinical in the patient or athlete who has symptoms of groin area pain but no evidence of hernia on exam. The symptoms are worse with sudden increases in intra-abdominal pressure, such as during sneezing, coughing, or bowel movements. The symptoms may also be reproduced by performing sit-ups or crunches.

Diagnosis

This is primarily a clinical diagnosis, but many imaging techniques may be useful to rule out other conditions that can mimic a sports hernia. Plain radiographs (X-rays) may detect osteoarthritis or stress fractures. A technetium-99m bone scan may show an increased uptake in the pubis region and can rule out osteitis pubis. An ultrasound scan may demonstrate occult hernias. MRI may show abnormalities in the musculature, bursitis, stress reactions, and many other conditions. Herniography is not usually used for detecting sports hernias.

Treatment

Treatment of the sports hernia is somewhat controversial as there is no true hernia. Surgical intervention is considered the standard of care, despite its not being well studied; clearly, this is an area for further investigation.

It is reasonable to have a period of rest for the athlete for 6 to 12 weeks. Treatment with rest should be accompanied by the use of nonsteroidal anti-inflammatory drugs (NSAIDs), ice, and physical therapy. Often, the athlete will want to return to play in a more timely fashion and will opt to have surgery. Surgery can be performed as an open approach through an incision or by a laparoscopic approach. There are many surgical techniques used for repair; however, most involve reinforcing the abdominal musculature surrounding the inguinal area or placing mesh supports. Since there are many different pathologies that can explain the groin pain, treatment is specialized around each diagnosis.

Recovery/Return to Sports

Return to play after sports hernia repair has not been well-defined. There are varying reports of postsurgery rehabilitation programs, both for open and for laparoscopic repairs. In general, laparoscopic repair offers earlier return to activities of daily living, as well as return to pre-injury activity levels. In general, sharp, sudden movements are avoided early in the rehab process. Deficiencies in core and leg strength, flexibility, and endurance are addressed early on. Walking is encouraged early in the rehabilitation process, with straight-line jogging and running by 3 to 4 weeks postoperatively. Sprinting and cutting are initiated by around 3 weeks postoperatively. Overall, return to competitive activity is allowed between 6 and 8 weeks after surgery. There have been other reports of earlier return to play after laparoscopic repair.

Group Fitness Instructor

A *group fitness instructor* (GFI) is anyone who leads three or more people at a designated time in a class with the objective of improving one or more health components. The specialized fitness classes led by an instructor focus on one or more of the following components of fitness: strength, endurance, power, flexibility, stability, and balance.

These components are covered in a class lasting from 15 minutes to 2 hours. On average, most GFIs lead classes that are 1 hour in length. Instructors in an average group fitness class may use the following format:

1. *Warm-up/movement preparation:* This is always covered at the beginning of class; otherwise the risk of musculoskeletal injury is high during the later portions of the class. This portion of the class takes 3 to 10 minutes, depending on the fitness components the instructor must focus on during the remainder of the class.
2. *Body of the class:* On the completion of the warm-up, the instructor will lead participants through exercises that focus on the overall fitness goals of the class. The instructor leads the class through auditory, visual, and proprioceptive cueing. Auditory instruction includes the explanation of the movement and the exercise's duration. Duration can refer to the number of repetitions of the said movement or the length of the movement pattern or exercise (time under tension of the working muscle groups). Visually, the instructor can show the participants how to execute the movement pattern or exercise by positioning himself or herself in front of all participants. This way, participants can replicate the movement pattern the instructor is demonstrating. Auditory and visual instructions are usually done in combination throughout the group fitness class. Instructors usually give proprioceptive instruction: They give participants the challenge of not allowing certain parts of the body to move during the movement pattern. An example of proprioceptive feedback would be to put a towel roll on the lower back of a class participant while he or she executes a standard push-up and instructing the participant not to allow the towel roll to fall off the lower back while executing the push-up. This type of feedback keeps the participant more cognizant of his or her form. The body of a 1-hour group fitness class will take approximately 40 to 45 minutes, or 75% of the total class time, to meet the participants' fitness goals.
3. *Cooldown/stretch:* This is a very important portion of the group fitness instructor's class because it allows the participants to reduce their increased heart rates, built up during the body of the class. This will reduce the onset of delayed muscle soreness and venous pooling of blood in the extremities. Traditional static stretching is generally the mode of flexibility that instructors encourage participants to employ.

An instructor leads an exercise class at the gym.

Source: Can Stock Photo.

GFIs are sought after in all major fitness centers throughout the world due to the high utilization of group fitness classes and the class's capability to retain membership. Most GFIs are highly motivated individuals with the ability to lead people, instruct participants well, and keep the participants motivated throughout the class. Personality traits of instructors vary depending on the format and type of class. Most high-intensity and high-volume classes, such as step aerobics, tend to attract energetic, zealous instructors who are passionate about that style of fitness. Low-impact group fitness classes, such as yoga, tend to draw instructors who are more subdued.

Classes Led by Group Fitness Instructors

The types and trends of group fitness have changed significantly in recent decades. Most people associate group fitness with step aerobics; however, group fitness instructors today offer a wide variety of classes. The following are just a few of the classes that instructors teach, and all require training and certification to lead:

- Stationary cycling
- Step aerobics
- Yoga
- Pilates
- Zumba
- Kettlebell conditioning
- Suspension training
- Boot camp
- Abdominal/core conditioning

All or most of these classes require instructors to have a third-party certification, as well as a certain number of hours of continuing education credits (CECs), to be considered well versed in class design and exercise progression for the participants.

Certifications

There are many certifying bodies for group fitness instructors. However, the most creditable and thorough for aerobics classes are the Aerobics and Fitness Association of America (AFAA) and the American Council on Exercise (ACE). These two certifying bodies have met the necessary requirements to be nationally accredited. National accreditation is given to third-party certifying bodies through the National Commission of Certifying Agencies (NCCA). Specialized group fitness systems such as yoga, Pilates, stationary cycling, and Zumba have specific course requirements that demand hundreds of hours of training and practice for a candidate instructor to be considered adequate to teach participants in classes.

The costs of becoming a group fitness instructor and maintaining certification will vary not only with the credibility of the certifying body but also with the specialization of the group fitness class and the class's popularity. The requirements for maintaining the certification constitute an additional expense, as instructors must go to seminars, conferences, and courses to maintain the continuing education requirements.

Most fitness centers that hire group fitness instructors require them to be CPR (cardiopulmonary resuscitation) and AED (automated external defibrillator) certified and to have the specific certification that is needed for the class they will be leading. The popularity of the class, the years of experience of the group fitness instructor, and, most important, the quality of instruction provided will determine his or her level of compensation for services rendered. Many group fitness instructors teach as independent contractors for one or more fitness centers in an area that is convenient to their home or primary place of employment.

Growth Hormone

Human growth hormone (HGH) is an anabolic hormone that has become very popular recently among elite athletes as a performance-enhancing drug. It has been shown to increase lean muscle mass and strength. It seems to assist an athlete in recovering from injuries or strenuous workouts and is of particular interest for professional athletes who endure long, grueling seasons. There have been several debatable attributes assigned to HGH, and some consider it an antiaging wonder drug. It is banned in all professional sports and in international competition, but it is currently almost impossible to detect. HGH is suspected to have been used in almost all sports, from football to baseball to track-and-field events, and even golf. It is likely used at all levels of competition, including high school athletics.

HGH is a naturally occurring peptide hormone that is produced in the pituitary gland throughout a person's entire life. In its naturally occurring (endogenous) form, it is referred to as *somatotropin*. The synthetic form is referred to as recombinant growth hormone, or rHGH. The highest levels of endogenous (naturally occurring) HGH are found during puberty and early adolescence. Endogenous GH goes through cycles of peaks or pulses throughout the day. Peaks last around 10 to 30 minutes, and the most reliable elevation occurs approximately 1 hour after the onset of sleep.

Anecdotal evidence and well-controlled clinical trials have shown an increase in lean muscle mass in adults. It is difficult to study, however, for the same reason that it is difficult to test for in athletes. HGH has a very short half-life, and blood levels vary widely for each person at different times of the day. They vary by age but generally decline with each decade of life. In addition, the exogenous (injected) form of HGH is identical to the natural form, so it is difficult to determine if someone who is found to have a high level of it has achieved it through doping. The urine levels of HGH are more than 100 times lower than they are in the blood. This alone makes athletic testing more difficult, as it requires more expense and equipment to effectively test, apart from concessions from professional unions for testing consent.

HGH's popularity among younger athletes and amateur athletes may be limited by its high price. Obtaining HGH via the Internet is disturbingly easy, but the cost is likely to be around $1,000 to $2,000 per month as of 2008.

Although HGH is a legal medication with therapeutic benefits, it is illegal to distribute or administer it without a prescription or for treatment protocols that are considered experimental. Although there have been antiaging claims made for this hormone and there exist antiaging clinics that have prescribed it, doctors or people taking it for these reasons or for athletic performance can be prosecuted.

The conditions for which HGH is an accepted and effective treatment include congenital short stature and GH deficiency in children, chronic renal failure, Prader-Willi syndrome, and Turner syndrome. Athletes who use HGH for performance enhancement may be using 10 to 20 times the normal amount, and the long-term effects of this are still unknown. Known potential risks include a significantly higher rate of joint pains, carpal tunnel syndrome, and diabetes. Increased skull circumference, peripheral neuropathy, hypertension, and behavioral changes have also been noted. There are also concerns that it could contribute to certain types of tumors.

Gymnastics, Injuries in

Gymnastics is both a competitive and a recreational sport. Injuries, which are influenced by age and gender, are often unique to the sport because of the intense physical demands and long hours of training needed to successfully complete routines on the floor, the balance beam, the vault, and the apparatus.

The gymnastic skill level, the training environment, and the methods used to build strength, flexibility, and endurance in the gymnast are all factors that influence both the number and the types of injuries that occur. The advanced gymnast needs to learn an increasingly difficult level of skills and complicated maneuvers, often done in combination, to develop a competitive routine.

Training for gymnastics, starting at a very young age, can produce world-class athletes at ages as young as 13 years. However, the intense and extreme physical demands of training and competing in the sport create a potentially injury-prone environment for the athlete at any age. Understanding the growth and development of muscles, bones, and joints in the developing gymnast can be helpful in recognizing the types of injury patterns typical of the sport.

Epidemiology

Gymnastics clubs and schools create opportunities for participation in the sport, starting as young as age 4 and continuing through adulthood. Male and female injury rates are high among competitive gymnasts; in women, it's the highest of all sports. In the United States, more than 900,000 athletes participate in gymnastic clubs and competition. Reportedly, 86,000 injuries are treated annually in children 18 years of age and younger. The injury rate recorded among elite gymnasts has been as high as 7 per 100 during the competition season.

Many causes of injury are related to the long hours and frequent training sessions required to compete in the sport. Complex and often risky skills expose the arms and legs, as well as the spine, to extreme forces and explain why injuries occur.

Most injuries are mild to moderate and affect the foot, ankle, knee, hand and wrist, elbow, shoulder, and spine. Tears of the ligament (the tough bands of tissue that connect bones together) and sprains, tears of muscle-tendon groups, and strains and stress injury to the bone make up this group of injuries. Stress fractures of the leg, arm, and spine are usually caused by overtraining. In younger gymnasts, growing and developing bones and joints in the arms and legs are vulnerable to more serious injuries, such as fractures. Knowing the nature of stresses each region of the body is exposed to can help in recognizing potential injury patterns in gymnastics. For example, different types of injures can be characteristic of floor, vault, and apparatus work.

Upper Extremity

The dominant use of the arms to support the body through various moving and stationary positions is unique to gymnastics. As a result, the large and small bones and joints of the hand and wrist are very prone to injury. The high incidence of wrist pain is due to the use of the upper extremity to balance, push, hold, and absorb forces repeatedly on both the floor surface and the apparatus. Of those training and competing in gymnastics, 88% of males and 55% of females reportedly experience episodes of wrist pain that limit practice time and performance. Upper extremity injury is more common in male gymnasts because four of the six gymnastic events they compete in require dominant use of the arm.

In gymnastics, skills on the apparatus, such as the bars and rings, which require swinging with a release-and-catch motion, can expose the hand and wrist to torsion and shear and compression forces.

Source: Can Stock Photo.

Hand and Wrist

The gymnast's hand is positioned flat for handstand support in both static hold and dynamic, or moving, positions when tumbling on the floor, performing on the balance beam, and vaulting. The hand is held in a firm grip/supportive position while using the apparatus, the pommel horse, rings, and uneven, parallel, and high bars. The small bones of the wrist and the ends of the distal radius and ulna, the two long bones of the forearm, absorb stress repetitively with the arm fully extended as the hand balances the body. This position exposes the wrist, its small bones, and the lower ends of the radius and ulna to body forces and impact loads that far exceed the body weight.

Tumbling and vaulting generate extreme forces to the hand and wrist when the entire arm and shoulder are fully extended. In gymnastics, the wrist's smaller bones are placed in opposition to the larger bones at the end of the forearm, the radius, and the ulna. A variety of injuries can occur from these and other potentially deforming forces from overextended positions the hand supports on apparatus such as bars and rings. Skills on apparatus such as these, which require swinging with a release-and-catch motion, can expose the hand and wrist to torsion and shear and compression forces. Injury can occur to bone and cartilage surfaces of the wrist joint and the structures that support the wrist, including the ligament tissue and tendons crossing the wrist joint. A strain to the muscles that provide supportive control for both static and dynamic gymnastic skills can also occur along the forearm.

Compression forces to the small individual wrist bones, called the *scaphoid*, *capitate*, and *lunate*, can result in fractures, stress fractures, and stress reactions around the wrist joint. With the arm in the extended position, forces generated along the radius and ulna onto the wrist press these structures together, and repetitive exercise, over time, causes mechanical failure and leads to an inflamed or painful wrist joint. Stretching and twisting motions can tear ligaments and cartilage structures. Repetitive, very small injuries to these structures over time can result in disturbances in growth patterns in the bone and lead to chronic pain.

In the skeletally immature gymnast, both male and female, wrist pain is of particular concern. Injuries to the growth plate of the distal radius and the articulating small bones, tendons, and ligament structures of the wrist occur acutely, all at once, or gradually over time. This is of particular concern during the years when the skeleton undergoes rapid growth. During this vulnerable time, the growth center of the distal radius, or epiphysis, is at greatest risk for damage and for the development of abnormal growth patterns. With long-term and repeated stress, normal bone growth patterns can be suppressed, and at the time of skeletal maturity, the gymnast may have an irreparable deformity and chronic pain.

With wrist injuries, X-ray or magnetic resonance imaging (MRI) studies are frequently used to diagnose the cause of an athlete's acute or chronic pain symptom. Accurately diagnosing a distal radius growth plate at risk of developing growth disturbances relies on images of the epiphysis best seen by X-ray and MRI studies. X-rays show stress reactions in the developing bones' epiphysis. Widening of the growth plate, bone chips, bone spurs, and abnormal ratios of length between the ends of the radius and ulna are the abnormalities that can be seen in X-ray studies of a painful wrist.

Forearm

As training aids and to improve their advanced swing skill performance, gymnasts use wrist splints and handgrips. Using doweled grips for difficult skills while training on the rings and bars can help improve their handhold for greater strength and support. The drawback of this is that the gymnast is exposed to a greater risk of fracture to the forearm bones, radius, and ulna. The gymnast also faces an increased risk of a sprained wrist and potential injury to the growth centers at the end of the radius.

Forearm injury is mostly the result of powerful and sustained efforts of the related muscles to maintain grip while the gymnast performs skills on the apparatus. Pommel horse training for men can injure muscular attachments to the periosteum of bone in the forearm and cause pain, limiting the athlete's ability to grip. This type of injury results in what is called *forearm splints*. Ongoing stress without appropriate rest can also lead to stress fractures or stress reactions in the bones of the forearm. An accurate diagnosis of the cause of forearm pain is done by MRI if an X-ray is negative for skeletal changes.

The hand exerts a powerful muscular effort while gripping apparatus to complete advanced swing skills. Tears and ruptures of tendons and supporting connecting tissues at either end of the forearm are the result of large tensile loads against muscular resistance. A rupture of the biceps tendon at its attachment below the elbow is an example of a major tendon injury. Surgery to reattach the tendon to the bone is required to repair this form of injury.

Elbow

Elbow pain and the accompanying symptoms from injury, such as swelling and loss of range of motion that don't allow for full extension of the arm, often limit the gymnast's ability to position the body through a handstand balance, something that is inherent to the successful execution of acrobatic skills.

Acute and often serious injuries to the elbow joint can occur from bearing weight on an arm that is outstretched from a completed maneuver on the apparatus, or from tumbling or vaulting. Dislocations; fracture dislocations; growth plate fractures; osteochondral fractures, identified as cartilage breaking with its bone attachments inside the joint; ligament tears; avulsion fractures, or ligament attachments that fracture bone near the elbow joint; and fractures of the bone that separates the muscle attachments near the elbow joint are all injuries that can occur as a result of gymnastic training or competition.

The elbow joint is forcefully extended when doing a basic tumbling skill called a *handspring*. Forward and backward handsprings are integrated into combinations of acrobatic skills performed as floor exercises, on beams, and on vaults. Handsprings can produce large compressive loads at the near end of the radius against the lower end of the humerus called the *capitellum*.

Repetitive compressive loads and direct trauma to the extended elbow over time can lead to small localized injuries to the end of the humerus at the elbow joint and cause an area of the cartilage and bone to fragment. This discrete region of bone and cartilage causes both pain and catching or locking sensations and sometimes becomes loose inside the elbow joint. *Osteochondritis dissecans* of the capitellum is the term used to characterize these disorders. Surgical treatment for this is aimed at restoring normal anatomical structure and biology to the surfaces of the elbow joint. Pinning cartilage and bone fragments that are fractures, transferring healthy cartilage and bone to the joint, doing an arthroscopy simply to remove inflamed soft tissues, or smoothing irregular joint surfaces all help stimulate healing.

Gymnastic routines that expose the skeletally immature athlete's elbow joint to repetitive extensions may result in injuries to the near end of the ulna, also called the *olecranon*. Continued stress to its growth center, by using the triceps muscle to hold a stable elbow position for the arm, can cause stress reactions, fractures, and abnormal growth patterns.

Most injures to the wrist and elbow joints can be managed by periods of rest followed by sharply reducing the volume of provocative skills and then gradually reintroducing them in training sessions. Failing to manage an injury can result in long-term problems in the growing bones and joints and chronic pain disorders. Restricted joint mobility and swelling, loss of strength, localized tenderness, and inability to bear weight without painful effort are all indications of injury. In such cases, abnormal patterns of growth can be detected using diagnostic imaging, such as an MRI, of bone and cartilage.

Shoulder

The shoulder girdle, made up of the shoulder blade, the upper end of the humerus, and all the muscle, tendon, and ligament groups that provide support between the bone structures, is vulnerable to injury from traumatic falls from the apparatus or technical mishaps. The male gymnast's shoulder is exposed to tremendous centrifugal forces from the swinging events performed on the still rings, the parallels, and the high bars. Female gymnasts experience the same type of exposure on the uneven bars. More advanced skills, often practiced with handgrips, expose the gymnast to an even greater risk of injury.

The shoulder joint, formed by the humerus sliding and rotating with the scapular surface referred to as the *glenoid*, is vulnerable to forces that misalign the joint. This type of movement places the shoulder's interconnecting soft tissue support structure, called the *joint capsule*, under strain. Acute injury to the capsule can separate it from its attachments to the glenoid, called the *labrum*. Tears of the labrum are also seen at the attachment of the long tendon of the bicep muscle. Surgery, usually arthroscopic, is required to repair these types of injuries.

A dislocated shoulder is one of the most dramatic and common types of shoulder injury a gymnast can experience. A torn labrum and torn ligament tissue within its structure, or torn from the humerus, can make the shoulder joint unstable. Less severe excursions of the humerus are called *subluxation*. Recurring subluxation of the humerus results in repeated injury to the muscles, tendons, and nerves of the shoulder girdle, which leads to pain. Gymnastic performance nearly entirely depends on the stability of the arm. Surgery is almost always required to restore stability following an injury to the shoulder joint capsule, or labral attachments.

Other types of pain disorders of the shoulder girdle include muscle and nerve injury from strain when the gymnast uses resistance against the forces of inertia during swing maneuvers. Similar types of injury to the rotator cuff can cause tendinitis. Pain is experienced at the top of the humerus from impingement of the rotator cuff against the top of the scapula as the gymnast attempts to use handstand support or swing skills on the apparatus.

X-rays can show reactive changes in the developing epiphysis of the proximal humerus. Radiographic studies may show a separation of developed bone in the acromion, termed os acromiale. The deltoid muscle attaches to the acromion, which is important for the support of the shoulder joint. If the os acromiale is symptomatic (i.e., pain is persistent), surgery is considered to repair the injury. An MRI scan is usually done to accurately diagnose the reasons for instability and stress reactions at the growth center of the humerus.

Most injuries to the arm and shoulder girdle respond to activity modification and rest, followed by reconditioning exercises directed at strengthening the upper extremity and core muscles. Medical intervention is often required to accurately diagnose, manage, and correct potential problems that affect athletic performance.

Spine

The primary support structure for the gymnast is the vertebrae and muscles of the spine. The vertebrae and muscles enable the gymnast to do acrobatic movements that propel the body through balanced and moving positions while tumbling and performing on the apparatus. The stacks of bony elements that make up the cervical, thoracic, and lumbar spine and the disks made of durable gel-like cushions that rest between each individual vertebra, as well as the interconnecting ligaments, muscles, and tendons, are all vulnerable to injury. Large compressive loads along the length of the spine are magnified by tortional shear forces when the body is flexed forward and backward, as well as while executing twisting skills on the floor and beam and when dismounting from the apparatus.

Many gymnastic movements position the spine in hyperextension; apparatus work exposes the spine to torsion against resistance. Powerful and explosive compressive forces expose the spine to catastrophic injuries from falls. The most severe injury to the spine is a cervical spine fracture that results in paralysis. A stress fracture, called *spondylolysis*, is a moderately severe injury to the vertebrae of the lower spine.

The skeletally immature spine is especially at risk for growth plate fractures. Ruptures or the degeneration and inflammation of the disks and the ligaments that support the spine can be the cause of a moderate degree of pain so persistent that the gymnast can no longer train. Moderate and minor strains are caused from long and demanding training schedules that may progress in severity over time. Muscle and tendon strains at their attachments to the spine are the most common injuries to this region.

Painful symptoms from lower spine injuries may be localized to the lower back or may radiate to the buttock or lower leg. When simple treatment measures fail to relieve symptoms, an X-ray, a bone or computed tomography (CT) scan, or an MRI scan can be used to accurately identify the cause. Effective treatment measures for the most disabling pain symptoms include injecting steroids with a local anesthetic near the disk, the nerve, or the small joints of the spine.

Removing provocative skills from training regimens, decreasing the volume of training, and using physical therapy to relieve pain and recondition core muscles are all measures used to treat the most common spine injuries. The use of a brace can also aid in the healing process, as it can be effective in supporting a proper body position of the spine. Improving the gymnast's training environment to more softly cushion dismounts and tumbling routines with matted surfaces promotes injury prevention.

Lower Extremity

The gymnast's lower extremity joints, such as the knee, the ankle, and the foot bones, are exposed to extreme forces during tumbling and vaulting maneuvers and while performing dismounts from the apparatus. Female gymnasts compete in three of four events. These events—floor exercise, vault, and beam—depend on the lower extremity and explain why there is a greater frequency of trauma recorded to this part of the body in gymnastic injury surveillance studies. The ankle joint, in particular, is prone to sprains. The knee and foot experience injuries to ligament structure, cartilage tears, and fractures to growth centers and developed bone.

Knee

The gymnast, when performing tumbling exercises on the floor, quickly accelerates with a rebounding movement, twisting, changing direction, and finishing, using a combination of acrobatic skills, with a sudden declarative stop at the end of a tumbling sequence. Tumbling surfaces are made of spring flooring to improve the gymnast's ability to increase vertical height, from which advanced skills, such as multiple somersaults, with or without twisting elements, are completed. The types of injuries can be better understood by considering these factors and by considering the increasing difficulty of skills performed by the elite gymnast.

Technical mishaps leading to injury can occur when tumbling on the floor or beam and when dismounting or landing from a vault. The most common serious injury seen is a torn anterior cruciate ligament (ACL). Twisting and high-compression loads cause cartilage tears inside the knee joint between the surfaces of the end of the thighbone, the femur and the tibia, or the shinbone. Injury to these half-moon and cushion-like cartilage structures, called the *meniscus*, and to the cartilage covering the ends of these bones can cause pain, swelling, and stiffness, limiting the athlete's ability to run, leap, jump, or land from dismounts.

Disorders of the kneecap that irritate the cartilage covering on its underside can also lead to disabling symptoms, making it difficult to run or land while executing gymnastic skills. An example of this would be when the patella is not moving along a symmetrical path or is not stable when moving. Both MRI and X-ray studies accurately diagnose these disorders of the knee joint. The majority of these injuries of the knee joint and patella benefit from arthroscopic surgery.

Lower Leg

During gymnastic routines, the ankle and foot are exposed to repetitive loads with frequent punching and torsion movements that propel the body through complex somersaulting that is often combined with rebounding and twisting movements. For such a small area, much like the wrist and hand, a remarkable variety of acute and overuse injuries can occur.

Injuries arise from the rapid accelerating and decelerating forces the gymnast places on the bone and muscle and tendon structures and the joint's ligament and cartilage tissues. Acute injury is usually related to dismounting from the apparatus, technical mishaps, and overtraining.

Because of the rigorous demands of gymnastic training and the effect of normal variations in growth and development, the athlete is exposed to stress injuries that develop slowly over time. For instance, an athlete with increased laxity of the connecting ligaments between the large and small joints is more prone to strains, leading to irritation of the tendon attachments around the joints of the ankle and foot and an increased risk of tears to the supporting ligaments. In the gymnast with relaxed or flat feet, painful stress reactions are felt along the bones forming the arch of the foot and the tendons traveling around the ankle and attaching to the middle and end of the foot.

Overtraining in the female gymnast with a flat, or pronating, foot can also lead to irritation along the front of the tibia from repetitive muscular contractions, called *shin splints*. This problem can be distinguished from stress fractures through radiological studies, including MRI or bone scans. Bracing, taping, and orthotic supports are used to improve ankle and foot alignment for these painful disorders.

Ankle

Gymnasts of all ages can experience injuries related to the Achilles tendon. These injuries result from the power generated through the gastrocnemius and soleus muscles, which form the calf. Their mechanism of action—pushing the foot downward—can injure the physis at the tendon attachment to the calcaneus, which is the prominent heel bone at the base of the foot. In the younger athlete, this is commonly referred to as *Sever disease*. Complete detachment of the tendon and bone can happen through the calcaneus's growth center during periods of rapid growth. In the skeletally mature athlete, rupture of the tendon structure can occur when tumbling, as the gymnast punches his or her feet against the flooring. Surgery is necessary to restore tendon continuity when a rupture or fracture occurs.

Ankle sprains are the most common injury in gymnastics. They are the result of an imbalanced load placing the foot in an inverted position, rupturing the ligaments on the outside of the ankle. The ankle becomes swollen, painful, and weak to weight bearing and is treated by physical therapy methods, along with taping, bracing, and pain-relieving medications, to restore mobility and strength. A recurring injury is disabling and requires surgical restoration, with repair or replacement with tendon grafts of the torn structure.

Ankle joint injury is common during impact from landing while tumbling, vaulting, and dismounting. The ankle when landing, a gymnastic skill, experiences estimates of forces 5 to 17.5 times greater than the gymnast's body weight. A less than full rotation from somersaulting can force the ankle bones and cartilage to absorb these forces, compressing their opposing surfaces at extreme angles. Fractures of cartilage, cartilage with bone attachments, and bone and stress fractures in the ankle joint are the disabling injuries recorded by gymnastic surveillance studies. Radiographs, CAT (computerized axial tomography) scans, and MRI scans are used to evaluate this form of injury. These acute fractures can be seen in gymnasts of all age-groups.

Chronic pain may be due to stress fractures or to small areas of injured cartilage and adjacent bone inside the ankle joint, called *osteochondritis*. The rounded surface of the talus is the most common site of this problem. A separation of an osteochondritic lesion leads to pain on weight bearing. The bone involved within the lesion and the cartilage covering it can become loose inside the ankle joint. Repeated injury to the ankle cartilage surface and incomplete healing from sprains can chronically inflame the ankle joint cavity and its lining, called *synovium,* and it may be a source of persistent pain.

Stress fractures are generally treated by an extended period of activity restriction. Sometimes bone healing is enhanced by the use of bone growth stimulation by electrical current, or ultrasound stimulation. Arthroscopic surgery is useful for chronic pain problems of the ankle joint. Arthroscopy can correct loose cartilage and bone structure and inflamed synovium found inside the ankle joint.

Tendons that cross the ankle on their way to their insertion sites on the front and back of the midfoot and forefoot can be irritated by overtraining. The attachment sites can become inflamed from placing the foot in a balanced position that generates and absorbs impact forces from the ball of the forefoot. These tendinitis disorders can be treated by exercise restriction, taping, and the use of orthotic inserts placed inside athletic slippers to balance foot positions. Use of these methods can also help in reducing pain symptoms.

Stress fractures and fractures are seen in a variety of locations in the developing and mature bones of the midfoot and the long bones of the forefoot, called *metatarsals*. Separation of the ephysis, or displaced growth centers, due to a fracture requires surgery. During surgery, the broken structure can be placed in its normal position, which will prevent further disability from growth disturbance and poor alignment.

Prevention

The numbers and types of injuries seen in gymnastics are related to age, growth, and development; skill level (i.e., club vs. elite); environment (training vs. competition); gender as it is related to the region of the body frequently involved; and period of skeletal growth. Risk, severity, and onset of injury, whether acute or chronic, are a function of training intensity, environment or venue, body structure and skeletal maturation, and increasingly difficult skill levels. The region of the body exposed to trauma is determined by the gymnastic skills practiced in training or executed in competition and by the types of events and dismounts.

Precautions and measures taken to reduce injury to bone and joint structures include the use of braces and tape to support and strap a joint, or region of the body, to prevent extremes of movement and the use of protected matting on floor surfaces for dismounts and when practicing landing and tumbling and vaulting skills. Progression to more advanced skill levels should be planned in concert with exercises designed to improve both strength and flexibility, by targeting the muscles surrounding the pelvic and shoulder girdles and core muscle groups and by way of proprioceptive training through developing muscular reflexes to coordinate the stabilizing joint motion.

Strategic planning should be used proactively in gymnastic training to allow for a variation of event selection so that the extremities are protected from overloading. This can be achieved by controlling the frequency and intensity of repetitive loads on the muscles and skeleton. Recognizing the symptoms that are characteristic of overuse, along with activity modification, can help limit the complications associated with injuries that are particularly severe during periods of rapid growth.

Having a coaching qualification and a certification in safety that provides instruction on physical preparedness, spotting techniques, training strategy, and environment is important to injury prevention. The evaluation of competition rules and the performance environment has led to important changes designed to minimize injury frequency and risk linked to competition.

Hammertoe

Hammertoe is a deformity of the second, third, or fourth toe in which the tip of the toe is bent downward at the middle joint (known as the *proximal interphalangeal*, or PIP, joint), and the middle of the toe is cocked upward, resembling a hammer. It is strongly associated with hyperextension of the *metatarsophalangeal* (MTP) *joint* (where the base of the toe attaches to the rest of the foot), as well as having a longer second toe than the first. Hammertoe deformity can be either flexible or fixed. Initially, the toe maintains flexibility. Flexible deformities allow the examiner to manipulate the toe and move the affected joint back into a neutral position. However, over time, the tendons may tighten and can become permanently stiff. Fixed deformities, such as these, do not allow repositioning. Rather, they are corrected with surgery. Hammertoe is approximately five times more common in women.

Causes

The most common cause of hammertoe is the long-term use of poorly fitting shoes. Shoes that narrow toward the toes, have high heels, and are too small are the common culprits. Shoes that narrow toward the toes cause crowding of the smaller toes and push them into a flexed (bent) position. The condition can be aggravated by the feet rubbing against the small toe box, and this can lead to the formation of corns and calluses. High-heeled shoes increase the pressure placed on the ball of the foot and the toes. They force the toes down against the narrow toe box and increase the bend in the toe. With long-term use, the toe muscles weaken and lose the ability to straighten the toe. Risk of hammertoe also exists in children who continue to wear shoes that they have outgrown. The toes pay the price when a foot is squeezed into a shoe that is too small. Deformities can occur at both the interphalangeal joints (the joints in the toe) and the MTP joint.

While the majority of cases are attributed to poorly fitting footwear, a combination of other factors can also increase the risk of acquiring hammertoe. Anatomical problems such as a long second toe, bunions (hallux valgus), MTP joint instability, and previous toe trauma warrant attention.

- A long second toe causes shoes to fit improperly, because the toe is forced into a bent position (flexion) to accommodate the shoe. An abnormal motion of the second toe triggers excessive motion of the MTP joint, and this can lead to MTP synovitis (irritation of the joint capsule where the base of the toe connects to the foot). The joint support structures (i.e., muscles, tendons, and ligaments) weaken with abnormal motion, increasing the risk of MTP joint instability. Patients often complain of a lump at the ball of their foot and pain at the top of their foot near the base of the toes.
- Bunions present with an angulation of the big toe. The resultant pressure placed on the second toe can cause abnormal positioning and bending

of the second toe, particularly while compressed into shoes.

- Prior trauma to a toe—such as a sprain, strain, fracture (broken bone), or dislocation—increases the risk of abnormal toe anatomy and the resultant positioning problems.

Medical conditions can also increase the risk of developing hammertoe. Studies have shown an association with connective tissue disorders, neuromuscular disease, degenerative disk disease, inflammatory joint diseases, and diabetes. Rheumatoid arthritis causes hammertoe deformity by progressive destruction of the MTP joint, leading to joint instability. Diabetics with peripheral neuropathy are prone to hammertoe because chronic nerve and muscle damage to the foot result in abnormal foot mechanics.

Clinical Findings

Hammertoe can be diagnosed solely from a physical exam. A proper examination includes a neurovascular evaluation, a sensory evaluation, and an evaluation of muscle bulk. The second toe is most commonly involved. Typically, only one or two toes are affected. In the rare case in which all the toes seem to be involved, a thorough neurological assessment is necessary to evaluate for nerve or spinal cord problems (Figure 1).

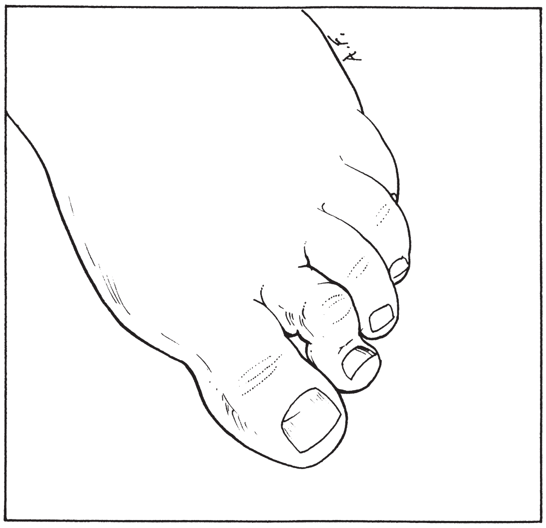

Figure 1 Hammertoe

Note: In hammertoe, usually the second toe, or sometimes another lesser toe, develops a C-shaped deformity.

Hammertoe affects the middle joint of the toe; it is in the bent position. The distal joint (closest to the toenail) does not have a deformity. The foot should be examined in both positions, while standing and while seated. It is important to evaluate the flexibility of the toe; the clinician will move each of the joints and look for dislocations or instability. Hammertoe is amplified by weight bearing.

There are three areas of the foot affected by hammertoe that tend to be painful. The skin on top of the middle toe joint (the dorsal surface of the PIP joint) can become painful due to the development of a hard corn. This is caused by the chronic friction and pressure due to the toe buckling and the skin rubbing against the inside of a shoe. A painful callus can also develop at the end of the toe, just below the tip of the toenail. This is referred to as an end corn. Bending of the toe joint closest to the toenail (the distal interphalangeal joint) causes the tip of the toe to press into the bottom of the shoe. The ball of the foot can also be painful due to the deformities of hammertoe. If the toe bone (proximal phalanx) that connects to the rest of the foot partially dislocates (subluxates) or becomes completely dislocated from the joint, chronic stress on the sole of the foot can trigger the formation of a painful callus. This type of callus is also known as intractable plantar keratosis. Pain at this location is called metatarsalgia.

Pain at any of these locations warrants close evaluation and monitoring. In patients with decreased sensation in the feet, such as diabetics or patients with myelomeningocele, there is a risk of ulceration and infection at these pressure points.

Additional Testing

Further testing is typically not necessary as hammertoe can be diagnosed clinically. However, radiographs may be done to evaluate the deformities. A lateral view is best for looking at hammertoe specifically. An anterior-posterior view of the foot is best for analyzing the dislocation of the MTP joint. Radiographs are routinely done prior to cases needing surgical intervention. Blood testing is done when underlying medical issues are suspected—for example, to rule out rheumatoid arthritis or other inflammatory conditions. There are no lab tests that diagnose hammertoe.

Conservative Treatment

A variety of nonoperative treatment options exists for hammertoe. The goal is to address the condition early in order to have the best results. Options include padding, strapping, taping, changing footwear, exercises, and manipulations.

Padding, strapping, and taping are helpful for reducing the degree of deformity and for relieving pressure over painful joints. Foam or viscoelastic padding is placed over the hammertoe or at the tip of the toe to prevent friction with shoes and corn/callus development. Tube gauze (e.g., a sleeve that slips over the toe) and toe caps are also used. Soft shoe insoles and arch pads are recommended in cases of intractable plantar keratosis to help redistribute weight away from the painful areas. Tape and toe slings are used to promote correct toe positions. They are carefully placed to keep the MTP joint in a slight plantarflexion (as in pointing the toes). The middle toe joint (PIP) compensates by straightening out.

Proper footwear is critical in reducing pain and progressive deformity. Recommendations include shoes with a low heel and a large toe box. Tight, narrow, and high-heeled shoes should be avoided. It is best to buy shoes that are half an inch longer than your longest toe. This reduces the chance of the toes buckling in the toe box. Shoes can be adjusted to accommodate the hammertoe; the toe box can be stretched so that it bulges around the toe, reducing the risk of contact at the top of the shoe.

Stretching and strengthening the toe muscles help correct muscle imbalance and instability. Exercises can be as simple as using the toes to pick up objects off the floor. Another suggestion is placing a towel flat on the floor and, while seated, using the toes to crumple it. Gentle stretching should be done daily. It is recommended that stretching be combined with manipulations—putting the toe in the correct position and taping it securely in place. Recurrence of the hammertoe is likely when stretching and daily manipulation/taping are discontinued.

Surgical Treatment

The most definitive treatment for hammertoe is surgery. Surgery is indicated when conservative therapies have failed and pain becomes disabling. There is a range of surgical options, and the choice is based on the type and severity of the deformity. Flexible deformities are treated with flexor tenotomy (also known as tendon lengthening or tendon release) or flexor-to-extensor tendon transfer. Tendon transfer involves repositioning of the tendon to straighten the toe.

Rigid deformities are treated with arthroplasty of the middle toe joint. Arthroplasty involves the removal of some bone and cartilage to remodel the joint and correct the deformity. The goal is to shorten the toe in order to relieve pressure, alleviate pain, and ultimately straighten the toe. In more severe cases, additional procedures may be necessary. These include reconstruction of the surrounding tendons and ligaments, joint fusion (arthrodesis), fixing a rotational abnormality (derotation arthroplasty), and metatarsal shortening. In cases of concurrent MTP joint instability or abnormality, hammertoe surgery should also include correction of the MTP to prevent a recurrence of the deformity.

Arthrodesis is a fusion of two bones. In cases of hammertoe, this is typically a fusion of the proximal and middle phalanges—the bones on either side of the middle toe joint. The bones are fixed together with a removable pin; they eventually fuse together.

Derotation arthroplasty is another technique for realigning a hammertoe. The surgeon removes a small wedge of skin and straightens the toe by rotating it into the correct position. In some cases, a small section of bone needs to be removed and/or tendons and ligaments need to be remodeled to correct a rotated toe.

Complications from surgery include infection, delayed wound healing, neurovascular injury, numbness, pain, and recurrent deformity.

- Infections may be superficial or deep at the surgical site. If there is an infection around the fixator pin, the pin should be removed and the patient should be treated with antibiotics for 10 to 14 days.
- Good peripheral blood supply is critical for proper wound healing. Physicians evaluate the patient's vascular status when considering surgical intervention. Patients with poor blood flow to the extremities—such as smokers, diabetics, and those with peripheral vascular disease—are poor surgical candidates due to an increased risk for delayed wound healing.

- Neurovascular injury is rare. When it occurs, it is typically seen in patients who have had severe, chronic deformities and more complicated surgical repairs. Manipulation of the nerves and blood vessels of the foot during surgery can irritate these structures, resulting in spasm of the vessels, numbness, or nerve pain. Decreased sensation and numbness are more common than heightened sensation (hyperesthesia). Hyperesthesia can be disabling as these patients are exquisitely tender to painful stimuli.
- Last, surgery is not always 100% effective. If the surgeon is unable to completely correct the deformity or if patients do not follow postoperative instructions (e.g., wearing appropriate footwear), the deformity can recur. Revision surgeries are not as reliable as initial repairs.

Hamstring Strain

Hamstring injuries are among the most common muscle strain injuries in all sports and exercise. A prior hamstring injury is the biggest risk factor. The goals of treatment are maximizing comfort and restoring function. Early recognition and optimal management are key to having the best possible outcome following a hamstring injury.

Functional Anatomy

Muscles connect different parts of the body, typically bones on either side of a joint, and when they contract (get shorter), they displace or move a joint. In moving joints, muscle groups have other muscle groups that either support or oppose the specific plane of movement (the agonist group or the antagonist group). *Concentric movement* occurs when a muscle group contracts and shortens to perform its main function—for example, the hamstring bending the knee. *Eccentric movement* occurs when a muscle contracts during the antagonistic function—for example, the hamstring restraining knee extension during sprinting; the muscle contracts but does not necessarily shorten in length, and in fact, it may be forced to lengthen by the opposing muscle group.

This concentric-eccentric relationship is important to understand the mechanism of injury involving the hamstring muscle group. The hamstrings include the biceps femoris, the semitendinous, and the semimembranous muscles. The three muscles originate at the ischial tuberosity, and the distal insertions vary based on the muscle. The biceps femoris attaches distally on the tibial lateral condyle and fibula head, the semitendinous attaches on the proximal medial tibia, and the semimembranous attaches in the medial tibial condyle pes anserine region. Like most muscle groups in the human body, the hamstring muscle group works by pulling the insertion toward the origin, so its function is to flex (or bend) the knee (bringing the heel toward the buttocks) and assist in the extension of the hip (moving the leg to the rear).

Mechanism of Injury and Risk Factors

The majority of hamstring injuries in sports occur in velocity athletes (e.g., sprinters, running backs, wide receivers, soccer and basketball players) and result because of an excessive eccentric force during the lengthening of the muscle—especially when running, sprinting, or coming to a sudden stop (deceleration). Hamstring injuries can occur when the muscle is contracting at the same time when other forces are causing the muscle group to lengthen, such as in sprinting and stopping suddenly. Mechanically, hamstring injuries occur frequently at the later part of the swing phase, when the hamstring contracts eccentrically to decelerate knee extension in preparation for foot strike. Another common mechanism of hamstring injury is during the stance phase, when the hamstrings contract in a concentric fashion to assist in hip extension.

An important risk factor for an acute hamstring injury is a past history of the same injury. Other proposed risk factors include a muscle imbalance or weakness of the hamstrings, poor flexibility, inadequate warm-up, muscle fatigue, and overtraining. Many recurrent or chronic hamstring injuries may, in part, be due to a less than optimal rehabilitation of the first initial injury (Figure 1).

Classification

The hamstring injury can occur at any location in the muscle (in the origin, insertion, or muscle belly). The traditional classification is based on the degree of muscle fiber injury. A first-degree strain signifies only minimal structural injury to the muscle fiber and results in minimal strength loss and almost no functional disability. A second-degree strain signifies a partial tear of the muscle, macrotrauma, and the athlete may have loss of strength and some function. A third-degree strain represents a complete rupture of the muscle and is associated with significant functional disability and often significant discomfort. When a third-degree injury to the hamstring occurs at its proximal origin, it may be accompanied by an actual avulsion fracture (bone fragment separation) of the ischial tuberosity.

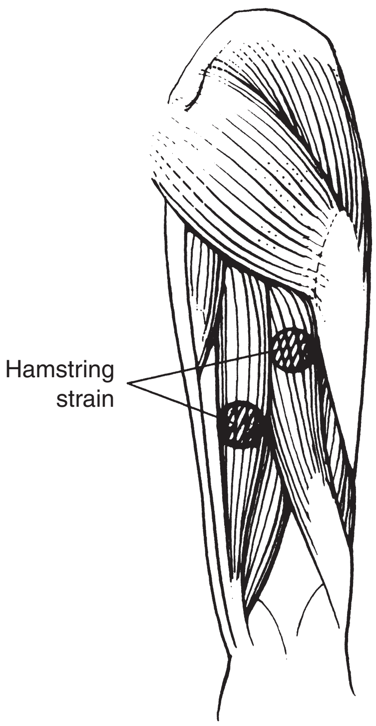

Figure 1 Hamstring Strain

Notes: Hamstring strain—a stretch, tear, or complete rupture of one or more of the three muscles in the posterior of the thigh—is one of the most common injuries in sports. The likelihood of injury is dramatically increased if the muscles are not sufficiently warmed up.

Treatment

The healing process in muscle strains involves three phases: the acute, subacute, and chronic remodeling phases. The first two involve the production and laying down of the connective tissue scar, and the third phase involves the attempted regeneration and remodeling of the affected musculotendinous structure.

After the immediate injury, there may be bleeding and/or fluid extravasation (the leaking of fluid and materials out of the blood vessels into the surrounding tissue). Inflammatory cells migrate to the area of injury and begin the process of cleaning up, scarring, and healing. The subacute phase continues the fibrous scar tissue formation. The chronic remodeling phase is the body's attempt to turn the scar tissue back into an organized muscle and tendon fibrous structure. After a second- or third-degree hamstring injury, the tissues of the injured area may never look completely the same under a microscope; fortunately, however, the clinical goal of restoring and maximizing function can often be achieved with timely and appropriate management.

During the acute phase, the approach to muscle strain treatment includes the mnemonic PRICES (*p*rotection, *r*est, *i*ce, *c*ompression, *e*levation, and *s*upport). Ice, compression, and elevation should be applied for 48 to 72 hours at least to help reduce pain and swelling; anti-inflammatory medicines such as ibuprofen or naproxen are commonly used as well. The rationale in this phase is to limit the amount of bleeding and inflammation to the point of comfort while, at the same time, permitting the healing process to start.

Once the acute phase is over and the athlete is more comfortable, the rehabilitative phase may start, and this can include several aspects, such as tissue mobilization, stretching, strengthening, balance training, and cross-training. Early mobilization allows for alignment of the regenerating muscle fibers, resorption of the connective tissue scar, and decrease in muscle atrophy. Mobilization includes a combination of stretching and strengthening exercises that should be relatively painfree to avoid further injury. The strengthening process can start with concentric contractions, progressing to eccentric conditioning.

If the athlete has significant or increasing pain, the intensity of the program should be decreased. If the athlete tries to return too soon to full activity, more damage and inflammation could occur. Cross-training activities may include stationary bicycling and swimming to help in rehabilitation and maintain cardiovascular conditioning.

The length of time for maximal recovery will vary from days to weeks for a mild, first-degree strain to months to a year or more for a third-degree, complete tear. Eccentric strengthening is the foundation of the latter stages of hamstring rehabilitation. Other therapeutic modalities including moist heat, ultrasound, electrical stimulation, deep friction massage, myofascial release, and neuromobilization have been recommended in treating hamstring injuries. Once the athlete has recovered normal strength and flexibility, he or she can start to jog at low intensity and progress as tolerated, avoiding painful activities. If pain recurs, the intensity of the program may be decreased before attempting to advance again. More advance rehabilitation exercises for the athlete may incorporate activities such as polymetrics (jumping or bounding) and neuromuscular proprioception (combining strength and balance). The rehabilitation program should be individually tailored to the patient's needs and functional expectations.

Most hamstring injuries can be treated nonoperatively and will have good outcomes with appropriate management. Surgery may be considered for a complete hamstring tear near the origin or distal insertion based on the patient's pre-injury function level and the postinjury functional expectation. Surgery could also be considered in cases of bony avulsion fractures with more than 2 centimeters (cm) of displacement; displacements of less than 2 cm heal adequately with the nonoperative approach described above in the normal, nonelite athlete.

Conclusion

In summary, hamstring injuries are common and could have significant consequences if they are missed or less than optimally managed. They are more often seen in sprinting athletes and those involved in sports with sudden starts and stops. A prior hamstring injury is the most common risk factor, and optimal rehabilitation is essential for these athletes. The key for hamstring injury treatment is early recognition of the injury, initiating the PRICES protocol promptly, and following with appropriately aggressive and optimal rehabilitation. Eccentric strengthening is the foundation for a successful rehabilitation program, and it should be started once the athlete is painfree and comfortable with concentric exercises.

Hand and Finger Injuries

Hand and finger injuries are extremely common in sports, particularly in rock climbing and ball-handling sports, such as basketball, football, softball, and volleyball. Hand and finger injuries are also common in boxing, snowboarding, skiing, and skateboarding. Injury rates vary from 15% to 65% of all injuries, depending on the sport involved. Injury patterns are sport specific, depending on the demands placed on the upper extremity. Both acute traumatic injuries and chronic overuse injuries are seen.

The majority of these injuries require minimal intervention. However, some are potentially serious, requiring immobilization, precise splinting, or surgery. Athletes often neglect these injuries, expecting them to resolve spontaneously, and they may present too late for effective treatment. Early assessment and management of hand and finger injuries is very important to avoid long-term deformity and functional impairment.

Hand and finger injuries are more common in younger populations than in adults. This is due, in part, to increased sports participation, particularly in extreme sports, by younger athletes. Other factors include the use of age- or size-inappropriate equipment, not wearing appropriate safety equipment, and poor supervision, coaching, and/or technique. Sprains are the most common injuries, accounting for 20% to 50% of all injuries, followed by contusions (15%–30%) and fractures (5%–35%). Fractures of the fingers are among the most common sports-related injuries. Hand fractures occur most often in the bones of the distal fingers (phalanges) (about 50%), followed by the metacarpals (30%–35%), proximal phalanges (15%–20%), and middle phalanges (8%–12%). Approximately one third of hand fractures are intraarticular (into the joint).

Anatomy

There are 27 bones in the hand and fingers. The fingers comprise the distal, middle, and proximal phalanges, whereas the thumb has a distal phalanx and a proximal phalanx. There are five metacarpal bones and eight carpal bones (capitate, hamate, triquetrum, lunate, scaphoid, trapezius, trapezoid, and pisiform). The scaphoid bone can be palpated at the base of the thumb in the so-called anatomical snuffbox. The floor of the anatomical snuffbox comprises the carpometacarpal joint of the thumb. The physes or growth plates of the phalanges are located proximally and close typically between 14 and 16 years of age. The physes of the metacarpals, with the exception of the thumb, are located distally in the metacarpal neck area. The physis of the thumb metacarpal is located proximally, near the carpo-metacarpal joint (Figure 1).

Joint stability in the hand and fingers is conferred by the ligaments. Collateral ligaments at the interphalangeal joints prevent excessive radial and ulnar deviation. The collaterals insert broadly on both the epiphysis and the metaphysis of the phalanges. At the metacarpophalangeal (MCP) joints, the collateral ligaments insert on the epiphysis of the more distal phalanx, making Salter-Harris III avulsion-type fractures in children and adolescents much more common at the MCP joint level. Another structure offering stability to the phalangeal joint is the volar plate, a thick fibrocartilagenous tissue found on the palmar or volar surface of the phalangeal joint. This is a common site of injury in the fingers.

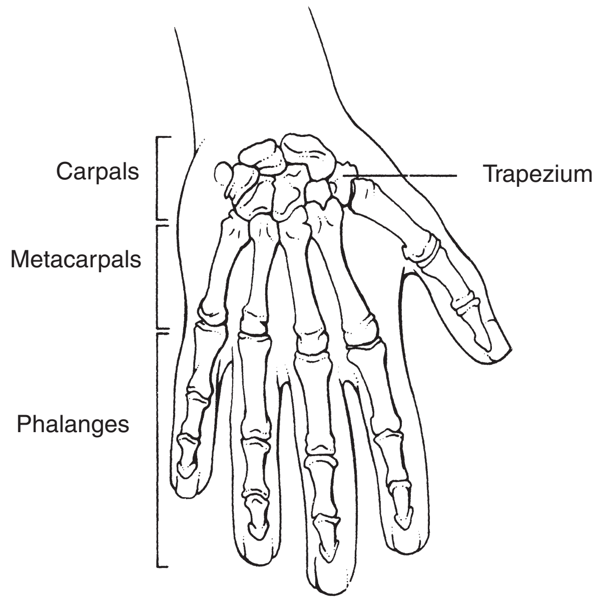

Figure 1 Hand and Finger Anatomy

There are several extrinsic tendons traversing the hand. These include the long thumb abductor (abductor pollicis longus), the thumb flexor and extensors (the flexor pollicis longus, extensor pollicis longus, and extensor pollicis brevis), the extrinsic digital extensors (the extensor digitorum comminus, extensor indicis proprius, and extensor digiti quinti), and the extrinsic digital flexors (the flexor digitorum profundus and the superficialis). In addition, there are 18 intrinsic muscles of the hand, including the thenar, hypothenar, lumbrical, interossei, and adductor pollicis muscles.

Evaluation of Injuries

Details of Injury

When an athlete presents with an injury to the hands or fingers, certain factors, such as hand dominance, sport(s) played, position played, and level of performance, may affect how the injury is managed. Determining the mechanism of injury, specifically the position of the hand or fingers, the direction and magnitude of the applied force, and the symptoms the athlete is experiencing (pain, weakness, and instability), is essential to help make a diagnosis. Athletes should be asked about initial management of the injury, including whether any manipulation or reduction maneuvers were performed and how the hand/finger was splinted. More serious injuries usually prevent an athlete from continuing with his or her sport, secondary to pain and loss of function.

Physical Findings

Injuries to the hands and fingers may result in swelling, bruising, lacerations, abrasions, wounds, or obvious deformities. There may be tenderness to palpation. Reproducible bony tenderness usually indicates a fracture. Tenderness to palpation in the anatomical snuffbox may indicate a scaphoid fracture.

Movement of the fingers and hand may be affected by injuries. Active range of motion of fingers includes flexion, extension, abduction, and adduction. Active range of motion of the thumb includes flexion, extension, palmar abduction, and adduction, as well as opposition (from the thumb to the fifth digit). Normal range of motion of the second through fifth digits is about 80° of flexion at the distal interphalangeal (DIP) joint, 100° of flexion at the proximal phalangeal (PIP) joint, and 90° of flexion at the MCP joint. In addition, there may be damage to the nerves of the blood vessels in the hand or fingers.

A bony or joint injury may cause an angular or rotational deformity of the finger or hand. The principle of tenodesis can help identify abnormalities associated with hand and finger injuries. Passive wrist extension in the normal hand and wrist results in obligate passive digital flexion, with all the fingers roughly parallel. In the presence of a rotational deformity, the affected digit will overlap or underlap the adjacent fingers. In the presence of a flexor tendon injury, the affected digit will not passively flex with the adjacent digits in the resting position or with passive wrist extension.

Resisted movements can test tendon integrity in each finger. The flexor digitorum profundus is tested by having the patient flex the DIP joint with the PIP joint held in extension. The flexor digitorum superficialis is tested by having the patient flex the PIP joint with the DIP joint held in extension. The extensor tendon is tested by having the patient extend the PIP joint with the MCP joint in extension. In addition, the ulnar collateral ligament of the thumb should be tested by applying radial and ulnar deviations to the thumb with the MCP in 10° of flexion.

Investigations

Any possible bone or joint injury of the hand or fingers should be evaluated with X-rays. Routine views include posterior-anterior (PA), lateral, and oblique views. Oblique X-rays will often identify bony injuries not apparent on anteroposterior (AP) or lateral views. Magnetic resonance imaging (MRI) or computed tomography (CT) may be useful in cases of suspected carpal, articular, or ligamentous injuries.

Types of Injury

Table 1 provides the different types of hand and finger injuries.

Table 1 Hand and Finger Injuries

Common	*Uncommon*
Metacarpal fractures	Bennett fracture
Phalangeal fractures	MCP joint dislocation
PIP joint dislocations	DIP joint dislocation
Ulnar collateral ligament sprain/tear (gamekeeper's thumb)	Sprain of DIP joint
	Mallet finger
Laceration	
Jersey finger	
Subungual hematoma	
Sprain of PIP joint	
Flexor/extensor tendinitis	

Note: DIP = distal interphalangeal joint; MCP = metacarpophalangeal joint; PIP = proximal phalangeal joint.

Prevention of Injury

Many hand and finger injuries can be prevented. Appropriate equipment should be worn for the particular sport being played. In younger athletes, age- and size-appropriate equipment should be used.

Return to Sports

Return-to-play recommendations following hand and finger injuries vary according to the type of injury, the treatment plan, the level of acuity or chronicity, and the sport-specific demands of the athlete. There are no universal guidelines; however, certain principles should be applied. Bony or ligamentous injuries generally take 3 to 6 weeks to heal. Injuries should be appropriately immobilized in a cast or splint to allow participation in activities. Full, unprotected return to sports should not take place until the athlete has recovered full, active and passive, painfree range of motion, as well as almost full strength, of the injured hand/finger. Injuries to the hands and fingers have the potential for delayed or failed healing, regardless of treatment, so athletes should be referred early to a hand surgeon for follow-up. Safety of the injured athlete as well as the other sports participants should be of paramount concern. If an athlete intends to return to sport wearing a protective device, coaches, trainers, and officials should be aware of this and should give their approval prior to participation.

Hand and Finger Injuries, Surgery for

Hand injuries are common in athletes, representing 5% to 15% of orthopedic injuries. While contusions and sprains are the most common, fractures and soft tissue injuries involving the tendons and ligaments of the hand do occur and often require specialized care. Given the importance of hand function in athletics as well as in activities of daily living, timely diagnosis and appropriate care are necessary to expedite return to play and to maximize long-term outcomes. This entry discusses common hand injuries in athletes, with an emphasis on those requiring surgical care.

Clinical Presentation

One of the great challenges in treating hand injuries in athletes is their varied clinical presentation.

In general, sports hand injuries occur from traumatic events during practice or play. Patients will often be able to recall a specific event during which their hand was injured (e.g., falling onto the outstretched hand, axial load on the finger from a ball, and a direct blow onto the hand by another athlete's stick). Understanding the mechanism of injury provides clear insight into the problem.

Clinically, there may be pain, swelling, and bruising. In more extreme situations, there may be wounds, lacerations, or obvious deformities of the hand/fingers. Furthermore, the athlete may report an inability to move the injured part. When athletes present days, weeks, or even months after an injury, the clinical complaints may be different. Pain, clicking, "giving way," and stiffness during athletic activities are common complaints in late-presenting injuries and should alert the care provider to an underlying orthopedic cause.

Physical Examination and Pertinent Anatomy

A thorough physical examination should be performed, based on the athlete's complaints and the care provider's knowledge of the pertinent anatomy. While a comprehensive review of the complex anatomy of the hand is beyond the scope of this entry, a number of important anatomic principles will be presented here as they relate to physical examination.

The examination begins with observation. Inspection for isolated swelling, bruising, wounds, and deformities will give clues as to the underlying problem. Normally, in the resting position, the fingers adopt a slightly flexed posture due to the action of the flexor tendons. In this position, all the digits should be parallel, with no overlap or underlap of one finger over another. If the wrist is passively extended, all the fingers should flex toward the palm. If the fingers do not passively flex in a parallel fashion, suspicion should be raised for a tendon, ligament, or bony injury. This is often referred to as the *tenodesis effect* (see images a and b).

(a) (b)

A patient with abnormal tenodesis

Source: Courtesy of the Children's Orthopaedic Surgery Foundation, Boston, Massachusetts.

Note: (a) All the digits appear aligned with the wrist flexed and (b) passive wrist extension demonstrates abnormal rotation of the ring over the long finger.

After inspection, all the bones and joints of the hand (or affected part) should be palpated. Any reproducible localized tenderness should alert the examiner to a possible bony injury. As each finger (excluding the thumb) has two flexor tendons—one bends the distal interphalangeal joint (DIPJ) and the other bends the proximal interphalangeal joint (PIPJ). Isolated testing should be performed to ensure that the athlete can bend each specific joint in isolation. Ligaments can be assessed by bending, extending, and providing side-to-side stress of the joint in question; as there is great variability in joint laxity and flexibility from individual to individual, comparison with the adjacent finger or the same finger of the uninjured hand is helpful. Finally, joint motion should be assessed actively (i.e., by asking the patient to make a fist and open his or her hand) and passively (i.e., by asking the patient to relax and allowing the examiner to move the finger/hand).

Diagnostic Testing

X-rays should be taken in cases of reproducible localized tenderness, joint stiffness, or deformity. Given the complex shape of the hand and fingers, X-rays of the specific injured part should be taken to obtain more detailed information and avoid missing injuries (e.g., X-rays of the index finger instead of X-rays of the entire hand). In cases where there is a question of specific soft tissue injury (e.g., ligament tear, joint instability, and tendon rupture), magnetic resonance imaging (MRI) can be helpful, though this is not routinely used.

Principles of Treatment

A number of general treatment principles apply to the management of hand injuries in the athlete. In addition to a careful and comprehensive physical examination, an appropriate radiographic imaging—including orthogonal views—of the affected part is imperative. Open wounds or lacerations should be treated with irrigation and wound closure, with the exception of "fight bites," animal bites, and late-presenting wounds. In cases of suspected or known fractures, the hand should be immobilized in *intrinsic plus position* until definitive orthopedic evaluation is obtained. Intrinsic plus position places the wrist in 20° to 30° of extension, the metacarpophalangeal (MCP) joints in 70° flexion, and the interphalangeal joints straight, to avoid soft tissue contractures and subsequent stiffness. Temporary splinting may also be considered for soft tissue injuries without fracture.

While the majority of hand injuries can be managed with nonoperative care, a number of injuries require surgery, including open fractures, intraarticular fractures, flexor tendon ruptures or lacerations, and ulnar collateral ligament tears of the thumb MCP joint. In general, referral to a hand surgeon within 5 to 7 days of injury is desired in cases where surgical treatment is deemed necessary.

Specific Injuries: Bony

Unicondylar Fractures

Unicondylar fractures refer to intraarticular fractures of the phalanges (image c). Typically sustained during "jamming" or "twisting" injuries, these injuries may lead to irregularity of the joint surface, deformity, stiffness, and even arthrosis in the long term. For this reason, surgical treatment is recommended to restore normal joint surface contour and to correct deformity; surgery is even considered in nondisplaced fractures due to the inherent instability of the small fracture fragments seen in this injury.

Phalangeal Shaft Fractures

Fractures of the phalangeal shafts are typically due to bending or twisting forces. Patients will present with pain, swelling, and reproducible tenderness at the fracture site. X-rays will confirm the diagnosis. In cases of excessive angulation or malrotation, surgery can be performed to realign and stabilize the bone to maximize functional outcomes.

(c)

An X-ray demonstrating a unicondylar fracture of the phalanx

Source: Courtesy of the Children's Orthopaedic Surgery Foundation, Boston, Massachusetts.

Volar Plate Avulsion Fractures

In hyperextension injuries to the PIPJ, often the stout volar ligaments will avulse a small portion of the base of the middle phalanx (image d). Although it is technically a fracture, the treatment principles for this injury are more like those for a sprain. Provided that the interphalangeal joint is stable with range of motion, excessive splinting is to be discouraged due to the real risk of long-term stiffness and joint contractures. In these situations, Coban wrapping and buddy taping of the affected finger to an adjacent finger will provide adequate comfort, prevent recurrent injury, and facilitate range of motion.

Boxer's Fractures

Boxer's fractures refer to fractures of the fifth metacarpal neck. Though rarely seen in high-level boxers, these injuries do occur from clenched-fist injuries. Despite the often dramatic appearance on X-rays, healing with up to 40° or more of angulation leads to little functional compromise, owing to the compensatory motion at the MCP and carpometacarpal (CMC) joints. Surgery is only recommended in cases of excessive angulation or malrotation resulting in "scissoring" of the small finger over the ring finger.

(d)

A lateral X-ray of a small volar plate avulsion fracture of the base of the middle phalanx

Source: Courtesy of the Children's Orthopaedic Surgery Foundation, Boston, Massachusetts.

Metacarpal Fractures

Fractures of the metacarpal shafts are common and are due to direct blows or falls onto the hand. Given the supporting soft tissues and adjacent bones, isolated fractures of the central metacarpals are usually stable and heal well with a splint or cast immobilization. Surgery is recommended in cases of open fractures, multiple metacarpal fractures, or fractures with malrotation and/or excessive angulation.

Base-of-Thumb Fractures

Fractures involving the base of the thumb metacarpal have distinct treatment considerations. In general, these fractures may be extra-articular, simple intraarticular, or comminuted. Extra-articular fractures are typically treated with closed reduction and splinting or casting; in cases of excessive instability or malalignment, surgery can be considered to stabilize the injury. Simple intra-articular fractures of the thumb metacarpal base are often referred to as Bennett fractures. These injuries are often quite unstable; percutaneous pin fixation or formal open reduction and internal fixation is often needed to restore the joint surfaces and realign the thumb. Rolando fractures refer to more complex, comminuted fractures of the thumb metacarpal base and are treated with surgical reduction and fixation.

Specific Injuries: Ligamentous

PIPJ Dislocations

Dislocations of the PIPJ are common, and the vast majority are treated with closed reduction, buddy taping, and early range-of-motion exercises. In rare situations where a dislocation is associated with a large avulsion fracture from the base of the middle phalanx, the joint may be persistently unstable. In these situations, surgery is recommended to reduce and stabilize the bony injury in order to keep the joint reduced.

Metacarpophalangeal Joint Dislocations

Metacarpophalangeal dislocations most commonly affect the thumb, index finger, and small finger. The vast majority may be treated by closed reduction, with excellent outcomes. Closed reduction is performed with the wrist flexed (to loosen the tension of the flexor tendons) by first hyperextending the MCP joint, followed by longitudinal traction and a subsequent downward (or palmar) pressure applied to the base of the proximal phalanx. In rare situations, immediate, straight longitudinal traction will cause soft tissue to be interposed into the joint, thus preventing closed reduction. In these situations, surgical reduction is required. In general, careful X-rays of the affected joint, including a true lateral view, are necessary to confirm adequate joint alignment following a closed or open treatment.

Gamekeeper's (or Skier's) Thumb

Gamekeeper's thumb refers to a tear of the ulnar collateral ligament of the thumb MCP joint, often resulting from a twisting injury or fall onto an abducted thumb. Patients will present with pain, swelling, and tenderness over the ulnar aspect of the joint. Instability with stress testing of the thumb, with the joint both in extension and in 30° flexion, will confirm the diagnosis. X-rays are often normal; MRI may assist in confirming the diagnosis but is typically not needed. In complete tears—particularly when there is gross instability in both extension and flexion—the avulsed stump of the ligament may be pulled away from its bony insertion, and soft tissue (the adductor pollicis aponeurosis) may be interposed. In these situations, surgical repair is recommended to provide joint stability and to maximize outcomes.

Specific Injuries: Tendon

Mallet Finger

Mallet finger refers to a disruption of the extensor tendon as it attaches to the distal phalanx—typically the result of an axial load. Patients will present with a "droop" and inability to actively extend the DIPJ. X-rays are taken to ensure that there is no associated bony fracture. Mallet injuries are treated with full-time splinting of the DIPJ in full extension for 6 weeks, leaving the PIPJ free. In cases where there is a large bony avulsion fracture and associated joint instability, surgery may be considered.

Jersey Finger

Jersey finger refers to a closed avulsion of the flexor digitorum profundus tendon from its insertion on the distal phalanx. Most often affecting the ring finger, this condition commonly occurs when an athlete grabs the jersey of another player while he or she is running away. Findings may be subtle, and careful examination for isolated DIPJ flexion is necessary to make the diagnosis. Surgery to reattach the flexor tendon to the bone is recommended within 5 to 7 days for these injuries. In situations where the diagnosis is not made acutely or treatment is delayed, multiple surgical procedures may be necessary, with mixed outcomes.

Flexor Tendon Lacerations

Cuts in the palmar aspect of the fingers or hand may result in flexor tendon lacerations. Careful examination of the digit will demonstrate an extended resting posture of the finger and an inability to actively flex the affected part (image e). Often, there is an associated laceration of the digital artery or nerves. After initial wound irrigation and skin closure, an early hand surgery referral is recommended, as these injuries are best treated surgically within 7 days of injury.

Miscellaneous Injuries

Fight Bites

The term *fight bites* refers to wounds sustained in the dorsum of the hand (the MCP joints) from a clenched-fist blow to the mouth. Despite the innocuous appearance of the wounds, there are a high percentage of cases in which the tooth penetrates the MCP joint(s), resulting in infection and bony or cartilaginous defects. After initial irrigation and appropriate doses of antibiotics, these injuries should be evaluated immediately by a hand surgeon. Surgical exploration and irrigation are recommended acutely, even when signs of infection are not initially present.

(e)

Source: Courtesy of the Children's Orthopaedic Surgery Foundation, Boston, Massachusetts.

Note: Note the extended posture of the affected finger in relationship to the adjacent uninjured digits.

Nail Bed Lacerations

Crushing injuries to the fingertips often cause nail bed lacerations, particularly in the setting of associated distal phalangeal tuft fractures and large subungual hematomas. Treatment typically involves removing the fingernail, cleansing the wound, and repairing the nail bed with sutures. This may be effectively achieved under a local anesthetic in the office or in the emergency department setting.

Fingertip Avulsions

Soft tissue avulsions of the fingertip or "pad" are common, particularly in younger children. In general, soft tissue loss of the fingertip may be successfully treated with local wound care and dressing changes provided no underlying bone is exposed and the area of skin loss is less than 1 square centimeter. In cases of exposed bone or larger areas of involvement, referral to a hand surgeon is advised for consideration of surgical treatment.

Handlebar Palsy

Bicycle riding is a common recreational activity. While most of the medical community is focused on head protection, and rightly so, there are other injuries that occur as overuse injuries in the more than casual rider. Handlebar palsy is a common result of too much pressure on the lateral (little finger side) side of the hand, which compresses the ulnar nerve and creates a pins-and-needles sensation (paresthesias) in the ulnar one and a half fingers (the little finger and the little finger side of the ring finger).

Anatomy

The relevant anatomy of the ulnar side of the hand (hypothenar eminence) is the Guyon canal. the Guyon canal is bordered by the pisiform bone, the hamate bone, and the ligament that attaches them. The ulnar artery also runs through this same canal. The ulnar nerve provides sensation to the ulnar one and a half fingers and motor function to most of the intrinsic muscles of the hand.

Clinical Evaluation

History

Commonly, a rider will come in complaining of paresthesias in the ulnar nerve distribution of the hand. This often occurs during a long ride initially, but often, it becomes progressively worse and can occur earlier on rides. Some athletes only have symptoms at night. The sensation of pins and needles can linger after the ride from as little as a minute to as long as a few hours. The athlete may also complain of some grip weakness. The rider's mileage and terrain should be considered, looking for any significant changes or increases. Any previous history of trauma to the neck, elbow, or hand is important as well. Any injury to the ulnar nerve along its course can cause similar symptoms. A fall off the bike onto the ulnar side of the hand could fracture the hook of the hamate and could also injure the nerve.

Physical Exam

The evaluation starts with a good cervical spine exam, trying to exclude a cervical disk problem as well as a possible thoracic outlet issue. Following the cervical spine examination, a thorough examination of the elbow and the ulnar nerve as it passes through the cubital tunnel is essential. Finally, an evaluation of the hand and wrist is undertaken. The Tinel test (tapping over the nerve as it runs through The Guyon canal) that is positive (paresthesias) is somewhat indicative of an ulnar neuropathy. Compression sign is also another specific test employed in diagnosing this entity. The examiner places a thumb over the Guyon canal and presses hard enough to blanch the nail bed and holds that compression for about 30 seconds. If this reproduces the paresthesias, it is considered a positive test.

When evaluating a cyclist for an injury, especially an overuse injury, the bike should be examined as much as the athlete. A proper bike fit for the cyclist is paramount for decreasing the risk of overuse injuries. Improper hand position on the handlebars or a too far forward position places too much pressure on the hands. Also, if the rider locks his or her elbows, it can result in too much force being applied to the hands.

Diagnosis

The diagnosis of ulnar neuropathy is mainly a clinical one. If the diagnosis is difficult, then one may start with a plain X-ray to look for a fracture (if there was a trauma). Advanced imaging (i.e., magnetic resonance imaging, MRI) is less helpful in diagnosing ulnar neuropathy unless there is a concern of a ganglion cyst or an ulnar artery aneurysm (both relatively rare entities). The use of electrodiagnostic testing is most common. The use of EMG/NCV (electromyography/nerve conduction velocity) testing can be diagnostic. The examiner must also consider that the paresthesias may be an early sign of an underlying medical condition, such as diabetes or thyroid dysfunction.

Treatment

Nonsurgical

Often, addressing training errors is the most important issue. Rapid increases in the duration, frequency, or intensity of training can increase the risk for any overuse injury. Then one needs to address the rough-terrain riding and how the handlebars are gripped. Teaching the rider to "hold" the handlebars and not to "grip" them is important.

Oral anti-inflammatory medications can be helpful, as well as working with a physical/occupational therapist. A wrist splint is employed to prevent the excessive motion and stretching of the nerve.

Clinicians usually find that the affected hand is the one that does not reach for the water bottle. Therefore, teaching the rider to alternate hands when reaching for the water bottle can be very helpful. Changing grip types and positions often is also helpful.

Bike modifications/changes are also part of the treatment. Doubling the handlebar padding and/or adding gel padding to the riding gloves can remove the pressure. Raising or shortening the stem height can also be of benefit.

Surgical

If the nonsurgical treatments do not resolve the symptoms, then surgical intervention is a viable option. The surgery involves releasing the ligament that extends between the pisiform and hamate bones and that forms the roof of the Guyon canal. Once the ligament is divided, the skin is closed.

Further Readings

Garrett WE, Kirkendall DT, Squire D, Kitowski MD, eds. *Principles and Practice of Primary Care Sports Medicine*. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.

Mellion MB, Burke ER. Bicycling injuries. Clin Sports Med. 1994;13(1).

Head Injuries

Head injuries are a common occurrence in organized sports and recreational activities, such as hockey, soccer, football, skiing, snowboarding, and cycling. Many sports, such as hockey and football, and recreational activities, such as bicycling, require helmets to prevent head injuries. Head injuries can range from minor contusions, lacerations, and superficial hematomas to more serious conditions including concussions, skull fractures, and intracranial hemorrhages.

Head injuries incurred by participation in sports and recreational activities are responsible for a significant number of visits to emergency departments and physicians' offices each year. More than 10% of all visits to emergency departments are for head injuries, and 3% of all sports-related injuries presenting to emergency departments are head injuries. The majority of sports-related head injuries occur in people under 20 years of age.

Anatomy

The brain is enclosed in the bony skull (cranium). Between the cranium and the brain are three layers of *meninges* (mater). (1) The outer dura mater encloses the venous sinuses. (2) The arachnoid mater bridges the sulci on the cortical surface of the brain. (3) The pia mater is a delicate vascular membrane lining the cerebral cortex. There are also three potential meningeal spaces: (1) the epidural space between the cranium and the dura, (2) the subdural space between the dura and the arachnoid, and (3) the subarachnoid space between the arachnoid and the pia, containing cerebrospinal fluid.

The brain comprises the left and right cerebral hemispheres. The cerebral hemispheres are divided into lobes corresponding to the overlying cranial bones: frontal, parietal, occipital, and temporal. The cerebral cortex is made up of *gyri* (folds) and *sulci* (grooves). The cerebellum and brainstem, consisting of the medulla oblongata, pons, and midbrain, are located posterior and inferior to the cerebral hemispheres.

Evaluation of Injuries

Head injuries can potentially be very serious. Loss of consciousness may indicate a very serious head injury. An unconscious athlete may also have a neck injury and, therefore, should not be moved from the field until the neck has been appropriately immobilized by trained health care personnel. If the airway is compromised or there are signs of neurological deterioration, such as posturing or pupillary abnormalities, the athlete should be intubated and hyperventilated by trained personnel (e.g., a doctor or a paramedic). The athlete should be transported on a spinal board by ambulance to the nearest trauma center immediately (Table 1).

A conscious athlete with a head injury should be removed from the field of play and examined by medical personnel as soon as possible. The athlete should not be left alone and should be frequently reassessed for any signs of deterioration.

Details of Injury

The mechanism of injury may give an indication of the type of injury. Head injuries may result in loss of consciousness, amnesia, or vomiting. Additional symptoms may include headache, nausea, or difficulty concentrating. Athletes may seem

Table 1 Indications for Immediate Transfer to Hospital of an Athlete With a Head Injury

dazed, irritable, or moody or may have difficulty answering questions.

The athlete's orientation, memory, and concentration may be affected. Orientation can be assessed by asking questions about the game, such as the opposing team, the score, and the position played. Memory can be evaluated by asking questions about events prior to the injury, such as when the last game was played, how the team got to the venue, or what the athlete did prior to the game. Immediate and delayed memory can be assessed by asking the athlete to recall a list of five words immediately and at the end of the assessment. Concentration and mental processing speed can be evaluated by asking the athlete to recite the months of the year backward or to do serial sevens. The athlete's ability to do the test may be affected by the injury, resulting in slow responses or mistakes.

Physical Findings

The level of consciousness in any athlete with a head injury can be assessed by using the Glasgow coma scale (Table 2). If the athlete is unconscious, neck immobilization should be performed by qualified medical personnel. Any athlete with a Glasgow coma score less than 13 should be rapidly transported to the nearest hospital for further evaluation.

Conscious athletes should be removed from the field of play. There may be areas of tenderness, lacerations, hematomas (large bruises under the skin), bleeding from the ears, or leakage of cerebrospinal fluid from the nose. Head injuries may result in neurological abnormalities, such as seizures, decreased vision, impaired eye movements, weakness, loss of sensation, or gait abnormalities. An athlete with any neurological abnormalities should be transported to a hospital promptly for further evaluation.

Athletes who are stable should be watched carefully on the sidelines by trained personnel to detect signs of deterioration. If there are signs of deterioration, the athlete should be assessed in hospital.

Investigations

On-Field/Office Assessment

There are various quick assessment tools that can be used on the field or in the office, including the Maddocks questions and the Standardized Assessment of Concussion (SAC). The most recent tool was developed by the Concussion in Sport Group at the Second International Conference on Concussion in Sport. The Sport Concussion Assessment Tool (SCAT) assesses orientation, immediate and delayed memory, and concentration. It can be downloaded from www.thinkfirst.ca.

Neuroimaging

Most head injuries do not require diagnostic imaging. If there are any neurological signs, such as seizures, decreased level of consciousness, or pupillary abnormalities, computed tomography (CT) or magnetic resonance imaging (MRI) should be performed to rule out any intracranial injury (Table 3).

Athletes with complex concussions and prolonged concussive symptoms should have imaging studies done (CT or MRI) as well as formal neuropsychological tests. In cases of simple concussion, imaging studies are typically normal and, therefore, are not routinely indicated. MRI is more sensitive to detect subtle structural injuries to the brain, such as contusions or diffuse axonal injury (DAI). Specialized imaging techniques are available in some centers that may be able to detect brain injuries following a concussion. These techniques include single-photon emission computed tomography (SPECT), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI). These tests are not routinely available or indicated.

Note: GCS = Glasgow Coma Scale.

Neuropsychological Testing

Head injuries can result in cognitive-functional deficits, such as impaired attention and concentration, mild disorientation, and memory difficulties. In athletes who have sustained a head injury and who experience persistent symptoms, neuropsychological testing can help identify specific areas of impairment and can help guide return-to-play decisions. Ideally, baseline data should be obtained prior to the occurrence of a head injury so that athletes can be compared with their own baseline following an injury to determine any deficits. Baseline data are also recommended because neuropsychological tests can be adversely affected by many factors, such as test anxiety, learning disabilities, previous head injuries, psychiatric disorders, and attention deficit disorders. Even in the absence of baseline data, neuropsychological assessment can provide objective information to help guide return-to-play decisions.

A unique concern with neuropsychological testing in pediatric athletes is that children and adolescents are undergoing rapid cognitive development. Studies have shown that there is significant improvement in simple and choice reaction time, working memory, and new learning in children between the ages of 9 and 18, with the biggest changes noted between 9 and 15 years of age. These developmental improvements can potentially confound the results of postinjury tests because cognitive impairments resulting from injury may be offset by maturational improvements. Baseline testing in pediatric athletes should therefore be repeated every 4 to 6 months to account for developmental improvements in performance.

Types of Injuries

Table 4 provides data on head injuries resulting from participation in sports.

Prevention of Injury

Many sports-related head injuries can be prevented. Appropriate protective equipment, including approved helmets, is required for participation in contact sports, such as hockey and football. Approved helmets should also be worn for recreational activities with a significant risk of head injury, such as cycling, skiing, and snowboarding. It is important to wear the equipment properly and ensure that it is well maintained. Damaged equipment should be promptly replaced.

It is important for all participants in sports, including athletes, parents, trainers, and coaches, to realize that helmets will not prevent all head injuries, particularly if athletes are participating in high-risk behaviors. Athletes should respect the rules of their sport and practice fair play to minimize the risk of head injury to themselves and others. Coaches and trainers must ensure that athletes learn the proper techniques of their sport to prevent head injuries.

Enforcing the rules of the particular sport will also help prevent head injuries. Limiting checking in hockey in younger age-groups, banning checking from behind, and eliminating fighting can help prevent head injuries in hockey. Equipment changes, such as padded goalposts in soccer and football, can help decrease the incidence of head injuries. Discouraging participation in sports in which intentional head injury is encouraged can also decrease the incidence of head injuries.

Return to Sports

Any athlete who is still symptomatic from a head injury should not participate in sports. Certain head injuries can be quite serious and may preclude return to contact sports (Table 5). Intracranial hemorrhages requiring surgery are a contraindication to resuming contact sports. An athlete who has sustained an intracranial hemorrhage not requiring surgery or who has a complete recovery may contemplate a return to contact sports a year or longer after injury in selected cases. However, this decision should be made after extreme deliberation between the physician and the athlete.

For other, less serious head injuries, such as concussions, athletes should rest from sports until they are completely asymptomatic. Athletes should not return to play on the day of injury because symptoms may evolve and progress later that day or the next day. Once they are completely asymptomatic

at rest for several days, they should progress through a medically supervised stepwise increase in activity to resume their sport. If symptoms recur during this stepwise process, the athlete should rest for 24 to 48 hours and try to progress again.

Headache, Exercise-Induced

Exercise-induced (exertional) headaches—the kind a person gets as a result of physical exertion—affect between 1% and 40% of athletes and exercisers at least once in their lives. Runners, swimmers, divers, rowers, cyclists, aerobic exercisers, and weight lifters are in the high-risk group, and men in their 20s are the gender and age-group most often affected. The headaches can go away in as little as 5 minutes or can last as long as 2 days. At least half of them go away quickly.

Other than causing immediate discomfort, most exercise-induced headaches are usually harmless. According to the National Headache Foundation, however, up to 10% of them are caused by potentially serious underlying problems, such as tumors, sinus infections, or defective blood vessels in the brain. A study conducted in New York and published in the journal *Neurology* found that exertional headaches were a symptom of heart disease in a very small group of patients. People who exercise and get headaches as a result may need medical help to learn how to tell the difference between headaches that are benign and those that are potentially life threatening.

Causes

There are several theories but very little compelling medical evidence regarding the cause of exercise-related headaches. Exercise causes an increase in the flow of blood throughout the body, as well as a rise in blood pressure. One theory says that some of that blood reaches the arteries in the scalp and the accompanying dilation of the vessels causes pain.

A second theory suggests that these headaches may be triggered by a previous injury or condition, such as a concussion or chronic migraine headaches. Individuals may not exhibit symptoms at rest but may develop painful headaches with vigorous physical activity.

A third possibility is that air is forced out of the body through airways that are partially closed, which may happen when a weight lifter completes a heavy lift. In this situation, blood flows from the arteries to the head at a normal rate, but the strain caused by lifting increases intracranial pressure while reducing the flow of blood out of the brain through the veins.

There is anecdotal evidence to show that the exercise environment could be a contributing factor. People who live at an altitude below 1,000 feet (304.8 meters) and exercise at altitudes higher than 1 mile (1.6 kilometers) may experience headaches because not enough oxygen-rich blood reaches the brain. Exercising in hot, humid weather is more likely to cause a headache than training or competing in less extreme temperatures.

Headaches can also be sport specific. "Swimmer's headache" affects some people who jump into cold water. "Swim-goggle headaches" are caused, not surprisingly, by goggles that fit too tightly. "Footballer's headache" is a European expression used to describe headaches caused by frequently heading a soccer ball.

Symptoms

Exertional headaches occur during or immediately after strenuous exercise, but at times they can be associated with sneezing, straining, or even sexual intercourse. They have been described as throbbing headaches (as opposed to dull) that affect the whole head, and most of them subside within a few minutes or a few hours after stopping activity. Some athletes report a feeling of nausea but not vomiting. Harmless exercise-related headaches do not get worse over a period of time, they are not usually described as "explosive," and they are seldom, if ever, accompanied by other physical symptoms. When they are, it is important to see a physician.

Treatment

The simplest treatment is to stop or at least modify the activity that causes the headache or to change the setting in which a person exercises.

The anti-inflammatory drug indomethacin is very effective for both treating and preventing exertional headaches (when taken 1 to 2 hours before a physical activity). Over-the-counter pain relievers, such as acetaminophen and aspirin, may also prevent headaches, but aspirin causes gastrointestinal problems in some people.

Applying a cold pack to the head or behind the neck can help numb the pain.

Prevention

The following measures are recommended for prevention:

- Avoid strenuous activities, especially endurance events, and hot, humid, or high-altitude environments, in which exercise-induced headaches are more likely to occur
- Warm up before an exercise session by jogging or performing light calisthenics and cool down afterward by walking several hundred yards.
- Observe the 10% rule: Never increase exercise intensity, duration, or frequency by more than 10% a week.
- Use relaxation, deep breathing, biofeedback, and imagery before a stressful athletic event.
- Drink 7 to 10 ounces (oz, 1 oz = 29.57 milliliters) of water or a sports beverage every 10 to 15 minutes during strenuous exercise.
- Take breaks to avoid overheating.
- Take an aspirin, acetaminophen, indomethacin, or propranolol before exercising. (Propranolol and indomethacin must be prescribed by a physician.)

Heat Illness

Heat-related illness occurs when the body is unable to transfer enough heat through the skin to keep the body's core temperature from rising to a dangerous level. During hot weather, especially with high humidity, the normal regulation of body temperature through sweating and evaporation may not be enough. Overexertion under such conditions can place exercising athletes at risk for heat illness. Older adults, young children, and those who are sick or overweight are most at risk. Drinking fluids, replenishing salt and minerals, and limiting exposure to heat can help. This entry describes the mechanisms of thermal regulation, the forms of heat illness and their treatment, risk factors, and recommendations for prevention.

Thermal Regulation

Physical work generates heat, and the human body is capable of efficient heat dissipation and temperature regulation. As exercise begins, heat production exceeds heat loss, creating an increase in the core temperature. Receptors in the brain and muscles detect the increase in temperature and produce increased blood flow to the skin, initiating sweating. External heat from the environment can also trigger heat-dissipating mechanisms. The diversion of blood flow to the skin also affects performance, with an increase in perceived exertion and earlier fatigue.

Heat transfer from the body is accomplished through the processes of radiation, convection, conduction, and evaporation. Radiation produces loss of heat energy through emission from the skin and is most efficient at temperatures less than 68 °F. If ambient temperature exceeds skin temperature, then radiation is ineffective and may result in heat gain. Convection leads to heat dissipation through loss of heat energy to the air and depends on the wind, becoming ineffective with increasing ambient temperatures. Heat is lost via conduction when heat is transferred from a warmer to a cooler object by direct physical contact. Loss of heat through evaporation occurs when heat is dissipated through the evaporation of sweat from the skin. With increased ambient temperatures, evaporation is a very effective mode of heat dissipation, but it becomes less effective with humidity over 75%.

Heat dissipation mechanisms maintain core temperature from 95 to 104 °F. Despite effective heat dissipation, the circumstances of exercise and the environment may lead to inadequate heat loss. With increased intensity of exercise, the amount of heat produced increases and may exceed the body's ability to dissipate heat, resulting in an increased core temperature. The environmental temperature and humidity also significantly affect the processes of heat dissipation, particularly the effect of high humidity on evaporation. As exercise is continued, dehydration may develop and decrease sweat production. As these systems continue to fail, the core temperature continues to rise.

Clinical Manifestations of Heat Illness

Heat Edema

Symptoms of mild swelling of the hands and feet occur during the first few days of heat exposure. The elderly are more susceptible to heat edema, which typically is resolved with leg elevation and proper acclimation.

Heat Rash

Heat exposure leads to an inflammatory reaction with a rash consisting of small red spots resulting from blockage of the sweat pores. The associated symptoms often include itching, which can be treated with antihistamines. Less commonly, secondary bacterial infections may occur and require antibiotic treatment.

Heat Cramps

Heat cramps involve painful, involuntary spasms of the muscles after exercise in the heat. The calf muscles are most frequently involved. Electrolyte imbalance and dehydration are the suspected etiology. Treatment includes rest, massage, stretching, and hydration.

Heat Syncope

Pooling of blood in the leg muscles causes an athlete's blood pressure to drop, leading to insufficient blood flow to the brain. If the athlete develops dehydration or has inadequate cooldown after running, the problem seems to worsen. Placing the athlete in a cool environment with legs elevated, along with rehydration, will typically resolve the symptoms. An assessment for possible cardiac or neurological causes is essential.

Heat Exhaustion

The athlete may develop fatigue, weakness, headache, lightheadedness, confusion, or a lack of coordination. The core body temperature measurement rectally is below 104 °F. Symptoms are theorized to result from an inadequate cardiac response to the heat stress and the effect of increased temperature on the central nervous system. Complete assessment and close temperature monitoring are essential as progression to heat stroke is possible. Treatment includes rapid cooling and rehydration, combined with close monitoring in an appropriate medical facility.

Heat Stroke

Heat stroke is the most advanced in the spectrum of heat illnesses, and it is important to note that any of the less severe forms of heat illness may rapidly progress to heat stroke. Early recognition and prompt treatment of heat stroke are essential to lessen the risk of morbidity and mortality. The classic symptoms include a dry, hot skin without sweating; altered mental status; and rectal temperature >104 °F. Athletes, however, may still demonstrate sweating. Heat stroke may lead to serious organ system damage, such as acute kidney failure and rhabdomyolysis (destruction of muscle cells leading to multiple physiologic complications). Rapid reduction in body temperature is the first priority to enhance recovery and minimize organ damage. Immersion in ice water can rapidly decrease the core body temperature to 102 °F in about 10 to 40 minutes. Cooling with ice packs in the groin and axilla, along with cool mist fans, is also useful. The causes of altered mental status other than heat stroke must be considered during assessment. Infections, stroke, drug use, and hyponatremia (low blood sodium) are also part of the differential during evaluation. Checking the blood sodium is central to ensuring correct treatment with intravenous solutions.

Risk Factors and Prevention

Many different factors may contribute to an athlete's risk of developing heat illness. The most significant factor relates to proper hydration. Thirst occurs after about 2% loss of weight and is an inaccurate measure of hydration. Regular replacement of fluids with cool water is recommended for the exercising athlete. Since there is not much salt in the sweat of athletes, water is most appropriate to maintain fluid concentration in the body and is most easily absorbed into the system. Exercise for more than 1 hour benefits from the use of a dilute concentration of about 6% of an electrolyte and glucose polymer solution.

Acclimatization is an adaptive process whereby repeated heat exposure leads to improved cardiovascular and metabolic efficiency. Typically, acclimatization develops within 7 to 10 days of heat exposure and is sustained for about 2 weeks. The elderly and children have less ability to acclimatize.

The Wet Bulb Globe Temperature combines ambient temperature and humidity to assess the safety of exercise in a particular environment. Additionally, clothing, equipment, and time of day may affect the body's heat-dissipating ability. A prior history of heat injury and febrile illness also increases the risk of heat illness. Use of some medications, such as diuretics, antihistamines, beta blockers, and stimulants, can predispose the athlete to heat injury, so they must be used with caution.

Hepatic Injury

Serious abdominal injuries occur, but these are relatively uncommon in sports. Some estimate that 7% to 10% of athletic trauma is related to the abdomen.

Anatomy

The spleen and the liver are solid organs located in the peritoneal cavity inside the abdomen. The liver is in fact the largest organ in the body, weighing 1 to 1.5 kilograms (kg) and representing 1.5% to 2.5% of lean body mass. The size and shape vary and typically match the general body shape. It is located in the right upper quadrant of the abdomen, under the right lower rib cage against the diaphragm, and projects for a variable extent into the left upper quadrant. The liver is held in place by ligaments attaching it to the diaphragm, the peritoneum, the great vessels, and the upper gastrointestinal organs. About 20% of hepatic blood flow comes from the hepatic artery and is oxygen rich; the other 80% comes from the portal vein arising from the intestines, stomach, and spleen. This blood source is rich in nutrients.

The risk of hemorrhagic shock from blunt abdominal trauma may be greater in athletes; ultrasound imaging has shown that the right and left lobes of the liver, plus the great vessels, are of greater diameter in well-trained endurance athletes than in sedentary adults.

Function

Hepatocytes (liver cells) perform numerous and vital roles in maintaining health and homeostasis. Their functions include the synthesis of proteins (albumin, coagulation factors, and hormones), the production of bile, the regulation of nutrients (glucose, glycogen, lipids, cholesterol, and amino acids), and the metabolism and conjugation of lipophilic compounds (bilirubin, cations, and drugs) for excretion in the bile or urine. The measurement of these activities to assess liver function is possible, the most commonly used being serum bilirubin, albumin, and prothrombin time (which is prolonged when coagulation factors are not being synthesized well).

Epidemiology

Although the spleen was previously asserted to be the most commonly injured intra-abdominal organ, the incidence of liver injuries may be similar. This is not surprising, considering the large size, soft substance, and unprotected position of the liver. With the evolution of computed tomography (CT) scanning, recognition of minor liver injuries has been enhanced.

There have been several case reports of hepatic traumatic injury incurred during contact sports, such as football. High-speed noncontact sports also have mechanisms that can result in hepatic injury. Motor vehicle accidents and bicycle-related events resulting in hepatic injury are reported with higher frequencies in some series. Often, other organs are also injured should the liver be involved. In the abdomen, this is most often the spleen, followed by a kidney, the pancreas, and the bowel. Head injuries, thoracic injuries, and fractures are often comorbidities, particularly in high-speed mechanisms.

Bicycle handlebar injuries have been reported to result in trauma to the liver or the biliary tract. Bicycle handlebar injuries resulting in hospitalization are reported to have an incidence of 1.15 per 100,000 in the pediatric population (18 years or less) in the United States.

Injury Mechanics

Injury can result from a direct blow, especially to the right upper quadrant; a sudden deceleration; or a fracture that displaces the right lower rib. In deceleration injuries, the liver shears a relatively thin capsule from the underlying attached parenchyma, usually at the site of the attaching ligaments. Direct blows can cause crush injury to the liver, which may result in subcapsular or intraparenchymal hematoma. Contracoup injuries are seen in children; hence, the trauma can be indirect, and contact may be to a location away from the right upper quadrant of the abdomen, where the liver lies.

Lacerations and contusions of the liver are seen and can have subacute presentations with potentially catastrophic late hemorrhage and a high mortality risk.

Severity Grading

Liver injuries are graded using the American Association for the Surgery of Trauma scale, with a spectrum from Grade I or Grade II injuries, which are considered minor (80%–90% of all injuries), to Grade III to Grade V injuries, which are severe, and Grade VI injury, which is usually fatal.

Risk Factors

Hepatomegaly results in an increased risk of injury, not only because of the increased size but also because an enlarged liver is softer than normal. Therefore, hepatomegaly is a contraindication for high-speed or contact sports.

Clinical Evaluation

The mechanism of injury, especially for lower rib fractures, is much more important than the physical exam to diagnose a possible liver injury. Individuals with liver injury who complain of right upper quadrant pain may have radiation of pain to the right shoulder or neck. These symptoms may be accompanied by nausea and vomiting. The physical exam technique should follow the traditional medical model of inspection, palpation, percussion, and auscultation. On inspection, an abrasion/contusion over the right upper abdomen may be noted; the back and flank should be regarded too in case of missed bruising. Injured athletes are typically tender in the right upper quadrant and sometimes demonstrate abdominal guarding, in which case the abdominal wall musculature is involuntarily taut. The ribs overlying the liver may also be tender. Percussion can help determine the presence of peritonitis, and auscultation can illicit bowel sounds unless an ileus has developed and the intestines have ceased to function. Hemodynamic instability may be present and can be ascertained from vital signs such as elevated heart rate and diminished blood pressure.

Laboratory evaluation may indicate aspartate aminotransferase (AST) and alanine aminotransferase (ALT) elevation, with a sensitivity of 92.9% and a specificity of 100% for a reported hepatic injury.

Management

Hospital management depends on the responsiveness of the patient and his or her hemodynamic status. The conscious athlete who is hemodynamically unstable with peritoneal signs should undergo immediate laparotomy. If the patient is unconscious or his or her physical signs are equivocal, a diagnostic peritoneal lavage (DPL) is recommended. An exploratory laparotomy is indicated if the DPL is positive. If the athlete is hemodynamically stable, a radiologic evaluation such as CT can be undertaken to determine the extent of injury to the liver and to optimize treatment.

An alternative to DPL is ultrasound, which can also be used to screen for hepatic injury. This can be performed in the emergency department and has been shown to be sensitive (85%) and specific (99%) in detecting intra-abdominal injuries.

A CT scan is warranted with any appropriate mechanism. The typical appearance of a liver laceration is illustrated in the image below. An abdominal CT scan is sensitive and specific in diagnosing liver, spleen, and retroperitoneal injuries. One study reported a sensitivity of 100% and a specificity of 96.8% prior to surgical exploration. The radiological grade on the CT scan alone may not predict a clinical outcome reliably in

pediatric patients. Liver injury outcomes may correlate more strongly with associated injuries at presentation and hemodynamic instability in this setting.

Unstable patients should have an immediate laparotomy. However, even high-grade injuries can be managed nonoperatively despite an imposing appearance on the CT scan if the patient is hemodynamically stable. Nonoperative management was originally successful in children, but this has now extended to adults. It involves careful hemodynamic monitoring, frequent physical exams and laboratory evaluations (e.g., serial hemoglobin/hematocrits), and strict bed rest. Hemorrhage from the liver typically occurs in the first 24 hours after injury, unlike the spleen, which can have delayed bleeding when injured. Hemorrhage from the liver is uncommon and is reported in less than 2% of the cases managed nonoperatively. Bleeding will often stop spontaneously (in 50–80% of all injuries), and even when a liver injury is determined in need of an operative approach, 70% of the time bleeding has ceased by the time of laparotomy.

With a stable clinical course, a CT scan will often be repeated after 5 to 7 days. In one investigation of hemodynamically stable children with isolated hepatic traumatic injuries managed with observation, all were discharged 48 hours after the injury if they had no abdominal tenderness, tolerated a regular diet, and had a stable hematocrit (see image, top of this page).

Return to Sports

Expert opinion previously asserted that return to play is only possible with clinical healing and an entirely normal CT scan. This often takes weeks to months to achieve after injury and has provoked some controversy recently. There are no return-to-play criteria; common sense would suggest normalization of liver function test enzymes (alanine transaminase [ALT], aspartate aminotransferase [AST]) plus a normal physical exam and a return to symptom baseline to be prerequisites for return to sports.

Hepatitis

Hepatitis is a general term that refers to inflammation of the liver. There are many causes of hepatitis, including infections, medications, toxins, and autoimmune diseases. Of the infectious etiologies, the most common are infections with the hepatitis A

(HAV), hepatitis B (HBV), and hepatitis C (HCV) viruses. These viruses account for more than 90% of cases of acute viral hepatitis. Acute infection with all three hepatitis viruses can result in similar clinical manifestations, including fever, abdominal pain and loss of appetite, nausea, fatigue, and jaundice. Most cases of acute viral hepatitis resolve spontaneously and carry an excellent prognosis for complete recovery. Less than 0.1% of infected individuals die as a result of acute viral hepatitis. The most common cause of death in the setting of acute viral hepatitis is the development of massive liver necrosis. A possible complication following acute infections with HBV and HCV leads to the development of chronic hepatitis.

It is estimated that there are more than 500,000 new cases of viral hepatitis each year in the United States alone, that more than 1 million Americans are chronically infected with HBV, and that greater than 3 million have chronic HCV infection. Of those individuals with chronic hepatitis, approximately 15,000 will die as a result of complications related to chronic liver disease, such as cirrhosis and hepatocellular carcinoma.

Given the high prevalence of viral hepatitis, athletic individuals are at risk for developing this disorder. Although athletes are much more likely to contract viral hepatitis as a result of activity unrelated to sports, a small risk of disease transmission during sporting activity does exist. Once an individual is diagnosed with viral hepatitis, concerns may be raised regarding the safety of ongoing sports participation. This entry will address the issue of exercise participation in the setting of acute and chronic viral hepatitis, examine the risk of disease transmission during sports participation, and discuss basic strategies to prevent the acquisition of viral hepatitis.

For many years, individuals with acute viral hepatitis were encouraged to avoid physical exertion. Then, studies conducted during the Korean and Vietnam wars, involving soldiers with acute infectious hepatitis, demonstrated that prolonged physical activity restriction was unwarranted. Soldiers who engaged in strenuous exercises once their symptoms became mild had no increased duration of the acute illness, no greater frequency of clinical relapse, and no increased prevalence of chronic liver disease, compared with soldiers who were treated with rest and avoidance of physical activity. A subsequent study involving a small group of patients with acute HBV infection demonstrated the safety of an exercise regimen involving moderate-intensity stationary biking. A joint position statement from the American Medical Society for Sports Medicine and the American Academy of Sports Medicine, published in 1995, recommended that acute HBV infection should be viewed similarly as other viral infections and that an athlete's ability to participate in sports should be based on his or her clinical signs and symptoms such as fatigue, fever, or liver enlargement. Although this publication did not discuss infection with HAV or HCV, there are no data to indicate that infection with these viruses should be managed in a different manner.

The ability of patients with chronic viral hepatitis to participate in athletic activity is quite variable. Those with mild disease activity often tolerate routine exercise quite well, and participation in higher-intensity activity and even competitive sports can be achieved without complications. Studies demonstrating the safety of high-intensity physical activity for patients with more advanced liver disease secondary to chronic hepatitis are lacking. Nevertheless, most patients should be allowed to participate in physical activity as tolerated based on their symptoms. Activity performed within the confines of their exercise tolerance is unlikely to be harmful.

An area of concern for individuals with viral hepatitis is whether the virus can be transmitted during sports participation. Direct transmission of HAV during athletic activity has not been reported. However, outbreaks of hepatitis A among groups of athletes have been seen. In such cases, the source of HAV was contaminated food or beverages consumed by members of the same athletic team. It is important to note that the risk of infection with HAV is particularly high when athletes travel to areas with less ideal hygienic conditions where HAV is endemic. Although the chances of an athlete contracting HBV or HCV are much higher as a result of non–sports-related activity, such as engaging in unprotected sexual activity or using injectable drugs, a small risk of virus transmission does exist when participating in sports where blood exposure can occur. Cases of HBV transmission have been described among sumo wrestlers and participants in American football. In contrast, HCV transmission during sporting activity has never been documented. However, non–sports-related cases of HCV infection through blood exposure raise concern about the theoretical risk of HCV transmission in sports where bleeding is more likely to occur, such as boxing. Relative to the risk of virus transmission with sexual activity and drug use, the chance of contracting HBV or HCV during sports competition is exceptionally low. As a result, it has been recommended that athletes infected with HBV or HCV should not be restricted from participating in any sporting activity.

Although the risk of transmitting viral hepatitis during a sporting activity is extremely low, some basic preventive strategies should be employed to help ensure the safety of the participants. Since contact with blood from an infected athlete poses the greatest risk of HBV and HCV transmission, prompt recognition and treatment of bleeding is critical. Individuals attending to an injured athlete should adhere to the standards of universal precautions. These are guidelines recommended by the Centers for Disease Control and Prevention (CDC) to reduce the risk of exposure to potentially infectious material and involve the use of barriers such as gloves, masks, and protective eyewear to prevent skin and mucous membrane exposure during contact with an injured athlete's blood. Preventive efforts should also focus on immunization, since safe and effective vaccinations against HAV and HBV are widely available. Unvaccinated individuals, or those who did not respond to the vaccine, who experience a known or potentially high-risk exposure to HAV or HBV should receive treatment with immunoglobulin, which is concentrated antibodies against the respective viruses. Additionally, educating health care professionals, as well as athletes, coaches, and sports officials, about viral hepatitis is another important strategy to help prevent the acquisition and spread of this disease.

High Arches (Pes Cavus)

The foot provides multiple functions during standing and gait, including support, shock absorption, adaptation to uneven surfaces, balance, power, and direction. In any running and jumping sport, proper foot mechanics can play a key role in performance. The arch of the foot serves an important role in these functions.

The arch can fall into one of three categories: (1) neutral, (2) pes planus (flat foot), and (3) pes cavus (high arch). Most people are familiar with pes planus, or the flat foot.

The other, pes cavus, describes an abnormally high-arched foot. This type of foot is much less common. The arch is rigid, and the inflexible nature of the pes cavus foot is what creates the problem when considering the biomechanics of gait.

Historically, high-arched athletes were thought to be fast, the arch providing a type of spring. While this is not necessarily true, as described below, athletes with high arches usually need less motion control in terms of shoe type and, thus, often can run in lightweight, cushioning shoes.

Gait Cycle

A review of the gait cycle is helpful in understanding this concept of overpronation and its contribution to injury. The gait cycle consists of four phases: (1) heel strike, (2) midstance, (3) toe-off, and (4) swing. With every run, this cycle is repeated over and over, hundreds and thousands of times.

During the first two phases, the heel strikes the ground with the foot inverted (outside first) and the ankle dorsiflexed (toes pointed up), followed by the foot pronating (rolling inward) as the body weight is loaded onto the foot in midstance. During the last two phases, the foot supinates again as the weight shifts onto the toes, allowing the foot to propel and swing forward. During the cycle, the weight starts at the lateral (outside) side of the hindfoot and ends on the medial (inside) side of the forefoot as one pushes off on the toe.

Foot Anatomy

The arch of the foot is supported by the medial longitudinal, lateral longitudinal, and transverse midfoot arches. Another important structure in the arch is the navicular, which articulates with the talus proximally and the first, second, and third metatarsals distally. Situated at the "roof" of the arch, it plays an important role, accepting and transmitting much of the foot's stress.

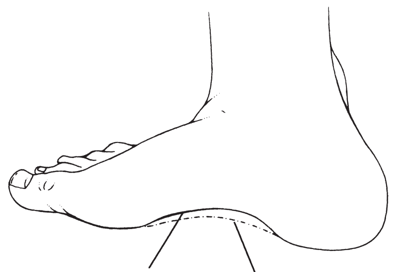
A high-arched and rigid foot will result in shock directly transmitting to these structures.

Pathophysiology

Because the pes cavus foot is rigid and unable to pronate adequately, repetitive stress is placed on the posterolateral structures of the foot. This increases the risk for injuries such as stress fractures. Injuries can also extend proximally up the kinetic chain.

Among basketball or soccer players, the rigidity and lack of pronation can increase the risk for ankle sprains.

Endurance runners or triathletes with pes cavus and high training loads often suffer from metatarsal or tibial stress fractures due to the lack of shock absorption from the pes cavus. Improper shoe choices that do not offer enough cushioning can increase the risk of stress fractures.



History

Patients with pes cavus often complain of repeated ankle sprains and difficulty in finding shoes that fit well. Many shoes do not offer adequate arch support. They may also note changes in the arch and toes, including painful calluses that can develop over time underneath the prominent metatarsal heads.

Endurance athletes may present with stress fracture symptoms as well. In this setting, a detailed history of training load, mileage, as well as other risk factors for stress fracture should be elicited (history of stress fracture, diet low in calcium, and loss of menses in women).

Physical Examination

The foot examination consists of the basic components of inspection, palpation, range of motion, and provocative tests. Inspection of the foot requires observing the foot from multiple views, including anterior, medial, lateral, and posterior. The arch is best assessed directly on the medial view. The plantar aspect of the foot should be examined for calluses under the metatarsal heads. The posterior standing view also provides information about the biomechanics of the foot. In a patient with pes cavus, the heel is noted to be in varus. Claw toes, which often result from the pes cavus foot, may be noted.

Treatment

For those with idiopathic pes cavus that is causing injuries, the standard of care involves shoe modification and arch supports.

In general, shoe prescriptions fall into one of three categories: cushioning, support, and motion control. Due to the rigid nature of the high-arched foot, a cushioning shoe is needed for pes cavus to help alleviate the lack of shock absorption. Each major shoe manufacturer has his or her own technology for shock absorption ("air," "gel," "shox," etc.). The key is choosing a well-cushioned shoe and replacing it every 300 to 500 miles (mi; 1 mi = 1.6 kilometers) before the cushioning breaks down. This will help reduce the risk of stress fractures.

A trial with over-the-counter prefabricated cushioned arch supports is recommended as well. If the support is found to wear out too quickly, a semirigid custom cushioning orthotic may be considered.

Hip, Pelvis, and Groin Injuries

Acute hip and groin pain occurs frequently in sports requiring twisting, pivoting, and kicking, such as soccer, rugby, and football. Symptoms can result from many structures, including the adductor muscles and tendons, the hip joint, and the hip muscles. Mechanisms of hip injury include high-velocity trauma, which may be seen in equestrian events or motor-racing accidents, and overuse injuries caused by altered biomechanics affecting the transfer of energy between the trunk and the lower limb.

Contusions (bruises) and muscle and tendon injuries are the most common injuries of the pelvis and hip. Apophyseal (the bony attachment of tendons) avulsion fractures are common skeletal injuries of the hip and pelvis in young athletes.

Groin injuries are particularly common in sports involving a lot of running, rapid changes of direction, and kicking, particularly kicking across the body. Soccer and Australian football are the two most common sports associated with groin pain. Groin injuries are also seen commonly in basketball, rugby, American football, and field hockey.

The diagnosis and management of injuries to the hip, pelvis, and groin can be challenging. Symptoms can result from numerous causes and are often diffused and insidious. Careful history taking and physical exam are essential to determine the etiology of hip and groin injuries.

Anatomy

Each half of the pelvis is made up of the following bones: the wing-shaped ilium, the pubis, and the ischium. The ilium joins the sacrum at the sacroiliac joint. The pubis and ischium join the opposite side at the symphysis pubis. The head of the femur articulates with the pelvis at the acetabulum, forming a ball-and-socket joint. There are three ossification centers of the femur: the capital femoral epiphysis, the greater trochanter, and the lesser trochanter. There are several apophyses on the hip and pelvis that have large muscle attachments, including the anterior-superior iliac spine (ASIS), the anterior-inferior iliac spine (AIIS), and the ischium. These apophyses have secondary ossification centers that allow for circumferential bone growth. The secondary ossification centers appear between 11 and 15 years of age. These apophyses are weaker than the surrounding tissues, particularly the muscles and tendons attached to them, which can result in avulsion fracture in adolescents.

Several muscle groups in the thigh, including the flexors, extensors, and adductors, attach to various points on the pelvis and hip. The sartorius, one of the quadriceps muscles, attaches at the ASIS. The rectus femoris attaches at the AIIS. These muscles function to extend the knee. The hamstring muscles, including the long head of the biceps femoris, the semimembranosus, and the semitendinosus, originate on the ischial tuberosity. The hamstrings cross both the hip and the knee and are responsible for hip extension and knee flexion. The adductor muscles, the adductor magnus, brevis, and longus, attach along the ischium. The iliopsoas attaches to the lesser trochanter, as does the vastus medialis (Figure 1).

The abdominal muscles attach to the pelvis and the pubic bone. The rectus abdominus attaches to the pubic bone. Other muscles of the abdominal wall include the external oblique, internal oblique, and transverse abdominus muscles. The inguinal ligament runs between the iliac spine or the pelvis and the pubic bone.

Evaluation of Injuries

Details of Injury

Knowledge of the mechanism of injury can help determine the type of injury. Acute traumatic events suggest muscle strains/tears. Certain activities may aggravate the injury. For instance, hip and groin pain is often aggravated by running, twisting/turning, and kicking. Aggravation of pain associated with twisting and turning activities and side-to-side movements suggests adductor-related pain. Pain aggravated by running and kicking suggests iliopsoas problems. Pain aggravated by sit-ups suggests inguinal-related pain. Performance may decrease. Pain that gets progressively worse and interferes with activity suggests possible stress fracture, nerve entrapment, or bursitis. Associated pain in the lower back or buttock indicates that the hip or groin pain may be referred from the lumbar spine or the sacroiliac joint.

The location of the pain can also help determine the structures that may be injured. For example, medial groin pain suggests adductor-related pain, whereas central groin and proximal thigh pains suggest iliopsoas-related pain.

Recent changes in training and competition, such as an increase in volume or intensity or new techniques/exercises, may contribute to an injury. Other risk factors for injury include footwear, surface conditions, and general conditioning, as well as the type of sport. The athlete's age is also important, as some injuries occur only in certain age-groups. For example, avulsion injuries of the pelvis occur only in adolescents.

"Red flag" symptoms such as fever, weight loss, night sweats, and night pain may indicate

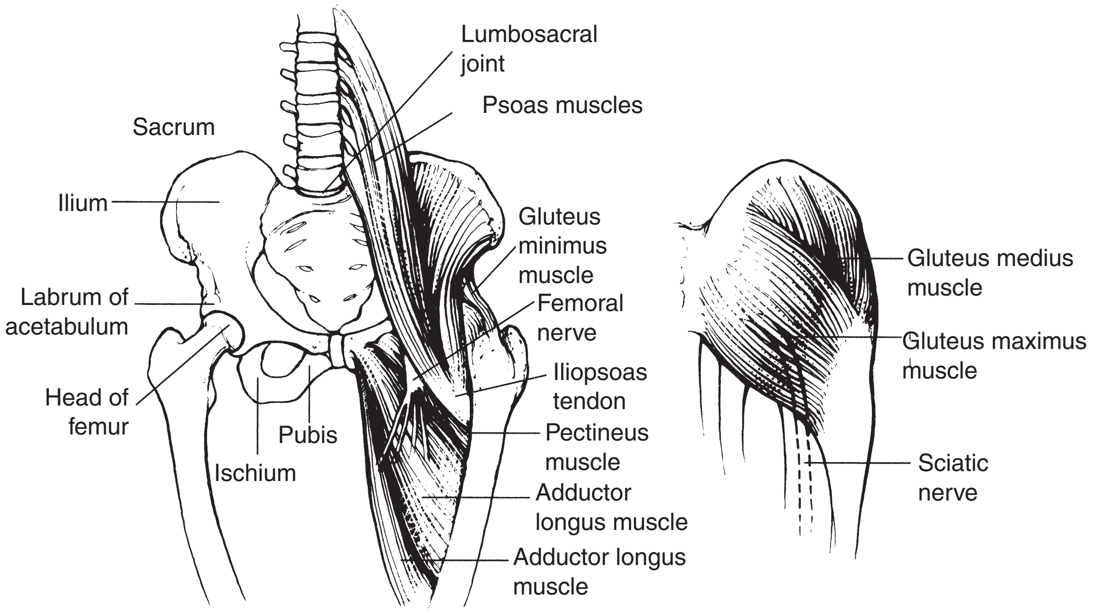

Figure 1 Anatomy of the Hip, Pelvis, and Groin

other causes of hip and groin pain, such as infection or cancer. Pain in the hip and groin region can be caused by abdominal conditions such as appendicitis, kidney conditions, conditions of the uterus or ovaries, and rheumatological problems such as ankylosing spondylitis.

Physical Findings

Hip, groin, and pelvis pain may come from the hip joint, the pelvis, the adductor muscles, the hip flexors, or the abdominal muscles. In addition, the lower back and sacroiliac joint may refer pain to the hip or groin.

An athlete with a hip or groin injury may have abnormalities in his or her gait, such as a limp. The pelvic alignment may be abnormal, or there may be abnormalities of the hips, such as excessive internal or external hip rotation. There may also be muscle wasting, bruising, or other deformities.

Range of motion of the hip may be affected by an injury. There may be decreases in hip flexion, extension, abduction, adduction, and internal or external rotation. The muscles around the hip, such as the adductor and quadriceps muscles, may be tight or may have lost flexibility. Certain tests of the hip may help determine the nature of the injury. A *hip quadrant test* is performed by the examiner, placing the patient's hip in flexion, adduction, and internal rotation. A FABER (*fl*exion, *ab*duction, *e*xternal *r*otation) test is also performed with the patient supine. The examiner places the affected hip in flexion, abduction, and external rotation, with the patient's foot next to the opposite knee. One hand applies downward pressure toward the bed on the flexed knee, while the other hand stabilizes the opposite hip. Pain in the ipsilateral lower back or buttock indicates possible sacroiliac joint pathology. A psoas muscle stretch or Thomas test may indicate hip pathology. The patient lies supine with the hips at the edge of the end of the bed. The examiner overflexes one hip, while the other hip is extended over the edge of the bed. Pain elicited in the flexed hip may indicate anterior impingement of the hip joint. Pain in the extended hip suggests psoas injury. Neural tension can be added to the Thomas test by adding cervical and upper thoracic flexion, then passive knee flexion. A positive test is elicited when the pain is reproduced and then reduced when the added tension is removed.

Strength of the hip and groin muscles may be decreased because of injuries. The athlete may be unable to flex the injured hip against resistance or adduct the hip against resistance. Injuries to the symphysis pubis may result in pain and weakness of muscles as well. While lying on his or her back, the athlete may be unable to squeeze his or her knees together against a fist with the hips and knees flexed. Abdominal muscle injuries (rectus abdominis muscle) may result in weakness, which prevents the athlete from doing a sit-up against resistance. The athlete also will be unable to hop because of muscle weakness or pain.

Injuries may result in tenderness to palpation of the soft tissues or bony tissues around the hip, pelvis, and groin, including the adductor muscles/tendons, the iliopsoas, the greater trochanter, the lesser trochanter, the iliac crest, the ASIS, the AIIS, the ischial tuberosity, the sacroiliac joints, and the buttock muscles. The pubic symphysis, rectus abdominis, and iliopsoas may also be tender to palpation. Hernias may be present on the side of the pain.

Hip stability can be assessed by the Trendelenburg test. With the patient standing, the examiner places his hands on the patient's iliac crests with the thumbs on the sacroiliac joints. The patient then stands first on one leg and then on the other. The patient should be able to keep the pelvis level. If the hip of the lifted leg falls, it indicates weakness of the gluteal muscle and poor hip stabilization.

Investigations

X-rays of the pelvis and hip should be obtained if bony pathology, such as an avulsion injury, slipped capital femoral epiphysis, or Legg-Calvé Perthes disease, is suspected. Bone scan may show increased uptake, which may confirm a stress fracture in the face of negative X-rays. Ultrasound may be used to image suspected muscle tears or confirm inguinal hernias. Magnetic resonance imaging (MRI), with/without an arthrogram, is useful in imaging the hip joint, particularly to diagnose labral tears.

Table 1 Causes of Hip, Pelvis, and Groin Pain

Common	*Uncommon*	*Must Not Be Missed*
Adductor muscle strain, tendinopathy	Iliopsoas strain	Legg-Calvé-Perthes disease
Synovitis of hip	Trochanteric bursitis	Slipped capital femoral epiphysis
Labral tear	Stress fractures (neck of femur, acetabulum, and pubic ramus)	Intra-abdominal abnormality (appendicitis, urinary tract infection, and gynecological pathology)
Chondral lesion	Referred pain (lumbar spine, sacroiliac joint)	Avascular necrosis of femoral head
Osteitis pubis (pubalgia)	Osteomyelitis	Tumors (osteoid osteoma)
Abdominal wall muscle strain (posterior inguinal wall, tear of external oblique, and rectus abdominis tendinopathy)	"Snapping" hip	
	Apophysitis/avulsion fracture (anterior superior iliac spine, anterior inferior iliac spine)	
	Rectus femoris muscle strain	
	Osteoarthritis of hip	
	Nerve entrapment (obturator, ilioinguinal, and genitofemoral)

Types of Injury

Table 1 lists the causes of hip, pelvis, and groin pain.

Prevention of Injury

Not all injuries can be prevented. However, the incidence of injuries can be reduced. Appropriate safety equipment for a particular sport should be worn and properly maintained. Proper stretching, adequate strengthening, and proper warm-up prior to activity can prevent many acute injuries, such as muscle strains. Playing with athletes of a similar skill level can help prevent injuries as well. Overuse injuries can be reduced by employing appropriate training regimens and avoiding training errors. Training errors include increasing the rate, intensity, and duration of training too rapidly. Ensuring the general conditioning of athletes, in particular maintaining flexibility, endurance, and strength, and properly rehabilitating any injuries can help prevent further injuries. Other risk factors such as footwear, playing surfaces, nutritional factors, and associated disease states can be addressed with proper education of athletes, coaches, trainers, and parents.

Return to Sports

The most important determinant of returning an athlete to play is to ensure that the athlete can return safely and effectively. Flexibility and strength should have returned to 80% to 90% of the normal state before the athlete returns to sports to prevent further injury and allow for effective movement. Therapy is a useful adjunct to help monitor the athlete's progress and to gauge the athlete's readiness to return to sports.

For most minor injuries of the hip, pelvis, and groin, such as muscle strains, bursitis, and nerve entrapments, a period of rest to allow the pain to resolve is necessary. This rest period should be incorporated with appropriate therapy, including stretching and strengthening, to allow athletes to regain flexibility and strength. Once the pain has resolved, sports activity can be resumed. For more serious injuries, such as acute fractures and stress fractures, the period of rest may be longer. Once the pain has resolved, there is radiological evidence of fracture healing, and the contributing risk factor(s) has been modified, resumption of activity is possible.

Hip, Pelvis, and Groin Injuries, Surgery for

Injuries of the hip, pelvis, and groin are quite common in sports. Among the most frequently occurring injuries are the following:

- Strains of the adductor and hamstring musculature
- Hip pointers
- Avulsion fractures to the iliac apophysis, the anterior-superior and anterior-inferior iliac spine, the ischial tuberosity, and the lesser trochanter
- Hip labral tears
- Osteitis pubis and sacroiliitis
- "Snapping" hip
- Femoroacetabular impingement
- Stress fractures
- Hip dislocations

In young athletes, it is important to consider other potential causes of hip pain. *Slipped capital femoral epiphysis* is a hip disorder that occurs in adolescents. *Legg-Calvé-Perthes disease* can occur in children between the ages of 4 and 8. Both normal radiographs and magnetic resonance imaging (MRI) can be useful in diagnosing these unique conditions.

Surgical Treatment

Most of the conditions described above do not require surgical intervention. Most can be treated with a period of rest, ice, and anti-inflammatory medications, followed by a focused rehabilitation program. However, it is important to recognize which conditions may go on to require surgical management. The main hip and pelvic conditions that may require surgical management are complete hamstring avulsions of the ischial tuberosity (or in the adolescent athlete, an ischial tuberostiy avulsion fracture), hip labral tears, femoroacetabular impingement, fractures of the proximal femur, and hip dislocations.

Hamstring Strains

Hamstring strains are generally treated conservatively. Grade III hamstring injuries are generally considered more severe and consist of complete tears of the hamstring insertion off the ischial tuberosity (or in skeletally immature individuals, the equivalent would be a displaced avulsion fracture of the ischial tuberosity). If conservative treatment of severe partial or complete tears of the hamstring is unsuccessful, surgical management can be considered. Surgery consists of reattachment of the avulsed tendon off the ischial tuberosity (or in the case of tuberosity avulsion fractures, an open reduction and internal fixation). Some suggest early surgical treatment of complete avulsions due to later retraction of the tendon, and thus, the timing as well as the form of treatment may be controversial in these cases. If lengthening cannot be achieved in chronic tears, an Achilles allograft may be used. Return to sports will be prolonged if surgical management is undertaken, and most likely, it will require at least 3 to 6 months of rehabilitation.

Hip Labral Tears

Initially, hip labral tears are similarly treated conservatively. Labral tears, however, may cause continued pain and catching, which may not resolve as the tear itself will persist. Advances in hip arthroscopy have made surgical treatment possible with less invasive techniques. The labrum can either be debrided or reattached with suture anchors. Rehabilitation will consist of partial weight bearing for 2 to 4 weeks, and return to sports will require at least 6 weeks if a debridement is performed and 3 to 6 months if a repair is performed.

Femoroacetabular Impingement

Femoroacetablular impingement is a condition that is gaining increasingly more attention and refers to abnormal contact between the proximal femur and the acetabulum, leading to further chondral and labral lesions of the hip. Two types of impingement are described: (1) a *cam lesion*, which is a prominence of the femoral head, and (2) a *pincer lesion*, which is the result of acetabular overcoverage. Surgical management consists of excision of the prominence leading to the impingement, either in an open fashion or arthroscopically. Arthroscopic treatment has many advantages, including being less invasive and obviating the need for dislocation or osteotomy, but it is technically much more demanding. Operative management will require prolonged protected weight bearing, and most likely, the injured athlete will not be able to return to sports for at least 3 to 6 months.

Stress Fractures of the Femoral Neck

Stress fractures of the femoral neck may be treated conservatively with non–weight bearing for approximately 6 weeks, progressing to full weight bearing if the fracture is the relatively stable compression type. There is, however, risk of displacement, particularly if the patient is weight bearing. As the blood supply to the femoral head lies along the femoral neck, displacement has implications with regard to healing of the fracture and future avascular necrosis. All distraction-type stress fractures and any patient whose compliance may be an issue should be treated operatively. Nondisplaced fractures of the femoral neck can be treated by placement of cannulated screws across the fracture site if the fracture is unstable or if there is fear of future displacement. Intertrochanteric fractures are treated with different types of fixations—usually, either an intramedullary nail-and-screw device or a plate-and-screw type of fixation—from femoral neck fractures. If treated operatively, fractures should be kept with protected weight bearing for 6 weeks, followed by progressive weight bearing and then rehabilitation. Return to sports will likely take at least 3 to 6 months.

Hip Dislocations

Hip dislocations are considered emergencies. Prompt reduction should be performed, but it should be done in a controlled, hospital setting. Following reduction, weight bearing will be restricted initially, and then progressive weight bearing will be allowed over 3 to 4 weeks. Rehabilitation is then started, but full recovery will be prolonged.

Other Injuries

Although this is much less common, surgical techniques may be used for other injuries to the hip and pelvic region. For chronic adductor strains, adductor releases have been described. For iliopsoas tendinitis, corticosteroid injections can be used. Both the lengthening and the releases have been described for iliopsoas tendinitis through both open and arthroscopic techniques. The same techniques also exist for the treatment of trochanteric bursitis and release of the overlying iliotibial band. These procedures, however, should be reserved only for cases where conservative treatment has failed.

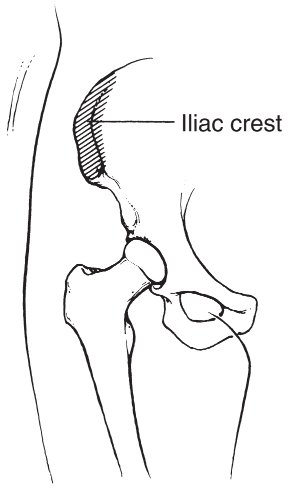

Figure 1 Hip Anatomy

Hip Contusion

A *hip contusion*, also called a "hip pointer," is in actuality either a contusion of the iliac crest and the surrounding soft tissues or a contusion of the greater trochanter of the femur. Typically, this injury occurs in contact sports such as football and rugby and is caused by a direct blow or fall. Obviously, however, this type of injury can also occur in any sport (contact or noncontact) if an athlete falls on his or her hip or side. Most of the time, these injuries are not major, and treatment is aimed at alleviating the symptoms associated with the contusion. In these cases, athletes can return to play as their symptoms resolve.

Anatomy

The anatomy of the pelvis is somewhat complicated and is beyond the scope of this book. Suffice to say, hip contusions can occur when the bony prominences in this area are injured, including the iliac crest, pubic rami, greater trochanter, and ischial tuberosity (Figure 1). The soft tissues in this area are often injured as well, and hemorrhage can occur into the muscle. This hemorrhage may occur almost instantaneously or slowly. If the bleeding into the muscle occurs at a slower rate, the athlete's symptoms and pain may actually worsen 1 day or so after the injury occurs.

History and Physical Exam

A detailed history should be obtained from any athlete complaining of hip pain. This should include the mechanism of injury and a description of the symptoms that the athlete is experiencing. Typically, the athlete can recall the exact injury, and often, the onset of pain is sudden. Activities that stress the area, including running, jumping, or simply walking, can increase the hip pain.

On physical exam, there may be an obvious area of swelling or contusion. The affected area is often very tender. The active and passive range of motion of the hip and nearby joints should be tested. Often, the range of motion of the hip will be limited by pain. The motor strength of these areas should also be tested, and motor strength should be near normal. Specifically, the hip flexors, extensors, abductors, and adductors, as well as the knee flexors and extensors, should be tested. The hip abductor and the external-rotation strength may be slightly decreased due to contusions in these areas. Sensation should be tested as well and should be symmetrical bilaterally to light touch.

Diagnostic Imaging

Plain radiographs can be ordered to rule out other injuries, including avulsion fractures of the iliac apophysis or other pelvic or femur fractures.

Bone scan can be used if a pelvis or femoral stress is suspected, if the initial plain radiographs are normal and symptoms do not improve or resolve over time.

Treatment

Early treatment during the acute phase of hip contusions consists of the RICE protocol—*r*est, *i*ce, *c*ompression, and *e*levation. The aim of these treatments is to control and decrease deep bleeding into the tissues. Anti-inflammatory medications such as ibuprofen, naproxyn, or ibuprogen can provide relief, but giving these too early may increase the amount of bleeding into the tissues. Heat, massage, and physical therapy should not be started for the first 48 hours because they may also increase the bleeding. In adults, after a fracture has been ruled out, local corticosteroids can be injected into the area, which may ultimately help alleviate pain in this area and allow athletes to return to sports quicker. As the pain decreases, passive range-of-motion and then active range-of-motion hip exercises can be started.

Severe muscular contusions can be more challenging to treat. Athletes may require long periods of physical therapy and rehabilitation that focus on maintaining flexibility, strength, and range of motion. Athletes should return to play only after they regain full strength. Early return to play before full strength has been achieved can lead to reinjury.

Complications

Deep contusions of the hip that have occurred in conjunction with significant hemorrhage can result in myositis ossificans. *Myositis ossificans* is a complication of hemorrhage and hematoma formation in the muscle, particularly if this occurs near the origin of the muscle on the bone. This often presents with abnormal bone formation around the injured site. These lesions can take up to 1 year to mature, and often treatment is symptomatic; however, in rare cases, surgical excision may be required.

Hip Dislocation

Dislocation of the hip joint occurs when the head of the femur is displaced from the acetabular socket. This potentially debilitating injury is usually the result of a high-energy impact; although it is relatively uncommon in the arena of competitive sports, it is considered an orthopedic emergency and bears consideration in the setting of any lower extremity trauma.

Anatomy

The hip joint consists of the junction of the femur (thighbone) and the acetabulum (hip socket). The femoral head is round and fits very snugly in the acetabular cup. Because of how well they fit together and the strong muscles around the hip joint, when the femoral head is dislocated, it can be very difficult to replace in the socket. In some cases, complications may result because the blood supply to the femoral head becomes more tenuous as we age. With dislocation, the vessels do not always stretch to accommodate the new position of the femur. If the blood supply is stretched for too long, the vessels may kink and clot, which prevents adequate circulation from reaching the femoral head, potentially leading to the death of that portion of bone.

There are two main ways in which the hip can dislocate. The dislocation is described by the direction in which the femoral head exits in relation to the acetabulum: anterior (in front) or posterior (behind) (see images next page). The posterior type is by far the more common, with the majority of injuries seen in common practice the result of the knee striking the dashboard in a motor vehicle collision.

The sciatic nerve, one of the main nerves of the leg, runs posterior to the hip joint and may be compressed or damaged by the dislocated femoral head. Symptoms of damage to this nerve include

An anteroposterior radiograph of the pelvis demonstrates a posterior-superior dislocation of the right femoral head.

pain and numbness in the foot and leg, as well as difficulty lifting the foot and ankle.

Causes

The most common cause of hip dislocation is motor vehicle collision, followed by falls. However, injury has been reported also as a result of impact in contact sports such as football, basketball, and rugby.

Clinical Evaluation

Symptoms

This injury is the result of a rapid, high-energy impact. Nearly all patients with a dislocated hip will be unable to walk and will complain of pain and decreased range of motion to the hip. Depending on the mechanism, patients may have other injuries to the affected leg, especially to the femoral shaft (midthigh) or the knee. The extremity may appear fixed in a certain position, and the patient will experience excruciating pain if attempts are made to move the leg.

Diagnosis

Patients presenting with hip dislocation will often have a difference in leg lengths or an appearance of the leg that is obviously not normal. If the injury is sustained in a sporting event or from a low-impact trauma, it may be the only injury; in motor vehicle collisions, there are often associated injuries that may even be life threatening.

In the case of *posterior dislocation*, the leg will usually be shortened, internally rotated or turned in, and flexed slightly at the hip. The patient may be more comfortable with a pillow beneath the knee to support the leg in this position.

With an *anterior dislocation*, the leg is often externally rotated, is abducted (angled away from the midline), and may be flexed or extended.

Regardless of the direction of the dislocation, a careful neurovascular exam is critical for the evaluation of the injured patient. The patient should also be subjected to careful scrutiny for other problems; the dislocated hip is often so painful that the patient may not be conscious of other injuries, even if he or she has other broken bones or internal injuries.

Treatment

Nonsurgical Treatment

Hip dislocation is considered an orthopedic emergency. Every attempt should be made to perform closed reduction as soon as it is safe for the patient. Optimally, the femoral head should be placed back in the socket, or reduced, within 6 hours of the injury; however, this should always be attempted in a hospital setting, where appropriate care can be taken to protect the patient.

For all attempts at closed manipulation, the patient must be completely relaxed. If there are associated injuries that require intubation, which requires that the patient be completely unconscious, with machines breathing for him or her, the reduction may take place at that time. If the patient is stable, the procedure may be performed under conscious sedation, in which situation the patient is relaxed but breathing without the help of machines. Regardless of the method, every consideration should be given to protect the patient's airway. If the first reduction is unsuccessful, it may be reattempted, but it is generally agreed that no more than two closed reductions should be undertaken, to protect the femoral head from any further compromise.

Surgery

There are several indications for the operative management of hip dislocations. If the joint cannot be reduced under closed conditions, an open reduction should be performed. Usually, this is due to an associated fracture where the bony fragment is blocking the femoral head from seating in the socket. The blockage may also be due to soft tissue interposition of the large muscles that surround the hip joint. Occasionally, the force of the dislocation will push the femoral head through the capsule that encases the hip joint; it is not commonly possible to obtain enough traction and excursion of the tissues to buttonhole the femoral head back through the capsule.

If the hip is reduced but not seated correctly, it is called an *incongruent reduction*. This also requires surgery as the anatomic structure that is trapped in the joint, most likely a bony fragment or muscle, must be cleared out of the joint space.

Periodically, associated fractures of the proximal part of the femur or of the acetabulum will not be evident until after reduction; in rare instances, they will actually be caused by the maneuver. In these cases, the injury should be evaluated and may require surgery to repair.

Finally, surgery must be performed on any patient who has evidence of sciatic nerve injury after the attempt at closed reduction. Given the close proximity of the nerve to the posterior part of the hip joint, it must be ensured that reduction has not caused any damage to the nerve.

Complications

The most common complication is arthritis of the hip joint; this condition occurs in up to half of all patients. A condition that is related, but slightly less common, is *avascular necrosis*. As previously described, the blood supply to the femoral head can be easily damaged. After this damage occurs, the femoral head may slowly die, which can lead to collapse and accelerated arthritis in the joint. This condition is not always painful, however, and radiographic findings do not necessarily correlate with the patient's symptoms.

Another less common complication is *heterotopic ossification*. With disruption of the structures around the hip, especially in cases of multiple trauma or fractures, excessive bone may form in the muscles and around the bones of the hip joint. This condition does not always manifest itself clinically, but when it causes problems, it may be treated with anti-inflammatory medicines or radiation therapy.

Rarely, a patient may experience recurrent dislocation. If this persists, surgery may be performed to tighten the capsule and regain stability of the hip joint.

Finally, damage to the sciatic nerve may also occur as a late complication. Under most circumstances, this is due to the formation of heterotopic ossification, which either entraps and compresses the nerve or pushes the nerve out of position, stretching the nerve fibers. If this occurs, surgery may be performed to excise the abnormal bone, which will relieve the pressure and allow the nerve to return to its normal position.

Return to Sports

After the hip joint has been reduced, a computed tomography (CT) scan should be performed to evaluate the reduction and to examine the femoral head and acetabular socket for any fractures. If no fracture is present, the patient is advised to rest for a few days, and then he or she may begin walking with crutches and limited weight bearing on the affected leg. Extreme range of motion of the hip is avoided for 6 to 8 weeks to allow the hip capsule and muscles to heal. Activity may be gradually increased during this time as the patient's pain permits. Some patients may require structured rehabilitation with a physical therapist to obtain optimal recovery.

In patients with no other injuries, it may take up to 3 months to regain pre-injury strength. Endurance training and cardiovascular conditioning may be continued throughout the recovery period as long as the weight-bearing and range-of-motion restrictions are observed. Even in patients who are asymptomatic, periodic follow-up with radiographs should be performed every 3 months for a year and at 6-month intervals for the next 2 years.

Hip Flexor Strain

The hip flexors constitute the main muscle group of the anterior hip and thigh. These muscles are primarily responsible for flexing the leg forward and are used in athletic activities such as sprinting and kicking. A hip flexor pull or strain can be a debilitating injury for athletes. It can occur during a strenuous event, such as a kick or jump, or it can be the result of repetitive activity or overuse.

Anatomy

The hip flexor muscles are the iliopsoas, rectus femoris, gracilis, and sartorius. These muscles connect the pelvis to the femur and help aid in flexion of the femur forward, bringing the leg up toward the body. These muscles, along with the rest of the quadriceps muscles, which act to extend the knee, are the largest and most powerful muscles in the body. They are responsible for producing large concentric, isometric, and eccentric forces, resulting in powerful movements of the leg.

Causes

Acute injury and overuse injury are the two main causes of hip flexor strain. Acute injury typically involves a forceful eccentric contraction (contraction while the muscle lengthens) of the iliopsoas muscle. The athlete may experience one specific instance when he or she may feel the hip flexor pull. This may be associated with specific activities including sprinting, cutting, or kicking. Tight muscles and poor flexibility will contribute to a hip flexor injury. When muscles are tight, there is an increased amount of tension on the tissues. When this increased tension is compounded by an explosive movement, injury can occur (Figure 1). Soccer players are at high risk for this injury due to the powerful kicks associated with crossing passes, corner kicks, and shots on the goal. Other activities that may predispose to hip flexor strain include dancing, ballet, resistance training (weight lifting), rowing, running (particularly uphill), track-and-field events, and gymnastics.

Overuse injury may occur in activities involving repeated hip flexion or external rotation of the thigh. Injury can also be the result of overuse (repetitive kicking or long-distance running) and associated microtraumas. Microtrauma can occur in the form of a tiny, imperceptible tear. These tiny tears accumulate over time and eventually result in a strain and pain. The onset of this type of hip flexor strain is less acute and is progressive over time. Hip flexor strains of this type are often associated with a recent increase in activity.

Symptoms

The most common symptom of a hip flexor strain is pain. It occurs along the front of the hip and may radiate down the front of the thigh. Pain increases with movement, especially when attempting to lift the knee toward the chest. Running, jumping, and even walking can be painful, and sports performance may be limited. There may be a small

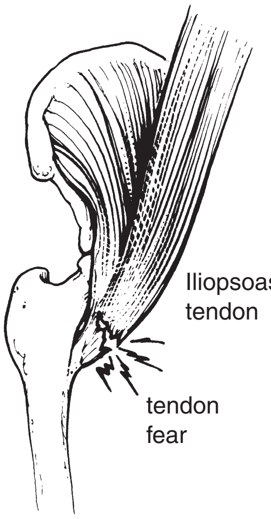

Figure 1 Hip Flexor Strain

Note: A powerful contraction of the iliopsoas muscle, usually when the leg is fully extended or trapped in place, can result in acute injury at the site where the tendon inserts into the femur.

amount of swelling, but this is not very common. Muscle spasm and bruising may also occur, depending on how severe the injury is. There is often weakness noted with activities associated with hip flexion. The injured athlete may notice a limp or pain with normal daily activities.

Diagnosis

Often, the history of a hip flexor strain is very straightforward, with either an acute injury or a history of overuse preceding the onset of symptoms. With any adult who has acute hip pain, there are "red flags" that may indicate a more serious medical condition as the source of the pain. Fever, malaise, night sweats, weight loss, night pain, a history of cancer, or a history of an immune system deficiency should prompt consideration of conditions such as tumor, infection, or inflammatory arthritis, as opposed to a simple muscular injury.

The physical exam begins with observation of the patient's gait and ability to move around the examination room. The examiner then observes the hip for asymmetry, swelling, or discoloration (bruising, redness). The exam continues with range-of-motion testing of the hip, comparing the affected hip with the normal hip to detect subtle limitations in strength or painful movements. Range-of-motion testing should include passive hip flexion and internal and external rotation. Next, the provider should test muscle strength to assess whether particular muscle groups are weak or specifically involved with the pain. Provocative maneuvers include resisted hip flexion, adduction, abduction, and external rotation and extension. In hip flexor strain, pain is increased with resisted active hip flexion and passive external rotation and extension.

Diagnostic Tests

In most cases, a thorough history and physical exam are adequate to establish a diagnosis of hip flexor strain. For high-energy ballistic injuries to the anterior hip, where the athlete describes a snap or pop at the time of injury, anteroposterior and lateral hip radiographs may be warranted to rule out avulsion or fracture. If initial conservative therapy is not effective, advanced imaging, including ultrasound and magnetic resonance imaging (MRI), can be used to assess the integrity of the muscle or the musculotendinous junction. Although ultrasound can be used for imaging following a hip flexor injury, MRI has emerged as the imaging modality of choice for diagnosing persistent hip pain in athletes because of its ability to identify the cause of injury more reliably.

The diagnosis of strains depends on the characteristic clinical findings. Hip flexor strains will usually present with tenderness to palpation over the anterior hip, with muscle weakness to hip flexion and pain with hip extension. Some athletes will also report loss of power or drive in the affected limb.

Strains are graded 1, 2, or 3 depending on severity. Grade 1 consists of minor tears within the muscle, Grade 2 is a partial tear in the muscle, and Grade 3 is a severe or complete rupture of the muscle. Symptoms and functional disability are progressive with the severity (grade) of the strain.

Treatment

Most musculotendinous injuries of the hip flexors can be treated nonoperatively. Initial treatment includes activity modification, ice, and compression to reduce pain and limit inflammation. After the pain subsides, emphasis is placed on regaining normal hip range of motion. After full, painless range of motion is achieved, strengthening exercises as well as proprioception exercises are started. The final stage of rehabilitation includes a functional return to sports activities. Surgery is rarely required for these injuries. The presence of a functional deficit despite adequate nonoperative treatment may warrant a surgical consultation.

Return to Sports

Return to full activity is permissible when the athlete has painfree range of motion and sport-specific function. This may take 4 to 8 weeks following an acute strain and up to 6 months following a chronic hip flexor strain. Typically, more severe acute injuries and chronic overuse injuries will require a longer period of recovery. It is rare for an athlete not to return to sports with proper treatment following a true hip flexor strain.

Hip Flexor Tendinitis

Hip flexor tendinitis is an inflammation of the muscles and tendons that function to flex the hip, typically involving the iliopsoas musculotendinous unit. It is interrelated with iliopsoas bursitis—an inflammation of the bursa overlying the iliopsoas. Some authors have advocated the term *iliopsoas syndrome* to better describe this clinical entity as the presentation and management of both entities are the same.

Hip flexor tendinitis is an uncommon cause of hip pain, and it characteristically localizes to the anterior or medial hip. It can arise as a result of systemic arthridities such as rheumatoid arthritis, from acute injury due to trauma, or from overuse in labor or sports characterized by repetitive vigorous hip flexion and extension. Injury due to the latter is better termed *tendinosis* as it is characterized by a weakened tendon with disordered healing of multiple small injuries rather than an acute inflammatory process.

This entry addresses the relevant anatomy, etiology, diagnostic features, and management of hip flexor tendinopathy due to overuse or acute injury.

Anatomy

The iliopsoas musculotendinous unit consists of the iliacus muscle, arising from the iliac wing of the pelvis, and the psoas muscle, arising from the vertebrae of the lumbar spine. Tendons from both muscles exit anteriorly over the brim of the pelvis and join into a single tendon, inserting onto the lesser trochanter of the femur. Contraction of these muscles results in the flexion and external rotation of the hip. Extension and internal rotation of the hip places these muscles on stretch. The iliopsoas bursa, a synovial fluid–filled sac, is the largest bursa in the body and separates the iliopsoas tendon from the underlying hip joint capsule and pelvis. Occasionally, the iliopsoas bursa communicates with the capsule of the hip joint.

Etiology

Injury to the iliopsoas musculotendinous unit and the associated bursa can occur as a result of significant trauma, such as a blow to the hip or a sudden forceful extension, or from microtrauma due to repetitive hip flexion/extension activity. The resulting musculotendinous injury can vary from contusion to strain to a tendon tear or avulsion of the tendon at the lesser trochanter. The accumulation of repetitive microinjuries to the tendon results in disordered collagen healing, yielding weaker tissues prone to further injury. In contrast, injury to the bursa causes inflammation and enlargement due to increased synovial fluid production within the bursa and/or hypertrophy of the synovium. The resultant mass effect causes friction between the tendon and the bursa, resulting in secondary inflammation and injury to the musculotendinous unit.

History

Patients present with anterior hip pain associated with activity and may complain of an audible/palpable snapping of the hip. An inguinal mass may also be present.

Pain is characteristically noted in the groin or inguinal region of the hip, is aggravated by hip activity and relieved by rest, and may radiate from the hip to the knee. Patients with a traumatic history may note a snap in the hip at the time of injury, followed by pain and limping. Patients with an insidious onset of symptoms are often involved in work or sports that demand repetitive or vigorous hip activity over a wide range of motions, including running, track-and-field events, ballet, rowing, kicking sports, and strength training. Following injury, patients may experience symptoms with daily activities such as walking, climbing stairs, or standing from a seated position.

A snapping sensation in the hip can be symptomatic or asymptomatic and can be due to many possible etiologies ("snapping hip syndrome"). When present as a feature of hip flexor tendinopathy, it is termed *internal snapping hip syndrome* and is typically localized to the medial hip. Snapping arises as the iliopsoas tendon moves suddenly over the bony prominences of the pelvis.

Very rarely in the athletic population, enlargement of the iliopsoas bursa can present as a groin mass and cause secondary compression of the neurovascular structures at the hip, resulting in weakness or numbness in the distribution of the femoral nerve, leg swelling, and urinary symptoms.

Physical Examination

On inspection, the patient may present with a limp, characterized by a shortened stance phase and stride length on the involved side as the patient attempts to limit hyperextension at the hip. The hip may rest in a posture of flexion and external rotation. Tenderness to deep palpation along the course of the iliopsoas confirms the diagnosis, but it is not always present. Active flexion and adduction of the hip can elicit pain, and testing the resisted external-rotation power in the flexed hip indicates weakness. Special tests include findings of anterior hip pain with the Thomas test (i.e., passive extension of the hip) and the snapping hip sign or extension test (i.e., extension of the flexed, abducted, and externally rotated hip that elicits an audible or palpable snap).

Imaging

The diagnosis of hip flexor tendinopathy is clinical, and imaging serves mainly to confirm the diagnosis.

Plain radiographs are useful as a screening tool to rule out bony pathology as the cause of the patient's symptoms, as is a computed tomography (CT) scan, but with greater detail than standard X-rays. Bursography involves fluoroscopic X-ray imaging after contrast has been injected into the iliopsoas bursa and allows real-time visualization of the sudden medial-to-lateral motion of the iliopsoas tendon in a snapping hip.

Ultrasound can be used to statically assess the iliopsoas tendon and bursa. In tendinosis, the tendon appears swollen and has a diffusely heterogeneous hypoechoic appearance. The bursa can be visualized and measured for size by comparison with the contralateral side. Ultrasound can also be used to guide the aspiration and injection of the bursa. Reduction of symptoms by injection of a local anesthetic into the bursa confirms the diagnosis. Dynamic assessment of the iliopsoas tendon for abnormal motion in the case of a snapping hip can also be carried out by ultrasound. The tendon is imaged as the hip is moved from external rotation and flexion/abduction to extension and adduction.

MRI can demonstrate the focal or elongated fluid collection between the hip joint and the iliopsoas tendon that is characteristic of bursitis, as well as signal a change or fatty atrophy within the tendon consistent with tendinosis. MRI can also demonstrate a gap or hematoma consistent with a tendon tear.

Management

The majority of cases of hip flexor tendinopathy are successfully managed nonoperatively.

Nonoperative management consists of rest, stretching and strengthening exercises with physiotherapy, local modalities, and anti-inflammatories for 6 to 8 weeks. Rest essentially consists of avoiding aggravating activities. Stretching focuses on the hip flexors and extensors and targets the isometric power of the internal and external hip rotators. Ultrasound therapy or diathermy is applied locally to the site. Failed resolution of symptoms beyond 2 months of therapy can be addressed by ultrasound-guided injection of a corticosteroid and a local anesthetic into the tendon or bursa and continuation of the conservative rehabilitation program.

Surgical treatment of hip flexor tendinopathy is rare and reserved for patients who fail prolonged, directed conservative therapy. Surgery to address the tendon consists of open lengthening or transection of the tendon near the pelvic brim or at the lesser trochanter. Resection of symptomatic bursae or plication of a communication between the bursa and the hip joint can also be carried out.

Complications

Complications in the management of hip flexor tendinopathy are uncommon due to the conservative nature of management and are largely a consequence of invasive diagnostic or therapeutic procedures. These include local infection or septic arthritis of the hip, injury to the femoral nerve, hematoma/vascular injury, and hip flexor weakness.

Hip Fracture

Hip fracture refers to a break in the bone in the region of the proximal femur or femoral neck. Fractures of the femoral neck and the proximal part of the femur occur more commonly after a fall in elderly patients with osteoporotic bone. In the athletic population, hip fractures occur far less frequently and are caused by high-energy trauma. An additional etiology of femoral neck fractures in the athlete is excessive, repetitive loads that can cause a stress fracture.

Anatomy

The hip joint is a complex structure that allows for weight bearing and a wide range of motion to position the lower limb during activity. The bony anatomy of the hip joint comprises a round femoral head seated within the bony socket of the acetabulum. A strong capsule surrounds the joint to help contain the ball within the socket throughout the range of motion and muscle force required of the hip during sporting activity.

The proximal part of the femur consists of the femoral head, the femoral neck, and the greater and lesser trochanters. The upper part of the femur develops from several growth centers that fuse and take on their adult appearance by age 14 in girls and age 16 in boys. The blood supplied to the femoral head flows closely along the femoral neck. Fractures of the femoral neck may disrupt the blood vessels and result in subsequent avascular necrosis, complicating the original injury.

Causes

The cause of hip fractures depends on the type of injury and the associated mechanism of injury. Femoral stress fractures are associated with repetitive activities such as long-distance running, jumping, and ballet dancing. They are frequently the result of training errors. Additionally, stress fractures can occur in athletes with underlying metabolic or hormonal abnormalities, making them susceptible to insufficiency-type stress fractures.

Displaced hip fractures in the athletic population are rare but can result from activities involving high speeds or energy, including motorized sporting activities, mountain biking, or skiing. These injuries can occur as the result of a fall or direct trauma to the hip. Such injuries can also be seen in collision sports such as football or ice hockey.

Symptoms

The presentation of an athlete with a hip fracture is variable depending on the fracture type and cause of injury. In patients with stress fractures or nondisplaced fractures, the only complaint may be groin or buttock pain. The pain may be activity related and may begin after a change in the training regimen or intensity. Pain may also be elicited with attempts at a straight leg raise or by taking the athlete through a range of motion at the hip.

However, in patients with an acute and displaced hip fracture, the combination of severe pain, inability to walk, and the appearance of a shortened and externally rotated lower limb is frequently seen. Recognizing the severity of the injury and the need for transport to a hospital is important when initially caring for the injured athlete to ensure prompt diagnosis and treatment.

Diagnosis

The diagnosis of hip fractures depends on the history, physical examination, and imaging studies. The nature of the injury and any associated trauma are important in making the diagnosis. Any athlete with severe pain and the appearance of a shortened and externally rotated lower leg after a collision or fall needs to be evaluated by a physician in a hospital setting with proper radiographs. The type of hip fracture can usually be determined by X-rays of the hip and pelvis.

Stress fractures of the proximal femur require an index of suspicion to be diagnosed. Critical in the history are changes in the athlete's training regimen or any metabolic or hormonal abnormalities. On physical exam, pain with active straight leg raises, pain with logrolling the affected leg, and a painful limp while walking provide clues to the possibility of a femoral neck stress fracture. Imaging studies, including X-rays of the hip and pelvis or a bone scan, may show the presence of a stress fracture. Recently, magnetic resonance imaging (MRI) has become an important imaging tool to diagnose stress fractures because of its ability to define the location of the injury, determine the extent of the bony stress reaction, and diagnose any associated soft tissue injuries.

Treatment

Nonsurgical Management

Compression-type stress fractures of the hip can be treated with good to excellent outcomes in many athletes. Often, patients are managed with a period of protected weight bearing with crutches ranging from 4 to 8 weeks. Physical therapy and pool therapy can allow the athlete to maintain some strength with some level of activity while the healing of the fracture occurs. With radiographic and clinical improvement in the stress fracture, the athlete can begin to return to activities once he or she is painfree.

Surgical Management

Surgical management of all displaced femoral neck and proximal femur fractures is recommended in the athletic population. Surgery is usually performed on an emergency basis to prevent potential complications such as avascular necrosis of the femoral head, which may result from increased pressure or interruption of the normal blood supply to the femoral head. Depending on the surgeon and the type of fracture, operative management may consist of the use of several screws, a combination of a plate and screws, or other implants to repair the fracture and allow for healing in the appropriate position.

Occasionally, stress fractures that are at risk for displacement, are tension type, or do not heal with nonoperative management require surgery, with the goal of allowing for proper healing and return to activity.

After Surgery

Rehabilitation and return to play after surgery depend once again on the severity of the injury and the surgical treatment required to fix the fracture. A period of 6 to 12 weeks of protected weight bearing with crutches to allow for fracture healing is typically required. Once the X-rays show satisfactory signs of healing, the athlete can progress to full weight bearing, with eventual return to activity below pre-injury levels and gradual progression to full activity under proper supervision.

Hip Stress Fracture

Stress fractures are common injuries facing athletes at all levels and at all ages, and they can cause a significant amount of time lost from training and competition. A stress fracture can occur in one of two ways: (1) an unusual amount of stress applied to normal bone or (2) a normal or usual amount of stress applied to abnormal bone. Typically in either process, stress comes from repetitive microtrauma to the bone, as occurs, for example, when an athlete increases his or her running mileage. A stress fracture in fact is a bit of a misnomer. There is no true fracture of the bony framework. Rather, there is edema and possibly hemorrhage within the intact bone.

Our bones are made of living tissue, which can change and become stronger in response to stress, a phenomenon encompassed in the medical principle referred to as Wolff's law. This is why weight-bearing exercise is important to maintain good bone health and to prevent osteoporosis (thin or brittle bones). However, when the forces on a particular bone exceed its ability to restore itself, injury can occur. Prolonged loading (stress) without giving the bone time to heal may lead to pain and a stress fracture. If untreated, a stress fracture may progress to a complete fracture—that is, an actual break in the bone.

The site of stress fracture varies depending on the sport, and it can occur anywhere in the body. Common sites include the bones of the foot, the tibia (shinbone), the femur (thighbone), and the pelvis. Stress fractures of the foot and lower extremity are very common in running athletes, while stress fractures of the ribs are seen in rowers and golfers. Stress fractures occur in up to 15% of runners and military trainees.

This entry focuses on a specific type of stress fracture, a femoral neck stress fracture (FNSF), which occurs in the hip joint. Stress fractures around the hip can also include the pubic rami, acetabulum, and sacrum. About 5% to 10% of all stress fractures occur in the femoral neck, and it is one of the more serious stress injuries with potentially more serious consequences than other types of stress fracture. Of note, this stress fracture can occur in as little as several weeks of intensive training.

Anatomy

The hip joint is a ball-and-socket joint made of the head of the femur (ball) and a part of the pelvis called the acetabulum (socket). The head of the femur is attached to its long axis by the femoral neck. Weight-bearing forces from the body are transmitted through the femoral neck. A compressive force is transmitted along the underside of the femoral neck, and a tension force is transmitted along the top. We, therefore, refer to the sides of the femoral neck as either the compression side or the tension side. The specific location of a stress fracture in the femoral neck becomes important in terms of treatment, which will be discussed later. It is important to recognize that the blood supply to the head of the femur travels through the neck, making it subject to injury through unrecognized or nonhealing stress fractures.

Causes

Femoral neck stress fractures usually result from overloading the hip joint with excessive running or training, for example, by increasing the amount of activity too quickly. The familiar phrase "too much, too soon" certainly may apply to an athlete who develops a stress fracture. A common setting for stress fractures described in the medical literature is in military recruits, who may not be in tip-top shape when they are subjected to a high level of running and marching. Among college athletes, track-and-field athletes have the highest incidence of stress fractures compared with other sportspersons.

There are other risk factors for developing stress fractures. Certain biomechanical characteristics, such as an abnormal amount of external rotation at the hip, may place an athlete at risk. Statistics show that women are at 1.5 to 3.5 times greater risk of sustaining a stress fracture. In particular, individuals with poor dietary intake of calcium and vitamin D, both important to bone health, are more at risk. Women who have low "energy availability" are also at risk. Low energy availability can be the result of not eating enough calories, exercising too much, or a combination of both. Low energy availability can contribute to malnutrition or can cause amenorrhea (the absence of menstruation). The change in hormone levels in female athletes due to amenorrhea may contribute to the bones being at increased risk of injury, including stress fractures (see the entry Female Athlete Triad).

Symptoms

Patients with stress fractures typically present with localized focal pain that worsens as they exercise. The pain can progress to the point of occurring with day-to-day activities such as walking or simply standing. With most stress fractures, usually the athlete can pinpoint the area of pain. Unfortunately, an FNSF is a bit more difficult to localize given its location deep in the groin. The patient may complain of a deep, achy pain in the groin or hip that becomes worse with weight bearing. The patient may also complain of pain with extreme range of motion of the hip. Pain will gradually worsen with continued activity, and if not addressed, it can lead to an actual fracture of the femoral neck.

Diagnosis

Physical Exam

It cannot be overstated that a diagnosis of FNSF should be considered in any athlete complaining of groin pain and must not be missed, due to the increased risk of this stress fracture advancing to a complete or displaced fracture. Other stress fractures are usually easy to palpate due to the superficial nature of most at-risk bones. The femoral neck, however, is too deep to palpate, and pain must therefore be elicited by other means. The hop test has been shown to be helpful in diagnosis. This involves having the athlete attempt to perform a single leg hop on the affected leg. A stress fracture makes this unbearable, and the patient will likely not comply with the examiner's request. The patient will likely also have reproducible pain with passive external rotation and, more significantly, passive internal rotation of the hip.

Imaging

If an FNSF is considered, it is important to document this with imaging. Plain X-rays may show changes in the stress fracture only after 4 to 6 weeks. Often, it may be too early for an X ray to detect the bone healing, or callus, as the bone tries to respond to the abnormal stress with new bone formation. A bone scan can be helpful in diagnosing a stress fracture. This test involves injecting a radioactive material into the patient's vein. This material is picked up by areas of bone with a high rate of cell turnover, as occurs in a fracture. For a suspected FNSF, however, an MRI may be a better choice of imaging test, as it gives the physician more information about the exact location and extent of the FNSF. In particular, it is essential to learn if the FNSF is a compression- or a tension-side fracture. The tension-side stress fracture is more likely to progress to complete fracture and then to displacement. Recurrent stress on an undiagnosed and untreated FNSF can lead to progression and a disastrous complication called avascular necrosis (AVN). AVN results from a disruption of the blood supply to the femoral head and causes death of the femoral head bone. The hip joint is then irreversibly damaged, and this can lead to the need for total hip replacement in a young, healthy athlete. As mentioned previously, early detection of an FNSF is crucial.

Treatment

Nonoperative

Treatment of an FNSF depends on the location. Compression-side stress fractures are generally treated with initial rest. This usually means total non–weight bearing on crutches at first, with gradual progression to weight bearing over a course of several weeks to months. Once weight bearing is tolerated or pain-free, the athlete is slowly returned to activity and eventually to his or her sport. Cardiovascular fitness can usually be maintained during this time by another form of non–weight-bearing activity, such as swimming. Once weight-bearing activity is begun, there may be some return of pain, but this should be minimal. If at any point more significant pain recurs, the treatment plan needs to be backed up, and one should progress more slowly. The key for all stages of rehabilitation is painfree activity.

Operative

For a tension-sided FNSF or if a compression-sided FNSF continues to progress clinically despite appropriate management, some authors recommend surgical correction. The surgery involves placing a pin across the fracture line. Rehabilitation and recovery procedures are similar to those for nonsurgical treatment, with a period of non–weight bearing followed by gradual progression to full activity.

Return to Sports

If there is no underlying condition such as osteoporosis or the female athlete triad, the athlete may reasonably expect full recovery and full return to play and sports in the majority of cases. It should be emphasized that starting at the time of diagnosis, and during the management of acute injury, attempts should be made by the provider and the athlete to identify and correct any contributing factors that led to the stress fracture, whether they be internal or extrinsic factors, such as a medical condition, errors in training, or biomechanical factors.

History of Sports Medicine

Sports medicine is considered a relatively new medical subspecialty. For those who entered medical school 50 years ago and completed their residency training in the 1960s, sports medicine did not exist as an academic subject. At that time in North America, there were no formal medical school curricula or postgraduate fellowships available in the diagnosis and management of athletic injuries. The term *sports medicine*, which originated in Europe, was not widely used in the United States. Although there were specific physicians and surgeons providing innovative and effective medical care for injured athletes, both before and after World War II, the majority of medical institutions and teaching centers in North America had not yet established formal educational programs that included specific sports medicine subject matter, and they would not do so until the early 1970s. Our European colleagues, however, recognized the importance of sports medicine in the 1920s and convened regularly before World War II to discuss their clinical and scientific observations at international congresses. Presently, in North America, sports medicine has become a very popular subspecialty and is a respected and vital part of the educational program in all medical centers.

Sports medicine includes the study of the management of musculoskeletal injuries and the medical problems encountered by athletes during competition and training. It also encompasses the study of the physiological changes and nutritional requirements of individuals involved in strenuous athletic activity and the rehabilitative process necessary to return athletes to a safe competitive level. Sports medicine incorporates the expertise of exercise physiologists, nutritionists, physical therapists/trainers, and sport psychologists, as well as a team of physicians and surgeons. It is, indeed, a specialty that includes multiple disciplines, each of which has made significant contributions to the understanding and management of sports-related injuries.

When and where did sports medicine begin? Human beings, since the beginning of recorded time, have fulfilled their basic need for recreation, entertainment, and competition by participating in exercise, dance, and athletic activities. Paintings found in the Egyptian tomb of Beni-Hassan, dating back to 2500 BCE, depict people participating in a variety of exercises, ball games, lifting, wrestling, and physical competition. The excavations at Knossus in Crete have unveiled frescos dating back to the Minoan civilization of 2000 BCE, revealing people boxing, wrestling, and bull jumping. Although there are no medical records of the specific injuries sustained during these activities, we know that some must have occurred and can only assume that a healer or bone setter, knowledgeable in the management of sports-related injuries, must have been available to treat them.

Who was the first "team physician"? It is, of course, impossible to be sure. We do know that the first recorded athletic competition, the Funeral Games for Patroclus, organized by his friend Achilles, was described by Homer in the Iliad and consisted of the athletic events subsequently included in the ancient Olympic Games. We also know that Homer identified two physicians, Machoan, a surgeon, and Podalirius, a physician, who were the sons of Aesculapius and had accompanied the Greek troops to Troy. They were reported by Homer to have been effective in treating the injured soldiers, even performing surgical procedures. We can only assume that these two experienced doctors may have been available to treat the injuries that likely occurred from the strenuous competition during the Funeral Games. Since Homer left no injury list, we can only assume that Machoan and Podalirius may have served as the first "game doctors."

Ancient Times

Herodicus, who lived in the 5th century BCE, has been suggested to be the father of sports medicine. Although his writings no longer exist, his medical contributions and reputation have been documented by his contemporaries—Hippocrates, Plato, and Aristotle—as well as by Galen in the 2nd century CE and the authors of the earliest textbooks of medical history.

Herodicus was born in Selymbria in Thrace and received his medical education at Cnidus, which along with nearby Cos were the two most famous medical schools in ancient Greece. These towns were located in Asia Minor in an area inhabited after the Trojan War by Podalirius and his descendants. All ancient Greek physicians—the Aesculapiads—were direct descendants of Podalirius. Jouanna in his biography of Hippocrates has traced Hippocrates's lineage back 19 generations to Podalirius. However, as the years progressed, individuals without documented lineage to Aesculapius were allowed to enter medical school and practice medicine provided they agreed to abide by the Hippocratic Oath.

What best qualifies Herodicus as the father of sports medicine is that prior to entering medicine he was educated and worked as an athletic trainer. Traditionally, during the 5th century BCE in Greece, physicians were not allowed into the gymnasia where the athletes were practicing and conditioning under the supervision of trainers. Herodicus, however, had a close association with the athletes as a sports trainer, and during that time he had the opportunity to establish a treatment philosophy centered on the importance of diet and exercise as it related to health and disease.

He could also be considered the first of the "aggressive rehabilitation" proponents, recommending both stringent diets, consisting primarily of grains, and strenuous exercises, especially prolonged walking. Since this program helped control his personal medical afflictions, he ordered the same vigorous program for his patients. The excessive physical demands of his treatment protocols were a matter of concern for some and were criticized by his contemporaries, including Hippocrates, Plato, and Aristotle, as being potentially harmful to some patients. Although Plato praised Herodicus and credited him for applying "the principles of gymnastics to the treatment of disease and the preservation of health" and even stated that Herodicus "belonged, no doubt, to the rank of fully accomplished physicians," he found his treatment protocols excessive, pointing out that "by a combination of training and medicine Herodicus found a way of torturing first himself and then the rest of the world by the invention of a lingering death." Galen, during the Roman period, wrote about Herodicus's theories and treatment protocols and commented that they were harsh and potentially injurious.

Snook has made a very convincing argument that Galen should be considered the father of sports medicine. Galen's research and scientific contributions, which were based on careful animal dissections, formed the standard of medical knowledge during the Roman period and remained the foundation of medical thought into the 19th century. He was a prolific writer, producing more than 2.5 million words, including the initial description of the longitudinal contraction of muscles, the pathways of nerves from the brain to the muscles, the connections within the muscles of arteries to veins that carried the vascular flow from the left to the right side of the heart, the physiology of urine production, as well as the importance of clinical history and physical examination. In addition to his medical writing, he produced numerous treatises on mathematics, grammar, philosophy, and law.

Galen was born in 131 CE in Pergamum in Asia Minor, where he was appointed as a physician at the gladiator school by Pontifex Maximus. He was subsequently brought to Rome by Emperor Marcus Aurelius to provide care for his own family as well as the gladiators and athletes. During his career, he carried out well-documented studies in exercise physiology and reported on the effects that training, exercise, and nutrition had on individuals of all ages. He was very much in favor of athletic activities, pointing out in his "Treatise on the Small Ball" how light as well as progressively more challenging exercises can have beneficial effects on the bodies of all age-groups, including children and the elderly. However, he condemned the professionalism and excessive practices that were increasingly evident among the competitive Olympic athletes. The abuses he commonly observed among the professional and Olympic athletes of his day had begun during the ancient Greek period and also parallel the problems we currently encounter. He deplored the specialization of athletes, particularly boxers and wrestlers, which rendered their bodies overweight and out of proportion to the point where they were unfit to participate in other sports or military duty. He noted that many of these athletes subsequently developed significant disabling medical problems after their competitive years, which often led to premature death.

The professional athletes commonly moved about from city to city, changing their allegiance and often their identity to be able to compete for large monetary awards. Victories at the major competitions were usually accompanied by enticing tax benefits and lucrative pensions. These temptations frequently resulted in illegal activities and corrupt behavior among both the athletes and the trainers in attempting to obtain victories and secure the rich financial awards. These abuses along with the rise of Christianity in Rome, which opposed the traditional paganism associated with these sports festivals, were two of the reasons why the ancient Olympic Games were terminated in 393 CE. Although there is evidence that the ancient Babylonians, Assyrians, Egyptians, Chinese, and Indian civilizations participated in athletic activities and undoubtedly had medical practitioners who may have functioned as team physicians and sports medicine doctors before the time of the Roman Empire, Galen's verifiable scientific contributions and impressive body of writings justify the label Dr. George Snook gave him as the father of modern sports medicine.

During the centuries after Galen and before the modern period, there were individuals who observed and wrote about the value of exercise in the prevention and treatment of injuries. Aurelianus, in the 5th century CE, described the use of weights and pulleys as an effective form of exercise and recommended their use, along with hydrotherapy, even for postoperative rehabilitation.

During the 10th and 11th centuries, Avicenna, from Persia, and Maimonides, who lived in Egypt during most of his professional life, wrote extensively about the value of therapeutic exercise taken in moderation. They were both disciples of Galen and were in agreement with and continued to follow his medical concepts.

In the 15th century, Gerolamo Mercuriale published six books on *The Art of Gymnastics* that were very popular and remained in print for more than 150 years. In these books, he classified exercises into preventive and therapeutic categories, and using detailed illustrations, he demonstrated the proper techniques for each. These books were purchased and used by both the public and the medical professionals.

In 1602, Marsilius Cagnatus of Verona published a book titled *Preservation of Health*, in which he encouraged physicians who had knowledge of sports to become more involved in the supervision of athletic contests. He recognized how important it was for the physician to have an interest in and an appreciation of the demands of the various sports in order to provide effective care, an observation that remains true even today.

The Modern Era

The term *sports medicine* had its origin in Europe in the beginning of the 20th century. In 1910, Siegried Weissbein of Berlin published *Hygiene in Sports*, a two-volume work that described the injuries encountered in athletes and outlined treatment options. His work was followed in 1914 by a chapter on sports injuries in the *Encyclopedia of Surgery*, published in 1914 by G. Van Saar. Unfortunately, the outbreak of World War I interfered with the interest and concern physicians had with sports injuries.

In 1928, at the second Winter Olympics in St. Moritz, Switzerland, Dr. Kroll of Switzerland, Dr. Buytendijk of Holland, and Dr. Latarjet of France met with 33 other physicians and planned the First International Congress of Sports Medicine, which was held at the 1928 Summer Olympic Games in Amsterdam. The organization they formed was originally known as the Association International Medico-Sportive, but in 1933, its name was changed to Federation International Medico-Sportive et Scientifique (FIMS). This society continues to hold regular scientific meetings, has representatives and participating members from around the world, and makes significant contributions to the science and specialty of sports medicine. Since its origin, many nations have established their own national sports medicine organizations and have collaborated in regional and international educational and scientific programs.

The popularity and importance of exercise in North America was also influenced by the Europeans who immigrated to America in the early 1800s and who introduced the gymnastic exercises popularized by the Prussian Frederick Jahn (Turnen Gymnastics) and the Swedish program created by Ling. As the Industrial Revolution progressed and people moved into cities from the rural areas, exercise facilities were constructed to provide a place for workers to have physical activity. Schools also recognized the importance of regular exercise. Dr. John Warren of Boston promoted the Boston Gymnasium and assigned Dr. Charles Follen as the instructor in German and gymnastics. At the Round Hill School in Northampton, Massachusetts, in 1825, Dr. Charles Beck, who had worked with Jahn, was appointed to teach Latin and to supervise the exercise program. Mary Lyon founded the first college for women in America, Mount Holyoke, in 1837 and made daily gymnastics a requirement for her students.

Dr. Edward J Hitchcock was perhaps the most important figure in college health during the second half of the 19th century. Appointed as the instructor of physical education and health at Amherst College in 1854, during the next four decades, he required all students to have preparticipation examinations, performed regular anthropomorphic studies, maintained detailed team injury statistics, provided careful nutritional guidance, and abided by strict fitness requirements. During his career, he published more than 150 articles in the *Journal of Social Science* on numerous topics related to health and athletics. In addition, he was an able and just administrator who recognized the importance of competitive sports in student life but insisted on some administrative control of these activities. In most colleges at that time, athletics were extracurricular activities organized and run by the students and the alumni. Dr. Hitchcock established the first athletic committee, which had representatives from the faculty, the alumni, and the undergraduate students. This worked effectively at Amherst and was the blueprint copied by many colleges and universities at the turn of the 20th century.

The earliest academic publication printed in the English language was written by B. J. Byles and S. Osburn in England on the topic of sports-specific injuries and their treatment options. This was included in the *Encyclopedia of Sport* and appeared in print in 1898. The following year, Dr. E. A. Darling published an article in the *Boston Medical and Surgical Journal* in which he described the physiological changes found in members of the Harvard crew during the strenuous training for their traditional 4-mile (6.4 kilometers) race against Yale. He concluded that the effects of sustained rowing on the body were such that competent supervision was needed to ensure the safety of athletes. His statements underscored the importance of having knowledgeable sports medicine physicians available for consultation when athletes are training and competing.

Two studies published in the *Boston Medical and Surgical Journal* in 1906 and 1909 by Dr. Edward Nichols of Harvard had a significant impact on the preservation of the game of football in America. His initial paper documents the high volume and severity of football injuries, which had provoked President Theodore Roosevelt to demand that the college coaches and administrators change the rules to make the game safer. He threatened to curtail all future football contests if this was not achieved. This threat was a stimulus to form the National Collegiate Athletic Association (NCAA), which has continued to serve as the governing body for college sports. The rules were changed, and Dr. Nichols's follow-up paper in 1909 confirmed the significant reduction of serious injuries and deaths.

As indicated earlier, the study of sports medicine encompasses many disciplines, including the contributions of the exercise physiologists. In 1890, Dr. Robert McKenzie from the University of Pennsylvania published "Exercise in Education and Medicine," in which he described the effects of exercise on the body as well as the practical application of physical therapy in the treatment of injuries. Subsequently, Professor A. V. Hill from Cambridge, England, published studies for which he shared the Nobel Prize in Physiology and Medicine in 1922 with Otto Meyerhof for their elucidation of the chemical and physical processes that underlie muscle contraction. His monographs titled "Muscular Movement in Man" and "Living Machinery" discussed the factors governing speed and recovery from fatigue and also defined the concept of "the steady state of exercise" and "oxygen debt." His presidential address at the British Association for the Advancement of Science in 1925 was titled "The Physiological Basis of Athletic Records" and remains a classic today. Two other major contributors to this specialty were A. V. Bock and D. B. Dill, who edited and published the third edition of F. A. Bainbridge's *The Physiology of Muscular Exercise*, adding new material from European scientists and data from the Harvard Fatigue Laboratory, where they performed their studies. Another international organization that provided educational and scientific research information around the world was the International Council of Sport and Physical Education, established as a subdivision of UNESCO (United Nations Educational, Scientific and Cultural Organization) in 1960. This council's research committee was chaired by Professor Ernst Jokl, a highly respected exercise physiologist from the University of Kentucky. Many nations and scientists were able to participate in these informative meetings and benefit from the exchange of research and educational material.

During the early decades of the 20th century, it was not uncommon for physicians to function as both coaches and team physicians. Perhaps, the most famous was Dr. Walter Meanwell, who was the professor of physical education at the University of Wisconsin and head basketball coach. Although known primarily as a winning coach, he published an article in 1924, "The Science of Basketball," that included a section dealing with the recognition and treatment of injuries. Dr. Marvin Stevens was a surgeon who served as the Yale football coach from 1924 to 1932, and he also wrote about the mechanism of athletic injuries that he observed in the fields or from his review of game films.

Organizations

As noted previously, the Europeans had established an international sports medicine organization, FIMS, well before the need for one was recognized in North America. Following World War II, sports medicine physicians in the United States recognized the value of a collaborative effort and founded the American College of Sports Medicine in 1954. The multidisciplinary membership consists of clinical physicians and surgeons, as well as physical educators, physiologists, and other scientists, who continue to meet regularly and publish their findings in their journal *Medicine and Science in Sport*. This remains a highly respected and productive organization that addresses the full spectrum of sports medicine issues.

The American Medical Association established an ad hoc committee on The Medical Aspect of Sports in 1954. Its chairman was Dr. Augustus Thorndike of Harvard College, whose 1938 book on athletic injuries was innovative and popular, extending through five editions. The other members of this committee included Dr. Carl Badgley of Michigan; Dr. Graeme Hammond, an Olympic physician from Boston; Dr. "Brick" Mueller, a Rose Bowl hero from San Francisco; and Dr. Allan Ryan, a former Yale track athlete, professor at the University of Wisconsin, and respected author of many articles and books on sports medicine. Dr. Thomas B. Quigley, also of Harvard, was subsequently added to the committee, and recognizing the needs of athletes, the committee published the Athlete's Bill of Rights, which stated that athletes were entitled to good coaching, good officiating, good equipment, safe playing facilities, and appropriate medical care independent of the influence of coaches or administrators.

The National Athletic Trainers Association (NATA) and the Sports Physical Therapy Section (SPTS) of the American Physical Therapy Association (APTA) are organizations that have provided vital care to injured athletes and whose members work collaboratively with team physicians in caring for their mutual patients. Although the profession of athletic training extends back into antiquity, in North America, Samuel E. Bilik is considered the father of athletic training. While attending the University of Illinois, he worked afternoons as a trainer and in 1914 published the first texts on this subject, *Athletic Training* and *The Trainers Bible*. Beginning in the 1920s, the Cramer brothers (Cramer Products) supplied training rooms with the essential products of their profession and helped stimulate interest in the profession by sponsoring workshops around the country. The original NATA was founded in 1938, but World War II interrupted its development. In 1950, NATA was reorganized by 125 attendees at a meeting in Kansas City sponsored by Cramer Chemical Company. The first formal meeting of NATA was held in 1951, and the society has continued to grow and contribute to sports medicine knowledge. In 1956, their research and clinical papers were published in the NATA journal. This respected publication is now known as *The Journal of Athletic Training*. In 1948, Indiana University introduced the first 4-year college program to grant a degree in athletic training. By 2008, there were 352 accredited college programs in North America, and the membership in NATA had grown to more than 30,0000, attesting to the interest in and significance of this profession as a career. In 1971, a certification examination was introduced to ensure the competence of the graduates of the athletic training programs.

The SPTS of the APTA was established in 1973 by 75 physical therapists dedicated to a career in sports therapy. They had their first formal meeting in 1974 and elected Ron Peyton as president. This subspecialty within physical therapy has continued to grow. It is now one of the largest sections in APTA, with 6,000 members. The American Board of Physical Therapy Specialties was established, and a board certification has been required since 1986. There are now 640 sports therapy clinical specialists who have been certified. Recertification every 10 years is also a requirement to ensure continued competence. It also has a successful journal, *The Journal of Orthopedics and Sports Physical Therapy*, which was begun in 1979 and is currently the largest physical therapy publication. The SPTS has worked collaboratively with the American

Orthopaedic Society for Sports Medicine (AOSSM), NATA, and the American Medical Society for Sports Medicine (AMSSM) in educational projects and has established postgraduate fellowships in its specialty, the first being at the Gunderson Clinic in 1992. Its vision is that all sports physical therapists will have doctoral-level training by 2020.

The AOSSM had its organizing meeting in 1972. It evolved from the American Academy of Orthopaedic Surgeon's Committee on Sports Medicine, which was founded in 1964, chaired by Dr. Jack Hughston, and arranged three educational meetings annually on the upper extremity, the lower extremity, and general sports medicine problems. The founding members of the AOSSM recognized the need for an orthopedic subspecialty society dedicated to sports medicine that would provide a more effective vehicle for collaborative studies, research, and educational programs. Dr. Don O'Donoghue of Oklahoma, Joe Godfrey of Buffalo, and Jack Hughston of Columbus, Georgia, all nationally recognized team physicians, served as the first three presidents of the organization. During the years since the AOSSM was founded in 1972, the parent Academy of Orthopaedic Surgeons has passed the responsibility and leadership in providing sports medicine educational programs for its members to the AOSSM. In 2008, there were more than 2,000 active members in the society. The research and educational materials submitted and presented at its meetings have been published in the *American Journal of Sports Medicine* since 1972. Members of the AOSSM have established certified orthopedic sports medicine fellowships within their academic and clinical practices, and following completion of one of these accredited fellowships, the fellows can take the formal certification examination to become credentialed as sports medicine specialists.

Several internists and primary care sports medicine physicians who had been members of the American College of Sports Medicine or had done sports medicine fellowships with their orthopedic colleagues saw the value of forming their own primary care subspecialty organization. Dr. David Hough, Dr. John Lombardo, Dr. Doug McKeag, Dr. Lee Rice, and Dr. Jim Puffer, along with 15 other pediatric, emergency medicine, family medicine, and internal medicine practitioners, organized the AMSSM and held their first meeting in 1992. The AMSSM's membership had grown to 1,124 by 2007, and the members have continued to produce excellent research and clinical studies, which are printed in its publication, the *Clinical Journal of Sports Medicine*. The AMSSM also collaborates to produce the annual Team Physicians Courses, which are cosponsored with the AOSSM and the American College of Sports Medicine (ACSM). Members of the AMSSM are able to take a certification examination that qualifies them as credentialed sports medicine specialists.

The international interest in sports medicine has continued and is confirmed by a number of impressive organizations that were formed during the decades of the 1970s and the 1980s. The organizational meeting for the International Society of the Knee (IKS) was held in Rome in 1977, and their first congress was convened in 1979 in Lyon, France, with Dr. Albert Trillat serving as the president. Dr. Ian Smillie of Scotland and Dr. Jack Hughston of the United States were the next two presidents and hosted the meetings in 1981 and 1983, respectively. Since the International Arthroscopy Association (IAA), which had been founded in 1974, shared many common interests and members with the International Society of the Knee, these two organizations began to meet at the same locations in 1985 in Sydney, Australia, joining together for 1 day of shared scientific presentations during their separate meetings. In 1995 in Hong Kong, the IKS and IAA voted to merge and become ISAKOS, the International Society of Arthroscopy, Knee Surgery and Orthopaedic Sports Medicine. The first meeting of ISAKOS was held in Buenos Aires, Argentina, in 1997, and Peter Fowler of London, Ontario, served as the first president. This organization has grown significantly with the addition of international members from numerous counties and all continents. Along with FIMS, ISAKOS has become an important and respected international sports medicine society.

Regional and national societies continued to form through the decades after World War II. Sports doctors from Switzerland, Austria, and Germany formed GOTS, the German Orthopaedic Traumatology and Sports Medicine Society; and in

1984, the first congress of ESSKA, the European Society of Sports Traumatology, Knee Surgery and Arthroscopy, was held in Berlin, Germany, with Werner Muller of Switzerland serving as the first president. These educational and research societies, as well as other regional and national societies around the globe, remain active participants in the scientific and clinical study of sports injuries.

As international interest expanded, Asian, Western Pacific, and South American countries formed their own national and regional sports medicine societies and have continued to collaborate in the international meetings with ISAKOS, AOSSM, and FIMS. In the 1980s, an exchange program was conceived by Dr. John Feagin of the United States and Dr. Werner Muller of Switzerland, in which three young sports medicine fellows and one senior representative of AOSSM would visit the European sports medicine centers and a similar number of European colleagues would go to North America to participate in an educational experience. This was a very popular and valuable experience for all involved and has been expanded to include similar exchange programs with Asian, Pacific Rim, and South American colleagues.

Conclusion

A historical review of sports medicine is by necessity selective and, therefore, may be criticized as being incomplete. Many books have been written about the history of medicine from ancient civilizations to the present time, incorporating the achievements of physicians from many continents and numerous societies. I sincerely apologize to those individuals and organizations whose contributions I have failed to include in this entry.

Sports medicine is an ancient subspecialty that has attracted the interest, scientific talent, and enthusiasm of many modern medical practitioners and scientists. In addition to the national and international organizations mentioned above, individuals and organizations have produced important basic science and clinical studies on sport-specific as well as anatomic region–specific injuries. Time and space do not allow one to mention all the important contributions these individuals have made or to list all the impressive surgical advances made in the reconstruction of upper and lower extremity injuries that have allowed athletes to return to competition more quickly and safely. It is clear that the problems created by sports injuries are of global interest, and therefore, it is important that the clinical and scientific cooperation continue both internationally and regionally so that there will be further advances in our understanding and management of athletic injuries.

HIV AND THE ATHLETE

The human immunodeficiency virus (HIV) pandemic continues to extend worldwide and as such may have an impact on individuals in all walks of life, including athletes. This entry discusses the nature of HIV disease and its recent epidemiology. There follows a description of how HIV disease might present and become diagnosed in an infected athlete. A review of the treatments that are available and at what stage in the disease process they might be initiated is presented next. Consideration is given to how athletic performance might be adversely affected by the disease, including by the infection itself, by the psychological impact of the diagnosis, and by the side effects of the medication. How training and exercise might affect progression is debated, followed by an analysis of safety of participation in sports—although it is clear that transmission risk is very low compared with most other infectious diseases in sport. Finally, varying legislation worldwide is discussed, which chiefly concerns not just the requirement to test but also travel restrictions that may detrimentally affect participation of athletes in their competitive sporting activities.

Epidemiology

The 2008 global summary of the acquired immune deficiency syndrome (AIDS) epidemic from UNAIDS (The United Nations Joint Programme on HIV/AIDS) estimates that there are more than 33 million people living with HIV, 2.7 million new HIV infections per year, and around 2 million deaths due to AIDS and complications of the infection. While most of the burden of the infection remains in sub-Saharan Africa and South and Southeast Asia, the pandemic continues to spread and increase in most countries worldwide.

HIV is transmitted through bodily fluids, in particular blood, seminal fluid, vaginal secretions, and breast milk. The main route of transmission is unprotected sex with an infected partner, which is thought to account for 70% to 80% of infections globally. This may be heterosexual or homosexual sex. The risk of transmission is increased by the presence of other sexually transmitted infections and decreased by circumcision. Sexual transmission is likely to be the commonest way in which an athlete might become infected. Blood and blood products, for example, infected blood transfusions, and organ or tissue transplants may also lead to infection, although this will be markedly reduced with appropriate levels of screening. Injecting illicit drugs still continues to lead to new infections with HIV as well as the other bloodborne viruses, hepatitis B and hepatitis C. Reuse of needles and inadequate sterilization for medical care may also be an important cause for the epidemic in some parts of the world. There is thus a risk from contaminated injection equipment, which could possibly lead to infection in athletes who use injectable products to legally (or illegally) boost their performance. Other modes of transmission are from an infected mother to the child at birth or through breast-feeding, which leads to some 5% to 10% of all HIV infections worldwide. Considerable efforts are being made to reduce this risk by the use of antiretroviral therapy for the mother and/or the child.

It is important to stress that HIV is not transmitted by casual physical contact; mosquito or other insect bites; kissing; coughing or sneezing; sharing toilets, changing facilities, showers, or other washing facilities; or consuming food or drink handled by someone who has HIV infection.

Clinical Effects of HIV Infection

Probably, most people who get infected with HIV develop acute symptoms (primary HIV infection, sometimes called an HIV seroconversion illness) within a few days to a few weeks of exposure. However, these symptoms may be dismissed as an ordinary flulike illness as the commonest symptoms and signs are nonspecific, such as fever, sore throat, and malaise. There may also be a rash or swollen lymph glands. However, the clinical presentation may show great variation as a whole host of other symptoms are possible, extending from diarrhea and weight loss to meningitis, or there may be very mild symptoms that may mean that the diagnosis is not entertained. Even if a patient presents to the doctor, the diagnosis may be missed, particularly if there appears to be no history of a risky activity. Usually, the symptoms resolve within 2 to 4 weeks, during which time the immune system controls the virus from its initial high levels of replication, and infected individuals may feel well for several years only to become symptomatic again when the immune system has been sufficiently damaged. At this stage, there is the risk of the HIV-related opportunistic infections and tumors (AIDS). Some people's immune systems control the virus so well that they remain healthy for many years (so-called long-term nonprogressors), whereas others succumb more rapidly.

One key factor, which can be measured, is the number of CD4+ lymphocyte cells (a subset of white blood cells important in controlling infection), and the numbers of these cells in the blood is used in guidelines to recommend when anti-HIV (antiretroviral) treatment should be started. Another commonly used test is to quantify the amount of HIV in the blood (HIV viral load), which tends to be higher in those who progress more rapidly. The levels of HIV in the blood around the time of seroconversion are particularly high, which increases the risk of transmission by any of the exposure categories discussed above.

The Importance of Early Diagnosis

Over recent years, there has been a lot of debate about how HIV infection might be detected earlier given the findings from ongoing surveillance studies that a significant proportion of HIV infection in the community remains undiagnosed. This might lead to people presenting in a late stage of the disease already with serious illness or with unwitting spread of infection. Thus, wider use of HIV testing is being recommended, particularly in patients with clinical conditions that might indicate the presence of HIV infection. There are now a number of guidelines being developed around the world recommending HIV testing in these HIV indicator conditions, such as tuberculosis or some severe skin complaints, and also in certain clinical settings such as antenatal clinics or where it is known that HIV prevalence in a population is greater than 1:2,000.

Antiretroviral treatment guidelines continue to evolve with recommendations to start treatment at earlier stages (with higher CD4 counts) than previously as the drugs become better tolerated and with the realization that HIV causes a wider range of problems than thought hitherto. There is thus an increased risk of heart and kidney disease as well as the traditional AIDS diagnoses, such as *pneumocystis jirovecii* pneumonia (PCP) and various tumors. How might the decision to commence on antiretroviral treatment affect an athlete? Even if he or she was otherwise well, the athlete would be advised to refrain from competition and major training for the first 3 months while he or she adjusts to the medication and it could be seen if he or she were tolerating the therapy well and not experiencing any significant side effects. After this initial period, the athlete is likely to benefit from the renewed vigor associated with improving immunity and relatively little inconvenience as the new regimens often have a small pill burden and are easy to take. It is possible of course that the medication may have demonstrable effects on the blood tests used for monitoring athletes, and at least one commonly used antiretroviral, efavirenz (Sustiva, Stockrin), has on occasion caused a false-positive test when screening for cannabis. This is mentioned in the pharmaceutical data sheet for Sustiva. Another important possible effect of the anti-HIV (antiretroviral) medication is that it may lead to important drug interactions with other prescribed or over-the-counter medication, and it is important that the athlete not take anything else without discussing it with his or her pharmacist or doctor.

Effects of Exercise on HIV

Generally speaking, exercise is beneficial for one's health, and this assertion also holds true for those who are infected with HIV. A number of studies have shown improved levels of immunity (including CD4+ lymphocyte counts) associated with exercise and no adverse effect on HIV viral load, and there is no suggestion that extreme exercise makes HIV infection progress more rapidly. Furthermore, progressive resistance training (circuit weight training) can also help develop muscle mass and muscle strength and plays a key role in maintaining bone mass, which has a tendency to decrease in HIV infection. Lifestyle modification with a better diet and more exercise in HIV-infected nonathletes has been shown to improve abnormal fat distribution (lipodystrophy), a condition that was particularly associated with some of the earlier antiretrovirals used to treat HIV. Psychological benefits and general improvements in health have been seen with exercise in many other chronic illnesses, and HIV infection appears to be no exception.

Prevention of HIV Transmission in Sports and Recreation

The risk of transmission of HIV during sporting activity is very low and is less than with the other blood-borne viruses, hepatitis B and hepatitis C. There has been one reported case of seroconversion of HIV as a result of a bleeding injury in a football match in Italy. However, a subsequent review of this early report in 1990 suggested that there was not enough evidence to confirm that transmission had occurred during this sporting activity and that the event could have occurred in the drug dependency rehabilitation center where the man worked. Transmission has also been reported in bloody street fighting; however, the risks here are likely to be greater than those of the physical contact in contact sports. Various risk estimates have been made suggesting that transmissions, even in contact sports, are likely to be lottery figure numbers of less than 1 in 1 million risks. The risk of infection by HIV and other blood-borne viruses during participation can be further reduced to negligible levels if universal precautions are introduced and observed. The following suggestions are made in many national and regional sporting guidelines:

- All blood and other body fluids should be considered infective regardless of circumstance.
- All sports persons should be encouraged to promptly report injuries, particularly those leading to bleeding, as it is in the best interest of all concerned.
- All injuries, especially bleeding wounds, should receive proper, adequate first aid using proper equipment, such as gloves.
- Blood should be cleaned from wounds with soap and water or antiseptic.
- Athletes with bleeding injuries (not minor cuts or abrasions) should be removed from an event as soon as possible.
- A blood-soaked kit should be promptly changed.
- Any skin injuries—for example, abrasions, cuts, or oozing wounds—should be covered during sports activities.
- Water containers should be available individually for each player in contact sports. Athletes should use squeeze water bottles.
- Appropriate protective equipment should be used at all times, including mouth protectors, in contact sports.
- Any equipment contaminated with blood should be removed from the sports activity area—for example, a wrestling mat.

Legislation Including Travel Restrictions

A number of professional boxing authorities require regular HIV testing and do not allow those found to be positive to participate. It is clear, however, that very few infected boxers have been identified by the organizations that have adopted this policy.

A more extensive restriction is the fact that many countries have regulations denying entry, stay, or residence based on HIV status. A recent review (2008) documented a total of some 67 such countries, which is clearly discriminatory. It is also pointless from a public health point of view as all these countries have their own endemic HIV populations. UNAIDS and other bodies have debated the injustice of these regulations and have made statements and recommendations to curtail the restrictions. Up-to-date information can be found in the website given in the Further Readings.

Conclusion

There have been major improvements in the management of HIV infection in recent years. If diagnosed in an athlete at an early stage, appropriate support and clinical monitoring can take place, which will allow maintenance of good health for many years and allow the athlete to continue participation in his or her sporting activity. There is no suggestion that the latter will be detrimental to the athlete's health, and it may indeed be beneficial. Should antiretroviral treatments be required, these can be instituted in a timely fashion before significant symptoms appear. Furthermore, newer treatment regimens appear to be better tolerated and are less likely to cause long-term side effects that might affect the athlete's sporting prowess. Athletes should be reminded that they are much more likely to catch HIV infection from unprotected sex (or the use of contaminated injection equipment) than from their sporting activities, where transmission risk is negligible, and most concerns are unfounded and are due to prejudice and stigma.

Home Exercise Equipment

Home exercise equipment qualifies as any resistance-based or cardiovascular-oriented item that will assist a person toward attaining a desired state of physical fitness. For people who wish to exercise but prefer not to join a fitness center, home exercise equipment offers the opportunity for an equally effective workout at home. The sports medicine professional will be able to provide sound advice on the equipment best suited to individuals according to their fitness goals and with the aim of prevention of injury.

Home Exercise Equipment Needs Analysis

Before prescribing home exercise equipment for individuals, the following information must be gathered:

- Fitness goals
- Available space
- Budget
- Time constraints
- Intrinsic motivation

Fitness Goals

Fitness goals are very important when deciding whether or not to advise an individual to invest in equipment such as treadmills or resistance training equipment. Investment in equipment for an endurance sport participant will be significantly different from that for a person who has recently suffered a heart attack, since their fitness goals obviously will be different.

Space Considerations

Space is a factor when purchasing fitness equipment for the home. Cardiovascular training equipment can take up a lot of space without offering versatility of use. This can also be the case with multigym equipment. Both are better suited for large dwellings than for a relatively small condo or apartment.

Budget and Time Constraints

Budget and time constraints usually will determine the type of equipment that is purchased. If the budget is limited, then the home exercise equipment will generally be basic and rather limited in versatility. However, if finding the time for exercise is an issue, then purchase of equipment with only basic functions and limited versatility is advisable.

Difficulty in finding the time to exercise is one of the major reasons why people do not exercise at all. Therefore, the home exercise equipment must be easy to use, with little or no setup involved. Resistance training equipment must allow a person to "grab and go." Cardiovascular equipment must allow a person the option of a "quick start."

Intrinsic Motivation

Intrinsic motivation is perhaps the most important factor. Some will invest heavily in home equipment assuming that the cost will create the motivation to use it. However, this is not usually the case. It's common for people to get sidetracked with domestic chores and pursuits, so that fitness becomes a low priority. If a person's intrinsic motivation is low, then having a personal trainer come to the person's place of residence initially or intermittently may increase motivation and accountability.

Cardiovascular Exercise Equipment

Currently, the most popular home equipment is cardiovascular equipment, including the following:

- Treadmills
- Elliptical trainers
- Upright/recumbent bikes
- Rowing machines
- Stair steppers

Treadmills

Treadmills were once the most popular piece of cardiovascular equipment until the recent development of elliptical trainers. Home-use treadmills are produced by dozens of fitness companies for walking and jogging on a level, declined, or inclined surface. The tread surface is a heavy-duty belt, varying in length and width, that is propelled by a motor no larger than a lawn mower engine. The size of the belt can be very important for someone who has a wide gait and long stride. If the belt is narrow or short, the risk of a person falling off is significantly higher. Most treadmills require a power source varying between 110 and 220 volts. There are, however, a few smaller, self-propelling treadmills on the market that are less durable and designed for walking.

Elliptical Trainers

Elliptical trainers have seen the highest increase in sales over the past decade due to the low-impact nature and a movement pattern similar to jogging. Many runners will look to this piece of equipment for cross-training so that the amount of impact on the ankles, knees, and hips is minimized, and they can elicit a training effect similar to jogging or running. Elliptical trainers have varying stride lengths, but most commonly they are between 18 and 24 inches (in.; 1 in. = 2.54 centimeters) in length. Other variables on this apparatus include upper body components where the person can mimic cross-country skiing.

Stationary Bikes

Stationary bikes primarily come in two models: upright and recumbent. Upright stationary bikes emulate the design of traditional hybrid bicycles, which have the rider in a slightly forward flexed posture with the handles in front and approximately shoulder width apart. Upright stationary bikes have saddles/seats much larger than a traditional bike's, with the rider's comfort in mind. Most electronic upright stationary bikes have a multitude of programs that the rider can use to focus on different components of his or her cardiovascular endurance.

For the cycling enthusiast, there are basic, non-electronic stationary upright bikes used for group fitness classes that closely replicate the resistance and ergonomics of performance road bicycles. The footprint of this type of stationary bike is significantly less than that of the electronic upright stationary bike.

Recumbent electronic stationary bikes provide the rider with a back support, while his or her feet are positioned out in front. This position is significantly different from that of the upright bike and, in general, is much more comfortable for the rider. People with back disorders or other orthopedic complications will benefit from riding on a recumbent bicycle more than an upright, stationary bike due to the ergonomics providing the rider with greater support on the lumbar and thoracic spine. Recumbent electronic stationary bikes are self-powered like the electronic upright stationary bike. The recumbent electronic stationary bike has similar programs to provide the rider with variations in his or her endurance training.

Rowing Machines

Indoor rowing machines, also called ergometers or "ergs," are another very popular piece of exercise equipment that can be found in all fitness centers and in many home gyms. Ergs have a much different physiological demand from that of treadmills, ellipticals, and stationary bikes due to the significant demand on the upper body in the movement pattern. Rowing machines are long and slender with a seat that slides forward and backward on a steel rail. As in a bicycle, the handle is attached to a chain that connects to a flywheel that provides the rower with drag and resistance. The indoor rowing machine is excellent for people with orthopedic issues, due to its low-impact nature. People with chronic back troubles should consult with their doctor or orthopedist prior to investing in this piece of equipment for home use. Indoor rowing machines are self-powered with a small LED (light-emitting diode) that is battery operated to provide the rower with feedback on the pace and distance that he or she has rowed and the duration he or she has been exercising.

Stair Stepping Machines

The stair stepping machine is another very popular cardiovascular machine that replicates the motion of walking up stairs. There are two types of stair stepping pieces of equipment: stair climbers and step mills. The first of these pieces of equipment is self-powered and takes up the least amount of space of all the cardiovascular machines discussed thus far. Two pedals approximately hip width apart are controlled by an alternator that allows the pedals to have variable stepping heights.

Step mills are another type of stair stepping machines. Step mills are significantly larger than the stair climbers, with a much higher price point. The difference between a step mill and a stair climber is that the step mill has a revolving stair case with a fixed step height. Step mills require a dedicated power source, whereas the stair climber is self-powered.

Resistance Training Equipment

Resistance training equipment is a very important component of any home gym. There are all types of resistance training equipment for home use. The most popular types of resistance training equipment for home use are as follows:

- Free weights
- Rubber tubing and bands
- Bodyweight training systems
- Stability and medicine balls

Free Weights

Barbells and dumbbells are used in traditional single and multijoint exercises such as bicep curls and chest presses. Dumbbells take up varying amounts of space depending on the number of pieces, the type of storage rack, and the weight of the dumbbell. There are space-saving dumbbells that have varying weights that may be adjusted by a pin or knob.

Kettlebells are used in nontraditional resistance training. This form of resistance training can be used to increase cardiovascular conditioning as well as muscular power, strength, coordination, and proprioception.

Rubber Tubing and Bands

Rubber tubing and bands are very popular tools to increase muscular strength. They were originally used as physical therapy modalities and found their way into fitness centers and quickly into households. Tubing and bands come in varying resistances and lengths and can be easily stored and used in any space, making them a popular choice for individuals who have little or no space in their residence to exercise.

Bodyweight Training Equipment

Bodyweight training systems are an excellent modality of training for a home gym with little or no space allocated for resistance training. Rings and similar types of equipment can provide variable resistance with the use of gravity for total body resistance training. While increasing strength, bodyweight training systems will also improve total body stability, balance, and proprioception.

Balls

Stability balls are very popular tools for resistance training. Often, they are used in combination with other resistance training tools, such as dumbbells and medicine balls. This form of resistance training will increase an individual's strength, stability, coordination, and proprioception with the proper exercise prescription.

Medicine balls are great for dynamic resistance training and take up minimal space. Total body strength, power, coordination, and proprioception can be developed with the proper exercises. They come in variable sizes and weights.

Conclusion

Cardiovascular and resistance training equipment for home gyms can be space efficient and just as, if not more, effective as the equipment that can be found in fitness centers. Consulting with a fitness professional before purchasing equipment is prudent so that the equipment invested in is not contraindicated for the fitness goal of the individual investing in the equipment.

Horse Riding, Injuries in

Injury is an inevitable consequence of the inherently dangerous sport of horse riding. Head and neck trauma are the most serious injuries and are frequently catastrophic. Helmets worn with a secure chin strap have been proven effective in preventing serious head injuries.

Epidemiology

Most serious equestrian-related injuries occur when a rider is thrown from the horse. Furthermore, injury may be incurred if the rider is then dragged or crushed by the animal. The two most common horse riding injuries are long bone fractures and head injuries. Head trauma is the injury most likely to result in hospitalization or death and is the most common career-ending injury for professional jockeys. The percentage of injuries causing death is higher in younger riders. Although most injuries are associated with the act of riding, approximately 15% of the injuries occur during nonriding activities such as shoeing and grooming. Hoof kick injuries to an unmounted rider represent about 30% of equestrian-related trauma.

There are several factors that contribute to making horse riding an inherently dangerous sport. The mounted rider's height, which places the average rider's head 12 to 13 feet (ft; 1 ft = 0.30 meters) above the ground, is by itself a major risk factor for injury. Good outcomes from riding activities, which can range from a slow-paced trail ride to competitive jumping over 6-ft gates at a fast canter, depend on the compatible pairing of two very different species. Factor in the animal's mass, strength, and speed (up to 40 miles/hour [mph; 1 mph = 1.6 kilometers/hour]), and the potential for a bad outcome becomes significant. Along these lines, the injury rates are especially high among event riders where successful jumping requires a coupling of considerable height and speed.

The majority of horse riding injuries occur during unsupervised leisure riding. However, experience in horse riding does not necessarily provide protection against injury, due, in part, to the inherent unpredictability of the horse–rider relationship.

Catastrophic Injury

Although the majority of horse riding injuries involve the extremities, the most catastrophic are those involving the central nervous system. Of the neurologic injuries, head injuries outnumber spinal injuries roughly by 5 to 1. Jumping is the equestrian activity posing the greatest risk for head and spine injury. The potential for catastrophic head injury in horse riding is directly related to the position of the rider coupled with the horse's speed. The head-forward stance, standard in racing and steeplechase, presupposes a significant increase in risk for head injury. Most head injuries in these scenarios occur as a result of the sudden acceleration-deceleration forces that occur with an unexpected fall.

At one extreme, the rider may be launched at high velocity in a projectile fashion, subsequently sustaining massive brain injury. More commonly, the rider will suffer a nonfatal concussion or cerebral contusion. Skull fractures most commonly occur when an unhelmeted rider is kicked. Among those seriously injured while grooming, the depressed skull fracture is the most common head injury observed.

Cervical fractures in equestrian sports tend to occur when a rider is thrown over the head of the horse unexpectedly and with such speed that there is insufficient time to protect himself or herself. As

A rider falls from his or her horse if it doesn't clear the hurdle. The most serious equestrian-related injuries occur when a rider is thrown from the horse. The two most common horse riding injuries are long bone fractures and head injury.

Source: Mikhail Kondrashov/iStockphoto.

result, the rider's neck is typically thrust into extreme flexion, which renders the cervical spine more vulnerable to fracture on impact. More commonly, the falling rider will respond to a fall with the natural protective mechanism of wrist, arms, and neck in extension. Considering the mechanism of injury, it is not surprising that roughly 50% of riders sustaining neck injury had concomitant head injury. A rider attempting to regain balance or to avoid falling risks catastrophic injury from pulling the horse down onto himself or herself. A significant number of horse riders with head and neck injury experience long-term disability.

Noncatastrophic Injury

Thoracolumbar fractures are the most common spinal injury seen in horse riding and are practically unique to the sport. The thoracolumbar junction (T12-L1 vertebrae) is the most common site of fracture. The injury is usually the result of a rider landing on his or her feet or buttocks subsequent to falling or being thrown.

Of the noncatastrophic equestrian injuries, overuse injuries are among the most common yet the least studied. Most overuse injuries in horse riders involve the shoulder, lower back, and lower extremities. Proper diagnosis and treatment of these injuries require knowledge of riding mechanics and the musculoskeletal demands placed on the rider. For example, the maintenance of balance and proper position at all times requires considerable strength and fitness of the lower back and thighs. The greatest forces during riding are absorbed through the rider's pelvis, sacrum, and lumbar spine. Because of this, maintenance of strong pelvic and core stability is the chief focus of most rehabilitative efforts. Equally important is a regular, balanced fitness program that incorporates postural training, routine stretching, and aerobic activity.

Injury Prevention

Current recommendations for the prevention of injury related to horse riding are fivefold and include the following:

1. Requiring helmet use on or near a horse.
2. Use of safety stirrups to prevent drag injury.
3. Matching the skill of the rider with the appropriate horse.
4. Providing close supervision of children and beginners.
5. Providing education programs primarily for novice riders, emphasizing the risks of riding and the methods employed to minimize them.

At present, the best standard for riding helmets is that established by the American Society for Testing and Materials (ASTM). To be fully effective, the helmet must be secured by a chin strap. Safety stirrups are designed to break away in the event of a fall in order to help prevent foot injury or trauma associated with being dragged. Wearing strengthened riding boots with heels, with emphasis on riding in "heels-down" position, greatly helps prevent the feet from sliding through the stirrup and potentially getting stuck.

Other general safety tips to consider include the following:

- When falling from a horse, try to roll to the side away from the animal.
- Do not ride if tired or under the influence of alcohol.
- Never walk behind a horse; it is always best to approach a horse at its shoulder as this is less threatening to the animal.
- The horse's ear movements provide important information about its demeanor. Ears that are pinned back indicate anger or apprehension of a threat.

Hydrotherapy and Aquatic Therapy

Hydrotherapy

Hydrotherapy is the immersion of the entire body or a body segment in water. Water immersion promotes an increase and/or decrease in superficial tissue temperature. The main goal of hydrotherapy is to decrease swelling, relieve joint pain and stiffness, and promote healing and relaxation.

Water has a number of physical properties, including buoyancy, viscosity, hydrostatic pressure, and a relatively high specific heat and thermal conductivity, that make it well suited for rehabilitation. There are many ways by which hydrotherapy may be implemented. Supplies include water and a "holder" such as the Hubbard tub for total body immersion and/or a whirlpool for a body segment. Bathtubs and buckets filled with water may also be used. Therapeutic hydrotherapy equipment has high-speed agitators that circulate the water to promote a massaging effect and relaxation.

Water temperature can be varied depending on the type and extent of the injury. In an acute injury, the water temperature should be cooler. In chronic injuries, the water temperature should be warmer. However, the water temperature should never exceed 105 °F. Hydrotherapy is indicated in the treatment of subacute or chronic traumatic and/or inflammatory conditions, muscle spasms, joint contractures, pain, muscle weakness, and alterations in peripheral conditions. Additionally, it can also be used for wound care and debridement. Some of the contraindications for hydrotherapy are uncontrolled seizures, unstable angina, uncontrolled diabetes, bowel incontinence, diarrhea, open wounds, bleeding, deep vein thrombosis, waterborne and kidney diseases, infectious diseases, and contagious skin rashes.

Some precautions for hydrotherapy are fever, infection, acute inflammatory condition, altered sensation, cardiac instability/hypertension, altered mental status, pregnancy, and communicable diseases. Abnormal responses to hydrotherapy include adverse physiological responses such as significant changes in blood pressure and respiration. Hydrotherapy should be discontinued as a treatment if the individual shows any adverse reactions or if the condition has resolved or there are no signs of improvement.

Aquatic Therapy

Aquatic therapy is a more specific type of hydrotherapy that must be delivered by qualified personnel. Aquatic therapy is used to restore function for persons suffering from acute, transient, or chronic disabilities, syndromes, or diseases.

The principles of water make it suitable for treating many conditions. The first principle, buoyancy, assists in supporting the weight of the individual, therefore decreasing weight bearing through the joints. By minimizing the stress placed through the joint, it is easier and less painful to perform exercises. This is especially helpful for individuals with weight-bearing restrictions, such as athletes recovering from surgery and/or a fracture. Water's viscosity provides resistance, which allows for muscle strengthening without the need for weights. When the resistance is coupled with buoyancy, strengthening muscles is easier with less joint stress. Aquatic therapy also uses hydrostatic pressure to create forces perpendicular to the body's surface. These forces decrease joint and soft tissue swelling, reduce spasticity, and also improve joint position awareness. This property is especially useful in sports medicine since it improves joint proprioception. Aquatic therapy is only performed in warm water, whereas hydrotherapy can be performed in either warm or cold water. The warmth of the water aids in muscle relaxation and promotes vasodilation of blood vessels, which increases the blood flow to the injured tissues.

Contraindications for aquatic therapy are the same as for hydrotherapy, though one must be especially careful as the whole body is typically immersed. Aquatic therapy can improve overall fitness and cardiovascular endurance, balance, and respiration. To obtain optimal benefit from hydrotherapy or aquatic therapy, one must take into account the risks and benefits of the treatment plan, the equipment selected, and the various means of applying hydrotherapy.

Hyperextension of the Knee (Genu Recurvatum)

Genu recurvatum is defined as excessive backward motion during active knee extension. This "knee hyperextension" may be an isolated finding or part of a generalized multidirectional joint instability.

Prevalence

The prevalence of joint hypermobility affecting a few joints is substantial. One study showed that 18% of healthy subjects had at least one lax joint and 11% had three or more lax joints. The prevalence of generalized joint hypermobility varies from 10% to 30% and tends to decrease with age. Congenital genu recurvatum is a rare malformation with knee hyperextension and marked limitation of knee flexion at birth. This rare condition is thought to be caused by in utero positioning and genetic factors and can be treated with gentle manipulation, followed by serial splinting of the legs to achieve a more neutral position.

Symptoms

The major presenting complaint of children with hypermobility is pain. Less commonly, a parent or patient will complain of abnormal gait or apparent joint deformity.

Physical Examination

The patient should be observed while walking toward and away from the examiner. The patient should also be examined while standing still with the feet slightly apart and parallel (pointing forward). During these parts of the examination, excessive backward motion of the knee should be noticeable if the patient has genu recurvatum. The patient will also be examined for knee range of motion and joint stability while sitting and lying on his or her back.

Importance in Sports Medicine

Hyperextension of the knee or excessive backward knee joint mobility can contribute to recurrent knee dislocations. In severe cases, leg braces may be required to help support the knee joint and prevent injury.

Patients with hypermobility may present with traumatic and overuse conditions of the affected joint, which is the knee in the case of genu recurvatum. The patient may have a history of joint "swelling" that lasts for a brief period of time, complain of joint and muscle pain without any other apparent abnormality, or complain of symmetrical joint pain with use that is relieved by rest. Patients who are known to have hypermobility of the joints should be monitored closely during the athletic season and counseled about increased risk of injury during sports participation, especially high-contact sports such as American football, ice hockey, wrestling, and lacrosse. Furthermore, all patients presenting with new sports injuries should be thoroughly evaluated and assessed for evidence of hypermobility.

Later in life, osteoarthritis (OA) may be more frequent in older patients who have joint laxity. The presence of hypermobility in childhood, however, does not necessarily place that person at increased risk for OA later in life if his or her joint laxity has normalized with age.

Diagnosis

Genu recurvatum is easily diagnosed if hyperextension of the knee joint is present. The examiner should also assess the mobility of other joints, as some syndromes exist that involve hypermobility in multiple or all joints.

Treatment

Muscle strengthening is an important part of treatment and injury prevention for genu recurvatum. The use of individualized resistance exercise to quadriceps muscles is helpful. Referral to a physical therapist may be beneficial.

Symptomatic use of anti-inflammatory agents can be implemented. As mentioned above, severe cases may require braces for support and prevention of injury.

Hypertension (High Blood Pressure)

Systemic hypertension is the most common cardiovascular condition seen in competitive athletes as well as among adults in the general population. The diagnosis of hypertension is based on blood pressure levels persistently at or above certain levels as measured on two separate occasions. The primary concerns for the athlete with hypertension are the effect of exercise and competition on blood pressure control, or progression of hypertension, and the acute risk exercise and competition may pose to the athlete.

The Joint National Committee on the Detection, Evaluation, and Treatment of High Blood Pressure VII (JNC VII) has published guidelines and recommendations on the diagnosis and treatment of hypertension. These hypertension guidelines for adults over 18 classify prehypertension as systolic blood pressure (SBP) 120 to 139 mmHg (millimeters of mercury pressure) and diastolic blood pressure (DBP) 80 to 89 mmHg. Stage I hypertension consists of SBP 140 to 159 mmHg and DBP 90 to 99 mmHg, with higher readings indicating moderate to severe hypertension. In children and adolescents, hypertension includes repeated blood pressure measurements at the 95th percentile or higher, adjusted for age, height, and gender.

Diagnosis

Since the diagnosis of hypertension is based on blood pressure readings, it is important that the blood pressure be measured accurately. Measurements outside the office setting may be useful as a screening tool; however, diagnosis should be made only based on accurate, repeated office readings. The recommended method for office measurements is the auscultatory (listening) method with a properly calibrated and validated sphygmomanometer (blood pressure cuff). The athlete should be seated quietly in a chair for 5 minutes with arms resting at heart level and feet on the floor. The sphygmomanometer should fit properly, with the bladder encircling 80% of the arm to ensure accuracy. Avoidance of caffeine 1 hour prior to the reading and smoking 30 minutes prior to the reading is recommended. Two readings should be taken, separated by several minutes if possible, and there should not be variation of more than 5 mmHg between readings. If the initial values are elevated, then another set of two readings should be repeated after 1 week. The cuff should be inflated 20 mmHg above the SBP (identified by the disappearance of the radial pulse) and deflated at 2 mmHg/second. SBP is the point where the first sound is heard, and DBP is the point where the sound disappears. The blood pressure, patient position, arm used, and cuff size should be documented.

Effect of Exercise on Blood Pressure

Before they begin training, blood pressure should be accurately measured in all individuals interested in participating in competitive athletics. Hypertension is the most common primary diagnosis in America, with 50 million adults being diagnosed with it; only 34% of cases of hypertension are adequately controlled. The primary goal in treating hypertension is to reduce morbidity and mortality from complications of the disorder. Modifications such as weight loss, proper diet, limiting alcohol consumption, and increasing physical activity can be effective in lowering blood pressure. The American College of Sports Medicine's position stand on hypertension and exercise examines numerous studies that identify lowered blood pressure readings in patients on regular dynamic/aerobic exercise programs. The paper also described a drop in blood pressure lasting about 22 hours after an exercise session. Even modest reductions in blood pressure of 2 mmHg have been shown to reduce the risk of stroke by 14% to 17% and coronary artery disease by 6% to 9%. Additionally, the exercise benefits in hypertension were observed across a range of ages, between genders and among different ethnic groups. There are insufficient data in children and adolescents to establish a pattern of benefits with exercise and hypertension.

A moderate level of training intensity (40–70% maximal heart rate) had the same or a slightly higher benefit in lowering blood pressure compared with high-intensity training. As with any exercise program, a gradual increase in the level and intensity of activity is recommended, especially in the untrained individual. Resistance training has typically been discouraged in hypertensive patients as a result of studies that showed a dramatic and acute elevation in blood pressure during heavy-resistance/weight training. Reports of adverse events of stroke or heart attack precipitated by heavy-resistance training have also been published. However, studies examining the effects of long-term resistance training have failed to demonstrate any deleterious effects. Circuit weight training has been found in studies to have more blood pressure–lowering benefits than conventional weight training strategies. The combination of dynamic aerobic exercises with resistance training would provide optimal benefit in lowering blood pressure.

Evaluation

The continuous rise in the prevalence of childhood obesity leads to increasing concern about the development of hypertension. Lifestyle issues such as diet and level of physical activity contribute to the risk of developing hypertension. The school sports exam is a unique opportunity to address these issues and other risk factors such as smoking, alcohol use, and use of illicit drugs and anabolic steroids by the athlete. Any athlete with persistent hypertensive readings should have a complete history and examination done in order to develop an appropriate plan of evaluation and treatment. Lifestyle issues are clearly important, but possible underlying disorders must not be overlooked during the evaluation. Diagnostic studies should include an electrocardiogram (EKG), urine tests, and blood tests to assess blood counts, blood chemistry, cholesterol, and kidney function.

The majority of patients with hypertension have primary or essential hypertension with no identifiable cause. Patients with essential hypertension often identify other family members with high blood pressure, indicating positive family history as a risk factor for hypertension. In some patients, hypertension is the result of an underlying problem that needs to be identified and treated in order to adequately control the blood pressure. Causes may include sleep apnea, use of drugs or alcohol, kidney disease, thyroid or other endocrine disorders, and pheochromocytoma (a rare, hormone-secreting tumor). Children and adolescents with hypertension should be evaluated with particular attention to kidney disease and coarctation of the aorta (abnormal narrowing of the aorta), which are often the cause of hypertension in this age-group. A thorough history will identify the symptoms of the patient that would raise suspicion for the above problems. Careful and close monitoring of the hypertensive patient is essential since poor blood pressure control with treatment will also raise suspicion for these secondary causes.

Evaluation of target organ damage is necessary before a treatment plan can be recommended. Assessment of the heart for evidence of heart attack, thickening of the heart wall muscle, or heart failure will influence greatly treatment choices and recommendations for physical activity. The brain is susceptible to stroke, while kidney function may decrease due to the effect of hypertension on the blood vessels. The retina of the eye and the arteries in the legs can be affected as well. Thorough evaluation for these complications is necessary before making recommendations regarding exercise.

The benefits of exercise for blood pressure control are well documented. However, underlying coronary heart disease in the setting of vigorous physical activities could precipitate sudden death. Even mild hypertension is a risk factor for heart disease, making an assessment prior to participation in an exercise program clinically important. The nature of the pre-exercise evaluation is based on various factors, including patient age, underlying medical problems, and type and intensity of activity to be performed. Exercise testing could be considered but has been shown to be a poor predictor of sudden cardiac death. The American College of Sports Medicine has published guidelines to assist clinicians in assessing patient risk for sudden death. These guidelines are helpful in making appropriate exercise-testing recommendations based on the risk assessment plus the goals and objectives of the exercise program. Each athlete with hypertension requires an individualized assessment to outline the appropriate evaluation. Only then can the clinician make recommendations regarding the exercise program that is the safest.

Treatment

Untreated hypertension in the athlete may cause some limitation in exercise performance. Many of the medications used to treat hypertension may have undesirable side effects and may also affect exercise performance. Initial treatment should be directed toward lifestyle modifications such as change in diet and avoiding tobacco products and excess alcohol. High-risk behaviors such as use of illicit street drugs and performance-enhancing substances, such as steroids or growth hormones, have adverse effects on blood pressure.

Patients who are unable to achieve appropriate blood pressure control with lifestyle changes may require treatment with medications. Numerous classes of medications are available for the treatment of hypertension. Unfortunately, many of these medications may have physiologic effects or side effects that could adversely affect exercise performance. Diuretics may impair the body's heat regulation and may cause dehydration or muscle cramps. Beta blockers prevent increase in heart rate with exercise, which affects performance and also may worsen asthma. Both diuretics and beta blockers are banned by the International Olympic Committee doping organizations. Diuretics may mask other banned substances in the urine during drug testing, and beta blockers are able to diminish tremors and anxiety, creating an unfair advantage in sports such as archery and shooting.

All classes of medications may have effects on hemodynamics with exercise. The choice of antihypertensive agent for an athlete requires careful consideration of all these medication effects as well as the athlete's exercise goals.

Hypnosis and Sport Performance

Hypnosis is a suggestive technique that has been used to help a person change thoughts, perceptions, sensations, or behaviors. The use of hypnosis for enhancing sport performance has enjoyed a steady increase over the past three decades. As athletes have recognized the importance of mental training techniques in their quest for excellence, effective interventions such as hypnosis have come increasingly into use. Although hypnosis has value if used properly in sports performances, it also has the potential for harm if applied inappropriately in sporting situations. This entry focuses on the characteristics of sports performers who can successfully be hypnotized, the ways hypnosis can be used effectively to empower sports performers, and the type of hypnosis thought to be most effective with the athlete population.

Characteristics of Hypnotic Subjects in Sports

Hypnosis is a psychological intervention that is often misunderstood by the general population, including athletes. Hypnosis consists of three distinct stages: (1) induction stage, (2) utilization stage, and (3) dehypnotization stage. Most sports performers are prone to trying any technique that is purported to enhance their performance, even if it can also be dangerous. Athletes are specially gifted physical specimens, but that attribute is far from the most essential characteristic that makes for an ideal hypnotic subject. The trait that influences a person to be an ideal candidate for hypnosis is suggestibility. Many authorities believe that approximately 95% of the general population can be successfully hypnotized. Strangely enough, most athletes are not easily hypnotized because, through experience and training, they learn to be guarded and untrusting instead of being open and receptive. Even though many sports performers express a willingness and desire to be hypnotized (because it is deemed to be a quick and effective process), initially athletes are not ideal subjects until they become educated concerning this technique and become more trusting. To facilitate learning the skill of being hypnotized, it is important for the hypnotist to debunk any myths surrounding hypnosis. Unfortunately, the "stage hypnosis" movement has served to reinforce these myths with all potential subjects, including athletes. Stage hypnotists usually do not have formal training in hypnosis and serve to perpetuate these myths. They are often very talented in the induction and dehypnotization stages but are lacking in ethical considerations during utilization. For instance, no person who uses hypnosis in clinical practice would use the stage for entertainment purposes. Sports hypnotists use this technique for the suggested aids in performance mentioned later in this article.

Empowering Sports Performers Through Hypnosis

Hypnosis has been used by sports performers in a number of different ways: (a) to receive more benefits from relaxation, (b) for controlling anxiety, (c) pain management, (d) for enhancing imagery, (e) to improve concentration, (f) for erasing a performance block, (g) injury rehabilitation, and (h) for ego strengthening.

Hypnosis and Relaxation

Many, if not most, hypnotists use fairly deep relaxation as an induction technique for entering a hypnotic trance. Naturally then, subjects surmise that hypnosis and relaxation are the same phenomenon, but this is inaccurate. Actually, the quelling of the active mind (relaxation) is a skill in itself and is a beneficial side effect that hypnosis seems to enhance. There are various forms of "active hypnosis" as well as passive hypnotic trances. It is even possible for an athlete to actively move in a hypnotic trance while performing. Also, there are various induction techniques that use active hypnosis as the most effective way to get the athlete to experience this state. For instance, an athlete could enter a trance and then actually perform or move to the rhythm of his or her event while in a trance state. This is a very powerful and effective way to mentally as well as physically practice a sport.

Controlling Anxiety and Arousal

Two of the most powerful factors that limit sport performances are the emotions of anxiety and arousal. As anxiety increases, the ability to focus effectively is greatly diminished. On the other hand, as arousal increases, the ability to focus narrows. These situations are crucial because most athletes experience anxiety and also need to reach an individual level of arousal to perform well. Hypnosis is beneficial in sports performance because it can contribute to creating a state of relaxation that mitigates anxiety. Also, hypnosis can be used as a technique to reach an optimal level of arousal prior and during competition. In other words, hypnosis can effectively train a performer "to be intense but not tense." This emotional balance is crucial for attaining great performances in sports situations. Suggestions can be made in the trance state for powerful emotional transitions. Suggestions made in the trance state are not questioned by the athlete and often last for long periods of time if the sports hypnotist uses posthypnotic suggestions.

Pain Management

The human mind has the unique ability to either recognize and feel pain or ignore it. While in a hypnotic trance, it is indeed possible to reach an altered state where pain is not felt at the conscious level. Since pain in sports situations is a common occurrence because of extensive physical exertion, athletes readily seek ways to eliminate or reduce the feeling of pain. Hypnosis trains the mind to ignore the feeling of pain. Hypnosis is so powerful that under this technique some athletes have been able to withstand surgery without anesthesia and remain fully conscious during the entire operation. The whole concept of "glove anesthesia" is a demonstration of pain management in a hypnotic state. The sports hypnotist must be very careful to always leave some pain awareness in the athletes so as not to induce complete anesthesia, which would be very dangerous and would increase the possibility of overreaching and injury.

Enhancing Imagery

For sports performers, the skill of imagery normally has two perspectives: (1) seeing (visualization) or (2) feeling (kinesthetics). Both of these perspectives of imagery are extremely important for high-level performers. One of the benefits of hypnosis is to experience "heightened awareness" in all the human senses. Sports performers use their senses in a variety of different ways so that simple posthypnotic suggestions can be employed to enhance or at least focus on the various imagery perspectives. Learning to ignore distractions, feeling more intensity, and reliving past events (regression) are examples of the use of hypnosis and its effecting competition with imagery. In fact, even an increased learning effect can be induced with hypnosis as athletes can remember more information and practice cues when in a trance state. This is a very effective way to do additional practice while away from the athletic area.

Improving Concentration

Being able to concentrate while in the appropriate attentional style and at the right moment is the secret to committing fewer performance errors. Sports performances require the athlete to be able to change attentional styles almost instantaneously and automatically. If an athlete has to stop and think about what to attend to, it is most likely too late to perform effectively. Again, heightened awareness is a benefit of hypnosis and allows a performer to focus more quickly and clearly. Through hypnosis training, athletes can learn to change attentional styles with minimal effort and precision effectiveness. The ability to focus is a crucial skill in athletic performances. Hypnosis has been proven to increase an athlete's ability to concentrate for longer durations and on the more appropriate cues.

Erasing a Performance Block

Performance blocks are frequently the result of overanalyzing or overthinking about a motor movement that has previously been made automatic. As soon as an athlete interferes with an automatic response, the rhythm of the response is disrupted, and this creates negative emotionality, which is very strong and contributes to the increased probability that the negative response will occur again. Hypnosis can be used to keep the mind focused on the correct response instead of worrying about the wrong one. Hypnosis can aid in putting the mind on "automatic pilot" instead of focusing on the particulars of an incorrect technique. The athlete's mind in a hypnotic state is unquestionably more susceptible to suggestion and, therefore, will move immediately to the subconscious suggestion for improved self-image and performance possibilities that may be blocked by the conscious mind.

Injury Rehabilitation

In addition to mitigating the pain associated with injury, hypnosis is useful in recruiting the mind's powers to aid in the rehabilitation process. An example would be having the mind (under hypnosis) focus on sending more blood volume to an injured area to aid in removing infected tissues or reducing swelling; then, the injured area will heal more quickly. Employing hypnosis techniques to attain long periods of relaxed states also helps the process of rehabilitation of an injury. Much research has supported the ability of a hypnotic trance to facilitate and accelerate the healing process for athletic injury as well as to reduce the fear of reinjury in the athletic population.

Ego Strengthening

Negative beliefs (fears) that interfere with ideal performances are often buried deep in the unconscious mind of the athlete. Under hypnosis, these fears can be reached and subsequently reduced. Once the fears are addressed and overcome, the ego is strengthened, which is a lasting benefit for future performances. The self-image is constantly being fed information in a conscious and unconscious manner. Self-talk or internal dialogue is an ongoing phenomenon. Hypnosis is a very valuable tool to aid in programming the mind in a positive way.

Building Confidence

After ego strengthening, athletes can again use hypnosis to help increase inner strength (self-confidence). By eliminating some of the detractors to being confident and then providing uplifting scenarios to work on, hypnosis helps sports performers to be more positive about themselves and their abilities instead of focusing on the negative.

Types of Hypnosis and Their Effectiveness

The two general types of hypnosis that are commonly used with sports performers are *hetero-hypnosis* and *self-hypnosis*. Hetero-hypnosis is facilitated by a hypnotizer, while self-hypnosis occurs when a person enters a trance without the help of another person. People respond to hypnosis in many different ways, and athletes are no different. With these thoughts in mind, most professionals who have used hypnosis with sports performers begin with hetero-hypnosis (to determine how suggestible a subject will be) and then eventually train the athlete to use self-hypnosis. This is ideal because self-hypnosis allows the use of hypnosis by the individual instead of waiting for the hypnotist to be available. It should be clear that hypnosis may not be the answer for all psychological issues in sports performers. It is also of great importance that hypnosis be used by properly trained and credentialed professionals only.

Hyponatremia, Exercise-Associated

Exercise-associated hyponatremia (EAH) is a life-threatening body fluid imbalance in which the sodium concentration within the bloodstream is below the normal reference range for the laboratory performing the test. A low (hypo) sodium (natremia) concentration (generally under 135 millimoles/liter [mmol/L]) within the bloodstream can cause all the cells in the body to swell because of corresponding changes in osmotic pressure. Rapid swelling of the brain (cerebral edema) and lungs (pulmonary edema) due to low blood sodium concentrations can lead to seizures, coma, and death. Once a rare and singular phenomenon that was first reported in athletic events more than 20 years ago, the percentage of EAH cases has increased significantly over the past decade. For example, as many as 13% of marathon runners and 30% of ironman triathletes have finished competitive events with EAH, while at least five deaths have been reported in marathon runners to date.

Exercise-associated hyponatremia is an acute hyponatremia that occurs during or up to 24 hours after prolonged physical activity and has rapidly become the most common life-threatening complication of endurance exercise. Because the number of EAH cases is increasing at an alarming rate in a wide variety of sports, it is prudent that the public be thoroughly educated on this topic as well as on the most appropriate fluid replacement strategies that ought to be followed during prolonged physical activity.

This entry discusses the causes, risk factors, symptoms, diagnosis, treatment, and prevention of EAH.

Causes

In simple terms, low blood sodium concentrations are caused by either a *depletion* of sodium from excessive salt loss or by a *dilution* of sodium from excess fluid intake. Current evidence suggests that the majority of EAH cases are caused by sustained fluid intake beyond the body's capacity to excrete any buildup of excess fluid (dilutional EAH). Although excessive sodium loss through sweat and urine may contribute to the development of EAH, this particular mechanism appears less common. The contribution of sodium loss in the development of hyponatremia may become more significant in endurance events lasting over 24 hours in hot environmental conditions; however, more research is necessary to fully clarify the role of sodium losses in EAH. Therefore, it should be emphasized that EAH is primarily a salt imbalance from the *ingestion* combined with the *retention* of too much fluid rather than from the ingestion of too little salt. Recent evidence suggests that the body's main antidiuretic hormone (arginine vasopressin) is stimulated during exercise so that any fluid excess cannot be appropriately excreted. At rest, any body fluid excess can promptly be excreted, so fluid overload hyponatremia is unlikely in healthy subjects under nonexercising conditions.

Risk Factors

Recognized risk factors have been identified in athletes developing EAH. Athlete-related (internal) risk factors include excessive drinking behavior, weight gain during exercise, low body weight, being female, slow performance pace, event inexperience, and ingestion of nonsteroidal anti-inflammatory medications. Event-related (external) risk factors include high availability of drinking fluids, exercise lasting over 4 hours, and unusually hot or extremely cold environmental temperatures. Although none of these factors can conclusively predict the development of EAH, a constellation of such risk factors, combined with any sign or symptom of hyponatremia, warrants urgent blood sodium measurement at a nearby medical facility.

Symptoms

Early signs and symptoms of EAH include bloating, "puffiness," nausea, vomiting, and headache. These signs are, unfortunately, very common during and after exercise in athletes with or without low blood sodium levels. As the severity of EAH progresses, more serious signs and symptoms associated with lung and brain swelling include difficulty in breathing, confusion, disorientation, agitation, and involuntary leg movements as if the athlete was still exercising. Seizures, coma, and death may result when blood sodium levels drop too quickly or descend below critical individual levels. Hyponatremia is a medical emergency, and the presence of any of these signs or symptoms is an absolute indication to measure the blood sodium concentration.

Diagnosis

A diagnosis of EAH can be confirmed via a blood test measuring serum or plasma sodium concentration. Portable electrolyte (sodium, potassium, and chloride) analyzers now exist, so venous blood samples can be obtained and analyzed at the bedside within a few minutes. Any collapsed athlete who is breathing, has a regular pulse, but is not responding to supportive care should undergo immediate measurement of rectal temperature and blood glucose and blood sodium to rule out heat stroke, hypoglycemia (low blood sugar), or hypernatremia (high blood sodium), all of which can present with similar signs and symptoms as EAH.

Some athletes with blood sodium levels below the normal reference range do not report any adverse clinical signs or symptoms (asymptomatic). However, in general, the lower the blood sodium value, the more severe the manifestations of underlying brain swelling. The most important point to consider regarding the diagnosis and concomitant treatment of EAH is that the actual blood sodium level is not as predictive of the actual "severity" of EAH as the clinical signs and symptoms are. For example, some athletes with sodium values less than 125 mmol/L walk around without obvious clinical signs or symptoms, while other athletes with sodium values between 130 and 135 mmol/L may have very severe symptoms. Thus, the presence or absence of clinical signs and symptoms (especially those related to altered mental status) are more predictive of the severity of EAH than the actual numerical blood sodium value. Therefore, the clinical signs and symptoms should serve as the more important treatment guide.

Treatment

EAH is a medical emergency, where any delays in diagnosis or in the most appropriate treatment may be fatal.

Athletes with asymptomatic hyponatremia should be treated with oral fluid restriction until urination begins. Athletes with this "biochemical" diagnosis should be thoroughly educated on the signs and symptoms of EAH and instructed to seek urgent medical attention should these signs or symptoms appear.

Athletes with mild signs and symptoms of EAH (without altered mental status changes) should also be treated with fluid restriction until the onset of urination and the concomitant resolution of symptoms. The administration of intravenous fluids with a sodium concentration that is below normal blood sodium concentrations (less than 135 mmol/L or a hypotonic saline solution) should be absolutely avoided. Intravenous fluids containing the same sodium concentration as is present in the bloodstream (an isotonic saline solution) should be considered *only* if (a) the athlete is under close medical supervision of a physician familiar with treating EAH, (b) there are clear documented signs of dehydration (hypovolemic hyponatremia), and (c) the athlete cannot tolerate oral food or fluids containing high amounts of salt. Athletes remaining in a field medical setting with mild symptoms that do not improve with fluid restriction and/or continued inability to urinate should be transported to a medical facility for further evaluation and treatment.

Athletes with EAH and altered mental status should be treated with a small intravenous bolus of a solution containing more sodium than what is normally present in the bloodstream (a hypertonic saline solution). Administration of a small concentrated amount of hypertonic saline solution should rapidly reverse brain swelling and facilitate an increase in blood sodium concentration by stimulating urinary excretion of excess body water. Once a diagnosis of EAH with severe cerebral symptoms is verified, emergent treatment with hypertonic saline can be lifesaving. Critically symptomatic athletes, once stabilized, should immediately be transported to an emergency care facility.

Prevention

Since EAH is primarily caused by the ingestion *and retention* of too much fluid rather than from the ingestion of too little salt, it is prudent that athletes avoid overconsumption of fluids before, during, and after exercise. Athletes, coaches, and health professionals should be advised that the best hydration strategies to prevent fluid overload hyponatremia are to drink according to the dictates of thirst and monitor body weight to avoid weight gain during exercise. Athletes participating in prolonged endurance activity should expect to lose roughly 2% of their prerace weight as a normal consequence of endurance exercise. Because the body's main antidiuretic hormone may be stimulated more vigorously during a race scenario, it is important to note that drinking strategies that worked well in training under similar conditions may lead to weight gain and EAH during competition.

Sodium supplementation in the form of salt tablets, salty snacks, or sports drinks will not prevent the development of EAH, although some evidence suggests that such supplementation retards the rate of blood sodium decline in athletes who drink in excess. Athletes should be advised that drinking any palatable beverage to quench thirst is more physiologically sound than adhering to any blanket guideline, predetermined hydration schedule, or baseline body weight during training and racing.

An educational program warning athletes about the potentially fatal consequences of overzealous fluid consumption before, during, and after exercise, combined with limiting fluid availability along the race course, has led to significant decreases in the number of reported cases of EAH around the world.

I

Ice Hockey, Injuries in

Ice hockey is a fast-paced contact sport played extensively in Canada, Europe, Asia, and the United States. The speed, contact, ice, encircling boards, and unique equipment, including sharp skates, a projectile puck, and long sticks, provide a unique set of risks for injury. Despite these risks, ice hockey has fewer injuries than most other popular team sports. Protective equipment, proper technique, adequate conditioning, and good sportsmanship are keys to prevention of serious injury.

The Game

In hockey, two teams compete to score points by moving a thick hard rubber disc called a puck into the opposing team's net. Games are played on a sheet of ice called a rink, which is surrounded by boards that help keep the puck in play. During normal play, each team has six players on the ice, consisting of three forwards, two defensemen, and a goalie. All players wear ice skates and use long, L-shaped sticks to advance the puck.

Although the exact origins of hockey are debatable, modern ice hockey dates back to the late 1800s. Professional ice hockey originated in the upper peninsula of Michigan and spread throughout Canada in the early 1900s. Today, ice hockey is a widespread sporting activity played at the youth, collegiate, Olympic, semiprofessional, and professional levels.

Demographics of Ice Hockey

According to 2008 USA Hockey data, there are 35,000 registered hockey teams and almost half a million registered hockey players in the United States. A small but growing number of players are female, with the number of registered female players in 2008 topping at 59,000. Organized teams span the age range from 6 years and under to 20 years and over. Overall participation in hockey remains steady. Regional data show a strong participation in large northern states, with residents of Michigan, Minnesota, and New York making up almost one third of all registered hockey players.

Injury Epidemiology in Ice Hockey

Data gathered from a variety of sources, including the National Collegiate Athletic Association (NCAA) Injury Surveillance System, the National Electronic Injury Surveillance System, and individual studies on sports injury epidemiology, show that ice hockey is among the safest collision sports and compares favorably with noncontact sports such as basketball, baseball, and soccer. Most of these studies take into account the fact that fewer people participate in hockey than in some of these other sports by representing injuries at a rate per 1,000 participants.

Despite the fact that hockey is relatively safe compared with other sports, several trends seen in the epidemiological analysis of hockey injuries are worth mentioning:

- Most injuries occur during games.
- Most injuries are due to contact with another player or the boards.
- Injury rates increase with increasing age of the player.
- Forwards have the greatest risk of injury and goalies the least.
- Injuries have decreased over the past 15 years corresponding to rule and equipment changes designed to improve the safety of hockey.

Specific Ice Hockey Injuries

Acute Traumatic Injuries

Head and Neck

Although the vast majority of injuries to the head are minor, these injuries can also be the most devastating in hockey. Cervical spine injuries are of the greatest concern. The mechanism of injury is typically a check from behind or a fall, causing head contact with the boards. Head injuries, including concussions, are relatively common and require medical management to prevent any complications. Eye injuries have dramatically decreased since the use of face shields but can be disabling when they occur. Laryngeal fractures and neck lacerations are exceptionally rare but catastrophic when they do occur. Neck guards have been recommended to decrease the chance of these injuries, but few data exist to demonstrate their efficacy. Dental trauma and facial lacerations are common and require immediate medical attention.

Lower Extremity

Lower extremity injuries are less common in hockey, but hip pointers or contusion to the hip and pelvic bone occurs from contact or collision. Groin strains are uniquely common in hockey, and although most resolve, they can become chronic, disabling conditions. Quadriceps contusions are a relatively common injury from collisions with other players and can result in significant time lost from sport. Knee ligament injuries are less common in hockey than in many other sports, but injuries to the medial collateral and anterior cruciate ligaments do occur and are typically caused by contact. Meniscal injuries can cause clicking and pain in the knee and can be seen in association with ligamentous knee injuries. High ankle sprains are seen more often in hockey due to the effect of the skate. Foot fractures can occur from impact with the puck or boards.

Upper Extremity

The upper extremity is the most common site of injuries in hockey. Sprains at the joints between either end of the collarbone are common in hockey and may cause pain, swelling, and deformity. Clavicle or collarbone fractures are also common and are typically associated with deformity, pain, and swelling over the middle of the collarbone. These injuries are often caused by a fall on the shoulder or a check into the boards. Shoulder dislocations are seen more commonly in older players and may result from falls on the ice or collisions. Fractures to the hand and wrist can be caused by slashing contact from the stick or falls on the ice. Injuries to the ligaments of the thumb can be caused by a fall on the ice with the stick in the hand, forcing the thumb away from the hand. Commonly known as “skier’s thumb” or “gamekeeper thumb,” these injuries can lead to chronic instability in gripping and pinching motions.

Trunk

Injuries to the chest or abdomen can lead to several serious medical problems, including lacerations or bruising of the spleen or kidney, or lung contusion.

Nontraumatic Injuries

Irritation of the tendons on the top of the foot from tight laces or ill-fitting skates can cause inflammation, a problem often called “lace bite.” Skin irritation and rash, or dermatitis, are commonly seen and are caused by mechanical irritation, bacterial infection, and accumulated moisture from sweating. “Sportsman’s hernia” can occur with chronic groin strains and involves injuries to the lower abdominal muscles. Tendinopathy of the wrist can result from frequent repetitive stick motions.

Prevention of Injury

Although hockey has many unique features predisposing to injury and a popular image as a rough, dangerous sport, the data show that it is safer than most other commonly accepted “noncontact”

An injured hockey player is attended to on the ice by the team doctor. Most injuries occur during games and are due to contact with another player or the boards.

sports. Prolonged skill development, appropriate competitive groupings, and adherence to the rules and recommended protective equipment appear to be crucial to the current safe state of hockey play.

Iliotibial Band Syndrome

Iliotibial band syndrome (ITBS) is an overuse injury seen most commonly in distance runners and other athletes whose sports require a great degree of knee flexion. ITBS, sometimes called *iliotibial band friction syndrome* (ITBFS), typically causes lateral knee pain that is insidious in onset. It is the most common cause of such knee pain in runners and accounts for up to 12% of running-related injuries. Diagnosis can be relatively straightforward, but ITBS is often very frustrating to treat, for both patients and clinicians.

Anatomy

The iliotibial band (ITB) is a tough, fibrous band of deep fascia that is extremely strong and rather thick. Proximally, the ITB originates at the iliac crest and then inserts distally at the Gerdy tubercle in the lateral tibia, as well as the patella and the biceps femoris tendon. The ITB, therefore, crosses two joints, the hip and the knee, and can be involved in pathology in both areas (e.g., the ITB is implicated in the development of some forms of "snapping hip" and in trochanteric bursitis).

The ITB appears to act as an anterolateral stabilizer of the knee, but its primary function appears to be controlling and decelerating the adduction of the thigh on heel strike during running.

The condition of ITBS is one of knee pain that results from excessive friction of the ITB over the lateral femoral epicondyle. At full extension, the ITB lies anterior to the femoral epicondyle; at about 30° of flexion, the ITB begins to traverse the femoral epicondyle as it moves posteriorly. With repetitive flexion and the associated friction, irritation of the ITB and underlying soft tissues can ensue.

The gross pathology and histopathology of the tissue involved in ITBS has been described from tissue obtained at the time of surgery and magnetic resonance imaging (MRI) evaluation. Changes in both acute and chronic inflammation have been found, confirming that ITBS is a true inflammatory condition (Figure 1).

Risk Factors for ITBS

Some observational studies have identified potential risk factors for the development of ITBS, including preexisting ITB tightness, high weekly mileage, training on a track, interval training, and muscular weakness of the knee extensors and flexors and hip abductors. Other authors, with less evidence, have noticed a possible association with the following: foot supination and compensatory pronation, running on hills (especially downhill) or on beaches, cycling seat height, anatomic factors (e.g., genu varus, tibia varus, heel varus, forefoot supination, and compensatory foot pronation),

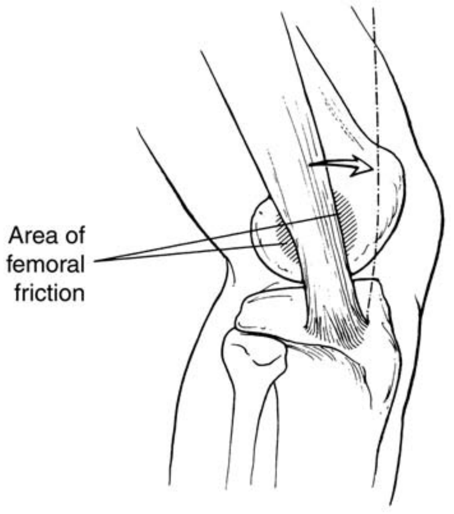

Figure 1 Iliotibial Band Syndrome

Note: Iliotibial band pain occurs where the band rubs against the lateral epicondyle of the femur.

tight hamstrings and tight quadriceps, and limb length discrepancies (ITBS typically develops in the shorter leg).

Risk factors are often divided into those that are "extrinsic" to the athlete (e.g., training techniques such as track running or equipment such as bicycle seat height) and those that are "intrinsic" (e.g., anatomic issues such as foot pronation or biomechanics such as hip abductor weakness). Both extrinsic and intrinsic risk factors can be targeted during treatment. It is incumbent on the astute clinician to identify these risk factors from the history and physical exam of the patient.

Presentation/Diagnosis

The history is usually one where the patient is able to identify no obvious macrotraumatic event. Most often the condition is found in runners; but it has also been described in cyclists, soccer and tennis players, skiers, and even weight lifters (e.g., those doing power lifting moves, such as squats). Lateral knee pain will have developed insidiously, and the athlete will typically complain of a sharp or burning pain approximately 2 to 3 centimeters (cm) proximal to the joint line that develops after a reproducible period of time or distance during a run or workout. Often the running athlete will specifically notice a worsening of the condition associated with running downhill. As the condition progresses, pain can develop earlier during a workout or may even occur during walking, particularly down stairs.

Further history taking should focus on identifying possible contributing extrinsic factors: If the patient is a runner, does he or she run on a track, on the beach, or on hills? Has there been a recent increase in training or a change in the training regimen?

The physical examination should not only focus on the knee but also include an analysis of the entire kinetic chain on the affected side. As always with lower extremity pathology, the clinician should ideally begin the examination with an inspection of gait. Is there an antalgic component to the gait? Does the patient's foot pronate or supinate? On one-legged stance inspection, is there a Trendelenburg sign? Is there a limb length discrepancy?

On focused examination of the knee itself, there should be no joint line tenderness or any significant effusion in isolated ITBS. Normal range of motion should be preserved. Palpation of the ITB, particularly over the lateral femoral epicondyle, may elicit pain. There may be localized swelling in the same area. Further palpation may elicit trigger points throughout the ITB as well as the vastus lateralis, and the distal ITB is often noted to feel ropy and thick. The vastus medialis obliquus (VMO) is often relatively underdeveloped.

Specialized tests include the Ober test, the Noble compression test, the Renee creak test, and the hop test.

The *Ober test* assesses ITB tightness and is performed with the patient lying recumbent on the unaffected side with the affected leg's hip and knee flexed slightly. The involved knee, which is off the table, is flexed to 90°, and the thigh is abducted passively and extended to catch the ITB over the greater trochanter. The thigh is then adducted passively. If the thigh remains suspended off the table, it indicates a shortened ITB.

The *Noble compression test* is a provocative test performed by having the patient lie on his or her side with the affected knee up and flexed to 90°; pressure is applied to the ITB overlying the lateral femoral epidondyle, and the knee is passively extended by the examiner; the test is considered positive if pain occurs as the knee approaches 30° of flexion.

The *Renee creak test* is a provocative test performed by having the patient stand on a step stool and then support all the body weight on the affected leg, allowing the unaffected leg to dangle over the edge of the step. The operator's thumb is placed over the lateral femoral condyle, and pressure is applied while the patient flexes the knee until about 30° by doing a one-legged squat. Reproduction of pain with this maneuver is considered a positive test for ITBS.

The *hop test* is another provocative test that is simple to perform. The patient is asked to hop up and down on the affected extremity keeping the knee flexed to roughly 30°; if this maneuver elicits pain, the test is considered positive.

The differential diagnosis the clinician should consider includes patellofemoral syndrome, stress fractures of the femur or tibia, discoid meniscus, lateral meniscal tears, fat pad syndrome, plica, politeus tendinitis, osteoarthritis, and lateral collateral ligamentous instability. A thorough history and physical examination are almost always sufficient to establish the diagnosis as ITBS and rule out other contenders. Plain X-ray films and MRI are occasionally necessary to evaluate other possible diagnoses. For ITBS itself, plain films would be expected to be negative, and MRI can show inflammatory changes in the area where the ITB crosses the lateral femoral epicondyle.

Treatment

Treatment consists of relative rest, controlling the inflammation, and addressing the underlying biomechanical factors, both intrinsic and extrinsic, that have contributed to the clinical scenario. Obtaining patient compliance is crucial to success.

The provocative activity should be avoided. Cross-training can sometimes be accomplished with swimming or pool running. As long as they remain painfree, flexibility and strengthening activities can begin promptly.

Inflammation must be controlled, and this is typically done with therapeutic dosages of nonsteroidal anti-inflammatory drugs (NSAIDs) and frequent icing. Occasionally, targeted steroid injections into the area of maximal pain can be used. One study has looked at the use of a local injection of 40 milligrams (mg) of methylprednisolone acetate and demonstrated good results. Some authors advocate injections as early as 3 days into the treatment period if other measures, such as rest, ice, and NSAIDs, have been unable to reduce the swelling and pain promptly. Physical therapists can use modalities such as cryotherapy, phonophoresis, and iontophoresis to control the inflammation.

The goals of physical therapy include targeted increases in flexibility and strength associated with some of the intrinsic factors contributing to the syndrome. Stretching the ITB, the hamstrings, and the quadriceps is vitally important. Strengthening the ipsilateral hip abductors, especially the gluteus medius and the ipsilateral vastus medialis, is also important. Almost all the exercises described in the literature listed in the Further Readings can be done without special equipment. The use of a hard Styrofoam (the trade name for expanded polystyrene) ITB foam roller (found in many gyms these days) for self-massage of the ITB is encouraged, as long as the user avoids direct pressure over the inflamed tissue.

Some patients will benefit from the correction of underlying limb length discrepancies and of foot biomechanics with devices such as heel lifts or orthotics.

The history and physical exam should give the clinician a good idea of what extrinsic risk factors have contributed to the onset of the syndrome and need to be addressed to prevent the return of symptoms. Bicyclists can often benefit from a custom fit of their bike; often, lowering the seat slightly is sufficient to avoid critical impingement of the ITB against the femur, which occurs at about 30° of knee flexion. Adjusting the foot position on the cycle pedals can be helpful as well. Runners should be encouraged to avoid running unidirectionally on banked surfaces (e.g., an indoor track, a beach, or a graded roadside). Avoiding intervals, track workouts, and hills and beginning at a lower mileage than pre-injury can be a good starting point for a runner to resume his or her training.

Conservative treatment is usually successful, though the condition can reoccur. Surgery is rarely necessary. Success has been achieved with a surgical procedure in which a triangular piece of the ITB is resected from the area overlying the lateral femoral epicondyle when the knee is in the critical position of 30° flexion. In one study, 84% of surgically treated patients reported good to excellent results. As with many acute and chronic inflammatory conditions, however, surgery should be considered as the last resort.

Imagery and Visualization

Imagery and *visualization* (terms often used interchangeably) represent a set of skills that are at the core of sport psychology interventions. Simply defined, imagery represents using one's mind to create images in multiple sensory modalities (hence making visualization somewhat of a misnomer), in an environment where one can relax, imagine excellent performance, adjust one's arousal or motivation level, and/or problem solve without ever leaving one's comfortable seated position. It is very similar to a real experience, and research has shown that parts of one's brain that are responsible for the actual movement of the body parts become active when engaging in imagery, similar to actually performing the task. In effect, imagery can be either a re-creation of past experiences or a simulation of what one will do in the future.

Modalities

As mentioned above, the terms *imagery* and *visualization* are often used interchangeably, but all of one's senses can be used to increase the vividness of one's imagery, and thus, it need not be limited to vision. Certain sensory images can readily bring the athletes to their sports arena: the golfer who smells the newly manicured greens, the gymnast who can feel the texture of the chalk on his or her hands, and the baseball player who recognizes the sound of a well-hit ball or the pop of the catcher's mitt. For athletes, the kinesthetic sense has the potential to increase the vividness of their imagery of engaging in sports activities. This is the sensation of where one's body is in space and how it feels while one is moving it. It appears that the more richly each sense is experienced and the more overall sensory experience the imagery contains, the greater the impact on the athlete.

Internal Versus External Perspectives

When an athlete imagines that he or she is actually participating in the sporting event and that he or she is either practicing or engaging in competition, it is referred to as the internal perspective, whereas the external perspective is when the athlete takes the role of an observer. He or she is "just watching" from the outside. Even if the athlete imagines that he or she is watching his or her own performance, as if seeing a replay on television, it is still considered an external perspective. Some research has pointed to internal perspectives being more helpful in generating kinesthetic feedback that could improve performance. However, there are differing opinions on this matter. There is no strong evidence that one modality or perspective is "better" than the other.

Though anyone can use imagery techniques, it has been shown that there is a fair amount of variability in one's ability to do so. How vivid the imagery is will be crucial to its effectiveness, and while some people are able to really engulf themselves in the experience as if it were happening in real time, there are some who have difficulty doing so. Similarly, there is also variability in one's ability to control what happens in one's imagery. For some individuals, it can be a perilous exercise that can lead to an increase in anxiety and, in turn, a decrease in their performance if they are unable to imagine perfect execution and are unable to solve problems to maximize performance while in their imagery. This is a critical message that should be remembered. Imagery can be a powerful tool, but not all tools work for all people with the same effectiveness.

Another cautionary note is the importance of asking permission before engaging in imagery exercises. When the sport psychologist or coach is guiding the imagery, it can be equated to walking around inside someone's mind, and the professional may stumble onto something unexpected. This is particularly true if the athlete has a history of trauma. Imagery exercises can result in dissociation. While the probabilities of this happening may be unknown, the risk is not worth ignoring simple precautions. Always explain to the athletes what imagery entails, how it works, and what you plan to work on with them. They should always have the ability to say "no," before or during the exercise.

Different Utilities of Imagery

Relaxation

It has been well established that to perform optimally one has to be able to balance one's arousal levels. Increased levels of anxiety and tension can affect an athlete's fluidity of performance; thus, the ability to relax is a very valuable skill, and imagery can be quite helpful in acquiring this skill. The ability to envision a peaceful, relaxing place is an excellent start to learning relaxation skills. Commonly, a beach scene or tranquil lake setting can elicit plenty of sensory images that lend themselves easily to a feeling of relaxation; again, the athlete should be allowed to dictate the pace and the details, but encouragement of multiple sensory modalities is advised. In these settings, imagery can be paired with diaphragmatic breathing and/or progressive muscle relaxation to provide a very powerful relaxing exercise. Learning to relax can then be fine-tuned by learning to modulate one's arousal to a workable level for the task at hand. Relaxation imagery can also be a valuable tool for athletes who have difficulty falling asleep.

Practice

Because imagery represents the opportunity to simulate athletic activity, it is the perfect place to practice. It doesn't require any equipment. It is not weather dependent. And it can be invoked at any time. In fact, like physical abilities, mental skills improve with increased practice, and athletes should be encouraged to practice on their own what they have learned about the use of imagery.

Imagery can be useful in building confidence and motivation, as well as improving performance strategy. Imagery provides an opportunity for athletes to imagine all the details that contribute to excellent performance. This is true whether they are learning new skills, trying to perfect skills, or trying to retain the skills they have previously learned. Athletes can improve their concentration by imagining themselves staying focused and ignoring distractions. They can build their confidence by imagining their success, which can carry over into their future performances. Athletes understand that if they can imagine something, it can be made to happen.

This idea should be approached with caution as well because imagining good execution does not necessarily translate into athletic success. For this reason, imagery represents not only a training opportunity to home in on the details necessary for optimal performance but also a training ground to solve the problems that arise due to in-competition adversities. Examples of this could include adapting to a breaking ball when the batter is expecting a fast ball, a sudden gust of wind that distracts the golfer during her backswing, the sudden heckling of a fan while the player is at the free throw line, or the running back who needs to cut back his run as the defense has read where the play is going and is in a position to tackle him for a loss. Athletes can practice their problem-solving skills and improve their "vision" by using imagery.

Emotion Management

Apart from management of anxiety (as described above) by using imagery as a relaxation skill, imagery can be used in many other ways for emotion management. For example, by eliciting different emotional states in an athlete (with the athlete's permission, of course), imagery presents an opportunity for the athlete to explore how different emotional states can affect his or her performance positively or negatively. For some athletes, imagery can provide an opportunity to "psych themselves up" and motivate them for competition. It can give an environment to work out one's fears about a particular competitor or venue. Imagery can also illustrate for the athlete how intense anger can interfere with problem solving, cognitive processing speed, impulsivity, and fine motor coordination without having an actual impact during competition.

Imagery During Injury Rehabilitation

Imagery provides an opportunity to practice when an athlete's body does not allow him or her to do so. It can be used to continue to "rehearse" and "practice" while injured, which can promote healing and reduce recovery time. Imagery can be effectively used to distract the athlete from pain and thus can be useful in pain management and tolerance building. When resuming one's prior level of activity and managing fears of reinjury (following, e.g., a serious skiing accident), imagery can provide a safe training ground. Sport psychologists using imagery techniques can be of great assistance to sports medicine personnel in injury rehabilitation. Other related areas that might lead sports medicine professionals to refer to sport psychologists for the incorporation of imagery in an athlete's treatment include recovery from body image disturbance, issues related to body dysmorphia, activity disorders, and treatment of career-ending injuries.

The uses of imagery in sports are quite numerous, and research has shown that it is not only one of the most commonly used mental skills but also one of the most effective.

Immune System, Exercise and

The interaction between the immune system and exercise is complex and not completely understood. As the body's defense mechanism against infection, the immune system plays an integral role on a daily basis in keeping both athletes and the general population healthy. Exercise can affect the immune system either favorably or unfavorably depending on the type, intensity, and duration of the activity. It is widely accepted that upper respiratory tract infections (URTIs) are a major reason for poor performance in competitive athletics. Many of these athletes have been training at a high level in the preceding weeks, which may contribute to the lowering of their body's resistance to infection. Recreational athletes may also suffer from URTIs following episodes of heavy or unaccustomed exercise bouts. Understanding the impact of exercise on the immune system and its role in health maintenance will ultimately lead to better sports and work performance.

The Immune System: Innate and Adaptive

A full appreciation of the complex interactions between the environment, training, infection, and the immune system requires an understanding of the basics of immune system function. The immune system is made up of two complementary defenses—the innate immune system and the adaptive immune system. The innate system is a collection of mechanisms that are the body's first-line defense against potential pathogens, or infection-causing agents. These include the skin and the mucous membranes, which are physical boundaries against invasion. However, not all portals of entry into the human body are protected by the skin. These sites, including the nasal passages and oropharynx, are equipped with special mucus, enzymes, and complex proteins that immediately start the breakdown process of unwanted pathogens. The innate system begins the process of activating the inflammatory response, which is an important sequence of events leading to the four classic signs of inflammation: rubor (redness), calor (heat), tumor (edema), and dolor (pain).

While the innate immune system is predictable and mechanical, the adaptive immune system is more involved and complex. This is largely due to the mechanisms that allow it to remember specific pathogens and subsequent inflammatory responses. Having "memory" enables the adaptive system to recognize a certain pathogen that it has already been exposed to and quickly mount an immune response on reexposure. This process is carried out through three mechanisms. The first entails recognizing specific proteins on cell surfaces, called *antigenic markers,* that signify specific pathogens. After recognition, the adaptive system is capable of a cellular and molecular attack against that specific pathogen. Finally, with subsequent repeat attacks from those same pathogens and their associated cell surface proteins, the body's memory system can mount an accelerated response to ensure a balanced immune response and maintenance of health.

Exercise and Immune System Function

The impact of exercise and training on the immune system has been a topic of great interest over the past couple of decades. Many of the currently accepted principles have been developed over this time period. Research is certainly ongoing and evolving in this relatively new field of sports immunology. As exercise grows as a cornerstone of health promotion and disease prevention, it is increasingly important to understand the interaction of exercise and the immune system. Furthermore, as URTIs are appreciated as a contributing factor to poor sports performance, as well as a frequent cause of absenteeism in the workplace, more research is necessary.

According to recent research, the intensity level of training is a primary predictor of immune system function. Studies have shown decreased levels of an important immune protein found in mucosal secretions, called *immunoglobulin A* (IgA), after intensive training. This secretory immunoglobulin is partially responsible for combating infections encountered at the mucosal barrier of the upper respiratory tract. Lower levels of IgA in mucosal secretions put the body at an increased risk for URTIs. These decreases in IgA levels can occur after as little as 1 hour of vigorous exercise, which is often classified as 70% to 80% of aerobic capacity. While high-intensity exercise may put the athlete at an increased risk for URTIs, studies have also demonstrated significantly higher levels of IgA in those participating in regular, moderate exercise. This may give credence to the belief that a moderate amount of physical activity strengthens the body's ability to fight off infections.

Two other types of cells in the immune system are affected by physical activity. The function of natural killer cells, or *NK cells*, is enhanced by intensive exercise. NK cells are part of the innate immune system and help fight off viral infections and aid in the destruction of tumor cells. They perform this by secreting enzymes that destroy the target cells by a process called *apoptosis*, or programmed cell death. A second important component of the innate immune system, the *neutrophil*, appears to exhibit decreased functionality with increased intensity of exercise. The *neutrophil*, also known as a white blood cell, is the primary cell type in the body responsible for attacking infections and foreign materials. A decrease in neutrophil count and function has been demonstrated when comparing sedentary individuals with highly active individuals. Suppression of neutrophil activity likely plays a role in increased URTIs in athletes who are involved in high-intensity training.

Interest in the interaction between exercise and cancer prevention has sparked more than 100 retrospective, population-based studies. Overall, the evidence seems to indicate a significant reduction in colon and breast cancer in those participating in regular, moderate physical activity. When compared with sedentary populations, even low-intensity activities, such as mowing the lawn, seem to modestly reduce cancer rates. Survivors of breast or colon cancers may see up to a 40% relative risk reduction in terms of cancer recurrence and cancer-related deaths. Since the specific mechanisms behind the etiology of these benefits are not well understood, further research is ongoing in this intriguing field.

Another population whose immune system benefits from regular physical activity is the elderly. As the human body ages, it becomes more susceptible to infections, caused by slower and less potent responses to attacks, leading to longer recovery periods. The first layer of defense, the skin and mucous membranes of the innate system, can become broken down and permeable. Specific immune system cells, such as the T cell, often become less responsive to activation. These cellular deficiencies, coupled with other factors involved in normal aging, such as deconditioning, comorbid medical conditions, psychological stress, and nutritional deficiencies, all lead to a dysfunctional immune system. Regular physical activity becomes an important component of the health maintenance strategy for the aging population. For example, weight-bearing exercises can help mitigate bone demineralization, which results in osteoporosis, as well as supporting healthy immune function.

Since many highly trained athletes do encounter untimely URTIs that may be caused by suppressed immune system function, effort has been placed in attempting to find nutritional supplements that might enhance immune system function. The evidence for efficacious use of vitamins or minerals in excess of the recommended daily amounts is sparse. Vitamin C, at 600 milligrams (mg) daily for 3 weeks, does appear to have some benefits in reducing the occurrence of URTIs in athletes training and competing in ultra-endurance events. This is believed to be due to its antioxidant properties, which help reduce the free radicals produced by the oxidative stress related to prolonged intense training. Further research is ongoing on vitamin C and its effect on the immune system. Other studies investigating supplements such as vitamin E and betacarotene have not shown any benefit in terms of immune system support. A well-rounded diet is still the recommendation for most athletes, with increases in caloric intake during high-intensity training. A simple multivitamin can be added to the diet, but excessive intake of specific nutrients should be avoided in general.

Knowledge gained from analyzing athletes' immune system function during and after strenuous training can be applied to the clinical setting when deciding on how to treat URTIs. Infectious symptoms in an athlete should be evaluated in the same manner as in the general population, but one should also take into account each individual's circumstances. If an athlete is in the midst of intense training and near his or her maximal efforts, one should contemplate being more aggressive in treating potential bacterial causes of URTIs with antibiotics. Common primary care medical practice demonstrates that most URTIs are viral in nature and do not respond to antibiotics. However, depressed IgA levels in mucus and secretions may place athletes at an increased risk for bacterial causes of infections. Recent studies have also demonstrated possible anti-inflammatory effects of some classes of antibiotics, such as macrolides and fluoroquinolones, in URTIs, which may be responsible for the benefits of these medications independent of their antibacterial effect. Also, the close proximity of athletic teams, drinking from common fluid sources, dormitory living, frequent traveling, and time spent in locker rooms may also raise the risk of transmission of infections. Furthermore, high levels of stress and anxiety, as one might endure during competitive athletics, have been previously demonstrated to impair immune system function, placing the patient-athlete at increased risk of infection. Certainly, each athlete's situation should be examined independently and critically so as not to overuse antibiotics, which can perpetuate bacterial resistance. One cannot overemphasize general hygiene principles, including regular showers, not walking barefoot, timely and appropriate skin care, and adequate sleep and nutrition.

Conclusion

In summary, the athletic population is at an increased risk for infections, especially URTIs, during times of high-intensity training. However, and perhaps more applicable to the recreational athlete and the general population, mild to moderate aerobic activity may help enhance the immune system. It may be prudent to recommend moderate exercise as a part of overall health maintenance as it specifically relates to improved immune system function. While the supplement business is thriving, so far only vitamin C has demonstrated positive effects in the treatment and prevention of infections in athletes. Emphasis on a well-rounded diet, adequate sleep, and productive stress management should be part of athlete education at all levels.

Infectious Diseases in Sports Medicine

Athletes are susceptible to illness due to close interpersonal contact, intense physical and emotional demands, and/or environmental exposures. Some infections have specific return-to-play criteria. This entry discusses common infections in the athletic population, their treatment, and guidelines for the sometimes challenging decisions on when an athlete may return to play.

Upper Respiratory Tract Infection

The term *upper respiratory tract infection* (URTI) encompasses a wide range of syndromes involving the nose, throat, and respiratory tract above the oxygen-exchanging alveoli. This section focuses on the common cold, influenza, and pharyngitis.

Viruses are the typical culprit in these infections, but the practitioner must be aware of bacterial presentations. These include bacterial sinusitis, strep throat, bacterial superinfections, and lower respiratory infections. The virus is spread by aerosols and droplets as well as by direct and indirect contact with the saliva of an infected individual. A large number of studies evaluating the influence of exercise on the immune system have been done. Evidence to date advocates moderate exercise as an immune protector, decreasing the risk of developing an URTI, while heavy, strenuous bouts of exercise increase the risk of infection due to negative effects on the immune system. Carbohydrate replacement before, during, and after exercise has been reported to assist in immunity maintenance. There are no definitive guidelines on returning the athlete to play. These determinations are based on returning the athlete safely based on his or her symptoms and not placing other athletes at risk.

Common Cold

The prevalence of the *common cold* is exactly as the name implies—common. It is a viral URTI caused by any of more than 200 viruses, the most common being rhinovirus, coronavirus, and respiratory syncytial virus. It is the most common cause of acute illness in the U.S. population and is responsible for the greatest number of missed days from school or work. It is spread via droplets in the air released when an infected individual coughs, sneezes, or talks. It is also spread by hand-to-hand contact when infected secretions contaminate an individual's fingers or hands and he or she then touches the eyes, nose, or mouth. Further transmission occurs via shared objects. Interestingly, studies have shown that person-to-person transmission depends on the amount of time people spend together and the amount of viruses shed by the infected individual. Viruses may survive on the human skin for up to 2 hours. Viral URTIs can result in secondary bacterial infections, causing sinusitis and pneumonia. The practitioner is faced with discerning the common cold from other, more serious infections and advising treatment and return to play.

Clinical Presentation

Athletes may complain of low-grade fever up to 102 °F, runny nose, congestion, sneezing, a sore throat, a mild to moderate hacking cough, and slight muscle aches and fatigue. The nasal discharge may become thick in consistency and change to yellow or green.

Diagnosis

The diagnosis is confirmed by patient history and symptoms. The physical exam findings are few in comparison with the patient symptomatology. Blood work rarely yields any useful information.

Treatment

Viral URTI is a self-limiting syndrome that can last from 5 to 14 days. Therapy is usually aimed at relieving symptoms. Antibiotics treat bacterial infections and are not indicated in viral infections. Congestion therapy includes hydration with water, juice, tea, or sport drinks to prevent dehydration and break up the thick mucus. Nasal decongestants come in oral form and nasal sprays. Oral decongestants commonly contain pseudoephedrine, which can have a stimulant effect and increase the heart rate and blood pressure and result in insomnia. Nasal sprays have a direct effect on the nasal mucosa, with fewer systemic side effects and a quicker onset of action than oral medication. These agents typically contain oxymetazoline. They are to be used for no more than 3 days due to the increased risk of rebound nasal congestion once the product has been discontinued. Antihistamines have been shown to reduce symptoms of runny nose and sneezing during the first 2 days of the cold. Vitamin C in 1 gram (g) or more daily dosing has been shown to produce 15% fewer symptomatic days per episode. Zinc may reduce the duration of cold symptoms. Over-the-counter cough suppressants such as dextromethorphan and expectorants such as guiafenesin may be used for dry, hacking coughs. The American College of Chest Physicians does not recommend over-the-counter cough syrups or cold medication in children younger than 14 years. Tylenol and nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen may be used for pain relief. Saltwater gargles are useful for sore throats. Aspirin should not be given to children due to the risk of Reye syndrome. It is vital for athletes to be aware that some over-the-counter preparations and supplements may contain banned substances.

Return to Sports

The decision to return an athlete to play is made on a case-by-case basis. Athletes may return to mild to moderate exercise with mild symptoms of the common cold. Some advocate using the "neck-check" criteria, whereby symptoms below the neck may preclude return to play. The American College of Sports Medicine recommends return to intensive exercise when an athlete is free of symptoms such as fever and muscle aches for several days.

Prevention

Good hygiene and social behaviors are essential in the prevention of the common cold. The infected athlete should cover his or her nose and mouth with a tissue when coughing or sneezing and then throw the tissue in the trash. Hand washing with soap and water or using an alcohol-based hand cleaner prevents the spread of the infection. It is important to avoid close contact with infected people by having them either stay at home or not participate in sport. Individuals should avoid touching their eyes, nose, or mouth.

Influenza

Influenza, also known as the flu, is a respiratory illness caused by the influenza virus that results in mild to severe illness. According to the Centers for Disease Control and Prevention (CDC), 5% to 20% of the U.S. population gets the flu each year, with 200,000 hospitalizations and 36,000 deaths. Its presentation can be similar to the common cold. The flu is spread via the same mechanism as the common cold (aerosols released by coughing or sneezing, touching the infected surfaces and then touching the mouth or nose, and so on). Risk of transmission is between 1 day before the development of symptoms and up to 5 days after. Pulmonary function can be diminished for up to several weeks in athletes with the flu.

Clinical Presentation

Influenza can present very similarly to a typical viral URTI; however, its symptoms are usually more severe. The onset of illness is typically abrupt. Fever ranges from 100 to 104 °F and may be associated with chills. Sore throat is a common complaint that may bring the patient to the practitioner for evaluation. Muscle aches range from mild to severe. Headache is common. Runny nose ranges from mild to severe. Severe fatigue and weakness may prevent the athlete from playing. Nonproductive cough and chest pain progress as the infection evolves. Children are more likely than adults to have gastrointestinal effects such as nausea, vomiting, and diarrhea.

Diagnosis

Diagnosis of influenza A or B is typically clinical but may be confirmed by nasopharyngeal or throat swabs that are sent for culture. The results may take 3 to 7 days to come. Recently, the Food and Drug Administration (FDA) approved three office tests for influenza, including the QuickVue. However, the cost and time restraints of these tests make clinical diagnosis of influenza preferable.

Treatment/Prevention

There is a saying, "An ounce of prevention is worth a pound of cure." The CDC has developed a brochure, titled "An Ounce of Prevention," advocating good hygiene in the prevention of spreading and/or contracting of infection. Actions such as covering the nose and mouth with a tissue while sneezing or coughing and then throwing the tissue away, washing hands with soap and water or using an alcohol-based cleanser, and keeping surfaces sanitized are all important. Teams should be vigilant for the onset of illness among teammates to initiate prevention.

Influenza is unique in that it has a vaccine to assist in prevention. The vaccine comes in two forms, a shot and a nasal spray. The shot is made from inactivated or killed viruses and can be used in individuals who are healthy, those older than 6 months, and those with chronic medical conditions. Typical side effects include soreness at the shot site, low-grade fever, and muscle aches. The nasal spray FluMist® is made from live, attenuated viruses or weak viruses that do not cause the flu and is used in nonpregnant individuals 2 to 49 years old. Side effects in adults include runny nose, headache, sore throat, and cough. In children, they include runny nose, wheezing, headache, vomiting, muscle aches, and fever. Antibodies develop that protect against influenza approximately 2 weeks after the vaccination. The vaccination period typically begins in September and may be continued through January or later. Influenza tends to peak in January. Winter teams are more susceptible to outbreaks and need vaccinations.

Note: Individuals who should not be vaccinated without first consulting a physician include the following:

- People who have a severe allergy to chicken eggs
- People who have had a severe reaction to an influenza vaccination
- People who developed Guillain-Barré syndrome (GBS) within 6 weeks of getting an influenza vaccine
- Children less than 6 months of age (influenza vaccine is not approved for this age-group)
- People who have a moderate to severe illness with a fever (they should wait until they recover to get vaccinated)

Antiviral influenza treatment is used to reduce symptom severity and duration and for prevention in people who have come in close contact with an infected individual and who were unable to receive the vaccine or in whom the vaccine was ineffective. Daily prophylaxis has been studied and supported in the prevention of outbreaks in nonvaccinated teams for 2 weeks after vaccine administration. Anti-influenza drugs include oseltamivir and zanamivir. These medications should be used within 2 days of symptom onset and for 5 days to shorten the duration of illness by 1 to 2 days and to decrease risk of transmission.

Pharyngitis

Pharyngitis, or sore throat, is responsible for 19 million clinic visits annually in the United States. Viruses are responsible for 50% of pharyngeal infections. Pharyngitis is a common presenting symptom for mononucleosis (mono), which will be discussed in the next section. Other implicated viruses include rhinovirus in the common cold, influenza virus, parainfluenza virus, herpes simplex virus, and human immunodeficiency virus. The cause of bacterial pharyngitis differs between adults and children. Group A β-hemolytic streptococcus (GABHS), or strep throat, is the most common cause of bacterial pharyngitis in children. Adult bacterial pharyngitis is caused by GABHS and other bacteria such as *Mycoplasma pneumoniae* and *Chlamydia pneumoniae*. Sexually active adults should raise the practitioner's suspicion for a gonococcal infection. Transmission is mainly through respiratory secretions but can occur via contact with food and fomites. The swelling may cause airway obstruction and/or inhibit the athlete from ingesting fluids, resulting in severe dehydration. GABHS pharyngitis that goes untreated may lead to rheumatic fever and kidney complications.

Clinical Presentation

The most common complaint is a sore throat worsened with swallowing that may radiate to the ears. Athletes with viral pharyngitis may have cough, runny nose, conjunctivitis, muscle aches, headache, pain with swallowing, and low-grade fever. Patients with the common cold tend to complain of a "scratchy" throat. On exam, viral pharyngitis presents with tonsillar swelling, redness, and/or exudates. Herpes pharyngitis is characterized by painful vesicles or shallow ulcers on the palate, lips, or mucosa. Bacterial pharyngitis clinically appears similar to viral pharyngitis, with tonsillar or pharyngeal swelling, redness, and exudates, but typically causes a fever of 38.3 °C or higher and tender anterior cervical lymph nodes and is marked by the absence of cough and runny nose. A sandpaper-like rash may develop over the chest and abdomen of individuals with GABHS pharyngitis.

Diagnosis

The rapid strep test is the first-line test for potential strep throat. Throat cultures take 24 to 48 hours to provide results and may reveal other pathogens. The mono spot test is discussed in the section on mono.

Treatment

Treatment is aimed at symptomatic relief in most cases of pharyngitis. NSAIDs reduce sore throat symptoms. Other treatments include saltwater gargles, throat lozenges, and hot soups or tea with honey. GABHS pharyngitis should be treated with an antibiotic to prevent complications, minimize spread, and shorten the duration of illness. Athletes with suspected or confirmed GABHS pharyngitis are no longer considered contagious after 24 hours of antibiotic therapy. Athletes may return to play if they have no systemic symptoms or fever.

Mononucleosis

The athlete and the general population are at equal risk of contracting *infectious mononucleosis* (mono). Mono is a viral illness caused by the Epstein-Barr virus (EBV), a member of the herpes virus family. The majority of infections occur in adolescents and young adults. The so-called kissing disease is transmitted via human saliva and secretions. Some patients may take up to 3 months to return to the premono level of activity. Serious complications have been reported in 5% of patients with mono. These include severe pharyngitis creating airway obstruction and splenic rupture in contact and collision sports.

Clinical Presentation

An athlete may present with the classic triad of fever, sore throat, and swollen lymph nodes. Fever typically does not go above 40 °C. Pharyngitis occurs in 80% of patients with mono. Again, it is important to remember that multiple other infectious agents, such as other viruses, strep, gonorrhea, and HIV, can cause sore throat. More than 50% of patients with mono have pharyngitis, with an overlying film that is white, gray-green, or necrotic appearing. Palatal petechiae, or pin-point–sized red dots under the surface of the tissue, are found in 25% of the patients. Swollen lymph nodes typically occur in the posterior cervical chain and can be found in the axilla and/or groin as well. The lymph nodes are large and resolve after 2 to 3 weeks. Further symptoms include headache and malaise. A rash on the upper extremities and trunk is present in 10% to 40% of patients. A rash may develop in patients treated with amoxicillin and ampicillin. It does not represent a true allergic reaction. An enlarged spleen, referred to as *splenomegaly*, occurs in 50% to 100% of patients with mono, posing the risk of splenic rupture. Studies have shown the clinical exam not to be a reliable indicator of an enlarged spleen, but when an enlarged spleen is suspected, typically the practitioner is correct. Athletes may present more of a challenge due to their developed musculature and/or size.

Diagnosis

Diagnostic studies typically start with blood work. This includes a complete blood count (CBC) and differential to evaluate for atypical lymphocytosis as well as a heterophile antibody latex agglutination test (Monospot test). A diagnosis of infectious mononucleosis (IM) is supported if an absolute and relative lymphocytosis is present with greater than 10% atypical lymphocytes on peripheral blood smear and a positive test for EBV. The heterophile test has a higher false-negative rate during the first week of illness, which declines in the second and third weeks. If the patient is early in the course of the disease and the monospot test is negative, it may be prudent to perform specific antibody tests. These reveal either primary acute infection or recent (within 3–12 months) infection by analyzing the pattern of IgM and IgG antibodies. Liver function tests should also be performed given that these are elevated in approximately 90% of individuals with mono.

Radiographic imaging, such as ultrasound and computed tomography (CT scan), has not been advocated for assessing the size of the spleen. There is variability in the size of the spleen among individuals, with men having larger spleens than women. A single spleen measurement is not predictive of splenomegaly or risk of rupture. Furthermore, data have not shown a correlation between splenic size and risk of rupture.

Treatment

Mono is a self-limiting disease. Supportive treatment focuses on symptomatic relief, including rest, hydration, and NSAIDs for fever or pain. Isolation is not indicated given the low transmissibility of EBV. Adolescents should not be given aspirin, because of the small risk of bleeding and low platelet count. Mono's effects on the liver necessitate caution with substances such as alcohol, acetaminophen, and other liver-toxic compounds. Corticosteroids such as oral prednisone are indicated in patients with upper airway obstruction, significant tonsillar hypertrophy, severe sore throat causing inability to swallow, splenic enlargement, inflammation of the heart known as *myocarditis*, low platelet count, or *anemia*. Antiviral agents are not recommended in uncomplicated EBV infection. Neither steroids nor antiviral agents have been shown to reduce time to return to play. Rest over a 2- to 3-week period is recommended given that exertion increases the risk of splenic rupture and the first 3 weeks have the greatest risk of splenic rupture. Patients who are suspected of having splenic rupture should be evaluated in the emergency department with access to acute surgical evaluation.

Return to Sports

No well-designed large clinical trials have been performed to help develop guidelines on when the athlete is allowed to return to play. Current literature supports focusing on symptom resolution and absence of splenomegaly. The athlete may return to light, noncontact activities 3 weeks from symptom onset, with a gradual progression of activity. The risk of splenic rupture is greatest in the first 3 weeks, with cases having been reported up to 7 weeks. Radiographic imaging is not always recommended given that a baseline and serial measurements are necessary to evaluate the normal value in a specific individual. The athlete should be educated on the risk of splenic rupture and should understand that physical exam is not a reliable tool. Return to contact activities should be at least 3 weeks from symptom onset and should correlate with the athlete being free of symptoms with a normal level of energy.

Cutaneous Infections

As discussed in the previous section, skin-to-skin contact is an effective mode of transmitting infections involving the skin. The term *gladiatorum* has been used in describing cutaneous infections contracted during activity. The major players in these infections are viruses and fungi. The provider must be able to recognize these common infections in order to treat them and prevent their spread among teammates.

Bacterial

Methicillin-Resistant *Staphylococcus aureus* (MRSA)

Staphylococcus aureus is a bacterium present on the human skin that is responsible for many skin and soft tissue infections. It is found in the nose of

30% of healthy, asymptomatic people and in 65% of people with staphylococcal skin infections. Methicillin-resistant *S. aureus* (MRSA), once considered a hospital-acquired pathogen (HA-MRSA), is a strain resistant to specific antibiotics in the penicillin and macrolide family. A new strain has emerged in the past decade in the general population, referred to as *community-acquired MRSA* (CA-MRSA). It is manifested in healthy individuals as skin and soft tissue infections. It commonly occurs sporadically but can occur in clusters in athletic teams. It has been characterized as a worldwide epidemic.

An athlete who plays contact sports is at particular risk given his or her skin-to-skin exposure and likelihood of skin breakdown. Sports at particular risk include football, rugby, and wrestling. Other individuals at increased risk include household members of infected people, military personnel, prisoners, urban dwellers in crowded living conditions, and HIV-infected individuals. Transmission occurs through person-to-person contact either via an infected wound touching another athlete's open skin or via secretions from an individual who is a carrier contaminating an open wound. The CDC has reported that repetitive skin trauma with inconsistent coverage places the athlete at greatest risk. Other factors that have been associated with the spread of CA-MRSA include contaminated items and surfaces, crowded living conditions, and poor hygiene. Nasal cultures do not predict risk of infection. There have been several case reports of outbreaks in athletic teams, with some patients requiring admission for intravenous (IV) administration of antibiotics. Studies have shown that infection tends to occur on exposed extremities with previous skin trauma. Skin injury has been reported to effect a threefold increase in the likelihood of staph infection in players. Other considerations include athletes with conditions that break down the skin's integrity, such as atopic dermatitis/eczema.

Clinical Presentation

Patients often present with the chief complaint of a spider or insect bite. On physical exam, they exhibit a variety of skin manifestations. They may have a focal area of redness, warmth, and swelling, with underlying fluctuance that is tender to palpation consistent with an abscess. There may be isolated skin redness, warmth, swelling, and pain in the case of skin infection or cellulitis. An abscess can also have an overlying cellulitis. Multiple cutaneous lesions do occur. These lesions are typically tender, indurated nodules with a history of rapid growth. Nodules can rupture spontaneously, contaminating the surrounding skin with infected pus. CA-MRSA can be severe or appear similar to a simple staph infection. Folliculitis secondary to CA-MRSA can occur in the chest, flank, and scrotum. There may be associated systemic symptoms such as fever and malaise. Regional swollen lymph nodes can also be present.

Treatment

Treatment involves systemic antibiotics and incision and drainage of the abscess. CA-MRSA is typically susceptible to sulfamethoxazole-trimethoprim (Bactrim) and clindamycin. Typically, these agents are used alone. CA-MRSA has variable sensitivity to fluoroquinolone antibiotics, such as ciprofloxacin, with rapid resistance. There is a geographic evolution of antibiotic resistance. It is advised to culture wounds in order to identify the organism and determine its susceptibility. A phenomenon called *inducible resistance* has been developing in various cities, where a pathogen reported to be resistant to erythromycin and sensitive to clindamycin develops resistance to clindamycin during the course of treatment. In this case, it is advisable to use Bactrim. The duration of treatment should be a minimum of 7 days, with many infections requiring up to 14 days of antibiotics for resolution. A topical antimicrobial ointment such as 2% mupirocin can be applied to the cutaneous lesions as an adjunct to oral therapy. Severely ill CA-MRSA patients require hospitalization and IV medication with antibiotics such as vancomycin or linezolid.

Prevention/Return to Sports

Mupirocin, a nasal ointment antibiotic, has been implicated in eradicating carriers of HA-MRSA. However, nasal cultures do not correlate with risk of infection. If used for treatment, it would likely be most effective if administered to all players. Further studies are needed to validate this. Athletes involved in repetitive skin-to-skin contact should protect the exposed extremities. Areas of skin trauma and/or infection should be clean and covered with a clean, dry dressing. The CDC recommends frequent hand washing and showering, and avoiding sharing of personal items, such as towels, razors, and uniforms, that may have made contact with an infected wound. Sheets should be cleaned and dried completely in a dryer. Equipment and surfaces should be cleaned and sanitized.

Fungal

Fungal infections are transmitted by person-to-person contact, by animal-to-human contact, or directly from the soil. Athletes most at risk include wrestlers, rugby players, and football players, because of close contact among players and skin trauma. Fungi invade the top layer of the skin, causing a scaly lesion. The term *tinea* refers to a fungal infection. Tinea capitis is infection of the scalp. Tinea corporis occurs on the body and is also known as ringworm. Tinea cruris involves the groin region and is known as jock itch. Infections of the feet, that is, athlete's foot, are called *tinea pedis*. Fungal infection can involve the toenails. *Tinea gladiatorum* refers to fungal infection of the skin or scalp. It is spread among athletes through skin-to-skin contact and in warm, moist environments, which encourage the development of infection. Fungus can also be present on equipment. Approximately 10% to 20% of the world population is infected by a fungus. The most common location is the foot. Athletes who swim and are exposed to pools or run marathons are at highest risk.

Clinical Presentation

The clinical presentation of tinea varies based on its location on the body. Tinea corporis lesions are typically well-demarcated, red, scaly plaques with a central cleaning associated with flaking and itchiness. Areas of exposure at highest risk are the head, neck, and upper extremities. Scalp infections are manifested by a patch of hair loss overlying a gray, scaly plaque. Tinea cruris has large, red, well-demarcated scaling plaques on the inner thighs, groin, and pubic region. Tinea pedis can present in a variety of ways, including red, weeping, macerated skin with a fissure in the web space between the toes.

Diagnosis

The sports medicine provider can typically make the diagnosis of tinea infection based on the appearance and location of the skin lesions. Direct microscopy can confirm the diagnosis by revealing the characteristic hyphae appearance of a fungus, using a potassium hydroxide solution applied to a skin scraping. Fungal culture can also be used.

Treatment

Topical and oral medications can be used to treat tinea. Topical medications have few adverse effects and come in inexpensive forms but may take several weeks to take effect. Oral or systemic medications have a quicker onset of action but can have significant side effects and a higher cost profile. Tinea capitis does require an oral medication. Patients with uncomplicated tinea corporis or cruris can be treated with topical therapy. If topical treatment fails, then oral medication is instituted. Mild tinea pedis can be treated with a topical regime, with oral treatment being reserved for the more severe or chronic cases. Infections with an inflammatory response may respond to topical steroids.

Return to Sports

The National Collegiate Athletic Association (NCAA) and National Federation of State High School Associations (NFHS) have return-to-play guidelines for fungal and viral lesions in an athlete. The NCAA guidelines disqualify an athlete from competition until 72 hours of treatment with a topical fungicide has been completed or, in the case of tinea capitis, a minimum of 2 weeks of treatment with oral therapy. Lesions need to be covered with a gas-permeable membrane, that is, Tegaderm. The NFHS disqualifies athletes until 7 days of oral or topical treatment has been completed, with a minimum of 2 weeks of treatment for tinea capitis. There are no return-to-play guidelines for tinea pedis.

Viral

Viral infections in athletes are common due to the close skin-to-skin contact and environmental exposures. Interestingly, the abrasive shirts used in wrestling have been linked to development of viral skin infections. The more common viral infections include herpes, molluscum contagiosum, and warts.

Herpes Simplex

The *herpes simplex virus* (HSV) can cause infection around the mouth ("fever blisters") and on the genitalia. HSV Type 1 is associated with oral lesions, while HSV Type 2 causes urogenital lesions. Unfortunately, once an individual has been infected, he or she is susceptible to recurrent episodes due to reactivation of the latent virus in a nerve. Multiple factors have been associated with reactivation, including sun, stress, caffeine, and physical stress. Herpes is widely prevalent in the wrestling world, with most of the case reports and studies originating from this sport. The term *herpes gladiatorum* refers to herpes skin lesions in the athlete but more specifically indicates infection in a wrestler. The term *scrumpox* refers to HSV infection in rugby players. As is the case with other skin infections, lesions typically present themselves on exposed areas of the body, such as the head, extremities, or trunk.

Clinical Presentation. Herpes infection may present with the typical viral symptoms of fever, headache, muscle aches, and fatigue. The lesions are manifested by a group of painful vesicles on a red base that may proceed to ulceration. These vesicles can appear on the lips, hands (called *herpetic whitlow*), and body, and, rarely, on the eye. Ocular involvement is an indication for immediate evaluation by an ophthalmologist. Healing occurs over a 2- to 3-week period with progression of the lesions to scabs. Reactivated herpes presents with typical vesicular/ulcerative lesions without the associated systemic symptoms.

Diagnosis. Herpes is evident by its characteristic appearance. However, the Tzank test may be used to evaluate the fluid from a vesicle. A viral culture takes 4 to 5 days and is not normally indicated.

Treatment. Antiviral oral and topical medications are available for treatment. These include acyclovir, valacyclovir, and famciclovir. Studies have shown that acyclovir and valacyclovir are equivalent drugs in terms of length of treatment and time to lesion healing. Acyclovir has variable dose ranges from five times a day to twice a day, and valacyclovir is typically taken twice a day. In athletes with a known history of herpes, suppressive therapy has been advocated to prevent the lesions from recurring. Acyclovir 400 milligrams (mg) twice a day, valacyclovir 500 to 1,000 mg once daily, or famcyclovir 250 mg twice a day have all been recommended.

Return to Sports. The NCAA and NFHS each have recommendations regarding return to play for athletes infected by HSV. These are further delineated by primary or initial infection and reactivated or recurrent herpes. The NCAA proposes that patients with primary herpes gladiatorum return after being free of symptoms for 72 hours, having no new lesions for at least 72 hours, and having completed at least 120 hours of antiviral treatment. The NFHS recommends at least 120 hours of oral antiviral treatment and no new lesions while on medication. The NCAA recommends no moist lesions and at least 120 hours of oral antiviral treatment for reactivated herpes. The NFHS requires at least 120 hours of oral antiviral treatment and no new lesions.

Warts (*Verruca Vulgaris*)

Warts are noncancerous skin lesions caused by different types of human papillomavirus (HPV). Transmission is via skin-to-skin contact.

Clinical Presentation and Diagnosis. Warts typically appear on an athlete's hands, fingers, or feet. They are flesh-colored, roughly contoured plaques of variable size. Lesions on the soles of the feet are referred to as *plantar warts* and appear similar to calluses. Differentiation between the two involves paring down the lesion to reveal multiple "seeds" in the case of *plantar warts*. These seeds are the clotted vessels supplying the wart. Plantar warts can be very painful, making it difficult for the athlete to bear weight on the lesion. Rarely does a wart need to be excised and sent for confirmation of HPV. Warts can progress in size and appearance. Some disappear spontaneously, while some increase in size.

Treatment. There are many treatment approaches to warts. These include watchful waiting, over-the-counter remedies, cryotherapy, and surgical removal. Several attempts at treatment are typically necessary.

One of the more common treatments is cryotherapy, where treatment with liquid nitrogen induces inflammation, blister formation, and eventual sloughing off of the skin. Topical treatment with salicylic acid or trichloroacetic acid requires soaking before application and paring down the lesion after application to allow the treatment access to the active virus. Duct tape has been advocated as an excellent home remedy. Cantharidin is an extract from the blister beetle that induces a blister when applied, allowing the dead skin to be removed. Difficult warts may be treated with immunotherapy or laser surgery. There are no data supporting one treatment over the other.

Return to Sports. The NCAA return-to-play guideline recommends adequately covering the lesions. This has been loosely described and may be difficult depending on the location of the lesion. The NFHS does not have a guideline.

Molluscum Contagiosum

Molluscum contagiosum is a member of the poxvirus family. It is spread among athletes via skin-to-skin contact as well as contaminated objects such as shared clothing or towels. It typically infects young children aged 1 to 10 years but can also be spread via sexual contact in the younger adult population. It infects only humans and is easily transmitted among individuals.

Clinical Presentation. The lesions appear on the face, neck, trunk, arms, hands, and/or legs or, in the case of sexual transmission, on the genitals, lower abdomen, and/or inner thighs. They are round, raised, flesh-colored papules or nodules with a small indentation or "umbilication" at their center. Most patients are typically asymptomatic. The lesions can become red or inflamed, and if picked off, the virus will easily spread to the surrounding skin.

Diagnosis. Diagnosis is clinically made by the characteristic appearance of the lesions. Occasionally, skin scrapings are examined under the microscope for validation.

Treatment. In individuals with an intact immune system, the lesions will self-resolve in approximately 6 to 12 months. Treatment is recommended given the infection's ease of spread. There are multiple treatment options available, including scraping or curettage, freezing or cryotherapy, and laser surgery. Topical agents include 0.7% cantharidin, the blister-causing substance from the blister beetle, and silver nitrate. Immune modulating therapy has also been proposed. Associated dermatitis around the lesion can be treated with over-the-counter 1% hydrocortisone cream application, but the cream should not be placed on the lesion itself.

Return to Sports. The NCAA recommends curetting or removing the lesions and covering localized or solitary lesions with a gas-permeable membrane before the athlete can return to play. The NFHS recommends keeping a wrestler out of competition for 24 hours following interventions such as curettage.

Ingrown Toenail

Ingrown toenails are a common cause of toe pain. Usually occurring on the lateral (outer) side of the large toe, they are caused by abnormal growth of the nail plate into the surrounding tissue. The affected tissue responds to the invading nail plate as if it were a foreign body and becomes painful, inflamed, and occasionally infected. Common causes of ingrown toenails in athletes are poorly fitting shoes, hyperhidrosis (excessive sweating), and improper nail trimming. This problem is rarely seen in preteens, and its incidence increases with age. Minor ingrown nails are often treated at home without requiring medical attention. Severe cases may require a surgical procedure to remove the offending portion of the nail plate.

Anatomy

Several structures comprise the nail unit. The nail plate itself is made from dead keratin (cellular protein), which is hard and translucent. The nail plate lies directly on top of and is attached to a structure called the *matrix,* which overlies the nail bed. The nail plate grows out from the matrix at the base of the nail near a white crest called the *lunula*. The lunula is the only visible portion of the matrix. The nail plate extends out from the matrix across the nail bed until the two begin to separate where the nail covers a short piece of waterproof tissue called the *hyponychium,* near the tip of the toe. The portion of the nail that extends beyond the hyponychium and is fully independent of the matrix is called the *distal groove*. The *nail fold* is the skin and tissue surrounding the base and sides of the nail plate.

Causes

Any factors that press the nail plate against the skin of the nail fold can predispose individuals to ingrown toenails. Although any toe can be afflicted, the most common site of an ingrown nail is the lateral side of the great toe. Tight footwear, especially with a toe box that does not accommodate widening of the foot while bearing weight, is a common cause. Nail shape and length are also important factors causing a predisposition for ingrown nails. Nail plates should be trimmed so that the corners are squared and extend beyond the hyponychium, so as not to allow lateral growth into the nail fold. *Onychomycosis* (a fungal nail infection; see the entry Toenail Fungus) can cause nail plate thickening, which if left unattended can curve the nail, causing the nail plate to grow into the nail fold or crowd the toe, putting pressure on the nail fold. Hyperhidrosis is another contributing factor for ingrown nails because of the softening effect on the nail fold, making it susceptible to the pressures and lateral forces placed on it by the nail plate during exercise. *Neoplasms* (cancer) or previous trauma can also deform the nail shape, leading to ingrown nails. Other factors, which are less common in athletes, are obesity, gait abnormality, and skeletal deformities such as those seen in arthritis.

Symptoms

The progression of ingrown toenails is described in three stages. The first is the mildest, consisting of localized inflammation, edema (swelling), erythema (redness), and slight pain when pressure is applied to the lateral nail fold. The symptoms in Stage 2 are similar to those of Stage 1 but are more severe, including drainage and increased amount of pain because of infection. In addition to the symptoms of Stage 2, in Stage 3 the nail fold forms thickened granulation (scarlike) tissue overlying the lateral nail plate.

Treatment

The treatment for Stage 1 ingrown toenails is fairly conservative. It involves lifting the edge of the offending nail plate out from under the nail fold. Gauze or cotton is then placed under the edge of the sharp nail plate to prevent further irritation. Warm water soaks several times daily while irritation is present help soften the nail fold prior to cotton application. Stages 2 and 3 ingrown toenails generally require surgical intervention. This procedure can be performed in the primary care setting for most patients.

Typically, the affected toe is numbed by injection with a local anesthetic. Then a portion of the nail plate parallel to the nail fold is separated from the nail bed and removed. Any excess granulation tissue formed at the nail fold can also be removed at the time of surgery. If the entire nail plate is deformed or thickened due to onychomycosis, the entire nail plate is separated from the nail bed and excised (removed). The nail fold anatomy is abnormal as a result of the ingrown nail. If left to grow back, the nail has a high probability of becoming ingrown. To prevent recurrence, the exposed matrix of the excised portion of nail plate is destroyed using phenol, sodium hydroxide, laser, or electric cautery (knife). The athlete can generally return to activities the next day, keeping the surgical site clean and covered. The area heals and then fills in with granulation tissue over several weeks, forming a new nail fold. Caution should be used in patients with diabetes, peripheral artery disease, or other medical conditions that inhibit healing.

Insect Bites and Stings

Insect bites occur commonly in athletes, particularly those who train and compete in outdoor venues. Most bites result in mild reactions and often do not need treatment. Certain types of bites may go on to create a more widespread reaction, such as a rash or infection or, in severe cases, anaphylaxis. Anaphylaxis is a severe allergic reaction that causes difficulty breathing, wheezing, and low blood pressure and has the potential to lead to death if not treated quickly.

Not all insects produce venom. Hymenoptera are the only class of insects that produce venom, and only the female of the species makes the venom. Included in this class of insects are bees, wasps, hornets, and fire ants.

Blood-feeding arthropods, such as mosquitoes, can be challenging for athletes as well; many athletic contests occur outdoors and near the end of the day, when these insects are active.

Prevention of Insect Bites

Perhaps the most effective way to treat insect bites is by preventing them from occurring. Wearing protective clothing, using protective insect-repellent sprays, and avoiding known habitats when possible are effective means to reduce the occurrence of insect bites. Insect repellents containing DEET (*N,N*-diethyl-meta-toluamide) have been shown to be the most effective at providing broad-spectrum, long-lasting coverage against bites.

Mosquito

Mosquitoes are the most prevalent of the blood-feeding arthropods and worldwide can transmit more diseases to humans than any other arthropod. The name translates as “little fly,” derived from 16th-century Spanish or Portuguese. They are vectors for diseases causing encephalitis (brain inflammation) and arthritis (joint inflammation) and various febrile illnesses, including malaria and dengue fever. The female mosquitoes are responsible for bites as they need to collect blood for egg production. Male mosquitoes do not bite humans but rather feed from plants.

Mosquitoes are inherently persistent. They can bite any unprotected skin and even through thin layers of clothing. They find their prey by scent and the carbon dioxide in the exhaled breath. They tend to feed in the early morning or dusk hours of the day. They can feed many times in one breeding cycle, which means that one insect can bite multiple hosts.

Tick

Ticks are the most common vectors of disease-carrying arthropods in the United States. Ticks are most often either directly contacted in the outdoors—particularly in woody areas—or brought into the home by household pets. Ticks embed the front portion of their body (the feeding organ) into the victim's skin and remain there while feeding on the source's blood. If the tick has fed from an animal with a transmittable disease, it may carry the disease and yet itself remain unaffected by it. It is possible that the disease can be passed during the feeding phase to its human host. Some of the diseases associated with tick bites in the United States are Lyme disease, ehrlichiosis, Rocky Mountain spotted fever, and tularemia.

Removal of a tick requires great care so as not to leave a portion of the tick's body in the host. The tick embeds its feeding organ (hypostome) into the host, and this organ is equipped with reverse barbs that make removal challenging. To remove a tick, it is recommended that the tick be grasped firmly with pointed forceps as close to the skin as possible, taking care not to crush the insect. It should be pulled in a linear fashion out of the skin. It is *not* recommended that ticks be removed with bare or gloved hands. Methods such as using petroleum jelly, a lit match, or isopropyl alcohol on the tick are not recommended; they are more likely to cause expulsion of the salivary contents, leading to higher rates of disease transmission.

Hymenoptera (Bees, Wasps, Ants)

The class of hymenoptera has the ability to sting with the use of venom. Generally, these wounds inflict pain and invoke a rash that appears as a wheal (raised area of skin) and flare (intense redness). Most bee or wasp stings result in this local reaction only. In some people, however, the venom can cause severe anaphylaxis, which requires rapid treatment to reverse or halt progression to a life-threatening state. The first sting in one's life from a bee or wasp is unlikely to produce anaphylaxis but can sensitize an individual to the venom so that a subsequent sting can result in a more serious reaction.

Prevention of bee stings includes avoiding use of perfumes or aromatic lotions to decrease attraction of the insects. Awareness of bee habitats is important to avoid disruption of a hive, which can arouse numerous bees willing to sting to protect their home. Hives can be found around human dwellings (most often wasp hives) or in wooded areas in burrows located on the ground.

Treatment of a bee sting involves ice or cold packs applied on the sting site after attempting to remove the stinger. The edge of a credit card swiped gently over the sting often works well to remove the stinger. If the patient complains of any trouble breathing or chest discomfort or has a change in alertness, anaphylaxis may be setting in, and rapid transport to an emergency room is recommended. Anaphylactic reactions can occur up to 12 hours after the sting.

Fire Ants

Fire ants are more vicious than expected for their size. They tend to attack in large numbers and produce intense pain at the site of the bites. The ants are only about 1/16 to 1/4 inches (in.; 1 in. = 2.54 centimeters) long and live in colonies that can be identified by their characteristic mound of soft earth on top. Contact with the ants generally results in a rapid response, often before the victim is aware of the ants. Stepping on the mound may cause hundreds of ants to travel to the leg of the person and bite seemingly all at once. The bite tends to cause a burning sensation (thus "fire" ants) and eventually leads to small blisters filled with white pus. In allergic individuals, life-threatening anaphylaxis may develop. Treatment involves cool compresses and antihistamine medications to decrease the intense itching.

Caterpillars

Exposure to caterpillars can create skin irritation from contact with the short hairs (setae) of the caterpillar. Caterpillars are the larval stage for butterflies and moths. The hairs of the caterpillar may become airborne with some species and can become entangled with clothes hung to dry or directly with the skin. The irritated rash generally appears as small, red-colored bumps or pustules that may or may not be itchy. Following the life cycle of the caterpillar, the rash usually shows up in early spring.

Identification of the hairs of the caterpillar will confirm involvement of a caterpillar. Placing a piece of sticky, clear tape over the rash to pick up any small hairs that may be present and then putting that tape sticky side down on a glass slide allows for evaluation of the hairs with a microscope. Hairs that are present will appear as short, threadlike objects when looked at under a microscope. Treatment for the rash involves removing the hairs (gently with sticky tape as above), treatment with antihistamines or calamine lotion, and avoidance of further exposure when possible.

Spiders

Spiders are eight-legged creatures credited with many insect bites. Despite there being more than 34,000 species of spiders worldwide, most are not inclined to bite humans unless they find themselves in danger of being crushed themselves. A few spider bites are known to cause fairly typical clinical reactions and can at times be identified this way, but for most bites, the lesions they create are not specific, and it is impossible to tell what the consequences will be unless the actual biting spider can be collected.

The only two spiders of predictable clinical significance are the black widow and the brown recluse. This is because they tend to cause characteristic lesions at the site of injury.

Black widow envenomation occurs by the female of the species only. Muscle cramping often develops and most commonly may progress to severe pain in the abdomen and lower extremities. The lesion itself may be fairly innocuous—a mild redness or warmth about the area and possibly the presence of small fang marks. Black widows tend to be located in woodpiles or barns but also may migrate indoors to closets or cupboards in the winter. They tend to be prevalent in the southern part of the United States but have been seen in every state except Alaska. To help limit the spread of venom, ice should be applied to the bite area immediately. Antivenin is used for severe envenomations.

Brown recluse spider bites have the potential to produce a much more impressive local reaction. The mildest is redness and warmth at the site. Blistering can develop, however, as well as darkening of the skin and necrosis (dying of the skin). The lesion can take months to heal. These spiders are most commonly seen in warm climates and tend to be very reclusive (thus their name). Treatment for the lesions is usually ice, elevation, and gentle cleaning. Some bites may require antibiotics or anti-inflammatory medications to aid in healing. Tetanus toxoid immunization is important for moderate bites by any insect.

International Federation of Sports Medicine

The International Federation of Sports Medicine is made up of more than 120 national sports medicine associations (NSMAs) that span five continents. It is the oldest and largest confederation of national medical associations in the world.

History

This organization was founded on February 14, 1928, during the Second Olympic Winter Games in St. Moritz (Switzerland) as Association International Medico-Sportive (AIMS). Delegates from 11 countries elected Wilhelm Knoll

(Switzerland) as its first president. The organization's stated goals were as follows:

- To cooperate with and support the International Olympic Committee (IOC) and the international sports federations
- To provide the best medical care for athletes
- To provide support for the further development of NSMAs
- To organize the exchange of information and experience about the basic science and practical aspects of sports medicine

The first International AIMS Congress took place during the ninth Olympic Summer Games in Amsterdam (the Netherlands).

In Chamonix (France) at the third International AIMS Congress (1934), the name of the organization was changed to Fédération Internationale de Médecine Sportive (FIMS). FIMS received its present name (International Federation of Sports Medicine) at the 26th World Congress (1998) in Orlando, Florida.

Structure

FIMS is governed by a Council of Delegates, which is made up of one representative from each of the NSMAs. The council meets every 2 years and elects the executive committee (EC) for a term of 4 years. The EC meets at least twice annually. The EC consists of a president, four vice presidents, a secretary general, a treasurer, and eight members. The four vice presidents are nominated by each of the four continental federations: The Pan American Confederation of Sports Medicine (founded 1975), the African Union of Sports Medicine (founded 1982), the Asian Federation of Sports Medicine (founded 1990), and the European Federation of Sports Medicine Associations (founded 1997).

The "fifth continent," Oceania, nominates one member to the FIMS EC.

Four Standing Commissions—the Scientific, Education, Interfederal, and Liaison Commissions—support the FIMS EC. The chairs of these commissions, appointed by the EC, participate in the FIMS EC meetings.

Representatives of the International Olympic Committee (IOC), the International Council of Sport Science and Physical Education (ICSSPE), and the United Nations Educational, Scientific and Cultural Organization (UNESCO) also participate, as co-opted members, in the meetings of the EC.

Objectives

FIMS promotes the study and development of sports medicine throughout the world; research on the implications of physical training and sports participation; education by organizing or supporting national and international scientific meetings, courses, and congresses; medical care for the benefit of athletes; and physical training and sports participation for the health and fitness of all people. In addition, FIMS publishes scientific information on sports medicine and cooperates with national and international organizations in sports medicine and related fields.

Interval Training/Fartlek

Athletic events such as distance running predominantly use the body's aerobic energy system for production of adenosine triphosphate at a muscle-cellular level. While training for such events, athletes and their coaches look for methods to stress the aerobic system to stimulate the system to work more efficiently. This will often result in performance gains for the athlete as a consequence of the increase in mitochondrial density, better capillary network, and improved extraction of oxygen from the blood.

Stressing the aerobic system has risks in that exceeding the limits of aerobic power typically requires vigorous exercise, which necessitates relative rest for adequate recovery. The need for balancing a sufficient amount of stress to the aerobic system without excessive exercise loads (and the risk of prolonged recovery) has led to the introduction of interval training. There may also be physiological benefits in interval training for non-athletic populations (persons with a history of chronic obstructive pulmonary disease, asthma, or stroke) seeking to improve clinical parameters.

Interval Training

Interval training is defined as repeated short bouts of exercise at intensities that are higher than what can be sustained aerobically. Each short bout of exercise (work phase) is followed by a period of rest or recovery. The intensity of the work phase dictates the sustainability of that intensity. Hence, depending on the training intensity, a single effort may last from a few seconds to several minutes, with multiple efforts separated by up to a few minutes of rest or low-intensity exercise. Intense interval exercise is considered a time-efficient strategy to stimulate endurance muscle adaptations comparable with traditional training.

Distance runners often practice intervals on a running track, running hard at a certain pace for a specified distance (or time) and jogging, walking, or resting in between (for a set distance/time). An example could be 12 repetitions of 400 meters (m) with a 200-m jog between each. Distances can also vary; one example would be a "ladder" workout consisting of one 1,600-m, two 1,200-m, three 800-m, and four 400-m repetitions, each at an appropriate speed and recovery.

Interval training elicits rapid skeletal muscle remodeling due to the high level of muscle fiber recruitment, engaging Type II fibers in particular. Signaling pathways have been shown to play a role in promoting coactivators involved in mitochondrial generation.

A sufficient amount of interval training, performed for at least 6 weeks, increases peak oxygen uptake and the maximal activity of mitochondrial enzymes in skeletal muscle.

Fartlek

Originated in the 1930s by the Swedish coach Gösta Holmér (1891–1983), fartlek means "speed play" and has been adopted by many physiologists since. It describes a type of training that lies somewhere between interval training and distance training. It consists of distance running with a burst of harder running at more irregular points, lengths, and speeds than in interval training. Not only is it an efficient training method; Fartlek training has been suggested to help avoid injuries that often accompany continuous, repetitive activity and provides the opportunity to increase exercise intensity without exhausting the aerobic and anaerobic systems, thus extending the period before the onset of fatigue. Most Fartlek sessions last a minimum of 45 minutes, with intensity varying from walking to sprinting. Fartlek training is generally associated with running but can include almost any kind of exercise.

Sessions should be at an intensity that causes the athlete to work at 60% to 80% of his or her maximum heart rate.

Example of Fartlek Training

- Warm-up—easy running for 5 to 10 minutes
- Steady, hard speed for 1.5 to 2 kilometers (km), such as a long repetition
- Rapid walking for about 5 minutes—recovery
- Easy running interspersed with sprints of about 50 to 60 m, repeated until tired
- Easy running with "quick steps" (speeding up to avoid being overtaken)
- Full speed uphill for 175 to 200 m
- Immediately after, fast pace for 1 minute
- Repeats of this routine until the time prescribed on the schedule has elapsed

One of the main reasons for the success of Fartlek training is its adaptability. It can benefit participants in field games such as soccer, field hockey, lacrosse, and rugby as it develops aerobic and anaerobic capacities, both of which are stressed in these sports. Athletes can make the most of the flexibility of Fartlek training by mimicking the activities that would take place during their chosen sport or event.

Soccer

Endurance interval training using an intensity at 90% to 95% of maximal heart rate in 3- to 8-minute bouts has proved to be effective in the development of endurance and for performance improvements in soccer play. The training seems to mainly accomplish $\dot{V}O_2max$ (peak oxygen uptake) with intervals, enhancing lactate elimination; hence, aerobic endurance capacity and soccer performance both improve.

Chronic Obstructive Pulmonary Disease (COPD)

In athletes and healthy older adults, interval training has been shown to improve $\dot{V}O_2max$, endurance capacity, and lactate and ventilatory threshold. Peak work rates are higher after interval versus continuous training. Interval training may be more physiologically beneficial for patients with chronic obstructive pulmonary disease (COPD). In such patients, exercise work rates that are above a certain critical power cannot be sustained due to rapidly developing hyperinflation and dyspnea. Interval training appears to reduce this ventilatory response, delaying hyperinflation and dyspnea and allowing a greater opportunity for exercise progression. Interval training also specifically targets skeletal muscle metabolism, the dysfunction of which also contributes to exercise limitation in COPD. Finally, interval training may better mimic the activities of daily living and, thus, has a greater potential to improve quality of life by directly enhancing performance in key tasks such as climbing stairs.

Intervertebral Disk Disease

Neck and back pain are very common reasons for seeking medical attention. About 20% of the population will experience low back pain lasting for a month over a 1-year time period. For the neck, this is about 10%. In athletics, this is variable and sport specific. After a week of touring, 40% to 50% of cyclists will experience neck pain, while 30% will experience back pain. Although there are multiple causes of neck and back pain, the intervertebral disk is one of the most common sources of neck and back pain. In the triathlete, the disk has been a causatory factor in about 25% of these pain syndromes. As such, it is important for the athlete to understand the biomechanics of the specific sport and how his or her particular body type and underlying problems might be affected.

Anatomy

The spinal column spans from the skull to the pelvis. There are 7 cervical vertebrae, 12 thoracic vertebrae, and 5 lumbar vertebrae. These vertebrae articulate with the adjacent levels via the intervertebral disk in the front and the facet joints in the back.

The lumbar vertebrae end on the sacrum, which is a fused, V-shaped vertebra and articulates with the pelvis to transfer forces from the trunk to the legs (Figure 1).

The intervertebral disks become progressively larger from the cervical spine down through the lumbar spine. These disks have three basic components: the *annular ligaments* on the outside, the colloidal gel (*nucleus pulposus*) on the inside, and the *end plates* of the vertebrae above and below. The annulus is composed of well-organized concentric ligamentous sheaths (10–20 layers). The nucleus pulposus is a hydrous gel with a few cells and some inflammatory enzymes. It provides shock absorption to the spine, as well as motion. The end plates are at the top and bottom of the vertebrae, where the disk attaches. Since there is no blood supply, the end plate provides nutrition to the disk from the hydrostatic pressure during motion. In the child and adolescent athlete, these endplates are composed of soft growth cartilage and are susceptible to injury.

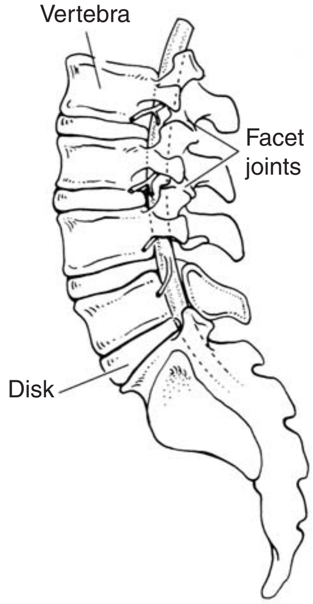

Figure 1 Portion of the Lumbar Spine Showing the Relative Positions of Intervertebral Disks and Vertebrae

The disks are crescent shaped, with the posterior curved away from the posterior spinal column. The one exception is the lowest disk at the lumbosacral juncture (L5-S1), which is round.

Pathologic Disk Problems

A number of changes occur to the disk over a lifetime. Some are part of a normal process that does not involve injury or pain. As we age, many disks will lose the hydration of the nucleus pulposus, losing some height and appearing darker on magnetic resonance imaging (MRI) studies. These are often normal, benign findings.

Conversely, a number of disk changes may occur that are sometimes associated with pain. However, it is crucial to understand that all the following changes may occur with no associated pain. Making the association between a pathologic change seen on an MRI scan and pain is often difficult. The different pathologies of the disk include degenerative disk disease, annular tears, herniated disks, and disk disease of adolescence. Degenerative disk disease occurs with disk dehydration and loss of the annular ligament strength, leading to instability with excessive motion and stress to the vertebrae above and below. This manifests with irregularities of the end plate and swelling (edema) in the adjacent bone. MRI may show edema in the bone, a dark disk, and tears of the annular ligaments. These changes can be correlated with pain.

An annular tear represents a tear of just the annular ligaments. Here, the nucleus is intact, but there is a simple tear in the outer annulus, where there are pain fibers. These tears may be from an acute traumatic episode or a chronic overuse syndrome. MRI will often show a white line in the normally dark annulus. (The nucleus is white, and the annulus is dark on some MRI scans.) This is called a *high-intensity zone* (HIZ) and has been somewhat correlated with pain.

A herniated disk is a more advanced phase of the annular tear. A herniated disk can be a bulge, a protrusion, an extrusion, or a sequestration. A *bulge* occurs when the ligaments are intact, but there is diffuse (180°) disk bulging. This common finding does not usually generate pain. A *protrusion* occurs with partial focal tear of the ligaments and is a broad-based disk protrusion of the nuclear gel. An *extrusion* represents a complete focal annular ligament tear and is a more narrow-based gel extrusion, but it remains in contact with the central gel. A *sequestration* occurs when this extrusion separates and migrates away from the disk (Figure 2).

The nerves of the body emerge from the spinal cord. The beginning portion of the nerve, as it emerges from the spinal cord and passes through the intervertebral foramen, is called the *nerve root.* A herniated disk may occur near or away from the nerve roots. When it affects the nerve roots, pain and weakness of the muscle groups may occur in the distribution of the nerve supply. In the neck,

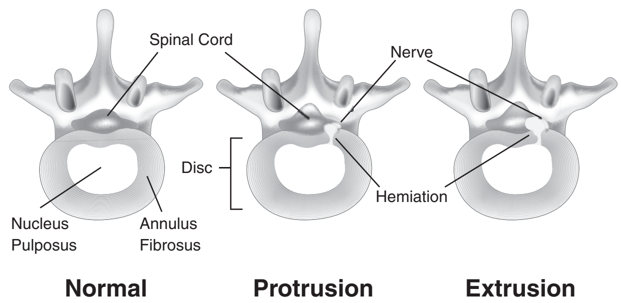

Figure 2 Stages of Intervertebral Disk Herniation

this will often produce shoulder, scapular, or arm symptoms. In the thoracic spine, the symptoms will often distribute to the anterior chest or abdomen. In the lumbar spine, the distribution involves the buttocks, thighs, lower leg, and/or feet. These radiating symptoms are called *radicular symptoms* and may be secondary to nerve compression from the herniation or nerve irritation from leakage of the inflammatory enzymes. Alternately, when the disk does not affect the nerve roots, there may be central pain in the neck, upper back, or lower back, depending on the level involved. This is called an *axial pain syndrome*.

Disk injuries in the cervical spine mostly occur at the lowest cervical levels: C5-C6 and C6-C7. Analogously, the lower lumbar spine is also affected: L5-S1 and L4-L5. Thoracic disk injuries are very uncommon but usually affect the lower thoracic spine.

Disks in children and adolescents are unique, with the end plate being a soft growth cartilage. Excessive pressure on the disk will cause a herniation through the weakest area of the growth cartilage, which will protrude down into the vertebral body, causing large end plate irregularities. In the thoracic spine, this will cause anterior wedging of the vertebrae, resulting in an excessively rounded back, called *Scheuermann kyphosis* (see the entry Scheuermann Kyphosis). When this occurs in the upper lumbar spine, it causes a more flat back and is called *atypical Scheuermann kyphosis*.

Risk Factors

Risk factors for disk disease include smoking, obesity, genetic factors, lack of core conditioning, hard labor, and sedentary lifestyles. From an athletic standpoint, there are a number of sports with strong associations with disk problems due to the biomechanics of the sport. These include wrestling, power lifting, crew, and cycling. When the spine is loaded in the flexed position, excessive pressure is imparted to the disk. For instance, power lifting and the catch phase of the crew stroke may place excessive pressure on the disk. Cycling is complex, depending on the type and duration; often the neck is placed in an extended position, which may apply shear force to the disk. Cycling in certain postures may also adversely flex the lumbar spine, causing low back pain from disk degeneration.

The young athlete with excessive flexion and extension, such as a gymnast, is at a much higher risk of atypical Scheuermann disease.

Clinical Presentation and Evaluation

Athletes with degenerative disk disease will more often present with an axial, nonradiating pain syndrome. It is often better during activity and worse at rest. But as the condition advances, it will be constant and will usually be somewhat relieved when the patient is in a recumbent position.

Athletes with an annular tear may present with an acute onset of axial pain related to one motion, such as a wrestling takedown, but the condition may also have a gradual, insidious onset, such as in a cyclist. This pain manifests classically during flexed activities, particularly sitting. On examination, forward flexion often causes pain, but pain may also occur on extension.

The athlete with disk herniation will present in a similar manner to the athlete with an annular tear but may have radiation along the nerve root path. In many cases, the arm or leg pain will far surpass the neck or lower back component. Again, flexion activities commonly aggravate the symptoms.

The young athlete with atypical Scheuermann disease will present with midback pain that worsens with both flexion and extension. On examination, there will be midback tenderness, aggravated with any motion, and a flat back appearance on forward flexion.

It is essential to inquire about any worrisome problems in the athlete that may prompt an immediate evaluation. These would include loss of ability to hold the urine or stool, fever, chills, weight loss, weakness of an extremity, or constant night pain. In the absence of these, full imaging is warranted if the symptoms last longer than 6 weeks in the adult or 3 weeks in the young athlete. Magnetic resonance imaging (MRI) is usually the most appropriate imaging tool, but a computed tomography (CT) scan may be useful if MRI is not possible.

Treatment

Treatment should follow a specific sequence: acute, subacute, rehabilitation, and sport-specific phases. During the first few days, there is relative rest with the use of analgesics. Rest should not exceed more than a few days. As the initial inflammation subsides, the subacute phase of isometric strength is begun. Here, the core muscles or upper trunk muscles, if the neck is involved, are activated without motion. When this is tolerated, the rehabilitative phase follows, with dynamic, low-resistance exercises used with progression. Finally, as the athlete regains full strength, the sport-specific phase begins, with conditioning aimed at simulating sport-specific motions and regaining proper form. One caveat is that the cervical spine disk involvement typically requires more gradual progression initially, as motion is poorly tolerated.

Since the disk involves inflammatory components, an anti-inflammatory medication is very useful, along with analgesics. In refractory cases, epidural injections of corticosteroids are very useful in accelerating the recovery phase. The adolescent athlete will often benefit from bracing to allow better rehabilitation.

Finally, surgery is considered in three situations: (1) progressive muscle weakness, (2) loss of bowel or bladder control (emergent), and (3) refractory symptoms. The latter situation is somewhat subjective. In cases of severe pain, surgery may be considered as early as 6 to 8 weeks after onset. In moderate cases, it may be months before surgery is considered. If surgery is performed, the athlete with a simple disk excision may possibly be ready for sports participation in 6 to 8 weeks.

Intracerebral Hematoma

A hematoma is a collection of blood outside the blood vessels. The term *intracerebral hematoma* refers to a collection of blood within the substance of the brain. These hematomas occur as a result of damage to the blood vessels that supply the brain tissue. In the general population, intracerebral hematomas are most often the result of head trauma or high blood pressure. Blood vessel abnormalities such as aneurysms, or abnormal masses in the brain, can also lead to hemorrhage and subsequent hematoma formation. In the setting of athletics, an intracerebral hematoma is usually the result of head trauma. It is a relatively rare but very serious type of head injury in sports and can lead to significant disability or death. Knowing the warning signs that can help identify an intracerebral hematoma can help prevent a potentially serious outcome. Quick medical attention is essential in these cases.

Anatomy

The majority of the brain's blood supply comes from a circuit of blood vessels known as the *circle of Willis.* The circle of Willis sits on the bottom surface of the brain and receives its flow of blood from two pairs of arteries that travel up through the neck. The left and right *carotid* arteries travel up through the front half of the neck. The left and right *vertebral* arteries course behind them. Soon after these four arteries pass through the skull, they join together to form the circle of Willis. The circle of Willis then sends off branch arteries to all regions of the brain. Each of these arteries separate into smaller and smaller branches throughout the entire brain. Intracerebral hematomas can occur when any of the arteries that lie within the brain itself become compromised.

Mechanism of Injury

An intracerebral hematoma can occur in sports as a result of a direct impact to the head or whenever enough force is transmitted to the brain and its arteries via an acceleration-deceleration mechanism. An intracerebral hematoma forms when the force is sufficient to cause physical damage to the arteries, resulting in blood leaking or hemorrhaging out of the vessels into the brain tissue. If the hematoma is being formed from damage to an artery rather than a vein, the blood is under tremendous pressure. This can lead to a quick expansion of the hematoma, which can then increase the pressure inside the skull. Given that the skull is a rigid, fixed space, this increase in pressure can quickly lead to damage to the brain itself and even death.

Risk Factors

The baseline risk of developing an intracerebral hematoma from sports participation is primarily a function of the type of sport being played, the equipment being used, and the playing technique of the athlete. While high-velocity contact sports such as football, ice hockey, and lacrosse may carry the most inherent risk, the use of proper equipment, especially helmets that meet the requirements set forth by the National Operating Committee on Standards for Athletic Equipment (NOCSAE), can lower the risk significantly. It is important to recognize that intracranial hematomas can occur in any sport in which an athlete experiences a head trauma. Certain sports that involve high velocities, entail less intentional contact, and require little, if any, protective equipment, such as soccer and field hockey, may pose additional risk.

Any athlete who is on a blood-thinning medication has additional risk of developing a hematoma. It should be noted that athletes using warfarin, or a similar medicine, do so for the purpose of preventing clots from forming in their heart or blood vessels. Since they are unable to form clots, as they would when not on the medicine, any hemorrhage can take on life-threatening characteristics quickly. The use of these medicines should therefore be a very strong consideration for avoiding contact sports. Other medications that thin out the blood, but to a lesser degree, such as aspirin, are relative contraindications for contact sports participation.

Another risk factor for developing an intracerebral hematoma is the presence of an abnormality in blood vessel anatomy. Certain congenital vessel abnormalities, such as an arteriovenous malformation (AVM), present significant bleeding risks. AVMs are typically identified on a brain magnetic resonance imaging (MRI) scan. The presence of an AVM requires consultation with a neurologist and/or neurosurgeon prior to clearing any athlete for competition. Connective tissue disorders can also lead to a weakening of the blood vessel walls.

Signs and Symptoms

The first sign of any type of brain injury typically involves some change in consciousness. The change can be subtle, such as mild confusion, or more dramatic, such as a complete loss of consciousness. The athlete may also have many of the signs and symptoms typically seen in concussion, such as headache, nausea, dizziness, sensitivity to light, and lack of coordination. Please refer to the entry Concussion for a more complete discussion of this injury. Any athlete who experiences a hit significant enough to cause concussion-like symptoms should be observed closely for any signs of the condition worsening. If any athlete develops new symptoms several minutes after a witnessed impact or if there is any perceived clinical worsening, emergency medical services should be notified immediately.

Clinical Evaluation

As with any athletic head injury, care should be taken on the field to first assess the "ABCs" (airway-breathing-circulation). The next consideration should be for cervical spine trauma, with cervical immobilization performed when appropriate. The athlete's level of consciousness should be noted using the Glasgow coma scale. Any language, memory, or orientation abnormalities should also be noted. A careful physical examination should be performed to evaluate for skull fracture or any focal neurological abnormality, such as pupil asymmetry, visual field loss, facial asymmetry, focal weakness, or coordination difficulties. Any evidence of fracture or focal neurological abnormality warrants activation of emergency medical services. Once the on-field assessment is complete, it is appropriate to monitor the athlete with serial physical examinations in order to document any changes in signs or symptoms. If worsening is noted, the patient should be further evaluated in a hospital setting.

Diagnostic Tests

The presence of an intracerebral hematoma can usually be confirmed with a computed tomography (CT) scan of the head. An MRI scan of the brain can also be used. While the MRI scan may provide more information regarding damage to the brain itself, it is more expensive, requires more time, and is not available at every medical facility. The initial diagnosis, therefore, is typically made with a CT scan.

Management

Athletes who are suspected to have any type of intracranial bleeding should be transferred via emergency medical services to the nearest emergency facility as soon as possible. If the injury is confirmed, the patient should then be evaluated for possible surgical intervention. Surgical options include evacuation of the hematoma as well as repair of the vascular structures and the skull, if needed.

Prevention

As with other head injuries in athletics, proper technique, well-fitted and certified equipment, and adherence to the rules of play are paramount in preventing an intracranial hematoma. Identifying any of the specific risk factors described above can help prevent significant injuries, disability, or death.

Return to Sports

No athlete should return to participation in contact sports as long as he or she is still symptomatic from any head injury. In the case of an intracerebral hematoma, the specific location and cause of the bleed need to be considered, and return to contact sports participation should only take place after consultation with a physician.

Intracranial Hemorrhage

An intracranial hemorrhage is a type of head injury that involves bleeding inside the skull. The term *intracranial* refers to the location of the bleeding being inside the cranium. *Hemorrhage* refers to blood leaving the blood vessels. When blood collects outside the blood vessels, *hematomas* are created. Intracranial hemorrhages occur when a blood vessel inside the skull is damaged, resulting in rupture or leaking. In the setting of athletic competition, this can occur when a significant mechanical force is applied to the head. The resulting hemorrhage can be extremely dangerous and should be considered a medical emergency. Early recognition of the warning signs and quick medical attention are critical.

Anatomy

The bones of the cranium fuse together during early childhood development, forming a hard protective covering around the brain. Together, the cranium and jaw, or mandible, constitute the skull. The delicate tissues of the brain are enclosed completely within the cranial compartment.

Intracranial hemorrhages can be further delineated by location into intra-axial or extra-axial. *Intra-axial hemorrhages* refer to bleeding inside the brain tissue itself. *Extra-axial hemorrhages,* conversely, refer to bleeding that occurs outside the brain tissue but inside the cranium. Extra-axial intracranial hemorrhages can be further classified by location based on the three protective tissue layers that encase the skull, the *meninges*. The innermost protective layer, the *pia mater,* is a delicate membrane lying on the surface of the brain. The second layer, the *arachnoid mater,* covers the brain and pia mater but does not follow the contour of the involutions of the brain. The outermost layer, the *dura mater,* provides a thicker and tougher layer of protection.

These three layers define three potential spaces for blood to collect. The *epidural space,* between the skull and the dura, the *subdural space,* between the dura and arachnoid layers, and the *subarachnoid space,* between the arachnoid and pia layers, each have their own potential sources of hemorrhage. The pia mater is too closely adhered to the brain and too fragile to act as a barrier for blood, and therefore, there is no potential space between the pia and the brain for a hematoma to form.

Mechanism of Injury

Intracranial hemorrhages can occur in sports as the result of a mechanical force applied to the head. This is usually from a direct blow to the head, but it can also occur with a sudden acceleration-deceleration mechanism without direct contact with the skull. The hemorrhage occurs when the mechanical force is significant enough to cause physical damage to the intracranial blood vessels.

Risk Factors

For any athlete, the baseline risk of developing an intracranial hemorrhage is primarily a function of the type of sport being played, the equipment being used, and the playing technique. While high-velocity contact sports such as football, ice hockey, and lacrosse may carry the most inherent risk, the use of proper equipment, especially helmets that meet the requirements set forth by the National Operating Committee on Standards for Athletic Equipment (NOCSAE), can greatly lower the risk. However, intracranial hemorrhages can occur in any sport in which an athlete experiences a head trauma. Certain sports that involve high velocities, entail less purposeful contact, and require little, if any, protective equipment, such as soccer and field hockey, may also pose additional risk.

Any athlete who is on a blood-thinning medication, especially a medicine such as warfarin, carries additional risk of developing a hemorrhage. It should be noted that athletes using warfarin, or a similar medicine, do so for the purpose of preventing clots from forming in their heart or blood vessels. Since they are unable to form clots, as they would when not on the medicine, any hemorrhage can take on life-threatening characteristics quickly. The use of these medicines should therefore be a very strong consideration for avoiding any type of contact sport. Other medications that thin out the blood, but to a lesser degree, such as aspirin, are relative contraindications for contact sports participation.

Signs and Symptoms

The initial signs and symptoms of an intracranial hemorrhage depend specifically on the location of the bleeding. As discussed in the cross-referenced entries noted below, the first sign of any type of brain injury occurs shortly after the head impact and typically involves some change in consciousness. The change can be subtle, such as mild confusion, or more dramatic, such as a complete loss of consciousness. The athlete may also have many of the signs and symptoms typically seen in concussion, such as headache, nausea, dizziness, sensitivity to light, and lack of coordination. Please refer to the entry Concussion for a more complete discussion of this injury.

Any athlete who experiences a hit significant enough to cause concussion-like symptoms should be observed closely for any signs of worsening of the condition. The most common type of intracranial hemorrhage that would occur in this setting is an *epidural hematoma.* In the classic presentation, an epidural hematoma causes the athlete to experience what is known as a *lucid interval.* After an initial period of altered consciousness that can last several minutes, the athlete improves significantly, or even completely. During this time, the physical examination can be completely normal. At this stage, the epidural hematoma is still small enough to be asymptomatic. As it expands, however, the increasing pressure inside the skull puts the brain at risk, leading to a quick return of symptoms. Continued expansion of the hematoma can then lead to rapidly progressive symptoms, coma, and even death. The lucid interval typically lasts only a few minutes, whereas the subsequent deterioration can occur even faster.

Clinical Evaluation

As with any head injury, the first step is to assess the "ABCs" (airway-breathing-circulation). The next consideration should be for cervical spine trauma, with cervical immobilization performed when appropriate. The athlete's level of consciousness should be noted using the Glasgow coma scale. Any language, memory, or orientation abnormalities should also be noted. A careful physical examination should then be performed to evaluate for skull fracture or any focal neurologic abnormality, such as pupil asymmetry, visual field loss, facial asymmetry, focal weakness, or coordination difficulties. Any evidence of fracture or focal neurological abnormality warrants activation of emergency medical services. Once the on-field assessment is complete, it is appropriate to monitor the athlete with serial physical examinations in order to document any changes in signs or symptoms. If worsening is noted, the patient should be further evaluated in a hospital setting.

Diagnostic Tests

The presence of an intracranial hemorrhage can most easily be confirmed with a computed tomography (CT) scan of the head. While a magnetic resonance imaging (MRI) study of the brain may provide more information regarding damage to the brain itself, it is more expensive, requires more time, and is not available at every medical facility. The initial diagnosis, therefore, is typically made with a CT scan.

Management

Athletes who are suspected to have any type of intracranial hemorrhage should be transferred via emergency medical services to the nearest emergency facility as soon as possible. If the injury is confirmed, the patient should then be evaluated for possible surgical intervention. Surgical options include evacuation of the hematoma as well as repair of the vascular structures and skull as needed.

Prevention

As with other head injuries in athletics, proper technique, well-fitted and certified equipment, and adherence to the rules of play are paramount in preventing intracranial hemorrhages.

Return to Sports

No athlete should return to participation in contact sports as long as he or she is still symptomatic from any head injury. In the case of an intracranial hemorrhage, the specific location and cause of the bleed need to be strongly considered, and return to contact sports should only occur after consultation with a physician.

Irritant Contact Dermatitis

Irritant contact dermatitis (ICD) is a condition of the skin in which chemicals or mechanical or environmental forces irritate the superficial protective layers. This irritation leads to a localized inflammatory response typically resulting in redness and swelling. Dermatologic injuries are common in athletics, and given the diverse environmental conditions and chemical exposures encountered in sports, ICD is a commonly seen diagnosis. Recognizing ICD is important as there are strict policies for athletes with infectious skin conditions, and identifying noninfectious conditions such as ICD will help avoid unnecessary treatments and competition restrictions.

Causes

Many substances can cause ICD, the most common being chemical detergents, solvents, acids, dust, and excessive water. Disinfectants in swimming pools, fiberglass in hockey sticks, field markings in football and soccer, and chalk in weight lifting have all also been implicated in athletic cases of ICD. By far, the hands are the most commonly affected area of the body, and frequent exposure to soaps and cleaners accounts for more than 80% of occupational skin disorders.

Pathophysiology

ICD occurs when an irritating substance or repeated physical action damages the superficial protective skin barrier, the epidermis, and allows foreign material to come into contact with the layers below. This then causes a localized inflammatory reaction in the lower skin layers. Both chemical and physical agents can cause cellular damage. While some chemicals are directly caustic to cell membranes, repeated physical forces, such as friction, pressure, or occlusion, can all directly damage the epidermal cells. Environmental factors such as heat, low humidity, and ultraviolet light can also contribute to epidermal irritation. Heat typically leads to sweat production, which can enhance the permeability of chemical irritants. Low humidity environments can dry out the superficial skin layers enough to decrease the effectiveness of the skin barriers. Finally, ultraviolet light can penetrate through the epidermal layers and directly cause release of inflammatory mediators.

The amount of substance, length of exposure, and concentration of the chemical solution are all factors that can affect the severity of ICD. Larger volumes and longer exposure times enhance chemical permeability and increase the likelihood that cell damage will occur. Higher concentrations of chemicals are typically more irritating than more dilute solutions. Many studies have also documented that individuals with an atopic predisposition (i.e., eczema) are more susceptible to ICD as their skin can have an enhanced reaction to certain irritants and environmental conditions.

Both acute and chronic ICD exist. Acute ICD involves direct cytotoxic effects on the skin with rapid cell membrane damage. This typically produces a more vibrant inflammatory response. Chronic ICD occurs when the skin is repeatedly in contact with an irritating substance, and cellular damage occurs more slowly as cell membranes decompose over time. While an inflammatory response also occurs in this setting, it is typically less intense but can involve a more extensive area.

Clinical Evaluation

History

In acute ICD, there is usually, but not always, a history of exposure to an irritant. Symptoms such as burning, stinging, or itching can immediately follow an exposure or may present within a few minutes. Chronic ICD symptoms set in more slowly, and similar symptoms occur only after cumulative exposures. Repeated exposure is required to break down the epidermal cells, which, in some instances, can take up to a few weeks. Unlike allergic contact dermatitis (ACD), ICD does not require prior exposure and can occur after the initial contact with an irritant. If numerous athletes present with similar symptoms, ICD should be considered if an infectious etiology is ruled out as multiple teammates are rarely allergic to the same substance. Identifying whether uniforms or equipment are causing excessive friction over the skin, causing breakdown, is also important.

Physical Examination

Skin findings of acute ICD include redness, swelling, and even blistering if significantly irritating. The location of the skin findings is limited to the area of exposure. Acute ICD does not spread on its own, so the borders of the rash are sharply demarcated. In the chronic state, skin findings include redness, dryness, chapping, scaling, and fissuring. The decreased inflammatory response limits the amount of swelling. The borders are less distinct as repetitive exposures rarely occur in the exact same location. Spreading to other areas of the body does not happen, unlike in ACD, where the allergen can be transferred easily by the clothes or hands. Skin patch testing, which identifies allergies to certain substances, can be helpful to distinguish the two processes.

Treatment

The mainstay of treatment is to avoid contact with the offending irritant by wearing protective clothing or by not touching the substance. That may be difficult if a chemical irritant is involved, as many different chemicals can cause ICD. Determining what chemicals may be used in cleaning pools or wrestling mats may be necessary. Acute ICD may need to be treated in the same way as burns if the irritant is caustic enough. Keeping the area clean and protected from reinjury will allow the body to re-form a protective barrier. Also, modifying the sporting equipment to prevent excessive friction or to aid in sweat dissipation can quicken the healing process and decrease the reoccurrence of ICD. For treatment of chronic ICD, besides limiting exposure to the irritant, using moisturizers (e.g., petroleum jelly, thick lotions) to help restore the protective border of the skin can be helpful. Typical corticosteroid creams can help alleviate the itching and burning sensations.

Return to Sports

Unlike infectious dermatologic disorders, ICD is not a contraindication for participating in sporting competitions. Differentiating between the two is helpful to avoid removal from play. Using a protective barrier to cover the ICD-affected area can help the athlete avoid reexposure or further injury while participating in sports.

Jersey Finger

The injury commonly known as *jersey finger* is an avulsion injury of the longer flexor tendon, the flexor digitorum profundus (FDP) tendon, that occurs after forceful extension during active flexion of the most distal part of the affected finger (aka the distal phalanx). The common name arises from the classic presentation caused by violent traction of a flexed distal phalanx as in catching onto the jersey of a running football player. In 75% of cases, the injury occurs in the FDP of the ring finger, followed closely by the middle digit. The injury most commonly occurs in athletes participating in rugby, football, and ice hockey, as well as those who have poor physical conditioning and a previous or untreated jersey finger.

Anatomy

The palmar side of the finger consists of both long and short flexor tendons. The shorter tendon works to bend the finger at the second crease (also known as the *proximal interphalangeal joint*, or PIP joint), while the longer one flexes the digit at the third crease (known as the *distal interphalangeal joint*, or DIP joint). The FDP originates from the proximal two thirds of the ulna and the tissue between the bones of the forearm, known as the *interosseous membrane*. The tendon then travels through the carpal tunnel (the divot at the proximal part of the palmar), extends just below the flexor digitorum superficialis (FDS) tendon (or the short flexor tendon) on the palmar surface, and then becomes more superficial as it inserts into the base of the distal phalanx. Neurologically, the ulnar and median nerves innervate the tendon at the little/ring and index/middle fingers, respectively. Segmental branches of the digital arteries provide its nutritional and vascular perfusion. An intact pulley system as well as adequate synovial fluid, which keeps the joint lubricated, define the range of motion of the FDP tendon, preventing it from gliding juxtaposed to the phalanges. Loss of either biomechanical utility leads to bowstring of the tendon, causing greater excursion of the FDP, increasing the amplitude of muscle contraction to obtain the same amount of phalanx flexion and, therefore, increasing the risk of injury.

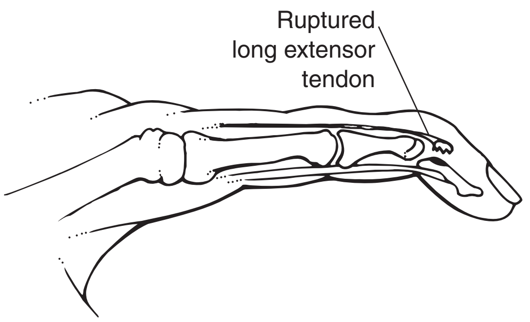

Figure 1 Jersey Finger

Mechanism of Injury

Defined as the disruption of the FDP on the palmar aspects of the distal phalangeal base, jersey finger leads to the loss of the bony or ligamentous attachment of the flexor mechanism into the distal phalanx, leading to loss of flexion at the DIP joint. The tendon can be torn directly from the distal phalanx, or it may avulse a bone fragment.

Three mechanisms of injury classically define the FDP avulsion. The type of mechanism plays a role in the determination of urgency in the treatment modality. In the first type, the tendon retracts into the palm, leading to substantial loss of blood supply. The second mechanism involves the FDP attachment retracting to the PIP joint with some blood supply preservation. In the third type of injury, the FDP avulsion (or chipped injury) can occur when a bony fragment avulses from the distal phalanx while preserving the blood supply.

Evaluation

Patients clinically present with localized tenderness and swelling with an inability to flex at the DIP joint. Some associated pain or fullness at the proximal course of the FDP tendon can occur due to retraction after rupture. When evaluating the natural resting position of the injured digit from a normal finger, the injured phalanx will appear in a more extended position, lying flat outside its normal cascade. Swelling, redness, and bruising can occur for up to 48 hours after the onset of injury.

To test the functionality of the FDP tendon, the examiner asks the patient to hold out the fingers in extension. Then the examiner stabilizes the PIP and metacarpophalangeal (MCP; at the first crease of the finger) joints, preventing them from moving when trying to test the DIP joint. Finally, the examiner asks the patient to flex the distal phalanx. Inability of the injured distal phalanx to fully flex signals a possible injury to the FDP tendon. The presence of a slight DIP flexion does not rule out an avulsion fracture. Some flexor force can be transferred to the distal phalanx without the tendon itself having a bony attachment. Concomitantly, compressing the forearm flexion muscles should draw the noninjured phalanx into flexion compared with the injured.

Initially, an X-ray of the affected finger should be obtained to rule out an avulsion fracture. Magnetic resonance imaging (MRI) can be used to accurately diagnose the disruption of annular pulley ligaments of the injured tendon. With the increasing use of ultrasounds, this modality has shown increasing promise as a tool for diagnostic purposes.

Treatment

Surgical intervention remains the primary treatment modality for all injuries involving the FDP tendon. Optimally, repair should occur within 24 hours of the injury. In the first type of injury, repair is warranted as soon as possible, while there can be some moderate delay of up to 2 weeks in the second type and up to 2 months in the third type.

Repair involves exposed knots and stitched or sutured ends to better promote adhesion formation, while core and running sutures placed around the tendon are used for tensile strength. Most individuals are successfully treated with this treatment modality, but in older patients and those with recurrent injuries, fusion of the DIP joint may be warranted for a better outcome.

After surgery, a dorsal splint (placed at the back of the hand) is used to keep the wrist and the joints in 30° and 70° of flexion, respectively, while placing the DIP and PIP joints in extension. A rubber band traction then maintains the digits in flexed position, providing tendon excursion to repair the injured FDP in order to minimize stress. The splint is kept on for 3 to 5 weeks, after which gentle hand exercises are started, with the protective splint removed only to perform the exercises. Removal of the splint occurs after the fifth week with advancement of light function of the hand and resisted exercises are started after 8 weeks.

Failure to treat the injury in time can lead to permanent deformity, joint stiffness or dysfunction, rerupture, and arthritis.

Return to Sports

After controlled motion in a customized splint 5 weeks postoperation to allow tendon healing and consequent physical therapy, considerations of return to play concern whether the patient's sport involves use of the affected part. Involvement in sports is often delayed for at least 3 months after surgery. If the patient requires use of the affected hand, then it is recommended that return to play is delayed 4 to 6 months after surgery while physical therapy is practiced.

Jet Lag

International travel is inevitable for elite athletes and their coaches, although many other people desire to exercise during international visits. The general travel fatigue associated with any international flight is quickly overcome, whereas jet lag is more long-lasting and is associated with desynchronization of circadian rhythms after time zones are crossed.

Jet lag symptoms, and their associated impact on athletic performance, depend on the duration and direction of the flight, the flight schedule, the time of day, and individual differences. Knowledge of the human circadian system can be used to develop interventions that accelerate adjustment of circadian rhythms and recovery from jet lag. In particular, the timing of outdoor or bright light exposure, meals, and exercise may be manipulated. Melatonin may be helpful, although daytime ingestion of this substance is discouraged among athletes, since it can induce drowsiness and can impair some aspects of athletic performance. Support staff should develop appropriate strategies for individual athletes, who might be assessed for chronotype (morningness/eveningness) or individual circadian phase (by measuring the circadian rhythm of core body temperature or salivary melatonin concentration). Informed strategies based on individual behavior can then be made to minimize the transient effects of jet lag on well-being and performance.

Travel Fatigue Versus Jet Lag

Any long journey by road, rail, or air can cause discomfort and fatigue. Long periods may be spent in a cramped posture, and there may be other stresses associated with delays, unplanned stops, or detours. When traveling by plane, there are added problems caused by hypoxia in the aircraft cabin. Although the cabin is pressurized, there is still some hypoxia present, which may lead to dehydration, dry airways, and headaches. Nevertheless, these transient problems can be remedied on arrival by rehydration, a rest or some light exercise, and a shower or bath. This travel fatigue is experienced when flying directly northward or southward, for example, from mainland Europe to Southern Africa or from North to South America. If only two or fewer time zones are crossed, travel fatigue is probably the most important problem to overcome, and jet lag symptoms will be negligible.

A syndrome distinct from travel fatigue, jet lag is experienced when long-haul flights cross multiple (more than two) time zones. Symptoms are due to a mismatch between the "body clock time" and the new local time and include feeling tired during the day in the new time zone and yet experiencing disturbed sleep at night, feeling less able to concentrate or to motivate oneself, decreased mental and physical performance, increased incidence of headaches and irritability, loss of appetite, and general bowel irregularities. The body clock gradually adapts to the local time in the new environment, and when this process is complete, the symptoms of jet lag disappear.

The Chronobiology of Jet Lag

The body clock works on a molecular level and is located within the suprachiasmatic nuclei (SCN) of the hypothalamus. The retinohypothalamic tract and the intergeniculate leaflet provide input pathways from the retina (photic signals) and other regions of the brain (nonphotic), respectively, to the SCN. A multisynaptic pathway from the SCN also leads to the pineal gland, where melatonin is secreted at night and suppressed by light. These pathways exist to help synchronize the body clock to a 24-hour period. Natural light is the predominant synchronizer for the body clock, and the effects depend on the timing of exposure. Light in the morning can advance circadian rhythms, and light in the evening can delay circadian rhythms. Exogenous melatonin can also shift the biological clock, but in opposition to the effects of light; melatonin in the morning delays circadian rhythms, whereas ingestion in the late evening leads to a phase advance. Additionally, melatonin has an acute lowering effect on core body temperature and alertness. The timing of physical activity has also been found to affect circadian rhythms, especially in animals. In humans, the effects are smaller and seem to depend on whether salivary melatonin secretion or core body temperature is measured as the marker of the circadian phase.

Factors Affecting Jet Lag

The severity of jet lag depends on the number of time zones crossed and, to a lesser extent, on the direction of travel. Symptoms are generally worse after traveling eastward compared with westward travel. Morning-type "larks" could have a theoretical advantage in adjusting to eastward travel (since their circadian phase is already relatively early in the day). Evening-type "owls" might cope better with a westward flight (since they may be naturally phase delayed). Nevertheless, the majority of people are intermediate in chronotype.

There is little evidence that jet lag symptoms are different between males and females, but older people may suffer more, especially in terms of sleep-related symptoms. If one has a choice over different flight schedules and arrival times, a late-afternoon or early-afternoon arrival might be advised, since individuals can "use" the travel fatigue to promote a full sleep at night in the new time zone sooner after arrival. Cultural differences in the country of destination do not affect jet lag, but the climate encountered may exacerbate symptoms of travel fatigue. For example, dehydration following a long-haul flight due to the dry cabin air may be exacerbated after arrival in a very hot country, especially if the destination is at a high altitude, as for a training camp.

Dealing With Jet Lag

The ultimate "cure" for jet lag is to allow enough time between arrival and any obligations (e.g., sports competitions) for circadian rhythms to adjust completely to the new time zone. This period will vary in accordance with the number of time zone transitions experienced. As a general rule, 1 to 1.5 days per time zone crossed should be sufficient. If this period of time is not feasible, strategies for minimizing the effects of jet lag can be applied preflight, while on board the aircraft, and following arrival in the new destination.

Some preflight adjustment of the sleep-wake cycle can be attempted in accordance with the direction of flight. Adjustment of more than 2 hours in retiring to bed is discouraged, since this change is liable to cause rhythm disturbance and impair the quality of training undertaken before departure. As soon as the flight begins, it is advised that travelers should set their watches and schedule meals and sleep periods in accordance with the time at the destination. Although the meal content has been found to affect human circadian rhythms, there is little evidence that the content of meals can be manipulated (e.g., made higher in protein or carbohydrate content) to hasten adjustment to the new time. It is the timing of the meal in the new environment that is more likely to help readjustment of the body clock. Adequate fluid ingestion is recommended, and caffeine can help in combating sleepiness experienced during the day.

Although benzodiazepines and nonbenzodiazepine soporifics have been advocated for inducing sleep, and some benzodiazepines may act as chronobiotics (i.e., change the phase of the body clock), their benefits are inconclusive in athletes. In contrast to benzodiazepines, melatonin can promote sleep without having any marked effects on the sleep EEG (electroencephalogram). However, the purity of melatonin bought in health food outlets or on the Internet cannot be guaranteed. It is also unclear whether melatonin helps most by consolidating sleep in the new time zone or by phase-shifting one's circadian rhythms. To achieve the latter, melatonin would need to be ingested during the day following some flights, depending on the direction of travel and the number of time zones crossed. Such dosing could impair daytime functioning and training.

Most chronobiologists agree that the safest and probably most effective factor in determining the rate of adjustment to the new time zone is seeking exposure to natural daylight and avoiding bright light at the most appropriate times. The timing of such behavior is crucial and should be based on the known phase-response characteristics to light (see above). After flying westward, the recommended times for exposure to, and avoidance of, light to phase-delay circadian rhythms tend to coincide with the daylight and nighttime periods, respectively, in the new time zone, and this could be one reason why westward flights are generally less problematic than eastward journeys. After flying eastward, a phase advance of the body clock is required. Therefore, exposure to light is recommended soon after the minimum in body temperature is reached. Nevertheless, a morning arrival in a new time zone 6 to 9 hours to the east of the home country may coincide with the body clock time that precedes this trough. At this time, the wearing of very dark sunglasses may reduce light exposure. According to the phase-response characteristics for light, exposure in the new afternoon is beneficial.

It should be noted that on the day of arrival, markers of circadian rhythms (useful for the most appropriate timing of light, etc.) will be unusually phased relative to clock time and will change throughout the postflight days. After an eastward flight across six to nine time zones, the minima of temperature and performance rhythms will be in the late afternoon (about 05:00 hours by time in the departure zone). Adjusting the body clock by phase advance will cause this nadir to advance through the afternoon and morning. Ideally, an athlete's circadian phase would be measured prior to the flight and throughout the postflight days to optimize the timing of behavioral strategies.

Jock Itch

Jock itch is the common name for tinea cruris, a fungal infection of the skin localized to the groin and medial thigh. It may extend to the genitals and back to the perianal region.

Pathophysiology

Tinea cruris, and similar fungal infections such as tinea pedis (athlete's foot), tinea corporis, and tinea capitis (ringworm of the body and scalp, respectively) are caused by *dermatophytes*. Dermatophytes can be found on humans, animals, and in soil. They are transmitted by direct contact. The most common cause of jock itch is the dermatophyte *Trichophyton rubrum*.

Clinical Evaluation

History and Physical Exam

As the name implies, jock itch causes a burning or itching sensation in the affected areas. The region is usually large, red, and has a border that is easy to see. The affected skin may be flaky. It usually advances down the thigh, with the leading edge remaining red and scaly. The skin that has been affected longer may turn brown.

There is usually a history of the athlete remaining in sweaty clothes after workouts. Specifically, tight underwear and jockstraps allow for a warm and sweaty environment. This helps the dermatophyte to grow and cause the infection.

Diagnosis

Jock itch is usually diagnosed on clinical grounds alone, based on the location, appearance, and history of the rash. However, if there is a question, the diagnosis can be confirmed by a KOH (potassium hydroxide) test. The affected skin is scraped, allowing debris to fall onto a glass slide. Potassium hydroxide is added to the slide, and under a microscope, the examiner can see the dermatophyte.

Treatment

Medication

Jock itch is almost always easily treated with topical antifungal lotions. These have minimal side effects. Terbinafine, clotriamazole, and ketoconazole have all been effective. The cream must be applied twice daily for up to 4 weeks to completely treat the infection and decrease recurrence.

Oral medications are saved for people who fail topical therapy or have very extensive disease. The common medications are griseofulvin, terbinafine, and fluconazole. These medications work well but often have significant side effects, such as sensitivity to sunlight, upset GI tract, rash, and headache.

Prevention

Educating athletes on proper hygiene is important. Athletes should shower with soap and water immediately following every workout. They should put on clean clothes after the shower and not the clothes they have just worked out in. They also need to be aware that skin-to-skin contact can transmit fungal infections. Athletes should not share equipment without thoroughly washing it first.

Jogger's Nipples

Also called runner's nipples or friction nipples, *jogger's nipples* results in painful, irritated, and sometimes cracked or bleeding nipples. Although it is most common in runners, as the name implies, it can be found in any type of athlete, male or female, where there is repetitive friction on the chest wall by clothing or equipment.

Epidemiology and Risk Factors

Although the data on the prevalence of jogger's nipples in athletes are scanty, it is a common occurrence. It is more prevalent in overweight individuals or large-breasted women, particularly with inadequate breast support. As expected, it is also more common in long-distance athletes who have prolonged or repetitive friction exposure. Cold weather, which leads to erect nipples, as well as rainy or wet environments predispose to irritation as well. Coarse fabrics or loose-fitting clothes can cause or worsen the friction.

Clinical Presentation

Patients usually present with a complaint of acute or chronic pain in their nipples, which can range from mild irritation to overt bleeding and significant discomfort. It is most often the nipple itself that is the most affected, but the areola (the dark area around the nipple) may be affected as well. Examination reveals a red, irritated nipple that may have cracks, scabs, or overt bleeding.

Prevention and Treatment

Prevention focuses on avoiding friction. Most commonly, this is achieved by bandage strips, commercially available nipple bandages (e.g., Nip Guards), or taping of the nipple. Petroleum jelly or a water-based lubricant applied before or during the event can also prevent friction. Clothing made from fine-woven and soft synthetic fabrics should be worn, and when running a race, new shirts or running bras should be avoided. For men, running without a shirt is the most effective prevention, if conditions and race regulations permit. For women, appropriate breast support is essential.

This is usually a self-resolving condition if further injury is prevented. Secondary infection can occur but is rare due to the excellent blood supply in the area. For mild irritation, a soothing aloe gel or simple skin lotion can bring comfort. For severe cracking and bleeding, an antibiotic ointment such as Neosporin can be used while the nipple heals.

Other Considerations

If nipples are not healing with appropriate treatment or if there is nipple discharge or bleeding without a history of trauma or friction injury, the patient should be seen by a physician or health provider to ensure that there is no other serious condition affecting the nipple or breast.

Joint Injection

Joint injection is a common medical procedure during which a medication is placed into a joint using a needle. It is only occasionally used in younger athletes, primarily because they tend to have normal joint function, but it is one of the cornerstones in the management of degenerative arthritis (osteoarthritis) in the older athlete. It can be helpful as well in athletes with inflammatory arthritis such as gout or rheumatoid arthritis. If present, joint fluid is often removed prior to completing the injection. Removing fluid from a joint is called *joint aspiration*. This can help relieve the pain produced by swelling and can aid in the diagnosis of the joint pathology. Joint injections are performed for diagnostic reasons as well. When a numbing medicine, such as lidocaine, is injected into a joint or around inflamed tissue, the athlete's response can help make the diagnosis. If the diagnosis is clear from the athlete's clinical presentation and examination, a joint or soft tissue structure may be injected with medication, typically an anti-inflammatory medication, to help relieve the athlete's symptoms of pain and swelling.

Indications

Diagnosis of Joint Pain and Swelling

There are many causes of joint pain and swelling. Infections (both bacterial and viral), degenerative changes, fractures, bleeding into the joint from trauma, inflammatory arthritis such as gout or rheumatoid arthritis, and mechanical irritation such as from a torn meniscus can all cause joint pain and swelling. Removing fluid from the joint can be very helpful in making the diagnosis. The physician can tell if blood, pus, or normal straw-colored fluid is present in the joint. Further analysis of the fluid with culture and microscopic examination of the types of cells in the fluid can help determine if bleeding, infection, or inflammatory arthritis is present. It is essential to determine the cause of joint pain and swelling in order to formulate an appropriate treatment plan.

Injection of a contrast material into a joint followed by computed tomography (CT) or magnetic resonance imaging (MRI) can help detect subtle injuries as well as more clearly identify the anatomic structures. This can help improve the sensitivity of these procedures as diagnostic tools.

Reduction of Inflammation and Pain

Once it is determined that joint injection is the appropriate course of action, medications can be injected into the joint to help reduce the inflammation and pain. Injected medications can be helpful when oral medications cannot be used or are not effective. It is a general rule in sports medicine that a joint should not be injected solely for the purpose of allowing an athlete to return to participation if there is a risk that further damage to the joint may occur.

Improvement of Joint Function

Sometimes, injections are given specifically to help with the joint function. Reduction of inflammation is certainly one way to achieve this, but there are also medications that when injected into a joint are believed to help with the healing of damaged articular cartilage. These can help improve joint function by decreasing pain.

Risks and Benefits

The decision to administer an injection should be made after careful consideration of the risks and benefits. The benefits are relief of pain and inflammation as well as improving joint function. Improvements may be temporary, and often several injections may be necessary to produce long-standing results. The risks include infection, bleeding, temporary worsening of the pain, skin discoloration, tissue degeneration, injury to the surrounding anatomic structures, and allergic reaction. The side effects of joint injection will depend, to some degree, on the type of medication injected. When using steroid preparations, it is generally recommended not to inject into weight-bearing joints (hip, knee, and ankle) more frequently than three times per year due to concerns about potentially accelerating joint degeneration.

There are several situations when a joint should not be injected. An anti-inflammatory medication should not be injected into an infected joint, and the needle should not be passed through an infected area of skin while performing the procedure.

Types of Medications Injected

Anti-Inflammatory Medications

The most common medication injected is a cortisone-related steroid. There are several different types, but they all produce a similar anti-inflammatory response. The most commonly injected medications are the long-acting steroids betamethasone and methylprednisolone acetate. It may take up to 2 weeks for maximum benefit, and the anti-inflammatory benefit typically lasts several months or longer.

Pain Medications

Both long-acting (marcaine) and short-acting (lidocaine) anesthetic medications can be used for joint injections. Long-acting medications will last 3 to 4 hours, and short-acting ones will last 1 to 2 hours. The anesthetic medication can be mixed in the same syringe with the anti-inflammatory medication and injected together. Pain relief is usually immediate. This rapid response can help confirm the diagnosis. It also helps confirm that the anti-inflammatory medication was placed in the correct anatomic location.

Viscosupplementation

Hyaluronan and hylan derivatives can be injected into a joint to help relieve osteoarthritis pain. These substances are components of articular cartilage and are thought to aid in the healing of the damaged articular surface. A series of three to five injections, given several weeks apart, is the usual course of treatment. Although not curative, some athletes can get temporary relief with the procedure. Occasionally, athletes experience an increase in joint inflammation from the medication.

Proinflammatory Agents

There is growing interest in injecting medications that produce inflammation in the joint. The theory is that this can promote healing and cause scar tissue to form. This can help reduce pain and improve function in specific clinical situations, such as when joint laxity is present. This procedure is commonly referred to as *prolotherapy*. The procedure remains controversial, and further research is needed to clarify its indications and effectiveness.

Common Injection Sites

Almost any joint can be injected. Some joints can be easily injected in the physician's office without the need for special equipment. These include the shoulder, knee, ankle, elbow, fingers, and toes. Other joints are more difficult to inject and require ultrasound or X-ray machines to visualize the anatomy. Joints most likely to require ultrasound or CT guidance include the hip, spine, and wrist.

Follow-Up

Athletes who receive joint injections are typically followed up by their physician to discuss the results of the joint fluid tests if fluid was removed and to assess the athlete's response. Exercise programs to help strengthen the muscles around the joint are often used along with injections to help improve joint function. In some clinical situations, repeat joint injections may be necessary.

JOINTS, MAGNETIC RESONANCE IMAGING OF

A radiologic evaluation of the joint typically begins with a series of radiographs to look for fractures, dislocation, or signs of degeneration. Other techniques such as computed tomography (CT), ultrasound, and magnetic resonance imaging (MRI) can provide more information regarding the internal structures that make up the joint, such as soft tissues, muscles, cartilage, ligaments, and tendons. Of these modalities, MRI is considered the gold standard and has most profoundly affected the practice of orthopedic surgeons.

In 2008 and 2009, arthroscopy of the knee and shoulder was the most frequently performed orthopedic procedure, with more than 1.5 million reported each year. Orthopedic surgeons use MRI to help select which patients are candidates for reparative arthroscopy in the knee and shoulder. Regarding diagnostic arthroscopy, many leading orthopedic surgeons prefer MRI due to its noninvasiveness and the accurate detailed information it provides. MRI is particularly helpful for sports medicine surgeons in evaluating the integrity of ligaments, tendons, menisci, and cartilage in the knee. Regarding the shoulder, MRI provides excellent diagnostic information regarding the rotator cuff and labrum, as well as identifying abnormalities that may mimic rotator cuff or labral pathology clinically.

Knee Imaging

Anterior Cruciate Ligament

The reported accuracy of MRI of the knee for anterior cruciate ligament (ACL) tears is nearly 100%, making it the examination of choice for evaluating the ACL. MRI can also delineate additional information on associated injuries such as medial collateral ligament, lateral collateral ligament, and meniscal injury. Given the global overview MRI provides of the knee, it is the exam of choice for evaluating suspected internal derangement.

Complex tear of the posterior horn of the medial meniscus. Anterior is to the left. The normally low signal triangular meniscus demonstrates two linear oblique tears extending to the articular surfaces. Sagittal fat-saturated image of the knee.

Source: Clyde Helms, M.D.

Menisci

The reported accuracy of MRI of the knee for meniscal tears is 90% to 95%. This high accuracy has resulted in MRI being preferred to diagnostic arthroscopy by most leading orthopedic surgeons. One of the most important benefits of MRI for the menisci is helping the surgeon determine whether the symptoms are attributable to the meniscus (see image above, right).

Posterolateral Corner Injury

In addition to the ability of MRI to aid the surgeon with meniscal pathology, it can show the findings of a potentially career-ending knee injury for the elite athlete, the posterolateral corner injury. This can be debilitating even for the non-athlete if it is not surgically repaired. The posterolateral corner is composed of the lateral collateral ligament complex, the arcuate ligament, the popliteus tendon, and multiple smaller ligaments such as the popliteofibular ligament. If two or more of these structures, along with the anterior or posterior cruciate ligament, are torn, the injury is deemed a posterolateral corner injury. Many surgeons feel that prompt surgical repair (<1 week delay) affords the best outcome in these athletes. MRI is crucial in helping establish this diagnosis as many of the components of the posterolateral corner cannot be seen arthroscopically (see next page).

Hyaline Cartilage

Another area in which MRI plays a vital role in sports medicine is the imaging of hyaline articular cartilage in the knee. Newer surgical techniques are evolving that rely heavily on MRI for help in the identification and classification of cartilage abnormalities. Imaging techniques are rapidly evolving and improving to aid the surgeon in diagnosing pathologic conditions of cartilage (see left image, page 740).

Normal rotator cuff. Coronal fat-saturated image of the shoulder demonstrates a normal broad footprint of the rotator cuff on the greater tuberosity.

Source: Clyde Helms, M.D.

Shoulder Imaging

Rotator Cuff

The tendons of the rotator cuff are normally low in signal on all pulse sequences and are best seen on the coronal oblique images, in the plane of the supraspinatus tendon. The tendon inserts onto the greater tuberosity of the humerus with a low-signal, broad footprint. Cuff tears are classified according to the depth of the tear and described as partial or complete discontinuity of the normally low-signal tendon, with the gap filled with fluid signal on T2-weighted images. The reported sensitivity for partial-thickness tears is variable but approaches 90% with the use of magnetic resonance arthrography (MRA), which involves instillation of diluted gadolinium into the joint prior to MRI. The sensitivity for full-thickness tears is approximately 90% and nearing 100% with MRA (see above image, right; next page).

Glenoid Labrum

The normal MR appearance of the labrum is a low-signal structure, on all pulse sequences, and triangular in shape. Labral tears or detachments can be described according to location. The MR appearance of labral injuries depends somewhat on the severity and duration of the injury. Tears are diagnosed when there is a linear high signal or contrast extending across as least 50% of the substance of the labrum. Detachment of the labrum is described when there is a high signal extending between the labrum and the adjacent glenoid cartilage/cortex or if the labrum is completely displaced from the adjacent glenoid, and it may involve stripping of the adjacent glenoid periosteum. Sensitivity is greatly improved with the use of MRA, with reported sensitivities for detecting superior labral tears ranging from 82% to 100% and specificities between 71% and 98%.

Tears involving more than one quadrant are uncommon, and much less common are tears involving at least three labral quadrants, the so-called *triple labral lesions* or 180° tears. These tears have been described both following acute traumatic dislocations of the shoulder as well as in heavily muscled young males who engage in regular weight lifting. Specifically in these patients, the degree or extent of the tear is underestimated on the MRI scan and is often found to be more extensive on arthroscopy. However, the involvement of the posterior labrum in heavily muscled young males should prompt a more thorough search for additional labral pathology (see images p. 742).

Paralabral Cysts

Paralabral cysts are thought to form from extrusion of joint fluid through a labral tear with the formation of a pseudocyst, which is a well-circumscribed unilocular or multilocular high-signal structure on T2-weighted sequences. Paralabral cysts are highly specific for adjacent labral tears, so that even when a labral tear is not identified, the presence of a cyst should prompt the assumption of adjacent labral injury. If the cyst extends into the spinoglenoid notch, there can be suprascapular nerve compression and subsequent trophy or neurogenic edema involving the infraspinatus muscle. The cyst cannot be seen in arthroscopy or open surgery. Therefore, MR imaging is critical in establishing the diagnosis and guiding the surgeon to the source of the pain (see image, next page, left).

Internal Impingement

Internal impingement can be used to illustrate the imaging characteristics of various soft tissue injuries of the shoulder, unique to the throwing athlete. It is a type of impingement that occurs with extreme abduction and external rotation of the humeral head during the cocking phase of the throwing motion. The exact etiology is debated but is generally thought to be secondary to contracture of the posterior band of the inferior glenohumeral ligament, resulting in shifting of the normal glenohumeral contact point more posterior and superior while the humerus is in the cocking phase. A combination of excessive

Source: Clyde Helms, M.D.

impaction of the posterior humeral greater tuberosity on the posterior superior glenoid as well as excessive torsional forces on the superior labrum and rotator cuff can lead to tearing of these structures. The combination of posterior superior labral abnormality, infraspinatus abnormality, and bony cystic changes in the posterior humeral head should suggest the diagnosis of internal impingement (see images, right).

Quadrilateral Space Syndrome

Quadrilateral space syndrome is a diagnosis that may be difficult to make on the basis of clinical grounds alone and may be confused with a rotator cuff tear or impingement, leading to unnecessary surgery. Quadrilateral space syndrome is a clinical syndrome with manifestations including poorly localized shoulder pain and paresthesias in the affected extremity in a nondermatomal distribution resulting from compression of the axillary nerve in the quadrilateral space, most often by posttraumatic fibrous bands. The quadrilateral space is an anatomic space in the

upper arm bounded by the long head of the triceps, the teres minor and teres major muscles, and the cortex of the humerus. On the MRI scan, this syndrome is manifested by focal atrophy involving the teres minor muscle without involvement of the deltoid muscle (see image below).

Parsonage-Turner Syndrome

Parsonage-Turner syndrome (PTS), also called *acute brachial neuritis*, is characterized by the acute onset of severe neuritic pain, sometimes waking the patient from sleep, that is accompanied in a few days by profound weakness. The cause is unknown, but PTS is typically self-limited, with no known treatment other than palliative measures. PTS is often confused clinically with more well-known and common disorders such as cervical spondylosis, rotator cuff tear, and shoulder impingement syndrome. Multiple patients have undergone unnecessary surgery of the shoulder or cervical spine owing to failure to diagnose PTS.

The MRI finding most typical of PTS is that of diffuse high-signal intensity, depicted on T2-weighted images, involving one or more muscles innervated by the brachial plexus, with T1-weighted MR images possibly showing atrophy of the affected muscle(s). The pattern of muscular involvement should match the distribution(s) of one or more peripheral nerves originating from the brachial plexus, with the suprascapular nerve almost invariably involved (see images above).

Juvenile Osteochondritis Dissecans of the Knee

Osteochondritis dissecans (OCD) is a condition where a small section of bone just below the joint cartilage surface loses its blood supply and eventually dies. The cartilage overlying this area of dead bone can fragment and eventually break off into the joint. The condition occurs as a result of repetitive trauma (impact) to the bone, which eventually disrupts the blood supply to a portion of the bone. The overlying cartilage softens, progressively fragments, partially detaches, and eventually separates from the surrounding cartilage. The detached cartilage can become a loose body that can get caught in the joint with knee motion.

OCD can be divided into adult and juvenile forms. Juvenile OCD is defined as OCD occurring in an individual who still has growth remaining. The adult form may be the result of an unresolved juvenile OCD lesion. More than 50% of juvenile OCD lesions heal without surgery, whereas lesions that occur in adults rarely heal without surgical intervention.

Juvenile OCD is more commonly seen in males than in females and can be bilateral in up to 20% to 25% of patients.

Etiology

The etiology of osteochondritis dissecans is unknown. Suspected etiologies have included inflammation, family history (genetics), ossification abnormality, ischemia, and repetitive trauma.

Konig introduced the term *osteochondritis dissecans* in 1887. He believed that the condition began as an inflammatory condition affecting the subchondral bone and overlying cartilage, which then progressed to spontaneous avascular necrosis of the subchondral bone.

The relatively frequent occurrence of OCD in patients who are involved in sports supports repetitive microtrauma is a likely cause of OCD. It is thought that repetitive joint loading causes a local area of ischemia in the subchondral bone. When the frequency of the trauma exceeds the ability of subchondral bone to heal, the overlying cartilage softens, fragments, and may separate from the underlying bone. If the cartilage fragment detaches, a loose body forms within the joint.

Clinical Presentation

A child with OCD of the knee typically complains of a history of poorly localized anterior knee pain. A typical history is joint pain that worsens with activity and is relieved with rest. Instability is an uncommon complaint. A knee effusion or mechanical symptoms, such as catching or locking, is uncommon unless the cartilage overlying the OCD lesion has fragmented.

The physical examination for an OCD lesion of the knee should include a complete examination of the knee to rule out other causes of anterior knee pain, such as patellofemoral syndrome, a synovial plica, patella instability, Osgood-Schlatter disease, Sinding-Larsen-Johansson disease, or other cartilage or bone lesions.

The most common location of an OCD lesion is on the lateral aspect of the medial femoral condyle. Wilson described a test where symptoms were reproduced by internally rotating the tibia so that the tibial spine pressed against the OCD lesion on the medial femoral condyle. The test is performed by bringing the knee into 90° of flexion, internally rotating the tibia, and then slowly extending the knee. Symptoms are reproduced at approximately 30° of flexion and relieved with tibial external rotation. This test has not, however, been shown to be very specific in diagnosing OCD lesions.

A point of maximal tenderness can sometimes be found overlying the OCD lesion by gently flexing and extending the knee while applying digital pressure over the femoral condyle.

Imaging/Staging

Initial radiographs of a child who presents with signs and symptoms suggestive of an OCD lesion should include an anterior-posterior (A-P), lateral, sunrise, and tunnel view of the knee. Occasionally, a lesion that would have been missed on an A-P view of the knee is discovered on a tunnel view. This is especially common when the lesion is located on the posterior aspect of the femoral condyle, a location not adequately visualized on a standard A-P view of the knee. A skyline view helps visualize patellar or trochlear OCD lesions.

An MRI scan is now considered a routine part of the diagnostic evaluation of an OCD lesion. An MRI gives a more accurate estimate of the size of the lesion as well as the status of the overlying cartilage and subchondral bone. MRI can also be used to evaluate the stability of the lesion. Bone edema surrounding the fragment and a line of increased signal intensity at the interface of the lesion are characteristics of an unstable lesion.

When a disruption in the articular cartilage of the OCD lesion is visualized, it is important to identify whether synovial fluid has leaked behind the subchondral bone, separating it from the surrounding vital bone. This synovial fluid barrier makes nonoperative healing of the OCD lesion unlikely.

MRI can also be used to stage OCD lesions (see below). In a Stage I lesion, there is a small signal change in an area of subchondral bone without clear margins surrounding the lesion. In Stage II, the osteochondral fragment is clearly demarcated from the surrounding bone, but no synovial fluid is present between the fragment and the subchondral bone. In Stage III, there is a break in the articular cartilage, and synovial fluid partially surrounds the subchondral bone. Fluid completely surrounds the lesion in Stage IV, but the fragment is in situ. In Stage V, the fragment is completely detached and has displaced in the joint (loose body).

Stages of OCD Lesions

Stage I: Small signal change in subchondral bone without clear margins

Stage II: Clear margins surrounding lesion, cartilage is intact

Stage III: Fragmented cartilage, lesion is partially detached

Stage IV: Completely detached lesion, lesion has not displaced

Stage V: Lesion has displaced into joint (loose body)

Treatment

Nonoperative

The initial treatment of stable (Stages I and II) lesions should be conservative. This includes a period of rest from impact activities to give the knee a chance to revascularize the area of necrotic bone.

Flynn recommends a three-phase program of nonoperative treatment for OCD lesions. We follow a similar program that includes an initial period of crutch-protected partial weight bearing if the patient's knee is painful with activities of daily living. The patient may begin bearing weight as tolerated once the pain has resolved with ambulation.

At the 6-week follow-up visit, radiographs are repeated, and a physical therapy program is begun for range of motion and to strengthen and stretch the quadriceps and hamstrings. Swimming and cycling are also allowed at this point.

MRI is repeated at the 3-month visit to assess healing. If healing is progressing on MRI and the patient remains asymptomatic, the patient's physical therapy is advanced to include a sports readiness program.

Return to cutting and pivoting sports and high-impact activities is delayed for several months (usually 6 months) depending on the size and location of the lesion.

Surgical Treatment

Surgical intervention is recommended for OCD lesions that present with an unstable cartilage fragment (Stages III–V) or have been unresponsive to nonoperative treatment.

Lesions that are unstable or fail to respond to nonoperative treatment are examined arthroscopically. During arthroscopy, the cartilage is examined to determine its stability, reducibility, and integrity.

For lesions with stable cartilage, the subchondral bone is drilled to stimulate vascular ingrowth. For lesions that are unstable, the cartilage is fixed in place with bio-absorbable or metal screws. Metal screws require a second surgery for removal but are sometimes used for larger lesions where there is an increased concern for lesion stability.

Large, unsalvageable lesions are treated with fragment removal and drilling or microfracture of the subchondral bone. Drilling the subchondral bone stimulates bleeding and formation of a fibrin clot of pluripotent stem cells. These stem cells then differentiate into fibrocartilage. Fibrocartilage is similar in appearance but not as resilient to shear forces as native hyaline cartilage.

Other options for the treatment of large cartilage defects include replacement of the cartilage with osteochondral plugs harvested from non–weight-bearing areas within the joint and autologous chondrocyte implantation.

After Surgery

Postoperatively, the repaired lesion is protected by restricting the range of motion with a hinged knee brace. A safe range of motion is determined intra-operatively based on the location and postfixation stability of the lesion. A common postoperative range of motion for lesions where fixation was used is 0° to 40° for the first 2 weeks. The patient is kept on partial weight bearing for the first 6 weeks to allow for early healing. Physical therapy is started 2 weeks postoperatively. At the 6-week follow-up visit, radiographs are performed to check for early healing, and bracing and crutches are discontinued. At 12 weeks, the patient is allowed to begin to run straight ahead. Return to cutting and pivoting sports is delayed until the patient is able to run without pain and 90% of the strength of the unaffected leg has been regained.

K

Karate, Injuries in

Many people around the world practice karate, a form of martial art. There are in fact many types of martial art commonly referred to as *karate*, depending on the country in which it was developed and its accompanying philosophy. In addition to the well-known forms of karate (e.g., the traditional Okinawan and the Japanese Shotokan), there are parallel Chinese (Wu Shu and Kung Fu) and Korean (Tang Soo Do) forms. Karate practitioners, known as *karatekas,* practice their martial art mainly for defensive and spiritual purposes.

History

Karate, in Japanese, literally translates to "empty hand" or "empty fist." The island of Okinawa, historically under Japanese rule, is widely considered its point of origin, but the rudiments were evidently adapted from earlier Chinese martial art forms. Regardless of where karate originally developed, it is generally recognized that karate and other martial arts emerged all over the world as a means of self-defense. Many believe that people who were oppressed and forbidden to use any weapons developed this martial art to employ the body itself as a weapon against armed opponents.

In the United States, some U.S. soldiers who had been stationed at Okinawa following World War II and had studied karate there brought back the art with them and established schools of karate. Karate became more widely popularized with the theatrical release of the *Karate Kid* movies in the 1980s. Integrating the use of Okinawan karate in their story lines, the *Karate Kid* series did portray effectively the underlying philosophy of karate as a means of defense and as a way to develop self-discipline and a sense of spirituality.

Competition: Forms and Sparring

In addition to practicing various open-hand and kicking techniques, karatekas practice a set routine of techniques known as *forms* (*Kata*). These forms are passed on from generation to generation and sometimes altered by newer generations. The practicing of forms allows the karatekas to develop focus and discipline during practice sessions. Weapons are also integrated into certain forms. Similar to the floor exercise in gymnastics, forms is a category of competition that serves to demonstrate the karateka's skill in executing techniques.

Karate tournaments have sparring competitions with varying rules. The common type of sparring tournament employs a point-based system, with various numbers of points given for the area of body contacted or even how much contact was made (except in full-contact karate). Sweeping an opponent may or may not be allowed depending on the tournament rules. In addition, "open tournaments" allow practitioners of any style of karate to participate, in contrast to "closed tournaments," where only one style or even one major karate organization/association is allowed to participate. Sparring gear may or may not include headgear and hand and foot pads depending on the requirements of each individual tournament. Karatekas are generally required to use mouthguards. Given the lack of uniform rules regarding sparring equipment, karatekas are susceptible to injuries depending on the rules of the tournament.

Injuries in Karate

Many types of injuries can occur in karate. However, several studies have demonstrated certain patterns of injuries in karate competition. Most of the injuries sustained by karate practitioners are head and upper limb injuries. It is likely that many of the upper limb injuries sustained were due to the karateka's efforts to block attacks from opponents. Many of the head and upper limb injuries are secondary to concussions, lacerations, or hematomas.

Concussions suffered during karate competitions are handled as they would be for any contact sport. There are multiple guidelines that can be followed, but the underlying theme in all of them is to determine the severity of the concussion as well as return to activity. An event of loss of consciousness warrants consideration of a head CT (computed tomography) scan for an acute intracranial hemorrhage. Return to activity is progressive: The athlete should be asymptomatic prior to engaging in any form of exertion and should then gradually increase his or her activity. A premature return to contact sport places the patient at risk for further brain injury, in particular the often cited "second-impact syndrome." It is believed that a second concussion that occurs prior to full recovery from the previous concussion leads to life-threatening increased intracranial pressure and irreversible brain damage and/or death.

Because many karate competitions do not require the use of protective hand or foot padding, competitors are at additional risk for lacerations. Certain lacerations sustained in the head area require the skills of a specialist. For example, any laceration that involves the eyelid margin or the lacrimal drainage system of the eye should be referred to an ophthalmologist. Ear lacerations must be evaluated for cartilage involvement and repaired prior to skin closure by a skilled physician.

In general, hematomas suffered by karate practitioners can generally be treated with the application of ice, compression, and elevation of the affected extremity. It is important to evaluate neurovascular status, as well as any possibility of fracture.

In addition to the common injuries described previously, there is a specific type of contusion, called a "Karate Kid" finger, that has been reported. This injury involves the nerve located on the ulnar (medial or closer to the body) side of the little finger. This type of injury is sustained when, for strength and conditioning purposes, practitioners perform karate "chops," often on hard objects such as ice, wood, or cinder blocks. Due to repetitive trauma, scarring may occur over the underlying nerve, and constant pain or numbness is present. Surgery has been reported to be curative.

Karate Today

Today, many people enjoy the benefits of practicing karate. Whether it is for defensive purposes or for fitness and personal development, karate is one of the many martial arts that people worldwide participate in. Karate has evolved into a martial art that borrows many techniques from other martial arts, and it is now common practice to integrate more "ground-based" fighting techniques. The newer generation of martial artists may question whether karate is still relevant today as an effective martial art due to the increased popularity of Mixed Martial Arts. Many defenders of karate will refer to Lyoto Machida, a light heavyweight professional fighter who employs Shotokan karate very effectively in Mixed Martial Arts competition. In the ever-changing world of martial arts, especially with the increasing popularity of Mixed Martial Arts, many karate practitioners will experience a transformation and evolution in their training.

Kidney, Absence of One

An athlete without a paired organ, such as a testis or a kidney, should be evaluated for participation in sports. A single kidney may be present congenitally or may be the result of surgical removal of the other kidney due to disease or trauma. It is estimated that 1 in 2,400 people are born with a single kidney.

Anatomy

The kidneys serve as a filter for the body to remove excess water and waste products from the blood. The kidneys lie in the abdomen, near the middle of the back, and are protected by fat (called *perinephric fat*) and the thoracic rib cage. Both kidneys function with extra capacity, and a significant amount of damage to the kidneys needs to occur before their productivity fails. This is why a person can survive with only one kidney.

Risk of Injury

The overall risk of injuring a kidney in team sports is quite low. Sports-related trauma to the kidneys can been estimated to be around 0.1% of all sports-related injuries based on two large studies evaluating any traumatic injury seen in a trauma center. Cycling, both recreational and competitive, was found to have the highest risk for injury to the kidney. Other sports and activities found to be of higher risk are winter sports, such as sledding and skiing, hockey, football, and equestrian events.

Injuries to the kidney are generally classified from Grade I through Grade V, with Grade IV and Grade V typically being considered higher-grade injuries. The higher-grade injuries may result in significant damage to the kidney so that surgery may be required, including complete removal of the kidney, known as a *nephrectomy*. There have been very few incidents of higher-grade renal injuries in team sports athletes, such as football or hockey players, requiring surgical management. Sports that involve higher velocities of impact, including bicycling, motocross, and winter sports such as skiing, do have a higher incidence of high-grade renal injuries. Some of these injuries have required nephrectomy; however, the risk remains quite small.

Participation in Sports

Currently, the American Academy of Pediatrics recommends that any athlete with a single kidney be individually evaluated prior to competition in sports, particularly contact sports. This may involve evaluation by a pediatrician or other general practitioner, nephrologist, or urologist. The use of protective gear may be considered, although no research has been conducted demonstrating its effectiveness in reducing renal injuries.

Kienböck Disease

Kienböck disease is an injury to the lunate, which is one of the carpal bones located in the wrist. The blood supply to the lunate is disrupted, causing damage or osteonecrosis (*osteo* = bone, *necrosis* = death). It is also known as *lunatomalacia* and *avascular necrosis of the lunate,* an injury similar to avascular necrosis of the femoral head. It can occur not only after an acute trauma but also after repetitive overuse motions. Early recognition and treatment can lead to better outcomes.

Anatomy

The lunate is one of the eight carpal bones located in the wrist. It is situated between the scaphoid (navicular) and the triquetrum bones. It also articulates with the radius (in the forearm) and the hamate and capitate (carpal bones). The blood vessels usually enter the lunate from both the palmar aspect and the dorsal aspect of the hand, but some (<20%) people have only a single blood vessel entering the palmar surface.

Causes

The cause of Kienböck disease is not known. It is thought to be caused by a single traumatic event, such as a fracture or a hard fall while playing sports, that disrupts the blood supply to the lunate. It can also be caused by repetitive motions that cause stress across the wrist, such as the swinging of a golf club or a racquet. This may cause recurrent compression of the lunate between the radius and capitate or cause shear forces across the wrist that impair the blood flow.

It is more common in people with negative ulnar variance. This is a condition where forearm bones (ulna and radius) do not have equal alignment at the wrist. The ulna is shorter than the radius, causing increased pressure on the lunate.

It is also thought to be more common in people with one blood vessel supplying the lunate.

Clinical Evaluation

Kienböck disease is best treated early in its course, so recognition and accurate diagnosis are very important. It should be considered in any athlete with wrist pain. It is usually unilateral (on one side of the body). Kienböck disease is twice as common in males and usually occurs between 15 and 40 years of age.

History

Most people will present with wrist pain and stiffness. This may or may not occur after a fall or other injury. The pain tends to gradually worsen without treatment, and it is made worse by activity, specifically with wrist movements. Typically, the wrist appears swollen. The pain may radiate up the forearm. Athletes may also complain of decreasing grip strength and trouble holding things, such as racquets, in that hand as the disease progresses.

Physical Exam

There will be tenderness and potentially swelling over the lunate. There will be decreased range of motion (ROM) of the wrist when compared with the unaffected side. This is most common with extension (moving toward the back of the hand) and flexion (moving toward the palm), while pronation and supination (turning or rotating the forearm and the hand together) are not affected. Moving the middle finger into extension (pushing it backward) will reproduce the pain. The patient may also have decreased grip strength when compared with the unaffected side.

Diagnostic Imaging

X-ray films should be obtained. Early in the disease process, they may be totally normal. However, as Kienböck disease progresses, X-rays will show sclerosis (as increased whitening) in the lunate. Eventually, the lunate becomes smaller or flattens, and the bone may fragment. Cysts may appear in the bone, and the wrist may show signs of degenerative change late in the disease process. X-rays should also assess for negative ulnar variance, which will increase suspicion of Kienböck disease (see image next page).

Computed tomography (CT) and magnetic resonance imaging (MRI) can be helpful in diagnosing Kienböck disease. A CT scan will demonstrate sclerosis and collapse in more detail and earlier

Kienböck disease in the lunate: increased sclerosis with cystic lesion

Source: Kevin D. Walter, M.D. Photo courtesy of Medical College of Wisconsin.

than X-rays. MRI can be helpful in diagnosing osteonecrosis earlier than X-rays as well.

Classification

The original classification by F. Stahl in 1947 was modified into four groups by D. M. Lichtman in 1977. The Lichtman classification remains in current use:

Stage I: This is the earliest sign of the disease. There is usually a linear fracture of the lunate seen on X-ray, CT, or MRI. The patient will usually complain only of wrist pain at this time.

Stage II: The bone will appear sclerotic or denser than usual and may begin to show a loss of height. Clinically, patients will have increased pain and often will have swelling at this stage.

Stage III: The lunate will have collapsed. This often causes other bony deformities in the neighboring carpal bones. A CT scan is needed to show the full extent of bone damage. Patients will usually have pain, swelling, and decreased wrist ROM.

Stage IV: This is the final stage of Kienböck disease. X-ray will show collapse of the lunate and generalized degenerative changes in the wrist. The patient will progress to greater loss of wrist motion.

Treatment

Immobilization can decrease motion and loading forces on the lunate but is not an effective treatment. Painkillers and anti-inflammatory medications can be used. Since Kienböck disease tends to progress even with immobilization, surgical intervention is the treatment of choice. Despite different opinions on the helpfulness of various treatments, physicians agree that early treatment is the best.

Many surgical procedures can be used to treat Kienböck disease. The surgeon will decide on the procedure that should be done based on the stage of the disease as well as ulnar variance and the wishes of the patient.

The objective of treating Stages I and II disease is to prevent further progression and to reverse damage to the lunate. Treatment of Stages III and IV disease is palliative and aimed at preventing further pain symptoms and disability.

A revascularization procedure may be done using a piece of the radius with attached pronator quadratus muscle, to attempt to create a new blood supply to the lunate bone, allowing it to heal. Revascularization can also be attempted by diverting a metacarpal artery into a hole drilled into the lunate bone after removal of the damaged bone. This usually can only be done in Stage I or Stage II, before the lunate begins to collapse.

Ulnar lengthening and/or radial shortening can also be done before the lunate collapses. These procedures attempt to level the wrist joint and take pressure off the lunate by redistributing it to other parts of the wrist. They are indicated if there is a negative ulnar variance.

There are many fusion procedures that may be done to treat Kienböck disease. During a fusion, the surgeon will remove the joints of some of the wrist bones to make them grow together into a single, larger bone. The most common is the scaphoid-trapezial-trapezoid (STT) fusion. Removal of the lunate may be necessary during a fusion. Fusion procedures may be preferred in patients with a neutral or positive ulnar variance. They are usually done in Stage III or earlier.

Lunate excision without fusion and lunate implant (silicone) are controversial and not very popular today due to potential complications, such as increased risk of degenerative change due to increased mobility of the remaining carpal bones and wrist joint irritation (synovitis) due to the silicone.

In Stage IV disease, surgical treatment is usually limited to proximal row carpectomy or removal of the scaphoid, lunate, and triquetrum. This allows patients to maintain a limited degree of wrist motion, but the wrist tends to remain functional. However, Kienböck disease may damage the joint surface of the radius and capitate, which can cause persistent pain after this procedure.

The final option is total wrist arthrodesis. This is for patients with severe degenerative change or patients who have failed other surgical procedures. This procedure fuses the entire wrist so that there is no remaining flexion or extension. This will relieve the pain but limits the function of the wrist.

After Surgery

The surgeon will discuss immobilization after surgery. Rehabilitation exercises after surgery can minimize weakness and improve strength. Return to activity and sports depends on the individual and the degree of residual dysfunction. The treating surgeon will be able to provide more insight on returning the patient to upper extremity athletics.

Kinesiology

Kinesiology, the science of human motion, analyzes the movements of the body and reveals the underlying biomechanical principles. Aristotle is credited with coining the term (ca. 300 BCE) and is referred to as the "father of kinesiology."

The purpose of studying clinical kinesiology is to understand the forces acting on the human body and their effects. By understanding the biomechanics and forces that act on the body, clinicians and coaches can reduce the risk and rate of injuries while optimizing the performances of the athletes.

A science of mathematical formulas and physical laws, kinesiology combines three disciplines—anatomy, biomechanics, and physiology. The integration of these studies provides the understanding of biomechanical modeling and application of motion that defines kinesiology.

Analysis of human movement is dictated by a number of biomechanical principles and laws. The most basic of these are muscle contraction and relaxation, the effect of gravity on muscle, and posture. As muscles are the principal movers of the skeletal system, they adhere to these practical laws and principles.

Biomechanical Principles of Muscle

The five basic principles of muscle action are as follows:

1. Muscles pull; they do not push.
2. Muscles contract in the center.
3. A muscle's attachment points will determine its action of on a joint.
4. Muscles create movement and/or maintain position.
5. Three types of muscle contraction are possible:
   - Shortening (concentric)
   - Lengthening (eccentric)
   - Static (neutral)

The contraction of muscle across its attached skeletal structure creates motion. Muscles contracting for the desired motions are called *agonists*, whereas the opposing muscles in those particular movements are termed *antagonists*.

The body is an excellent computer that allows for turning muscles on and off in microseconds. This sequential muscle activation allows the muscles to fire in proper sequence. A gymnast performing a back somersault completes the task in less than 1 second but uses more than 100 different muscles contracting and relaxing to perform this complex task.

Kinesiology of Posture

Muscle tissue constitutes 40% to 50% of the adult human body. Muscles are responsible for the movement, posture, and support of both the skeletal frame and the internal organs.

Our body's deeper muscle layers, found near the spine, neck, pelvis, and legs, function as antigravity muscles. These muscles contract and relax to maintain the body in an upright, erect position.

More superficially, the abdominal muscles function to support internal organs such as the liver, spleen, and stomach within the abdominal cavity.

Muscles are responsible for movement and posture. The body is supported in position by two types of postures, static and dynamic. Static posture is one of maintaining balance, whereas dynamic posture is a corrective response to movement.

Postural muscles work on constant stimuli and feedback to maintain balance. The feedback mechanism for control of these postural muscles comes from two major sources, the stretch and the righting reflexes.

The stretch reflexes are activated from those skeletal muscles that are responsible for maintaining proper tone, length, and tension to help the body maintain an upright position.

The righting reflexes control body posture. These are primitive reflexes present in infants. Newborns rely on five primitive reflexes for their basic functional movement. These help maintain righting postures. The five major primitive righting reflexes are as follows:

1. Optical righting reflex
2. Body righting reflex acting on the head
3. Body righting reflex acting on the body
4. Neck righting reflexes
5. Labyrinthine (ear) righting reflexes

These righting reflexes are important in maintaining posture and motion, especially before a child is able to stand upright or walk. The effect of these righting reflexes diminishes as the child grows, usually around 2 years, but still can be observed in adults when assessed by a trained clinician.

Kinesiology of Sport

The practical application of kinesiology has expanded the understanding of sports technique and performance. The complexity of biomechanical analysis depends on the type of sporting activity. The earliest studies relied on slow-recording film cameras for motion analysis. Thus, early kinesiological studies concentrated on simpler activity such as level walking or running, where the influences of environment and equipment were minimal. As the technology advanced with higher-frame-per-second filming, more complex motion could be more accurately analyzed in different environments. As the body can move within many different types of environments, this newer filming technology can capture the necessary data to study its motion.

The body may be studied in motion within any of these four environments or a combination of these environments:

1. The ground supports the body.
2. The body is supported by water.
3. The body is unsupported, such as falling through space.
4. The body is suspended.

In addition to filming athletic motion, other environmental factors such as air, water, and ground influences must be taken into consideration and calculated.

Kinesiological studies in water require assessing water resistance forces in the mathematical calculations. As a result of kinesiological analysis, swimming technique and performance were improved through mathematical modeling and advanced recording technology.

For an athlete performing in midair flight, elements such as gravity and air resistance forces need to be calculated in mathematical modeling. Athletes who perform off the ground, such as in gymnastics and diving, require this multidimensional analysis of their motion through space.

Kinesiology as a Predictor of Athletic Potential

The science of kinesiology has assisted coaches in identifying talent and athletic potential. Coaches have tried to identify predictors of a child's potential in developing into an elite athlete. In some countries, such as Russia and China, clinical assessment systems of selection have been implemented. Radiographic analyses of skeletal growth plates have been used to predict potential height in young gymnasts and ice skaters, since a shorter stature was believed to facilitate athletic success. In track-and-field athletes, testing muscle types and their percentages have been used to help identify and distinguish between speed and distance athletes.

A review of many sports studies found that in early childhood, physical fitness should be the focus of instruction, without specialization in an individual sport. Each sport has an optimal age period of commitment to that sporting activity. In many cases, starting the children at too young an age may be detrimental to their athletic potential and may predispose a child to leave the sport.

Gender Differences in Athletics

Gender also plays a role in athletic potential. Comparative muscle strengths have been extensively tested in males and females. Studies found that general muscle strength in the female is estimated as being two thirds that of the male. In terms of absolute strength, women were found to be weaker in their upper body strength; however, in leg strength women were actually slightly stronger when correlated equally to units of lean body weight. If muscle size were equal in the male and female, the forces exerted by the muscles would have been identical in both genders.

Hormonal differences in genders play a significant role in athletic ability. Testosterone was found to be a significant factor in promoting muscle size. Consequently, as males naturally have a greater concentration of testosterone, they are more apt to have larger muscles, or hypertrophied muscles. There have been studies that show that estrogens may play a role in increasing ligamentous laxity and predispose women toward a higher incidence of anterior cruciate ligament ruptures of the knee.

Owing to anatomical differences in genders, women are generally found to be smaller in stature and lighter in weight than males and with a lower center of balance. The center of balance for women is found at 55% of standing height, whereas in men, it is at 57% of standing height.

The pelvis size and shape also differ between males and females. The female pelvic cavity is wider in all its diameters and rounder than that of the male. Because of the wider pelvis, women have a greater tendency for knock-knees. Research has found that the wider the hips, the slower the potential speed in running.

Women generally have narrower shoulders and shorter upper arms than men. As a result of the narrower shoulder, the woman's elbow compensates with a larger carrying angle than in men, and this larger elbow angle creates a disadvantage in overhead throwing events for women.

Components of Sports Performance

Three components constitute sports performance. They are physique, physical conditioning, and psychological adaptation. When all three are optimal, one finds an elite athlete. There is little to differentiate the top level of elite athletes in any sport. As most elite players already have an athletic physique and their physical conditioning is similar, the psychological preparation may be the largest variable in their performance.

Coaches and instructors who study biomechanics and kinesiology potentially hold an advantage in optimizing their student athletes' performance. The goal of studying the athlete's biomechanics is to provide proper correction to flaws in technique that impede successful athletic performance. Understanding sports biomechanics helps eliminate the trial-and-error approach to coaching and instruction. Studying the athlete's motion allows the coach to identify the body's weakness, recognize injury-related faults, and offer corrective biomechanical solutions to these problems.

Sport kinesiology relies on the study of biomechanics. Simple and complex mathematical models and formulas have been used to describe and illustrate athletic performance in most sporting activities. In general, this mathematical modeling is a good starting point for the instructor in understanding sports mechanics. However, these models do not account for the uniqueness of each individual athlete. Each athlete is unique in flexibility, range of motion, joint mechanics, conditioning, and injury characteristics.

Identifying each athlete's variation is critical in applying a predictive model to truly understand that particular athlete's strengths and weaknesses and to decide how to maximize the athlete's performance. Golf swing mechanics is a great example of mathematical modeling. The quest for the perfect swing focused on identifying a model of optimizing acceleration. Unfortunately, most golfers have many flaws in their physique, range of motion, and flexibilities that will not allow them to duplicate a mathematical schematic model. As a result, the golf instructor is left to correct obvious swing flaws while adapting the swing mechanics to the unique physical abilities of the golfer.

Biomechanics Predict Sport-Specific Injury

Kinesiological models can identify motions or movements of increased tension or strain that can predict injury. Improper overhand throwing mechanics can lead to severe elbow injuries in baseball pitchers. Poor diving technique can lead to serious wrist injuries. Kinesiological analysis can help identify these sport-specific activities and their correlations with injury risk.

Certain sports have a characteristic pattern of consistent, well-defined injuries. A few examples are as follows:

- *Baseball:* shoulder injuries
- *Bicycling:* ulnar nerve (arm) and pudendal nerve (groin) compression injuries
- *Golf:* lower back and wrist injuries
- *Rugby:* neck injuries
- *Running:* iliotibial band syndrome and foot injuries
- *Skiing:* thumb ligament injury and anterior cruciate ligament (ACL) knee injury
- *Soccer:* groin and knee injuries
- *Swimming:* shoulder injuries
- *Wrestling:* elbow and knee injuries

Maximizing Athletic Potential: Muscle Memory

Athletic performance is often studied to maximize an athlete's potential. The study of biomechanics allows scientists and coaches to assess technique and movement. While it is important that physical trainers and educators have a good understanding of biomechanics, it is generally agreed that athletes do not require this level of scientific knowledge. The reason for withholding these complex data from the athlete is based on the idea that the athlete must act instinctively and should not be actively thinking about specific athletic action.

The value of biomechanics is demonstrated when the athlete has encoded complex muscle movement into unconscious memory. This encoding has been referred to as *muscle memory* or *mind–muscle* memory. To create mind–muscle memory, the athlete must unconsciously coordinate many muscles that are going to be needed for the task required. If the athlete is able to unconsciously perform this task, then fluidity of motion will be optimized, whereas if the athlete must think through the movement, this fluidity will be compromised. It is the ability to incorporate a complex movement into the subconscious mind that allows for the creation of mind–muscle memory.

Critics have argued that since muscles react directly to electrical stimuli, they do not have a capacity for memory. The logic states that it is the brain initiating the complex electrical sequence that activates muscle contraction and relaxation. Repeated practice of the desired motion or movement enhances memorization of this sequence, and when called on, the athlete executes this action flawlessly. This is the phenomenon of mind–muscle memory. To quote the great Baseball Hall of Fame player Roger Hornsby, a lifetime .358 hitter, "A great hitter isn't born, he's made. He's made out of practice, fault correction, and confidence."

Some athletes are easier to train than others. Those athletes who have exceptional visual motor learning abilities are the quicker learners. Prior to video instruction, those athletes who can learn through observation of elite athletes become successful in their sport. Quick hand-eye coordination is another favorable attribute that successful athletes share.

Athletic Injury

Unbalanced muscle strength can lead to strains and tears of muscle tissue. Overtraining the agonistic muscle or undertraining the antagonistic muscle increases the risk of muscular injury. In contrast, athletes who demonstrate full muscular flexibility and are proportionately strengthened and conditioned have a significantly lower incidence of strain or tear. The strain or tear usually occurs at peak muscle contraction, coinciding with peak acceleration.

Major Studies of Kinesiology

As noted earlier, kinesiology is the study of motion based on mathematical modeling and physical laws. The science of kinesiology along with biomechanics can be divided into 12 major areas of study:

1. Whole-body segmental models
2. Kinematics of movement
3. Force measurement
4. Kinetic or force-motion analysis
5. Part-body models
6. Motion of the center of gravity
7. Human–equipment interaction
8. Feedback control
9. Descriptive mechanics
10. Statistical studies
11. Physiological studies
12. Equipment design

Whole-body segmental modeling studies the way the body responds to the varying changes in body weight distribution while in motion.

Kinematics of movement is the analysis of motion across time, studying the effects of speed and accelerations on the body.

Force measurement is the essence of biomechanical study—measuring the effects of the different types of forces that act on the body through mathematical modeling and formulas.

Kinetic or force-motion analysis is the study of the body's motion response to the external forces that are acting on it. This coincides with Newton's second law: "Force equals mass times acceleration."

Part-body models examine the action of a specific section of the body, which at the most basic level is the action of a muscle across a single joint.

Motion of the center of gravity studies the relationship of the center of gravity of the body in different positions and motions.

Human–equipment interaction studies the interaction between human and machine. This type of analysis of man–equipment interactions can be very complex in mathematical modeling.

Feedback control allows the body to change its movement based on the information it receives from the body's sensory system. Scientific research in this field has been difficult, limited by our sensory technology, and overall very few studies have been published.

Descriptive mechanics is the application of technical concepts such as force, static equilibrium, work, and energy in mathematical modeling of motion.

Statistical studies involve using statistical formulations in determining whether a relationship can be consistently observed and predicted in mathematical modeling.

Physiological studies observe the effects of energy, work, and power and their relationship to exercise physiology and biomechanics.

Equipment design is primarily used by manufacturers of sports equipment. This study is extremely difficult, as one must incorporate scientific formulation with the subjective feel. As each individual athlete has his or her own subjective feel, the satisfaction of using a particular sports equipment design holds many variations. This variety of equipment is noticeably evident in golf equipment design and manufacture.

Tools of Kinesiological Study

Measuring movement and energy is now possible with the invention of high-speed cameras and sensitive sensors. The study of kinesiology and biomechanics has exponentially grown with advancements of this technology. With precise measurements, scientists can assess specific variables in athletes to help correct their weaknesses as well as to potentially optimize their performance.

Klippel-Feil Syndrome

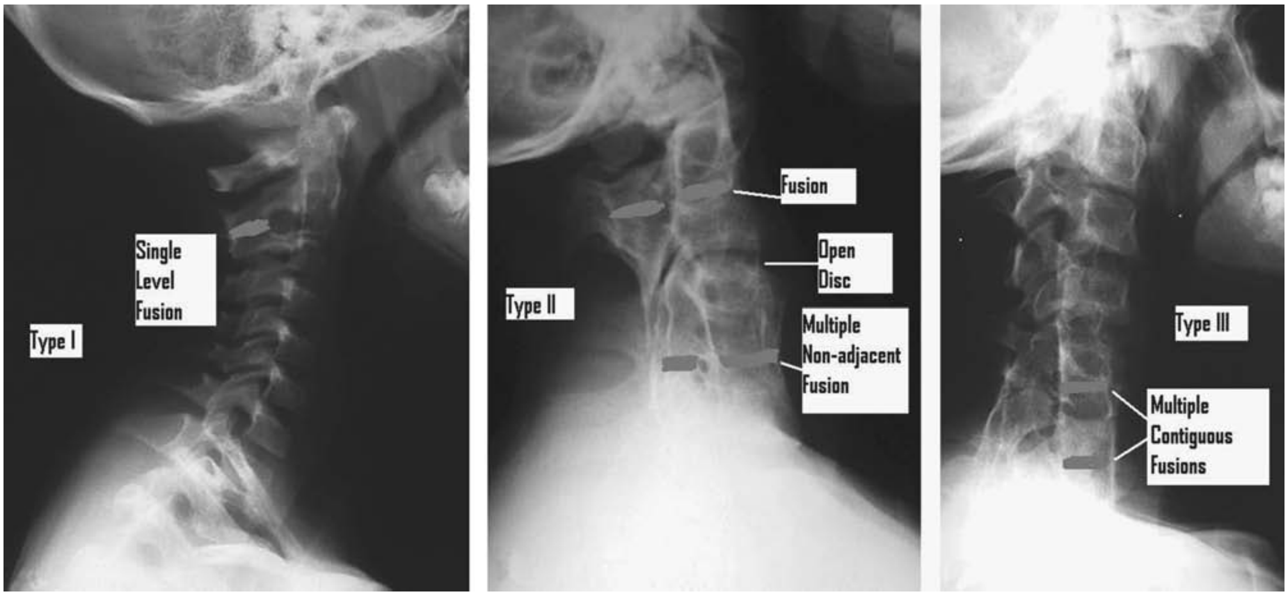
Klippel-Feil syndrome was originally described in the early 1900s by Maurice Klippel and Andre Feil. The hallmark of this syndrome involves a congenital fusion of at least two of the seven cervical vertebrae. These fusions represent incomplete separation of the cervical vertebrae during the first few weeks of life, which may indicate some fetal insult during this early development. The initial description was of individuals with a short webbed neck and a low hairline.

Klippel-Feil syndrome was originally classified into three categories. Type I involved a massive cervical spine fusion of multiple contiguous levels. Type II involved a fusion of only one or two levels. Type III included both Types I and II with associated thoracic or lumbar spine fusions. However, this classification did not necessarily correlate with development of neurologic abnormalities. Recently, a new classification of these cervical spine fusions was suggested by Samartzis and colleagues. They categorized Type I as a single-level fusion; Type II as multiple, non–adjacent-level fusions; and Type III as multiple, contiguous-level fusions (see Figure 1). This classification allows better prognostication of the development of pain and neurologic dysfunction.

Since this syndrome involves a congenital insult, other associated abnormalities include possible hearing disorders such as conductive problems of the hearing bones of the middle ear as well as sensor neural elements. Cardiac abnormalities may occur, such as a ventricular septal defect, which is a small hole in the cardiac septal division of the ventricular chambers. Urologic defects of the kidneys and collecting system may also coexist. In the musculoskeletal system, scoliosis and a Sprengel deformity are also often associated. A Sprengel deformity involves a bony or cartilaginous connection of the scapula to the cervical spine. This will limit shoulder motion. Scoliosis is an abnormal curvature of the spine when viewed from the back.

Although the classic description of these fusions involved the outward clinical appearance of a short neck, low hair line, and decreased range of neck motion, this only occurs in about 40% of cases. Often, the fusions will be noted incidentally on radiographs taken for trauma or other reasons. The motion loss may be subtle and most often involves axial rotation, which means that there will be reduced ability to turn to one side.

Participation in contact sports is one of the first concerns for many of these athletes. The major issues are instability and stenosis. Instability occurs because the disk levels above or below the fusion have excess motion to compensate for the loss at the fused level. This excessive motion will compromise the central spinal cord. Instability is most severe with high fusions that involve the craniocervical and C1-C2 junction. *Stenosis* is degenerative narrowing that occurs over time due to the excessive motion of the contiguous levels and can cause compression of the spinal cord. Stenosis is often a concern at a free level between two fusion masses. Sports considerations are discussed below.



Cervical spine fusions (Samartzis classification)

Natural History

Some studies have examined pediatric and adolescent patients, while others have looked at adult patients. Klippel-Feil syndrome will present throughout life, often as an incidental finding. In the pediatric population, the majority noted at presentation are Type II (as described by Samartzis). In the adult population, Type I is the most common seen at initial presentation. The adult presents at an average age of 35, with nearly 70% complaining of some cervical spine symptoms. This is usually just neck pain and occurs less often with neurologic findings. Conversely, in the pediatric population, only 40% complained of cervical spine symptoms. The increased pain may reflect the gradual degenerative changes that occur over a lifetime.

Overall, there is a predisposition for females to have this condition more than do males. However, there appear to be more significant fusions (Types II and III) in the male population. Patients with Type I fusions will usually complain of central neck pain if symptoms occur. Although uncommon, radicular and myelopathic symptoms occur in Type II and III patients. Radicular symptoms represent pinching of the nerve roots as they exit the spine. This may manifest with radiation of pain, numbness, or muscle weakness into the upper extremities in a specific pattern to the involved nerve root. This will occur more often in Type II and III patients. Alternately, myelopathy represents a more serious injury to the central spinal cord. Manifestations of this are more nondescript, with weakness, imbalance, and spasticity of the upper and lower extremities. This is most often reported in Type III patients. The significant neurologic complaints tend to occur more in adults than in the pediatric population. This would indicate that there is a component of progressive degeneration that causes the neurologic symptoms. Similarly, patients with surgical fusions tend to have degenerative findings at the noninvolved levels, similar to Klippel-Feil patients. Furthermore, this implies that the fusions, surgical or congenital, will alter the biomechanics of the adjacent disk regions. For this reason, there is concern for the long-term consequences of repetitive-impact sport activities.

Evaluation

Musculoskeletal evaluation involves careful screening for loss of cervical motion that commonly involves rotation. Scoliosis is an abnormal curvature of the spine and has been described as a frequent association secondary to abnormal fusion of the thoracic and cervical vertebrae. A Sprengel deformity is seen in up to one third of these patients. This is suspected with a restricted shoulder range of motion. A careful neurologic examination is critical. Neurologic impairment is common when there is involvement of the upper cervical and occipitocervical juncture.

Imaging considerations are very important. Evaluation should include plain X-rays with lateral flexion and extension views to detect instability. During flexion, there may be some slippage of the nonfused segment over the fused segment. This will often correct when the spine is extended backward. This would indicate instability. Magnetic resonance imaging (MRI) is very useful in defining the amount of stenosis that is narrowing around the spinal cord. The MRI scan is also helpful in detecting associated abnormalities of the base of the brain and spinal cord. This would include herniation of the cerebellar tonsils into the spine, called an *Arnold-Chiari malformation*, and upward migration of the cervical vertebrae into the base of the skull, called a *basilar impression*. A flexion and extension MRI scan may be useful in borderline cases to define functional stenosis or narrowing that only occurs in the extremes of motion. Thoracic and lumbar plain radiographs will detect fusion masses at these lower levels.

Other evaluations include audiometric evaluations for hearing loss. A kidney ultrasound should be done to detect congenital kidney abnormalities. When cardiac murmurs are found, an ultrasound of the heart (echocardiogram) is indicated.

Return-to-Sports Considerations

Collision sports participation is the most common concern for athletes who have been detected with a Klippel-Feil fusion. The primary concern revolves around instability, with the potential for catastrophic neurologic injuries. Over time, degenerative stenosis or narrowing may occur and expose the spinal cord to critical impingement during hyperextension or hyperflexion impact activities such as football tackling. This can cause a catastrophic neurologic injury.

As such, collision sports such as football, rugby, and ice hockey are contraindicated with high fusions of the occiput-C1 and the C1-C2 vertebrae. Single-level fusions below C2 may be considered for collision activities provided there is no instability on flexion and extension plain radiographs, no stenosis on an MRI scan, no coexisting spinal cord anomalies, and clinically no pain or neurologic complaints. However, the athlete should be cautioned that repetitive impact may cause degeneration over time, with later development of instability or stenosis.

Concern should also be shown with involvement in sports that require repetitive extreme motion as the free disk spaces may again be predisposed to premature degeneration. It is known that painful symptoms occur later in adults and may reflect earlier overuse injuries. This would include sports such as soccer, which involves repetitive minor impact with a soccer ball. Proper counseling of the athlete to avoid some of these repetitive motions is appropriate.

Knee, Osteochondritis Dissecans of the

Osteochondritis dissecans (OCD) *of the knee* is a focal acquired injury to the bone just underneath the cartilage of the femur. It can be thought of as a stress fracture to a small area of this bone that can progress to involve the overlying cartilage of the knee. It is most commonly present in the most athletically active children and is believed to be an overuse injury occurring from repetitive microtrauma to the bone.

Anatomy

The knee joint is the articulation between the femur (thighbone) and the tibia (shinbone). The ends of the femur and tibia are covered with cartilage that resembles the shiny smooth white end of a chicken bone. The cartilage provides a smooth, low-friction surface for the knee to allow movement. The bone directly underneath the cartilage is called the *subchondral bone*. The purpose of the subchondral bone is to support the cartilage during weight-bearing activities. The femur forms two bulbous ends in the knee joint called *condyles*, through which our weight passes. The medial femoral condyle is on the inner aspect of the knee. The lateral femoral condyle is on the outer aspect of the knee.

Causes

OCD injuries occur in athletes involved in high-impact running sports, such as soccer, football, basketball, and lacrosse. Many athletes who develop OCD injuries play multiple sports and are involved in athletic activity for many hours every day. The OCD lesions begin as a small stress-related injury to the subchondral bone. The most common location for OCD of the knee is in the posterior (back) aspect of the medial (inner) femoral condyle. This particular area of the knee receives less blood flow and is subject to high forces with activity. It is thought that repetitive microtrauma causes a small stress fracture in one area of the subchondral bone. If the overuse activity continues, the area with the stress fracture will not be able to heal appropriately and, eventually, will lose its blood supply. At this point, the subchondral bone will no longer be able to properly support the cartilage over the top of it, and if activity continues, the cartilage over the lesion will break.

Symptoms

OCD of the knee can occur in children of all ages, although it most commonly occurs in adolescents involved in multiple sports, with daily participation for several hours. It occurs most commonly between the ages of 11 and 13. It presents with aching knee pain that becomes worse with running during sports. There is usually no history of an actual fall or injury. The pain is often located at the inner or outer aspects of the knee, depending on the location of the lesion. Pain may be severe enough to cause a limp. If the overlying cartilage is cracked and injured, the knee will often swell, and mechanical symptoms such as catching or locking of the knee may be noted. In 25% of the cases, the other knee will be involved as well.

Diagnosis

An active athlete playing multiple high-impact running sports for many hours every day who presents with activity-related knee pain and swelling may have an OCD of the knee. A physical exam is the first step toward diagnosing OCD of the knee. The femoral condyles of the knee are palpated with the knee flexed to determine if there are any localized areas of tenderness. The knee is examined for signs of swelling. In patients in whom OCD is suspected, the other knee must be carefully examined, and X-rays should be obtained.

Since the lesion is most commonly located at the posterior (back) aspect of the medial femoral condyle, it is often not seen on an X-ray taken with the knee straight. Instead, a "tunnel view" X-ray with the knee flexed often best shows the lesion. On an X-ray, the OCD lesion appears as a small round crack in the subchondral bone (see X-ray, next page). The X-ray can also be used to determine if the child is still growing, as the growth plates of the femur and tibia will be visible in growing children.

The knee cartilage will not be visible on the X-rays. Therefore, a magnetic resonance imaging (MRI) scan may be obtained. The MRI scan is used to determine if the cartilage over the lesion is intact or cracked. If the cartilage over the OCD lesion is cracked, there will often be knee fluid underneath the lesion, which can be seen well on the MRI scan.

OCD lesions are classified as "stable" or "unstable." Stable lesions involve only the subchondral bone—the overlying cartilage is intact. In unstable lesions, the overlying cartilage is cracked. Making this determination is important because stable lesions tend to heal well with rest. Unstable lesions do not heal as well and if left untreated can completely break off, forming a "loose body."

Treatment

The two most important factors involved in planning treatment for OCD of the knee are the age of the athlete and the stability of the lesion. In general, most stable lesions in children who are still growing heal without surgery. For partially unstable lesions in growing children or for stable lesions in patients who have already grown, a short period of nonsurgical management may be attempted. However, if the lesion does not heal after 3 to 6 months, surgery is often recommended. Most unstable OCD lesions are treated with surgery. OCD lesions that persist after the patient is already grown also usually require surgery.

Nonsurgical Treatment

The most important principle for nonsurgical treatment of OCD of the knee is to stop the repetitive activities that cause the pain. This means that the athlete must be removed from most sports activities. Impact activities such as running and jumping must be completely avoided. Nonimpact activities such as swimming and low-resistance cycling are encouraged. Crutches and knee bracing are sometimes recommended during the initial stages of the treatment. Compliance with these measures is often difficult in this highly active patient population.

The initial treatment phase of rest, possibly combined with limitation of weight bearing and immobilization, usually lasts about 6 weeks. Physical therapy is then initiated, focusing on knee range of motion and strengthening activities. At periodic follow-ups, the physician ensures that the patient's symptoms are improving and may follow the appearance of the lesion with serial X-rays. Full healing of the lesion can often take anywhere from 3 to 12 months. Return to sports can take anywhere between 3 and 12 months and is allowed when the athlete is painfree and the lesion has shown signs of healing.

Surgery

Surgery is recommended for lesions that do not heal after an appropriate time period of nonsurgical management, for unstable lesions, and for lesions that persist in patients who have already grown. OCD of the knee is most commonly treated with knee arthroscopy. During arthroscopy, the surgeon will look at and use a tiny arthroscopic probe to "feel" the cartilage over the lesion. Depending on the appearance and feel of the cartilage over the lesion, the surgeon will decide on how to proceed.

In some cases, the cartilage over the lesion will be completely intact, with no cracks or fissures, and will be felt as a soft mass. In these cases, the surgeon may elect to drill tiny holes across the lesion. This technique is called *transarticular drilling,* which is done to stimulate the underlying subchondral bone to bleed in an attempt to start the healing process. If the lesion is very large or if the cartilage over the top of the lesion is cracked, the surgeon may also perform internal fixation. In these cases, metal or bioabsorbable screws or pegs may be placed across the lesion through the cartilage and subchondral bone to compress and stabilize the OCD lesion.

In some cases, the cartilage will be completely destroyed over the lesion or would have broken off to form a loose body. In these cases, the surgeon will often just remove the cartilage. The subchondral bone will then be exposed. The surgeon may then elect to perform a *microfracture procedure,* which uses an arthroscopic pick to create tiny holes in the subchondral bone. These holes will bleed, and a blood clot will eventually form over the lesion. Over time, the blood clot can repair the lesion with fibrocartilage, which although not as smooth as regular cartilage is better than leaving the bone exposed. Newer cartilage transplantation techniques are often reserved for patients who have already had the microfracture procedure done but still have pain.

After Surgery

After surgery, the patient is placed in a knee brace that limits knee motion and is instructed to use crutches. Depending on the surgeon's preference and the procedure employed, crutches and bracing may be used for 6 weeks after surgery or more. Knee motion is gradually increased over time. Physical therapy is often initiated to help the patient regain knee motion and strength. The patient is not allowed to resume impact activities until the lesion is felt to have healed. Return to sports is allowed once the patient is painfree and has regained full motion and strength and the lesion has shown signs of healing. This may take between 3 and 12 months.

Knee Bracing

Although considerable controversy still surrounds the use of knee bracing in the sports medicine patient, several recent randomized controlled trials have shed new light on the subject. This entry reviews the current clinical and biomechanical evidence supporting the efficacy of four brace types: prophylactic, rehabilitative, functional, and offloader knee braces. Brace-fitting techniques and tips are also presented.

Knee Biomechanics

A keen understanding of the normal biomechanics of the knee is essential to brace design, selection, and fit. Forces that are applied to the knee are resisted by an interdependent combination of muscle, ligament, meniscocapsular components, surface shape, and loading factors. The anatomic description of the knee as a simple diarthrodial hinge joint belies the very complex kinematic reality of the joint. The knee moves on six different axes and planes (Figure 1). The anterior cruciate ligament (ACL) and posterior cruciate ligament (PCL) are critical to normal knee biomechanics as they constrain and guide the femur and tibia during the arc of motion.

Brace Design

The principles underlying the design of an ideal knee brace hold true for all the categories of braces. The brace should produce a synergistic effect with the normal soft tissue knee stabilizers through a normal range of motion and should not interfere with normal knee function. It should not increase the risk of injury to other parts of the athlete's lower extremity or other players the braced athlete may come into contact with. It should protect the knee from external forces causing excess varus (bow-legged position) or valgus (knock-knee position), rotation (twisting), or anterior-posterior translation (linear motion). Finally, it should adapt to various patient shapes and sizes as well as being cost-effective.

Prophylactic Knee Bracing

Prophylactic knee braces (PKBs) are commonly used during a variety of sporting activities, including

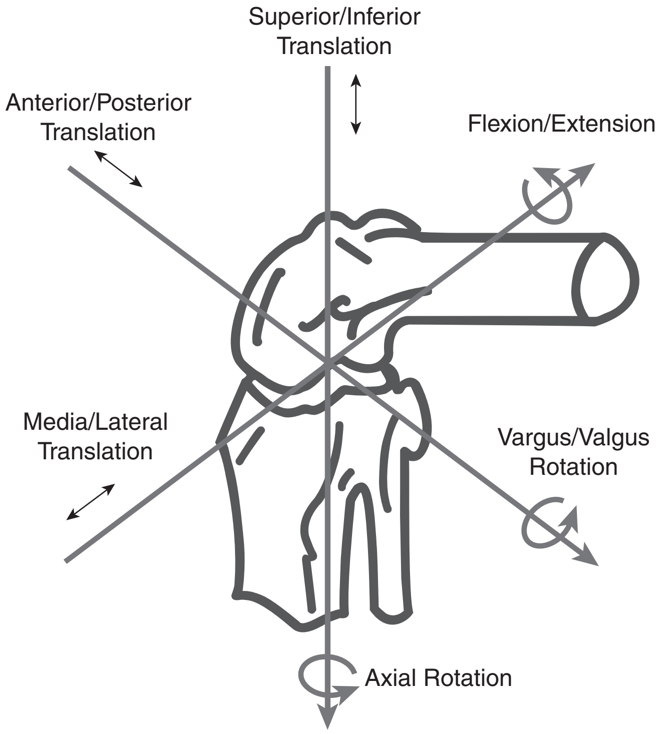

Figure 1 The Six Degrees of Knee Motion Freedom

Figure 2 Single Lateral Upright Prophylactic Knee Brace (Assist Off-the-Shelf Knee Brace, by DonJoy)

Source: Image courtesy of DonJoy.

Figure 3 Double Upright Prophylactic Knee Brace (Defiance III Custom Carbon Frame Brace, by DonJoy)

Source: Image courtesy of DonJoy.

football and soccer, in an attempt to decrease the frequency of both contact and noncontact knee ligament injuries. PKBs are commonly available in two designs. The traditional prophylactic brace has a single lateral upright with a single-axis, double-axis, or polycentric hinge at the level of the knee joint (Figure 2). A second prophylactic brace design has bilateral uprights with a polycentric hinge. The medial and lateral uprights in this latter brace have an interconnecting band (Figure 3). The results of basic biomechanical and functional studies demonstrate considerable inconsistency; however, we can still glean valuable knowledge from the results.

Prophylactic Knee-Bracing Evidence

Knee models with spring-loaded, remotely teetered steel cables have been developed to test the performance of PKBs. PKBs seem to be more effective when they allow adequate distance between the knee and its hinges and when the braces are sufficiently stiff to inhibit premature joint contact during loading. The brace ideally will disperse the force from the imparted blow away from the joint to the distal brace attachments at the thigh and calf. The PKB seems to have a more favorable protective effect for the ACL than for the medial collateral ligament (MCL) in braced patients during an impact on the outside of the knee. The brace has provided consistent protection against MCL strain in the range of 20% to 30% when compared with the unbraced knee.

Braced athletes can have a significant but reversible increase in compression of leg musculature during both activity and rest. It has been theorized that the high pressure in the leg muscles could lead to impaired blood flow and decreased performance. The performance of male football players and female lacrosse players has been examined using measures of the quadriceps muscle compression and time to muscle fatigue. Evidence suggests that females' performance scores may be more adversely affected than those of male athletes. Two well-designed prospective epidemiologic studies, the so-called West Point and Big Ten Conference studies, have been performed. Football participants in defensive positions were shown to have a significant reduction in the frequency and number of MCL injuries with brace use.

Figure 4 Rehabilitation Knee Brace (Telescoping Cool Trom, by DonJoy)

Source: Image courtesy of DonJoy.

Rehabilitation Knee Bracing

The *rehabilitation knee brace* is routinely used in the ACL-deficient, -injured, or -reconstructed knee and is recommended during the initial healing period immediately after surgery. The off-the-shelf rehabilitation or postoperative brace limits the bending arc and prevents excessive force transmission through the knee during early rehabilitation with both conservative and surgical management. To function in this context, these braces commonly contain adjustable locking hinges on both sides of the knee. The brace also contains conforming foam liners that fit the calf, thigh, and knee and nonelastic straps to secure the brace at the top and bottom (Figure 4).

Rehabilitation Knee-Bracing Evidence

A variety of rehab braces have been shown to significantly decrease the twisting, bending, or straight-line forces on the knee that are caused by an indirect stress or direct blow to the knee. Often, however, the forces used in the research setting are well below those seen in real life.

When comparing braced and nonbraced patients during postoperative rehabilitation after an ACL reconstruction, there seems to be very little difference, if any, in the subjective (patient based) or objective (external measurement based) outcomes. The knee function, knee stability, and complication rates have been noted to be similar between the braced and unbraced patients. Recently, high-quality studies using prospective, randomized controlled trials have reaffirmed these results. Braced and unbraced patients have similar activity levels, knee function, and knee stability in the long term. This has led some authors to conclude that there is no significant benefit in the use of a rehabilitation knee brace after ACL reconstruction.

Functional Knee Bracing

The *functional knee brace* helps normalize knee motion in the ACL-deficient or ACL-reconstructed knee. It should provide stability without impeding performance and act to limit abnormal knee rotational (twisting) and translational (straight line) forces that could be detrimental during sporting activities. Functional knee braces contain either straps that suspend the brace or a shell that encloses and attaches the brace to the thigh and calf. Both designs use either a unilateral or a bilateral upright, as well as a variable extension stop (Figure 5).

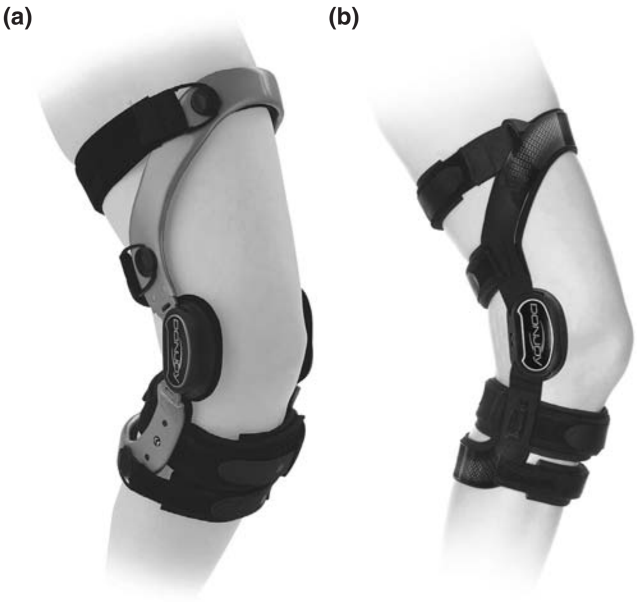

Figure 5 (a) Unilateral and (b) Bilateral Hinged Upright Functional Knee Braces (Defiance III and Full Force Knee Brace, Respectively, by DonJoy)

Source: Image courtesy of DonJoy.

Functional Knee-Bracing Evidence

Testing of braces using cadavers and artificial models in which the ACL has been severed has allowed for a detailed understanding of their ability to support and protect the knee. Functional knee bracing can improve stability by more than one third in the ACL-deficient knee by reducing the forward displacement of the tibia on the femur, a function the ACL would normally provide. There has been a concern that while the brace functions well during low-load conditions, it may not provide the same protection during a larger impact.

Evidence suggests that under subjective questioning, patients using functional knee braces report improvements that are more pronounced than would be expected from the objective experimental data. Patients reported less knee pain, swelling, and instability with brace use, as well as enhanced confidence and performance during sporting activities. Prospective, randomized clinical trials monitoring the intermediate and long-term outcomes of braced and unbraced patients have suggested that there is no significant difference in knee pain, knee joint laxity, knee range of motion, or muscle strength between the two groups. Thus, knee bracing during the postoperative period may not change the clinical outcome for young, active, ACL-reconstructed patients.

Offloader Knee Bracing

The medial *offloader knee brace* is one of an array of nonoperative treatment modalities for the management of unicompartmental knee osteoarthritis (OA). An offloader brace for osteoarthritis involving primarily the medial compartment of the knee incorporates a hinge mechanism and straps that apply a valgus force (inward-directed force toward the midline of the body) to the knee. The braces can be custom-fit or off-the-shelf (Figure 6). There is a variety of evidence on the efficacy and mechanism of function of these braces.

Offloader Knee-Bracing Evidence

Complex technology such as three-dimensional gait analysis and instrumented braces has been

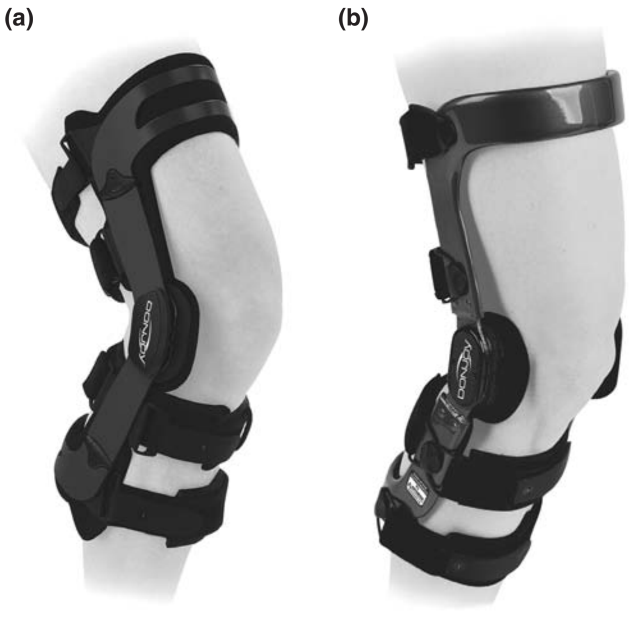

Figure 6 (a) Off-the-Shelf and (b) Custom Medial Offloader Knee Brace (OA Adjuster Off-the-Shelf Knee Brace and Defiance OA Custom Knee Brace, Respectively, by DonJoy)

Source: Images courtesy of DonJoy.

used to demonstrate the effectiveness of valgus bracing in reducing medial knee joint pressures, improving walking patterns (gait), and decreasing the malposition of the knee. Patients have consistently noted significant improvements in their knee function and gait and a reduction in the valgus knee angle during brace use.

The brace can produce a significant improvement in objective and subjective patient-based outcomes. Some studies have shown an almost 50% reduction in symptoms and a 70% improvement in function with the use of a medial offloader knee brace.

Brace-Fitting Techniques and Tips

Brace fitting is often underemphasized clinically. The treating health care team should play a key role in ensuring that the brace is appropriately fitted. To be effective, both off-the-shelf braces and custom-made braces must be specifically contoured to the soft tissues envelope of the involved limb. The primary interface between the brace and the extremity is the soft tissues of the thigh and calf. If the brace is not optimally matched to the patient's limb, poor rotational adherence and brace loosening can be a real concern. Improved translational and twisting stability can be imparted on the brace-limb construct with the use of suitable straps and by adding points of contact directly over subcutaneous bone. Contouring at the top of the tibia and adding pads to the flare of the distal femoral can help with brace fit.

Both elastic and rigid straps can be used to secure the brace. Elastic straps may provide less structural support but are much better tolerated by the patient during physical activity. Most braces have at least three or four points of fixation to maintain the brace's position. The balance between brace fit, function, and comfort must be specifically tailored to each situation, so that every patient may derive maximal benefit from the prescribed brace.

Knee Bursitis

Knee bursitis, a common problem in athletes, can be difficult to distinguish from other knee problems. A *bursa* is a fluid-filled sac that provides a cushion and low-friction surface for tendons to glide over, thus protecting the tendon and adjacent structures. *Bursitis,* an inflammation of a bursa sac, can present in many different ways but can be classified as *acute*, *chronic*, or *septic*. Most of the time, these conditions can be treated conservatively and will do well. If suspected, a septic bursitis needs to be recognized, diagnosed, and treated expeditiously to avoid complications such as septicemia. The most commonly seen types of knee bursitis in athletes are pes anserine, prepatellar, infrapatellar, and tibial collateral.

Anatomy

The bursae of the knee are found in areas where tendons glide over bone or soft tissue. Often it is difficult to differentiate bursitis from other conditions of the knee.

The pes anserine bursa lies beneath the pes anserine tendons on the anteriomedial aspect of the inferior portion of the knee. The pes anserine tendons are composed of the confluence of the gracilis, sartorius, and semitendinosus. Beneath the pes anserine bursa lies the tibial attachment of the medial collateral ligament. The infrapatellar bursa is composed of a superficial and a deep component. The superficial infrapatellar bursa lies superficial to the proximal portion of the patellar tendon. The deep infrapatellar bursa lies deep and just proximal to the insertion of the patellar tendon on the tibia. The prepatellar bursa is a large bursa that lies directly superficial to the patella. And last, the tibial collateral bursa lies beneath the medial collateral ligament directly over the medial meniscus.

Causes

Any bursitis can be acute, chronic, or septic. Most common in athletes are the acute and chronic forms. The septic form is usually seen in older individuals, those who are immunocompromised, and those who have had trauma; it can also be iatrogenic, resulting from injection of a nonseptic bursa.

Acute bursitis is often caused by trauma, repetitive stress, gout, or rheumatoid arthritis. Chronic bursitis is often seen following single or repeated episodes of acute or septic bursitis. In addition, overuse injuries or minor repetitive trauma can also lead to this condition.

Prepatellar bursitis and superficial infrapatellar bursitis are seen in individuals who are on their knees frequently. Superficial infrapatellar bursitis, or “vicar’s knee,” is usually caused by kneeling in the upright position, whereas prepatellar bursitis, or “housemaid’s knee,” is caused by kneeling in the bent-over position. It is also more common in sports that are at risk for a direct blow to the knee, such as football and rugby. Pes anserine bursitis is often seen in individuals with an abnormal gait or knee alignment. It is also commonly seen in patients with arthritis of the knees. And last, athletes with hamstring tightness can be at increased risk for this disorder.

Symptoms

In acute or septic bursitis, the symptoms are similar. Patients will often complain of pain and swelling over the affected bursa. They may even notice increased warmth over the bursa. In addition, the patient will often have pain and limited range of motion when the tendon overlying the bursa is active. For example, with prepatellar bursitis they will have pain and limited range of motion with flexing or extending the knee. With septic bursitis, the pain with range of motion is often more pronounced and is often associated with fever and chills.

In chronic bursitis, often patients will have minimal to no pain. They may present with chronic or increasing swelling of the involved bursa that has occurred over weeks to months. Chronic bursitis will not have redness or warmth associated with it. If the bursa has become distended, patients may have minor discomfort with range of motion.

Diagnosis

The diagnosis of knee bursitis can usually be made by a history and physical exam. The constellation of the history of trauma, overuse, repetitive kneeling, or other risk factors discussed above can help make the diagnosis. In acute or septic bursitis, the exam will often show swelling, erythema, and warmth over the affected bursa as well as tenderness to palpation. If fever is present, then it is diagnosed as septic bursitis. In chronic bursitis, the clinician will usually be able to appreciate swelling over the affected bursa, but it will not be associated with erythema or warmth. Tenderness to palpation can be variable with chronic bursitis but will be minimal if present.

On exam, differentiating acute bursitis from septic bursitis can be difficult. An open wound or penetrating trauma would suggest septic bursitis. If one cannot differentiate acute from septic bursitis, then the bursa needs to be aspirated. The fluid should then be sent to the laboratory and tested (blood cell count, microorganisms, Gram stain, and presence of crystals). The white cell count in septic bursitis can be lower than that seen in septic arthritis. If a threshold of >2,000 cubic millimeters of white blood cells is used, it will give a sensitivity of 94% and specificity of 79%. The examination of the fluid for crystals will help rule out gout or pseudogout.

Deep infrapatellar bursitis can be difficult to differentiate from other disorders of the knee such as Osgood-Schlatter disease and patellar tendinitis. Tenderness to palpation is superior to the tibial tubercle and deep to the patellar tendon. Tibial collateral ligament bursitis can be difficult to differentiate from a medial meniscus tear, as they will both create tenderness over the medial joint line. The absence of an injury to the knee makes the diagnosis of tibial collateral ligament bursitis more likely.

Imaging can play a role, especially to help differentiate bursitis from other conditions or to rule out a retained foreign body in cases of trauma. Plain X-ray can be useful to see a foreign body or to evaluate for other conditions such as Osgood-Schlatter disease. Magnetic resonance imaging, computed tomography, or ultrasound can be used in cases where the diagnosis is not clear-cut, such as in differentiating tibial collateral ligament bursitis from a medial meniscus tear.

Treatment

Most knee bursitis can be treated conservatively. Rarely do these conditions require surgical intervention.

Nonsurgical Treatment

In acute prepatellar bursitis, initial treatment with rest, ice, compression, immobilization, and nonsteroidal anti-inflammatory drugs (NSAIDs) is often effective. Immobilization should only be used for short periods. In knee bursitis, the decision to aspirate and inject the bursa with steroids depends on the degree of swelling, which bursa is involved, and the need for quicker return to play. If septic bursitis is not ruled out, a steroid should not be injected. The prepatellar bursa is the most commonly aspirated, but if it is swollen enough, the infrapatellar bursas can be aspirated. Typically, the pes anserine and tibial collateral ligament bursa are only injected and not aspirated. A bursa aspiration or injection should be done under sterile conditions so that acute bursitis does not become septic. After aspiration, the knee should be immobilized and a compressive dressing applied (see Figure 1). In chronic bursitis, avoidance or protection against the aggravating activity, for example, kneeling, can help reduce the swelling. If symptoms persist, aspiration followed by an injection of steroid can be helpful.

Septic bursitis is treated similarly as acute bursitis but with the addition of an antibiotic and without the injection of a steroid. In the knee, it is rare to have septic bursitis except in the prepatellar bursa. If the symptoms are mild and the patient has no systemic symptoms, oral antibiotics can be used. Recommended antibiotics would be a penicillinase-resistant antibiotic or a first-generation cephalosporin, such as cephalexin. In penicillin-allergic patients, clindamycin can be used. If there

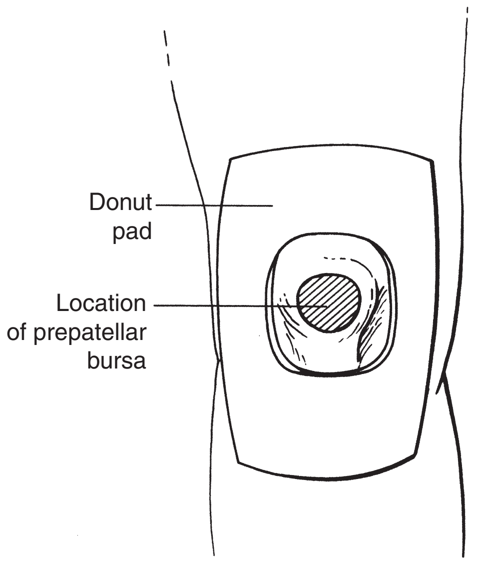

Figure 1 Use of Donut Pad to Compress Bursa

is a concern for methicillin-resistant *Staphylococcus aureus* (MRSA), then trimethoprim-sulfamethoxazole or clindamycin can be used. In case of severe infection, failed oral antibiotics, or an immunocompromised patient, hospital admission and intravenously administered vancomycin are recommended until the culture and sensitivities are back. Duration of therapy depends on the clinical response, but often 2 to 3 weeks of treatment with antibiotics is required. In addition, daily knee aspiration is usually adequate for drainage.

Surgical Treatment

In recalcitrant cases of chronic bursitis or recurrent septic bursitis, excision of the bursa is indicated. In septic bursitis, surgery is warranted if the bursa cannot be adequately drained with a needle, if a foreign body is present in the bursa, if there is a need for debridement of adjacent structures, or if antibiotic therapy is failing. In these cases, the bursa is opened, drained, and washed out. A drain can also be placed if necessary.

Prognosis

Most cases of knee bursitis do well with conservative treatment regardless of whether the bursitis is acute, septic, or chronic. The rare cases in which surgery is necessary usually do well.

Knee Injuries

Knee injuries are common in sports, particularly in the pediatric age-group. In the United States, there were 229,298 knee injuries reported in children under 18 years of age in 2001. This is likely an underestimate as many injuries are not reported and many others are seen by family doctors or in walk-in clinics, which do not report injuries. The incidence has been steadily increasing. The most common sports-related injuries resulting in permanent and long-term morbidity are knee injuries. Knee injuries are seen most commonly in sports that involve twisting movements and rapid changes in direction, such as American football, basketball, and skiing.

Both acute and chronic or overuse knee injuries are seen in athletes, resulting from sports participation. Acute knee injuries, such as ligament tears or meniscal tears, occur frequently in basketball, hockey, skiing, soccer, and football. Overuse knee injuries, such as Osgood-Schlatter disease or patellofemoral pain syndrome, are seen frequently in running and jumping sports. Chronic anterior knee pain is a very common presenting complaint in the sporting population.

Risk factors for knee injuries are listed in Table 1. These include both intrinsic and extrinsic factors. Intrinsic factors are anatomical and inherent factors that may not necessarily be modifiable. Extrinsic factors are associated with biomechanical and environmental issues that may be more easily modified.

Anatomy

The bony anatomy of the knee includes the femur superiorly, the tibia inferiorly, and the patella

Table 1 Risk Factors for Knee Injuries

Intrinsic Factors	*Extrinsic Factors*
Female gender	Excessive loading to knee (single event or recurrent)
Q angle	Poor training techniques, conditioning
Knee malalignment (genu valgus/varus)	Poor coaching/supervision
Limb length discrepancy	Improper use of equipment/not wearing appropriate equipment
Poor muscle flexibility	Type of activity
Patellar hypermobility	Warm-up and stretching
Previous injury	
Inadequate rehabilitation of injury	
Age	
High body mass index (BMI)	
Low level of physical fitness	

anteriorly. The proximal fibula articulates with the tibia but not the femur. The medial and lateral prominences of the distal femur are known as the *medial* and lateral *femoral condyles*. The depression between the condyles is the intercondylar notch or trochlear groove. This is where the patella articulates with the femur. The tibial plateau is the flared articular surface of the tibia, and the tibial spine is the bony eminence in the center of the tibial plateau.

There are several ligaments in the knee joint, including the anterior cruciate ligament (ACL), the posterior cruciate ligament (PCL), the medial collateral ligament (MCL), and the lateral collateral ligament (LCL). The ACL originates from the medial aspect of the lateral femoral condyle and inserts on the anteromedial area of the tibial plateau. The main function of the ACL is to prevent the excessive anterior translation of the tibia on the femur. The PCL originates at the lateral aspect of the medial femoral condyle and traverses behind the ACL, inserting on the posterolateral area of the central tibial plateau. The PCL functions to prevent excessive posterior translation of the tibia on the femur. The MCL originates on the distal medial femoral condyle and inserts on the proximal tibial epiphysis. The MCL protects the knee against excessive valgus force. The LCL originates on the lateral femoral condyle and inserts on the proximal fibular head. The LCL protects the knee against excessive varus forces (Figures 1a and b).

Other important structures in the knee joint are the menisci. The medial meniscus (MM) and the lateral meniscus (LM) are C-shaped masses of hyaline cartilage located on the medial and lateral surfaces of the tibial plateau. The menisci act as shock absorbers that protect the knee from high mechanical loads. They also contribute to joint lubrication and nutrition.

There are two main muscle groups affecting knee function. The quadriceps muscle group in the anterior thigh extends the knee. There are four muscles constituting the quadriceps muscle group: the vastus lateralis, vastus medialis obliquus, vastus intermedius, and rectus femoris. The vastus lateralis, medialis, and intermedius all originate on the proximal femur and insert on the patella via the quadriceps tendon. The rectus femoris originates on the anterior iliac spine, crosses both the hip and the knee joint, and inserts on the tibial tubercle via the patellar tendon.

The hamstrings muscle group, in the posterior thigh, flexes the knee. The hamstrings consist of the short and long heads of the biceps femoris, the

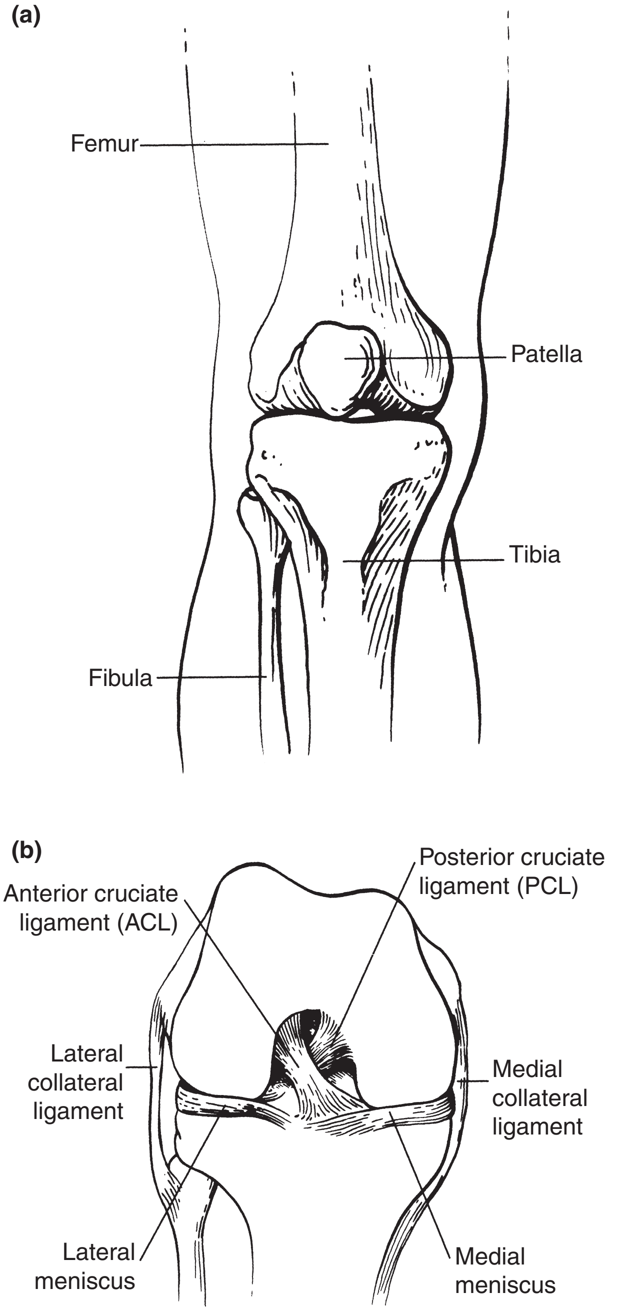

Figure 1 (a) The Knee Joint and (b) Ligaments of the Knee

semimembranosus, and the semitendinosus muscles. The hamstrings originate on the ischial tuberosity. The biceps femoris inserts on the head of the fibula. The semimembranosus and semitendinosus insert medially on the proximal tibia. Other muscles contributing to knee flexion include the sartorius and gracilis muscles, as well as the plantaris, gastrocnemius, and popliteus muscles. The sartorius and gracilis muscles originate in the pelvis and cross the knee medially to insert on the medial aspect of the proximal tibia. The popliteus, plantaris, and gastrocnemius muscles originate on the distal femur and cross the knee posteriorly. The iliotibial band (ITB), a tight band of fascial tissue, crosses the knee laterally. The ITB originates from the tensor fascia latae, gluteus medius, and gluteus maximus muscles and inserts at the Gerdy tubercle, just lateral to the tibial tubercle.

In young athletes who are still growing, the long bones have open growth plates, where new bone is formed. The proximal tibial growth plate and the distal femoral growth plate contribute more than half of the longitudinal growth for these bones. Other sites of bone growth are the sites of attachment of tendons, called *apophyses*. In the knee, there are four apophyses: the tibial tubercle, the inferior patellar pole, the superior patellar pole, and the superior-lateral aspect of the patella. The patellar tendon attaches superiorly at the inferior patellar pole and inferiorly at the tibial tubercle. The quadriceps tendon attaches to the superior aspect of the patella. The growth plates and apophyses are susceptible to injury, which may affect the growth of the athlete.

Evaluation of Injuries

Details of Injury

The key to a correct diagnosis of a knee injury rests on an accurate description of the presenting complaint and the mechanism of injury. An athlete with a knee injury may have pain, instability, or swelling. The mechanism of injury may help determine what injury has occurred. The location of pain also helps delineate the exact injury. An important diagnostic clue is the degree and timing of swelling. Significant swelling that occurs within the first 1 to 2 hours postinjury indicates a hemarthrosis (bleeding into the joint), which is usually associated with a major ligament rupture (ACL, PCL), a patellar dislocation, or a fracture. An effusion that occurs over several hours or the next day is more indicative of a meniscal injury.

Athletes will sometimes volunteer that they heard a “snap” or a “pop” at the time of injury or had the sensation of something having “moved” or "popped out" at the time of injury. This is usually associated with an ACL rupture or a possible patellar dislocation.

There may be mechanical symptoms, such as clicking, locking, or giving way, associated with a knee injury. Clicking or locking is classically associated with a loose body or a meniscal tear. Locking refers to significant loss of passive range of motion, particularly extension. Giving way can occur with instability, loose bodies, or muscle weakness. It can also be related to pain.

Previous injuries to the knees, including previous surgeries, can make athletes more susceptible to further knee injuries. Management of knee injuries may depend on the athlete's age, occupation, and sports and leisure activities and the level of sports played, as well as particulars of training, including frequency and any recent changes to the training regimen. Current and future goals of the athlete can also help determine treatment.

In the absence of an acute traumatic event, there may be other causes of knee pain. Multiple swollen joints, fevers, night sweats or night pain, or changes in weight or growth may indicate an infection, arthritis, or cancer as a cause of knee pain.

Physical Findings

An athlete with a knee injury may be unable to put full weight on his or her injured leg and may walk with a limp. The alignment of the legs can predispose an athlete to injury. Common alignment abnormalities include bowlegs (genu varum), knock-knees (genu valgum), knees that bend backward (genu recurvatum), flat feet (pes planus), kissing/squinting kneecaps, and femoral anteversion (rotation of the femurs). Range of motion of the injured knee may be decreased compared with the uninjured knee. Range of motion of the hip may also be decreased in situations where a hip injury causes knee pain.

An injured knee may be swollen, bruised, or deformed. There may be atrophy or asymmetry of the muscles around the knee. The presence and amount of joint effusion can be assessed by milking the joint. The examiner's right hand occludes the suprapatellar bursa, and the left hand milks any excess joint fluid across the joint from the lateral to the medial side. A bulge of fluid seen at the medial aspect of the knee is consistent with an effusion.

Tenderness to palpation may indicate the type of injury. With the knee in flexion, the medial and lateral femoral condyles can be palpated. Tenderness in this area suggests an osteochondral injury, such as fracture or osteochondritis dissecans. The medial and lateral joint lines can also be palpated with the knee in flexion. Tenderness along the joint lines indicates meniscal injury. The kneecap may be tender to the touch at the lateral, superior, medial, or inferior areas in patellofemoral pain syndrome. Areas of bone growth (apophyses), including the tibial tubercle and the inferior pole of the kneecap, may be tender to palpation in the setting of apophysitis, such as Osgood-Schlatter and Sinding-Larsen-Johansson syndromes. The patellar tendon, MCL, and LCL may also be tender to palpation.

There are a number of special tests to assess injuries to the knee. The anterior drawer, Lachman, and pivot shift tests assess the integrity of the ACL. The anterior drawer test is performed with the patient in the supine position with the knee flexed to 90°. The patient's lower extremity is stabilized by sitting on the foot. The proximal tibia is held with both hands, and as the hamstrings relax, the examiner attempts to glide the tibia forward. With an intact ACL, there is a firm end point. A positive test is obtained when there is more glide on the affected side than on the unaffected side. With experience, a "soft" end point is appreciated.

The Lachman test is also performed with the patient lying supine with the legs extended. One hand stabilizes the distal femur while the other hand attempts to glide the tibia forward with respect to the femur. Excessive glide indicates ACL incompetence. Comparison with the uninjured leg is important, particularly in children and adolescents who may have ligamentous laxity.

The pivot shift test is performed with the patient supine. With the tibia internally rotated and the knee fully extended, a valgus stress is applied to the knee as the knee is flexed. If the ACL is torn, the femoral condyles will be subluxated. As the knee is flexed, the examiner looks for a "clunk" as the tibia reduces (positive pivot shift). The knee is then extended, noting any click into subluxation (positive jerk test).

The posterior drawer test and posterior sag test assess the integrity of the PCL. For the posterior drawer test, the patient is positioned as for the anterior drawer test. However, the tibia is forced posteriorly with respect to the femur. A positive test is indicated by excessive posterior glide of the tibia. Again, comparison with the uninjured leg is helpful. The posterior sag test is performed with the patient supine, with the knees flexed to 90° and the patient relaxed. The position of the tibia relative to the femur is observed. A positive test is indicated by a relatively posterior position of the tibia.

Meniscal injuries are assessed with McMurray and Apley tests. The McMurray test is performed with the patient lying on his or her back with the legs extended. One hand holds the heel of the injured leg and flexes the knee. The other hand is placed on the knee with the fingers along the medial joint line and the thumb along the lateral joint line. The knee is alternately externally and internally rotated and extended while a valgus force is applied. A positive test results when pain is elicited or the examiner feels a click or pop in the joint.

The Apley test can be performed when there is confusion about whether medial knee pain is coming from an MCL injury or a meniscal injury. In both MCL injuries and medial meniscal injuries, palpation of the medial joint line can reproduce pain. The Apley is a two-part test. The first part is the compression test, which assesses for meniscal injury. The Apley compression test is performed with the patient lying in a prone position with the injured knee flexed to 90°. The heel is held, and an axial load is applied while rotating the tibia externally and internally on the femur. Pain is elicited along the joint line if there is a meniscal tear. The second part of the Apley test is the distraction test. The examiner applies traction on the lower leg while twisting it. A positive test elicits pain along the medial aspect of the knee.

The collateral ligaments are assessed with the patient lying supine. One hand applies a valgus (toward midline) stress to the injured knee at 0° and 30° of flexion while the other hand applies a counterforce to the ankle. This stresses the MCL. A positive test elicits pain or laxity along the medial aspect of the knee. A varus (away from midline) force is then applied to the knee at 0° and 30° of flexion, with a counterforce applied at the ankle. This stresses the LCL. A positive test elicits pain or laxity at the lateral aspect of the knee.

The Ober test assesses the tightness of the ITB. The patient lies on the uninjured side with the injured leg abducted at the hip. If the ITB is tight, the hip will be unable to passively adduct past an imaginary horizontal line.

The kneecap may be injured in sports. Injuries to the kneecap can make the athlete feel as if the kneecap is unstable. The stability of the kneecap can be assessed by a patellar apprehension test. The athlete lies on his or her back with the legs extended. The examiner places both thumbs along the medial aspect of the kneecap with the index

Table 2 Ottawa Knee Rule

A knee radiograph is indicated after trauma when one of the following is present:

- patient age is more than 55 or less than 18 years
- tenderness at the fibular head
- tenderness over the patella
- inability to flex the knee to 90° (hemarthrosis, fractures)
- inability to weight bear for four steps at the time of injury and when examined

Table 3 Acute Knee Injuries

Common	*Uncommon*
ACL tear	LCL sprain
MCL sprain	Patellar tendon rupture
Meniscal tears	Quadriceps rupture
Patellar dislocation	Fracture of tibial plateau
Contusions	Avulsion fracture of tibial spine
	Osteochondritis dissecans
	Bursitis
	Avulsion of biceps femoris tendon

Note: ACL = anterior cruciate ligament; LCL = lateral collateral ligament; MCL = medial collateral ligament.

fingers along the lateral patella. With the athlete's quadriceps muscles relaxed, and watching the athlete's face, lateral force is applied to the patella with the thumbs in an effort to move the patella. Patients who have had a previous patellar dislocation or subluxation will become apprehensive as the patella moves laterally.

Investigations

X-rays should be performed in cases of acute trauma, particularly if swelling is present, to assess for fractures. A set of decision criteria to determine the need for knee X-rays, known as the *Ottawa knee rule*, was developed in the 1990s (Table 2).

A computed tomography (CT) scan may be used to further delineate fractures, particularly if X-rays do not indicate an obvious bony injury. A CT scan also may be helpful to look for loose bodies.

Magnetic resonance imaging (MRI) is helpful as an adjunct to clinical assessment when the diagnosis is uncertain. MRI is useful to assess meniscal injuries; ligament tears, particularly ACL tears; articular cartilage damage; and some bony injuries, such as osteochondral edema (bone bruise) and osteochondritis dissecans.

Ultrasound can examine the patellar tendon as well as bursal swelling. It can also be used to assess meniscal cysts.

Arthroscopy (camera scopes introduced into the joint through the skin) can be used as both an investigation and a treatment. In cases where the diagnosis is uncertain, diagnostic arthroscopy can help clarify the problem. The clinician can usually treat the injury at the same time.

Types of Injury

Tables 3 and 4 provide a list of acute and chronic knee injuries.

Prevention of Injury

Not every injury can be prevented in a sport setting, but some guidelines may help prevent some injuries. Sport safety is essential to help reduce the incidence of injury. Appropriate safety equipment for a particular sport should be worn and replaced

Table 4 Overuse or Chronic Knee Injuries

Area of Knee	*Common*	*Uncommon*
Anterior	Patellofemoral pain syndrome Patellar tendinopathy Osgood-Schlatter disease Sinding-Larsen-Johansson disease Patellar subluxation	Pre-patellar bursitis Quadriceps tendinopathy Osteochondritis dissecans Slipped capital femoral epiphysis (SCFE) Legg-Calvé-Perthes disease
Posterior	Biceps femoris tendinopathy Referred pain from back, patellofemoral joint	Baker cyst Popliteus tendinopathy Gastrocnemius tendinopathy Posterior cruciate ligament (PCL) sprain Deep vein thrombosis
Medial	Patellofemoral pain syndrome Medial meniscus tear, degenerative changes, cyst	Synovial plica Pes anserinus bursitis Osteoarthritis of medial knee compartment Referred pain from back and hip
Lateral	Iliotibial band friction syndrome (ITBFS) Lateral meniscus abnormality (tear, degenerative changes, cyst)	Osteoarthritis of lateral knee compartment Biceps femoris tendinopathy Patellofemoral pain syndrome Referred pain from spine and hip

as necessary. Surfaces and equipment should be well maintained according to safety regulations. The rules of the sport should be adhered to. Proper sporting techniques should also be emphasized to avoid injury. For instance, balance training may help reduce ACL injuries in cutting sports.

Preparticipation evaluations prior to the start of a sporting season can help identify potentially modifiable factors to help prevent injuries. In particular, any previous injuries and muscle imbalances or inflexibilities can be assessed and appropriate rehabilitation instituted before the season gets under way.

General fitness is also essential to reduce injury. Athletes should maintain a general level of fitness year-round. Participating in a variety of activities, particularly during the off-season, is helpful to achieve global strength and fitness. It is important to have an off-season from a sport to allow for adequate rest of the muscles used repetitively during the season. Athletes shouldn't participate in the same sport all the year round. Although there are no specific exercises that have been shown to reduce knee injuries, athletes should continue a general strengthening and conditioning program that is complementary to their chosen sport. In addition, warm-up and cooldown sessions, with stretching exercises, should be done prior to and after playing sports.

During a sport season, it is important not to overtrain. Adequate recovery time and rest are essential to allow the body to recuperate. Attention should be paid to the frequency, duration, and intensity of training to ensure that the training program does not exceed the athlete's abilities.

In children and adolescents, additional measures to prevent injury include modifying the standard rules of the games for specific age-groups, shorter periods of activity, modifying the court or field size for various ages and skill levels, and matching opponents in size and skill level to provide safe, level fields of engagement. Emphasis in sports should be on skill development and having fun rather than on winning at all costs. Adequate adult supervision and officiating, as well as proper coaching, should be ensured.

Return to Sports

Return-to-play guidelines following a knee injury are specific to the particular injury. In general, athletes should have regained a baseline level of conditioning before returning to sports and participating in practices and drills. Most athletes should be able to continue to participate in some aspect of their sport while an injury is healing. Athletes should progress from general strengthening and conditioning to sport-specific rehabilitation exercises. Once the athlete has mastered sport-specific exercises, gradual return to play can be initiated. Athletes should continue to wear any prescribed brace or support until advised otherwise by the treating therapist or physician.

Knee Injuries, Surgery for

The knee is one of the most commonly injured joints of the body. In sports, meniscal (spacer cartilage in the knee) tears, anterior cruciate ligament (ACL) tears, and patella (kneecap) injuries are common major injuries. Fractures of the bones of the knee are less common but occur in sports with high-energy activity, such as motorcycle racing and skiing. For many traumatic injuries to the knee, surgical treatment is necessary. Overuse injuries occur much more frequently than traumatic injuries and are generally treated without surgery. Sometimes, nonoperative treatment fails, and surgery is necessary to resolve an overuse condition.

Anatomy and Function

The knee is mostly a hinge joint. It also functions as a ball-and-socket joint to some extent. (For an illustration of the anatomy of the knee joint, see the entry Knee Injuries.) At the end of the femur (thighbone), there are two rounded condyles covered with slippery smooth cartilage. On the other side of the hinge is the tibia, with two matching hollow areas also covered by smooth cartilage. Allowing the femoral condyles to more perfectly match the flatter tibia are two crescent-shaped cartilages on either side. These are the menisci, medial and lateral, whose job is to provide a better fit and some cushioning and to help distribute joint fluids. Holding the knee together are four main ligaments: the medial and lateral collateral ligaments (MCL and LCL, respectively) and the anterior and posterior cruciate ligaments (PCL). The ligaments provide static restraint to abnormal motion.

The muscles that control and stabilize the knee are the quadriceps group in front to straighten the knee and the hamstring group at the back to bend or flex the knee. In addition, the gastrocnemius calf muscles help bend the knee. When the quadriceps contracts concentrically, it shortens, straightening the knee as in jumping. The hamstrings shorten concentrically during sprinting to strongly flex the knee. Muscles also work by contracting against forces that are trying to lengthen the muscles. This is eccentric contraction, and for the quadriceps, it occurs when landing from a jump. The muscles actively stabilize the knee and absorb the forces around the knee.

The patella (kneecap) is a bone within the tendon of the quadriceps and serves three purposes: (1) it protects the rest of the knee joint from trauma; (2) it elevates the quadriceps tendon, giving the muscle increased mechanical force; and (3) it provides a gliding cartilage surface over the end of the femur, protecting the tendon. The patella has the thickest cartilage in the body and bears the highest loads.

Knee Injuries

When forces bend the knee in ways it was not designed to go, ligaments tear. If there is compression or twisting within the knee, meniscus tears can occur. A direct blow to the patella can dislocate it to the side. An indirect twisting motion of the knee can also cause the patella to dislocate. Blunt force to any bone can break or bruise the bone. Most injuries involve a combination of forces, so that in landing incorrectly from a jump, an athlete can have abnormal compression on one side of the knee, abnormal distraction forces on the opposite side, and a twisting component to the injury as well. Such an injury can result in meniscus tear, bone bruising, surface cartilage injury, and tears to the collateral and anterior cruciate ligaments. The orthopedic surgeon depends on the history, the physical examination, and studies such as magnetic resonance imaging (MRI) to determine the extent of injury and what is necessary to repair all structures.

There are many knee problems that are treated with surgery. Some of the more common injuries include meniscus tears and ACL tears. Patella dislocation is not necessarily treated surgically, but frequently, there is a loose piece of bone or patella instability, and surgery is required. Overuse knee injuries that require surgery include patella overload problems, osteochondral stress fracture (osteochondritis dissecans), and chronic inflammatory or degenerative problems of cartilage, synovium, or tendon.

Surgery of the Knee

Decision Making

In most cases, the decision of whether or not surgery is necessary is not a simple yes or no. For example, a torn meniscus does not automatically mean an operation is necessary. In a young athlete with a small tear without symptoms, the tear may simply be allowed to heal. In an older athlete with knee osteoarthritis, there are frequently meniscus tears that are completely symptom-free, and surgical removal can actually make the patient worse.

The best surgeons use specific guidelines to help them make their decisions. These are no typically written guides but rather known sequences to follow depending on various parameters. They result in specific recommendations by the surgeon based on the variables associated with the particular injury at hand.

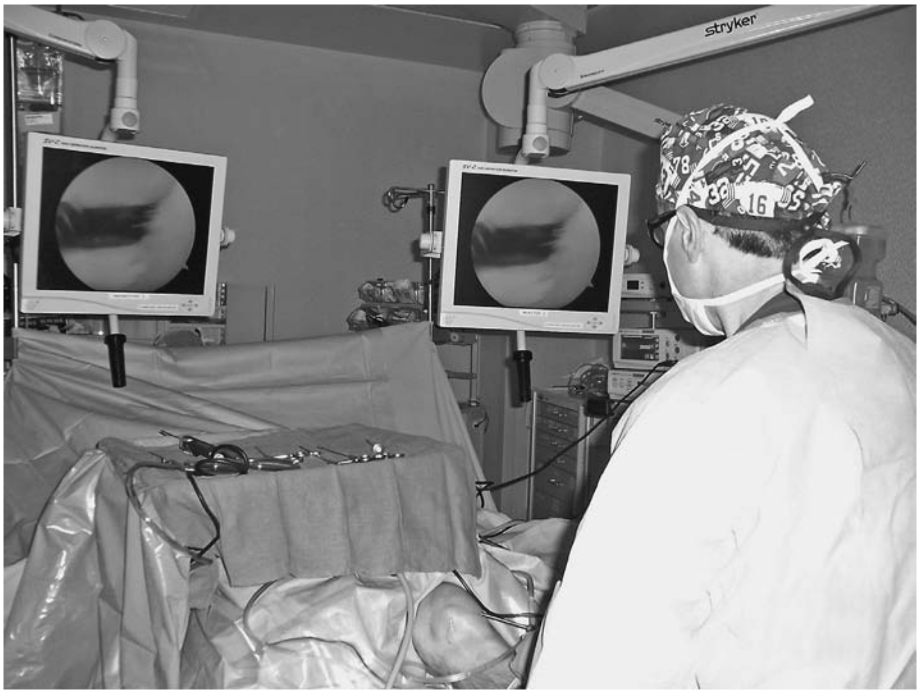
Informed Consent

Before any operation is scheduled, the surgeon must obtain informed consent from the patient. The concept of informed consent has evolved over the years and can be very different for different patients. Some patients require detailed descriptions of the operation technique, the possible complications, and the plan for rehabilitation and may want several opinions from different surgeons. Other athletes will take the opposite approach, telling the surgeon, "Doctor, I trust you, just make me better." The Internet provides an abundance of free advice, some good and some bad, regarding every type of knee injury. Using the resources of the Internet is usually helpful, but frequently, the surgeon must correct misconceptions.

Neither of these approaches is ideal. The surgeon cannot teach the patient every nuance of knee surgery, and the patient cannot be expected to become a doctor overnight. Likewise the patient who doesn't want to know any details and who leaves all decision making to the doctor is not fulfilling his or her obligations. The informed consent process is a collaboration between the surgeon and the patient where the surgeon gives the patient the information that a "reasonable" person would need to know to make a sound decision. The patient must use his or her judgment to decide whether to accept the risks of surgery in order to achieve the benefits.

Surgical Technique

These days, almost all knee surgeries are done arthroscopically or with minimally invasive techniques (see photo below). This means that visualization is done with fiberoptic telescopes connected



Typical surgical setup for arthroscopy of the knee

Note: The knee is in a sterile field, all instruments are sterile, and the fiberoptic telescope is paired with a camera with the inside of the knee displayed on the monitor.

to small, high-definition video cameras through 0.25-inch (in.; 0.6 centimeter) skin incisions. Repair, removal, drilling, and sewing of tissues is also done through 0.25-in. holes. Most of these skills require a fair bit of practice, and so sports medicine physicians have to become experts at these techniques. Arthroscopic surgery has several advantages over open surgery. If the repair can be done as well with open surgery, the advantages include smaller scars, less pain, decreased risk of infection, and faster recovery. Many of the repair techniques now used can only be done arthroscopically, and surgeons are constantly finding innovative ways to improve techniques and results.

Complications

No surgeon is perfect, and no operation is perfect. The main reason to have informed consent is to make sure that the patient understands what result can be expected and what can go wrong.

Take, for example, reconstruction of the ACL. This operation can lead to many different complications. Early in the development of this operation, a patient's knees were casted for 6 weeks following surgery. This led to a condition called *arthrofibrosis,* in which excessive scar tissue forms around the kneecap, making motion more difficult.

Infections can occur following any operation, and these can have severe consequences. The patient can develop blood clots in the deep veins of the leg (deep vein thrombosis, or DVT), and these can break off, travel to the lungs, and cause death (pulmonary embolus).

Excessive bleeding into the knee following surgery can slow down rehabilitation and induce restrictive scar formation. The hardware used to secure a graft may become painful or fail. Most of these complications are very rare, but each of these and many others have occurred and will occur again. Even with a perfect knee operation, the operated knee is never as good as the original knee and will still wear out faster than the other side, leading to earlier arthritis.

Knee Surgery: Meniscus Tear

The classic meniscus tear occurs in an athlete who has a twisting knee injury under load. There is initial pain, the knee swells overnight, and there is persistent pain at the site of the torn meniscus. The athlete sees the surgeon, who suspects meniscus tear based on history and physical examination. These days, most patients would undergo MRI to confirm the diagnosis. An arthroscopic partial meniscectomy would be recommended. The factors leading the surgeon to this recommendation are as follows:

1. High activity level of the athlete
2. Pain
3. The presence of locking
4. The knowledge that few meniscus tears heal on their own
5. The understanding that left untreated, a meniscus tear can cause further joint cartilage and bone damage and lead to early arthritis

Arthroscopic surgery is used for treating a torn meniscus. This is virtually always done as an outpatient procedure, meaning that the athlete returns home the same day the operation is performed. The sequence of events begins with early arrival of the patient to the surgical center. The nurses prepare the patient for surgery, and both the surgeon and the anesthesiologist talk to the patient. In the operating room, the anesthetic is given, and the operation is done.

The surgeon examines the entire knee arthroscopically and then addresses the torn meniscus. Depending on the location of the tear in the meniscus, the pattern of the tear, and the age of the patient, the surgeon will make a decision as to whether the meniscus can be repaired. Since the meniscus only has blood supply to the outer one third, repairing the inner two thirds is unlikely to heal the tear. On the other hand, children have a better blood supply and greater healing potential, so many surgeons will repair a middle one third meniscus tear in a young person. Tears that occur longitudinally in the meniscus (either vertically or horizontally) heal better than radial tears or tears that result in a flap.

If the surgeon feels that repair is not possible, he or she uses various small instruments to remove the unstable parts of the torn meniscus. The goal is to avoid leaving tissue behind that can cause impingement leading to pain and/or further tearing.

If repair is possible, the surgeon must decide how best to stabilize the tear. Many different techniques exist for sewing a torn meniscus. Some allow complete repair by placing sutures (stitches) in the meniscus without having to make additional skin incisions. Other techniques require incisions to capture the long needles passed through the joint to the outside and for tying the sutures outside the joint. Still other techniques involve passing sutures from outside in and then tying the knots outside the joint below the skin in a small skin incision. Each technique has its pluses and minuses. No one technique is correct for every situation.

Once the repair is complete, the surgeon tests the repair with a probe and by putting the knee through a full range of motion. The small incisions are closed, and dressings are applied. Frequently, a system for providing cold therapy is used, and sometimes, a brace is used to restrict motion. Depending on the strength of the repair and the size of the tear, full weight bearing may be restricted for a period of time. If no repair has been done, the patient is allowed to bear weight as tolerated. A rehabilitation program, either self-directed or with a physical therapist, is prescribed, and the athlete follows up with the surgeon until fully healed and rehabilitated.

Knee Surgery: ACL Tear

ACL tear is another common knee injury in athletes. This large ligament in the center of the knee prevents forward motion of the tibia with respect to the femur. The ligament can tear in one of several ways. If the athlete's knee is struck from the outside (clipping-type injury), the MCL and ACL can tear. Compression on the outside part of the knee can result in lateral bone bruising and lateral meniscus tear. Another more common mechanism for ACL tear is called "indirect." This occurs when cutting or landing from a jump, and the knee gives out under the stress. The athlete hears and feels a "pop" and is unable to continue playing, and the knee swells with blood within an hour. The diagnosis is made, and an MRI scan is obtained to assess all damaged structures.

In athletes, most of the time, a torn ACL requires repair to achieve a stable knee. The original ACL tissue cannot successfully be repaired (as yet). Instead, surgeons must create a new ligament with graft material. The graft material can be the athlete's own tissue (usually a tendon from an area that can afford to lose some tissue) or can come from the tissue bank (tissue harvested from a cadaver). Other decisions include how soon to do the operation after injury, what type of fixation to use, whether to use braces, and what type of rehabilitation to follow. The surgical technique is demanding and constantly evolving, with new theories and techniques being published every year.

In the operating room, the surgeon first performs a standard knee arthroscopy, examining all aspects of the knee. If there is a torn meniscus, it is repaired or partially resected as described earlier. The torn ends of the original ACL are removed, and new holes are drilled to receive the new graft. If the patient's own tissue is being used, that material is removed and reconfigured to become a ligament. Depending on the fixation technique selected by the surgeon, sutures or other devices will be added to the tendon to allow secure fixation of the graft. If allograft (processed cadaver tissue from a tissue bank) is used, it is washed, measured, and prepared for fixation.

The graft is then passed through the tunnels in the tibia and femur, and it is locked in place on both sides with any of several metal, plastic, or absorbable devices. Critical aspects of the operation include the location of the tunnels, the tension of the graft, whether the graft rubs the femur, and whether the graft remains under uniform tension through a full range of motion.

The incisions are closed and the dressings applied. A cold therapy device is frequently used, as is a range-of-motion brace. Research has shown that using a brace after ACL surgery does not provide any additional protection from reinjury, but many patients and surgeons prefer the security a brace offers. ACL reconstruction is typically an outpatient procedure, and the patient goes home the same day.

Rehabilitation is a critical part of ACL reconstruction. It begins with early motion of the knee with or without a machine to assist with motion. Physical therapy is usually involved, and several detailed protocols exist to allow healing of tissues and restoration of strength and balance without placing excessive strain on the new ligament. Athletes are usually rehabilitated enough to return to sports in 4 to 6 months, even though the graft takes up to 3 years to become fully mature.

Knee Surgery: Patella Dislocation

Surgery for patella dislocation is standard knee arthroscopy as described earlier. If there are loose bodies (cartilage or bone fragments), they are removed. A large fragment of bone and cartilage can be replaced and held in place with screws or pins. The patella must be realigned to its track, and usually the medial patellofemoral ligament (a ligament that tethers the patella to the inside of the femur) must be repaired. Sometimes, to achieve central tracking of the patella, the outside (lateral) tissues are too tight and must be released. Rehabilitation involves protecting the repair while strengthening the knee muscles.

Knee Surgery: Patella Maltracking

One of the most common overuse injuries requiring surgery is patella overload from a patella that is tilted to the outside of the knee. This results in too much force on one part of the patella, causing pain there. If bracing and selective muscle strengthening have not succeeded in correcting the problem, the surgeon may recommend a lateral release. In this operation, a standard knee arthroscopy is performed. The tilt and lateral tracking are confirmed by direct visualization, and the tight lateral tissues are cut, allowing the patella to move medially in a more central, balanced position. Rehabilitation is similar to patella dislocation surgery, with bracing and muscle strengthening the key aspects. In the past, this operation was done excessively for many problems around the knee. Surgeons are now very careful about deciding who will benefit from this operation.

Conclusion

Knee surgery for athletic injuries is common. Most of the time, the decision-making process is based on hard facts with scientifically justified results. Arthroscopic surgery is used for most operations of the knee following athletic injury. Informed consent is necessary to ensure realistic expectations on the part of the athlete. Despite all the advances in medicine and surgery, complications will occur and are ultimately unavoidable. Surgeons, other health professionals, and athletes continuously work together to refine the decision-making process, maximize understanding, improve surgical technique, minimize complications, and optimize rehabilitation.

Knee Ligament Sprain, Medial and Lateral Collateral Ligaments

The medial and lateral collateral ligaments (MCL and LCL, respectively) are two of the four main stabilizing ligaments in the knee. (The anterior and posterior cruciate ligaments [ACL and PCL, respectively] are discussed in a separate entry.) The MCL and LCL can be injured during many sporting activities, especially sports involving "cutting." Spraining these ligaments is common, and injury to the MCL is the most common ligamentous injury to the knee. Spontaneous healing with nonoperative treatment usually occurs; however, operative treatment may be beneficial if multiple ligaments of the knee are injured.

Anatomy

MCL is a complex ligamentous structure consisting of the superficial MCL and deep MCL. The superficial MCL is also called the *tibial collateral ligament*. It is the largest structure of the MCL complex. The superficial MCL attaches proximally on the medial femoral condyle and distally to the medial tibia in two places. The more proximal is 2 centimeters (cm) from the joint line, and the more distal attachment is approximately 4 to 5 cm distal to the joint line beneath the pes anserine insertion. The deep MCL is made up of medial capsular thickenings from the knee capsule. Additionally, the semimembranosus muscle gives off a tendinous expansion that is called the *posterior oblique ligament* and adds additional resistance to valgus stress when the knee is fully extended. The MCL complex's collagen fibers are arranged in parallel, giving the MCL its strength as the main medial stabilizer to resist valgus force on the knee.

The LCL is also called the *fibular collateral ligament*. It acts as the main restraint to varus stress of the knee. The LCL also helps provide additional resistance to rotation. It is part of a group of stabilizers called the *posterolateral corner ligament complex*. The LCL attaches to the femur on the lateral epicondyle and inserts onto the lateral fibular head. Additionally, there are attachments from the long head of the biceps femoris that insert onto the LCL and lateral capsular ligaments that lie deep in the LCL.

Causes

MCL injuries are caused by valgus stresses to a slightly flexed knee, such as a blow to the outside of the knee with the foot fixed. These injuries can occur in noncontact or contact sports. Noncontact maneuvers such as pivoting or cutting can result in an MCL injury. Contact injuries are usually from a lateral blow to the knee, which often occurs in football, and result in more complex injuries and complete tears.

LCL injuries are much less common and rarely occur in isolation. Most occur with injury to the posterior lateral corner ligamentous complex or the ACL or PCL. The mechanism of injury is often an anteromedial blow to the knee. Less commonly, the injury could occur from twisting or hyperextension with or without contact.

Symptoms

Athletes with MCL or LCL injuries will often complain of pain, stiffness, redness, and swelling on the medial or lateral side of the knee, respectively. The athlete will often be able to walk after injury. In more severe injuries, the athlete may complain of a feeling of instability in the knee.

Diagnosis

Physical exam starts with inspecting the knee for an effusion within the knee or swelling or redness on either side of the knee. The examiner should palpate the MCL and LCL on both the tibial and fibular attachments as well as the respective femoral condyle insertion. The range of motion (ROM), both active and passive, should be checked. The knee should then be examined using the valgus stress test at 0° and 30°. To perform the valgus stress test, the examiner should place the leg at 30° of flexion. One of the examiner's hands should then be placed on the lateral side of the femoral condyle, with the other hand grasping the athlete's ankle medially and holding it in neutral position. A valgus stress is then placed on the knee, and the amount of joint line opening is assessed. The same maneuver is repeated at 0° of flexion. Likewise, the LCL should be assessed with the varus stress test at 0° and 30°. This is performed with the examiner placing the leg over the side of the table, placing one hand on the medial femoral condyle and the other hand on the lateral ankle, holding it in neutral position. A varus stress is then placed on the knee, and the size of the joint line opening assessed. The noninjured knee should also be examined to compare the injured side with the noninjured side. The American Medical Association's guidelines for grading an MCL or LCL injury are as follows:

Grade I: 0 to 5 millimeters (mm) of joint line opening

Grade II: 5 to 10 mm of joint line opening

Grade III:>10 mm opening, with no firm end point

Grades I and II are sprains and partial tears, whereas Grade III injuries are complete tears. A complete physical exam of the knee and leg should be done to assess for additional ligamentous injury. Additional tests including the Lachman test, anterior and posterior drawer test, pivot-shift test, and dial test are to be performed and are described elsewhere in this encyclopedia. A neurovascular exam, including motor sensation and palpating the popliteal, dorsalis pedis, and posterior tibial pulse, must be completed.

After the physical exam, plain radiographs should be ordered, including anteroposterior, lateral, 45° postero-anterior, and sunrise views. Varus and valgus stress radiographs may yield additional information. Additionally, magnetic resonance imaging (MRI) without contrast medium may be useful as it is highly sensitive in detecting tears of the collateral ligaments as well as other pathology.

Treatment

Nonsurgical Treatment

Medial Collateral Ligament

Isolated Grade I or Grade II injuries are treated nonoperatively. Ice, elevation, and compression are necessary. The patient may continue weight bearing as tolerated. Initially, the athlete may require the use of crutches. Nonsteroidal anti-inflammatory drugs often help decrease inflammation, pain, and swelling. Hinge knee bracing may be used. Early ROM is encouraged. Physical therapy for quadriceps strengthening and closed-chain exercises should be performed. The goal for recovery is full ROM, adequate strength, and no laxity within 4 to 6 weeks.

Isolated Grade III injuries are also initially treated nonoperatively. Ice, elevation, and compression are again necessary. Initially, the patient should be non–weight bearing and should wear a hinged knee brace for support. Early ROM and physical therapy are also initiated. Examination of the knee throughout the rehab process is imperative. At 4 weeks after the injury, if valgus stress testing is improved to Grade I or less, full weight bearing may commence. The athlete may be allowed to return to activities when full ROM, adequate strength, and Grade I or less laxity is achieved. Grade III injuries may take up to 8 to 12 weeks to heal.

Lateral Collateral Ligament

LCL injuries often heal more slowly than MCL injuries. Grade I and II injuries are treated conservatively. Ice, elevation, compression, and nonsteroidal anti-inflammatory drugs are the mainstay of therapy. The athlete should be placed in a hinged knee brace and should continue weight bearing as tolerated for 4 to 6 weeks. Early ROM is encouraged. Physical therapy for quadriceps strengthening and closed-chain exercises should be performed. The goal for recovery is full ROM, adequate strength, and no laxity within 6 weeks.

Grade III injuries often do poorly with conservative therapy due to rotational instability with posterolateral corner ligamentous injury.

Surgery

Surgery on either the MCL or the LCL is reserved for athletes who have symptomatic Grade II or Grade III instability after completion of a functional rehabilitation program or knees with multiple ligaments injured and recurrent instability. The goals of surgery include restoring normal stability and ROM.

Medial Collateral Ligament

Repair of the MCL is possible when the tear is at the bone-ligament junction. The ligament can be anchored to the bone with suture anchors. Additionally, this can be reinforced with a semitendinosus graft. If the tear is in the middle of the ligament, reconstruction can be performed with gracilis or semitendinosus autograft or Achilles tendon allograft. Additional tightening of the deep MCL and posterior oblique ligament can help reinforce the reconstruction.

Lateral Collateral Ligament

Early repair within the first 1 to 2 weeks after injury has better outcomes. Suture anchors, direct suture repair, recess procedures, and autograft or allograft reconstructions are all possible surgical options for LCL repair and posterolateral corner reconstruction.

After Surgery

Medial Collateral Ligament

Apart from ice, elevation, and compression, rehab protocols vary. Most would initially immobilize the knee in a hinged knee brace locked in extension for 4 weeks. During these 4 weeks, the athlete can perform quad sets and patellar mobilization, and continuous passive ROM from 0° to 45° can be initiated. Without active ROM, the patient can do weight bearing as tolerated with a hinged knee brace locked in extension. From 2 to 4 weeks, the patient can begin active assisted ROM from 0° to 60°. At 4 weeks, active assisted ROM from 0° to 90° may be completed, and the brace may be opened. At 6 weeks, active ROM may begin from 0° to 100° in the hinged knee brace. The brace may be removed around Week 8, and rehab should be continued with the goal of return to sports in 10 to 12 weeks.

Lateral Collateral Ligament

Ice and elevation with non–weight-bearing restrictions in a knee immobilizer in full extension are the mode of treatment in the first 6 weeks. During this time, passive ROM, quadriceps sets, and straight leg raises in the knee immobilizer are performed. After 6 weeks, the knee immobilizer is discontinued, and weight bearing as tolerated is begun. Stationary biking with low resistance is initiated at 6 weeks. It may take up to 4 months to return to the previous level of activity.

Knee Plica

Knee plica syndrome, or synovial plica syndrome, is among the common knee injuries that occur in athletes. *Plica syndrome* refers to the injury or irritation of the synovial plica folds in the knee, followed by severe pain in the joint. Although the condition does not damage the knee (rarely, a large plica can rub on the articular cartilage and cause wear), it can be very painful. Diagnosing plica syndrome can be challenging, but treatment is simple.

Following a description of the anatomy of the knee, this entry discusses the signs, symptoms, causes, and treatment of knee plica syndrome.

Anatomy of the Knee Joint

The knee joint is the most complex joint of the entire body, formed by the condyles at the distal ends of the femur and the condyles at the proximal end of the tibia. It is a synovial joint of the hinge variety, the articular surfaces being the two femoral condyles, the adjacent surfaces of the superior aspect of the tibial condyles. The ends of the femur and tibia are covered with cartilage that resembles the shiny smooth white end of a chicken bone. The cartilage provides a smooth low-friction surface for the knee to allow movement. The bone directly underneath the cartilage is called the *subchondral bone*. The purpose of the subchondral bone is to support the cartilage during weight-bearing activities. The articular surfaces between the femur and the patella are the V-shaped trench on the anterior surface of the femur at its lower end and the adjacent surfaces on the posterior aspect of the patella, or kneecap. The joint is lined by the synovial membrane, which extends from one articular surface to the other. Also referred to as *synovium*, the synovial membrane secretes a clear fluid called the *synovial fluid*, which lubricates the joint, thus helping bones move easily during joint movements. Other structures that help in reducing friction between the bones and the muscle tendons are the synovial bursae and the *plicae,* folds of the synovial lining of the knee joint capsule.

The ligaments of the knee joint that provide stability are the collateral ligaments, the cruciate ligaments, the oblique popliteal ligament, and the patellar ligament. The joint is made stable by the tone of the quadriceps femoris muscle.

Synovial Plicae

As noted, plicae are extra folds in the synovium; they are the remnants of the mesenchymal tissue and septa, which are formed during the embryonic development of the knee joint. There may be several of these folds in the normal knee. Commonly, there are four such plicae in the knee; these are normally small and smooth, but once injured or irritated, they may become thick, causing pain. Among the four plicae, the one on the inner side, called the *medial plica*, is more prone to injuries, running from the lower end of the kneecap to the lower end of the femur.

Causes

Normally, plicae are small and smooth and may be present for years without producing symptoms until they get inflamed or irritated, most commonly through either overuse or direct traumatic injury.

Plica pain can occur either suddenly (acute) or over a long period (chronic).

Acute Plica Pain

A sudden injury to the knee, either by a fall or due to the knee getting badly hit by an object, causes the medial plica to respond by becoming irritated and thick. The thickened area thus begins to catch on the femur as the knee moves.

Chronic Plica Pain

Chronic plica problems develop when the plicae get irritated by exercise, repetitive motion, or kneeling. Activities that involve repeated bending and straightening of the knee, such as running, biking, or use of the stair climber, can irritate the plicae and cause pain.

Signs and Symptoms

The most common signs and symptoms in a patient with painful knee plicae are as follows:

1. A patient with knee plica syndrome usually arrives with a history of knee pain in the front or just on the inner side of the knee. Extensive bending of the knee aggravates the pain.
2. Localized swelling is observed in rare cases where the plicae have been severely irritated.
3. There may also be a clicking or snapping sensation along the inside of the knee as it is bent.
4. Patients often experience knee locking, a condition in which the knee can be flexed but cannot be extended fully.
5. Knee weakness often occurs when knee plica is left untreated for a very long time.
6. The area around the knee is also tender to the touch, and a thickened, cordlike structure can usually be felt.

Diagnosis

Medical History

The patient provides details about symptoms and describes any injury, condition, or general health problem that might be causing the pain.

Physical Examination

The clinician bends, straightens, rotates (turns), or presses on the knee to feel for injury and discover the limits of movement and the location of the pain. The patient may be asked to stand, walk, or squat to help the clinician assess the knee's function.

Diagnostic Tests

As knee plica syndrome is difficult to diagnose, other common knee injuries must first be eliminated from consideration. Imaging techniques including X-ray (radiography), computerized axial tomography (CAT), and magnetic resonance imaging (MRI) may be performed to rule out the possibility of any fracture, soft tissue injury, or meniscus tear. The clinician then performs simple tests such as the Stutter test and Hughston plica test.

Stutter Test

The patient is seated with his or her knee flexed over the edge of the table; the examiner stands lateral to the involved side, and lightly cupping one hand over the patella, the examiner has the patient slowly extend his or her knee. The test is positive when there is irregular patellar motion/stuttering between 40° and 60°. A positive test indicates symptomatic medial synovial plica.

Hughston Plica Test

The patient is supine with his or her knee flexed to 90°. The examiner internally rotates the tibia and passively moves the patella medially while palpating the anteromedial capsule. The examiner flexes and extends the knee from 90° to 0° while the tibia is internally rotated. The test is positive when there is pain and/or palpable clicking. A positive test indicates symptomatic medial synovial plica.

Arthroscopy

To confirm knee plica syndrome, arthroscopy is performed. A lighted optic tube (arthroscope) is inserted into the joint through a small incision in the knee, and images of the inside of the knee joint are viewed on a video screen.

Treatment

Nonsurgical

The majority of people with knee plica syndrome will get better without surgery. The treatment is directed along a three-phase protocol: (1) control of pain and inflammation, (2) restoration of function, and (3) return to sports.

Inflammation can be reduced in the following ways:

- Administer nonsteroidal anti-inflammatory medications such as ibuprofen, indomethacin, naproxen, oxaprozin, and celecoxib.
- Reduce activity such as running, biking, or using a stair climber.
- Apply ice to reduce swelling in the area of the plica. Rub ice for 3 to 5 minutes around the sore area until it feels numb.
- A cortisone injection into the plica, or simply into the knee joint, may quickly help reduce the inflammation around the plica. Cortisone is a powerful anti-inflammatory medication.
- Ultrasound and friction massage may be used to reduce inflammation in the plica.
- To reduce the inflammation, modalities such as *iontophoresis* (using low-intensity electric current to transport medications through the skin) and *phonophoresis* (using ultrasound to transport medications through the skin) are employed.

Rehabilitative Exercises

Once the inflammation has been controlled and pain levels begin to fall, rehabilitative exercises should be started. The goal is to increase overall quadriceps, hamstring, and calf strength, as well as increasing the overall flexibility of muscle. Examples of such exercises include painfree squats that progress to one-leg squats, side step-ups, closed-chain terminal knee extension, and applicable sport-specific exercises. However, care should be taken to avoid deep squats as they can increase the pain. These exercises should be performed using progressive resistance exercise (PRE) principles, gradually increasing load and intensity as the pain and inflammation allow.

Surgical Treatment

If treatment fails to relieve symptoms within 3 months, the clinician may recommend arthroscopic surgery to remove the offending plica. Once the plica is located with the arthroscope, small instruments are inserted through another incision to cut away the plica tissue and remove the structure. Rehabilitation sessions after surgery are designed to ease pain and swelling and help the athlete begin gentle knee motion and thigh-tightening exercises. Patients rarely need to use crutches after this kind of surgery.

Prevention

Warm-up and stretching before exercising or participating in sports activities is strongly recommended. Stretching the quadriceps and hamstrings reduces tension on the tendons and may reduce irritation of the knee during activity. For patients who are prone to irritation of the plica, activities that repeatedly bend and straighten the knee, such as biking or use of a stair stepper machine, should be avoided until they consult their physician.

Kneecap, Subluxating

The *patella*, commonly called the kneecap, may become partially or completely dislodged from its normal position. Partial dislodgement is termed *subluxation,* and complete dislodgement is termed *dislocation*. The spectrum of dysfunction between subluxation and dislocation is referred to as *patellar instability*. The first time a dislocation occurs, an acute dislocation is diagnosed. Repeated dislocations or subluxations are known as *recurrent* or *chronic instability*. Acute patellar dislocation is the most common knee injury in children and adolescents.

Anatomy

Muscles are connected to bones via thick tissues known as *tendons*. The tendon of the quadriceps muscle attaches to the patella on its upper or superior end. The patellar tendon connects the patella to the lower leg by attaching to a specific part of the shin termed the *tibial tubercle*.

As the knee bends or flexes from a straight (extended) position, the patella engages and becomes constrained within a contoured portion of the end of the thighbone, known as the *femoral trochlea*. Stability of the patella within the trochlea depends on several soft tissue structures with specific names. These stabilizing structures may be thought of as biological "brakes."

In the early stages of flexion, before the patella engages within the trochlea, the position of the patella is primarily stabilized by a band of tissue known as the *medial patellofemoral ligament*. This ligament runs from the side of the patella to a portion of bone on the side of the femur. Once the patella becomes engaged within the trochlea, the primary restraint to subluxation of the patella is the complementary geometry of the patella and the trochlea. Other sources of stability to the normal position of the patella are the quadriceps and patellar tendons and the bottom or inferior aspect of the quadriceps muscle known as the *vastus medialis obliquus*.

Causes

Patellar dislocation or subluxation may occur with or without preceding injury. Instability without prior trauma occurs in patients with underlying abnormalities of the normal anatomy. These abnormalities include an abnormal shape of the trochlea (known as *trochlear dysplasia*) and malalignment of the legs, which places excess stress on the patella as the knee moves through flexion and extension. Knock-knees, or genu valgum, is one type of malalignment that can place excess stress on the patella. Rotational malalignment, in which the thighbone causes the patella to point inward (increased femoral anteversion) in combination with a tibial tubercle that is pointed outward (external tibial torsion), is another type of abnormality that can place excess stress on the patella. During growth and development, the amount of genu valgum and rotational malalignment may be decreased, as in teenagers. Other abnormalities that can cause patellar instability include loose joints (ligamentous laxity) with a hypermobile patella that is located higher in relation to the end of the thighbone than normal (patella alta). Certain medical conditions, such as Down syndrome, are associated with loose joints.

Traumatic dislocation may occur following a fall, twisting injury, or direct blow to the knee. The anatomy of the knee may be normal prior to the injury, but some underlying pathology is often present. With the dislocation, there can be damage to the knee, including rupture of the medial patellofemoral ligament. In addition, bone and cartilage can be injured. A piece of bone and cartilage can break off, causing a "loose body."

Symptoms

Patellar dislocation most commonly results in the patella being moved to the outside of the knee, a lateral dislocation, and the bony prominence is noted on the lateral side of the knee. The patella will often return to its normal position shortly after the dislocation occurs and the bony prominence disappears.

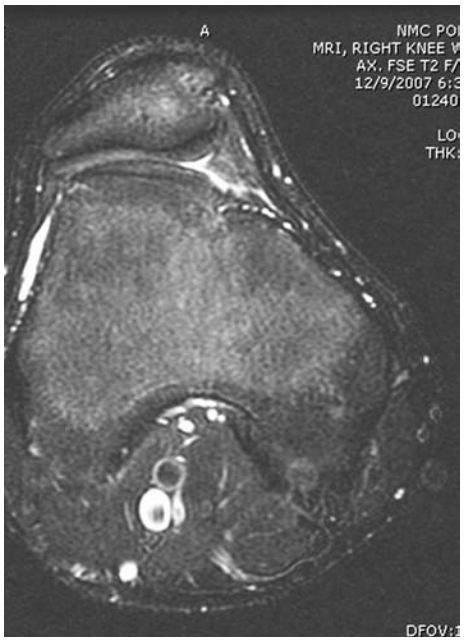
Patellar subluxation may cause pain as the patella moves to the outer edge of its normal position.

Diagnosis

Patellar dislocation may be diagnosed by examining the patient and noting the absence of the patella from its normal central position and the laterally located bony prominence. Radiographs (X-rays) are not necessary to diagnose the dislocation. However, certain X-rays will help identify the condition. The Merchant view radiograph will reveal that the patella has been moved out of the trochlea.

Patellar subluxation may also be demonstrated by following the position of the patella as the knee is moved through flexion and extension. The examiner may also attempt to judge how much the patella can move laterally. This is known as the *apprehension test*, as the patient may experience apprehension if he or she feels like the kneecap is about to dislocate.

Further examination and radiographs can help determine the cause of the patellar instability. Patients are checked for signs of ligamentous laxity and hypermobile patellae. The alignment and rotation of the legs are checked for knock-knees or increased femoral anteversion in combination with external tibial torsion. Radiographs of the knee, including anteroposterior, lateral, and Merchant views, are obtained. The lateral view will demonstrate patella alta (previously described) when present. The Merchant view will demonstrate abnormal tilt or position of the patella within the trochlea.



Magnetic resonance imaging (MRI) demonstrating tilted and subluxated patella (*top*)

Treatment

Both nonoperative and operative treatment options are available for patients with patellar instability. Physicians will individualize treatment based on a number of factors. These include the types of sports/activities played by the patient, the age of the patient, the severity of injury, the number of dislocations, and other injuries present.

First-Time Dislocation

The initial action after the first dislocation occurs is to verify that the patella has been reduced, or returned to its normal position. If the patella has not reduced on its own, this must be done by the medical provider. Reduction is facilitated by placing the patient on his or her belly (prone position), extending the hip, and then gradually extending the knee. Rarely, a patient must go to the operating room to reduce the patella.

Once the patella is reduced, it is then determined if surgery is necessary. Surgery is needed after a first dislocation if a portion of cartilage from the femur or patella was dislodged, resulting in a loose body. A loose body may be visualized on X-ray or a magnetic resonance imaging (MRI) scan (see image, left). If a loose body is present, arthroscopic surgery is performed to remove the loose body and address the cartilage damage. In addition, the underlying cause of the dislocation may be addressed at that time.

More commonly, a loose body is not present, and nonoperative treatment is begun. Nonoperative treatment consists of immobilizing the knee in a brace and then starting range-of-motion exercises and muscle strengthening with balance training. Some surgeons consider repairing the medial patellofemoral ligament after the first dislocation. However, success can occur with nonoperative treatment if loose bodies are not present within the knee.

Chronic Instability

Chronic instability can result in cartilage damage as repeated dislocations occur. Physical therapy is used to strengthen the vastus medialis obliquus muscle in order to decrease the risk of recurrence. Patellar-stabilizing braces or special taping can be used to provide additional support. Activities may be modified to avoid sports that place the patella at risk for dislocation. If repeated dislocations occur, surgery is indicated more by patient preference to eliminate recurrence than by a certain number of episodes.

Surgical treatment is directed at the underlying anatomical abnormalities that are resulting in instability. If the alignment of the legs is normal, soft tissue procedures such as lateral release and medial imbrication are performed. The lateral release reduces tension on structures that are causing the patella to be tilted, while the medial imbrication tightens tissues on the medial side of the knee that have been stretched. This procedure can be performed open with larger incisions or via arthroscopy. Another soft tissue procedure that can be performed is reconstruction of the medial patellofemoral ligament using a hamstring tendon or a donor/cadaver tendon.

Procedures that cut and realign the bones are performed when malalignment is present. The procedure that cuts the bone and moves the position of the patellar tendon is known as a *tibial tubercle osteotomy*. This procedure requires the patient to be skeletally mature so that the growth plate of the bone (physis) is not damaged. In younger patients with malalignment, procedures that redirect the patellar tendon by moving a portion of the tendon itself or by attaching a hamstring to the patella can be performed. At the time of surgery, the knee is inspected via arthroscopy for other injuries, as cartilage or meniscus injuries may be present as well.

After Surgery

Treatment protocols following surgery vary depending on which procedure was necessary to address the underlying anatomical abnormalities. Typically, the knee is moved early to prevent stiffness. Recovery is often faster after soft tissue procedures than following osteotomies. Return to sports is feasible when quadriceps strength, balance, and endurance have been achieved. Usually, sport-specific drills are begun first.

KNOCK-KNEES (GENU VALGUM)

Genu valgum (knock-knees) is an angular deformity of the knees. Young children and youthful athletes are often evaluated for this condition, but most patients are found to be within normal limits. Most cases of knock-knees will resolve on their own. It is important to identify patients outside the normal limits who need further evaluation and to give families reassurance about those patients who are within normal limits.

Normal Development of the Legs

While developing, the fetus is usually positioned with hips and knees flexed in the uterus. The feet and tibia can be internally rotated (pointed in). This positioning causes a tightening of the medial ligaments of the knee, leading to genu varum (bowlegs) at birth. The bowlegged position at birth is normally the maximum for the patient.

As the child begins to walk and grow, the tightened ligaments begin to stretch, allowing the knees to straighten out. Between 18 and 22 months, the angular deformity begins to correct, and the legs will appear straight.

This straightening will continue over the next 3 years and actually lead to an overcorrection, causing genu valgum (knock-knees). This is usually most evident at about 4 years of age. As the child continues to age and grow, the genu valgum begins to correct. By about 7 years of age and into adulthood, most people will retain a slight valgus deformity of about 5° to 8°.

Clinical Evaluation

History

One of the most important things to consider is the patient's age. Genu valgum occurs most commonly between 3 and 4 years. It is common in obese girls as well. It is important to identify whether the deformity is worsening. If possible, it can be helpful to review old photographs of the child's legs. Pain is an uncommon complaint.

Dietary history can reveal important information that may lead to nutritional deficiency. Family history and past medical history should also be reviewed. A history of fracture of the tibia can lead to knock-knees during the following 12 to 18 months.

Physical Exam

Physical exam should begin with plotting overall height, as short stature is common in patients with rickets and skeletal dysplasia.

With the patella facing forward, the clinician measures the angle of the knee. Measuring the intercondylar distance (between the two medial femoral condyles) and intermalleolar distance (between the two medial malleoli) can provide objective information to assess the deformity. There are charts available for plotting these measurements to help identify normal versus abnormal angular deformities.

Intercondylar measurement with genu varum

Source: Kevin D. Walter, M.D. Photo courtesy of Children's Hospital of Wisconsin.

Intermalleolar measurement with genu valgum

Source: Kevin D. Walter, M.D. Photo courtesy of Children's Hospital of Wisconsin.

The child may need to return every 3 to 6 months for repeat measurements to ensure that the deformity is not worsening. It is important to take the measurements in the same fashion (lying down or standing) each time for consistency.

Radiographs

Ideally, X-rays should be done in the standing position with kneecaps facing forward. X-rays should include the hips to the ankles.

Diagnosis and Treatment

Observation and reassurance are the hallmarks of treatment of genu valgum. However, if there is pain or loss of function, surgery should be considered. Also, many patients will want surgery for strictly cosmetic purposes.

Physiologic Knock-Knees

This is symmetric and occurs usually between the ages of 2 and 6. Parents may report improvement in the deformity. The family history is negative. The patient should have a normal height and normal screening measurements. The family should be reassured, and the measurements should be followed every 3 to 6 months if needed.

Posttraumatic Genu Valgum

This results from an overgrowth of the tibia about 12 to 18 months after a fracture of the proximal tibia. This complication may be unavoidable, even with proper treatment of tibia fractures. Over the following years, there may be a slow reduction in deformity.

Treatment of posttraumatic genu valgum begins with proper management of proximal tibial fractures by ensuring proper alignment and immobilization. The family will need to be reassured that this will not damage the joint and will decrease in time. If it persists, there is a role for operative intervention by an orthopedic surgeon. The procedure involves an osteotomy or a hemiepiphysiodesis.

Rickets

Nutritional deficiencies (lack of calcium, lack of vitamin D, or malnutrition) and vitamin D resistance (hypophosphatemic) can lead to rickets. Rickets is associated with both genu valgum and genu varum. Children with rickets usually have short stature and a family history of angular deformities. X-rays will show poor calcification in the bones (osteopenia) and wide physis of the joints (wide bones in the joints). There may also be bowing of the tibia and femur. Labs reveal low calcium and phosphorous.

Rickets is primarily treated by an endocrinologist to help medically manage the patient. By correcting the diet and returning the patient to his or her normal metabolic state, the deformity will usually correct. If it does not, then the orthopedic surgeon may consider bracing or surgery, such as an osteotomy or stapling. It is important to ensure that medical therapy is maximized before attempting surgical intervention.

Other Causes

There are less common causes of angular deformity. These include metabolic disorders, chronic infections due to tuberculosis, and fibrous dysplasia. These issues are best managed by a medical team of specialists.

Krebs Cycle and Glycolysis

Living cells require an energy resource to function. In the human body, this "energy currency" is adenosine triphosphate (ATP). ATP is used by cells to grow, to reproduce, and to respond to the stresses and strains of life, including exercise and muscle contraction.

ATP is a molecule that is made of the nuceloside *adenosine* and three (tri) inorganic phosphate groups. When water is added to ATP, one phosphate group breaks off and releases energy. This leaves adenosine with two phosphate groups, becoming adenosine diphosphate (ADP).

In cells, ATP is stored in very small quantities, which would sustain exercise only for a few seconds. Therefore, the cells in muscles must keep making new ATP to keep the muscles exercising for longer durations.

To make new ATP, chemical reactions occur, adding a phosphate group back to ADP to create a new ATP molecule. If this process is done in the presence of oxygen, it is called *aerobic metabolism* or oxidative phosphorylation, and if no oxygen is present, it is called *anaerobic metabolism*.

The most common and easily accessible way for the body to make ATP is through the breakdown of glucose. The foods that we eat contain carbohydrates, which are taken up by the cells and stored in the muscles and liver as a compound called glycogen. When needed, glycogen can be broken down into individual molecules of glucose. This process is called *glycogenolysis* (the breakdown [lysis] of glycogen). Once glucose is available, three processes can occur in the cell to make ATP: (1) glycolysis, (2) the Krebs cycle, and (3) the electron transport chain.

Glycolysis

Glycolysis is a metabolic process that begins with one molecule of glucose and ends with two molecules of pyruvate. In the process, a net of two molecules of ATP are produced.

The 10 steps of glycolysis are diagrammed in Figure 1.

Once pyruvate is created from glycolysis, it has two potential fates. What the pyruvate becomes next depends on whether or not there is oxygen available in the cell.

If oxygen is not present (anaerobic metabolism), then the pyruvate is converted to lactic acid. Lactic acid can accumulate and is thought to cause muscle fatigue and soreness. This occurs during exercise involving explosive, fast movements, such as weight lifting or sprinting. Since lactic acid cannot be further broken down for ATP production, the two molecules of ATP from glycolysis are all that can be produced from this type of metabolism. If, however, oxygen is available (aerobic metabolism), then the pyruvate is made into another compound called acetyl-CoA (coenzyme A) and enters the Krebs cycle to produce more ATP. This aerobic metabolism occurs during mild, moderate, and longer-duration exercises such as walking, jogging, or biking.

Krebs Cycle

The *Krebs cycle*, also known as the tricarboxylic acid (TCA) or citric acid cycle, is a series of reactions that continue the breakdown of glucose from glycolysis.

The eight steps of the Krebs cycle are diagrammed in Figure 2.

The Krebs cycle occurs in the mitochondria (the powerhouse of the cell) and ultimately produces both ATP and hydrogen ions. The hydrogen ions (which are transported by the enzymes NAD [nicotinamide adenine dinucleotide] and FAD [flavin adenine dinucleotide]) are used in the electron transport chain to make even more ATP.

Electron Transport Chain

The electron transport chain is the final phase of energy production in the cell and occurs across the membrane of the mitochondria. This pathway takes the hydrogen ions created in the Krebs cycle and uses them to pass electrons down an energy chain to form a proton gradient. This gradient powers ATP synthase at the end of the electron transport chain to produce ATP.

Altogether, during aerobic metabolism, 1 molecule of glucose is able to produce up to 38 molecules of ATP. This is the reason why muscles are able to make enough ATP for long periods of mild to moderate exercise.

Other Energy Sources

If all the glucose is used up and no dietary carbohydrate is available (which can occur during prolonged

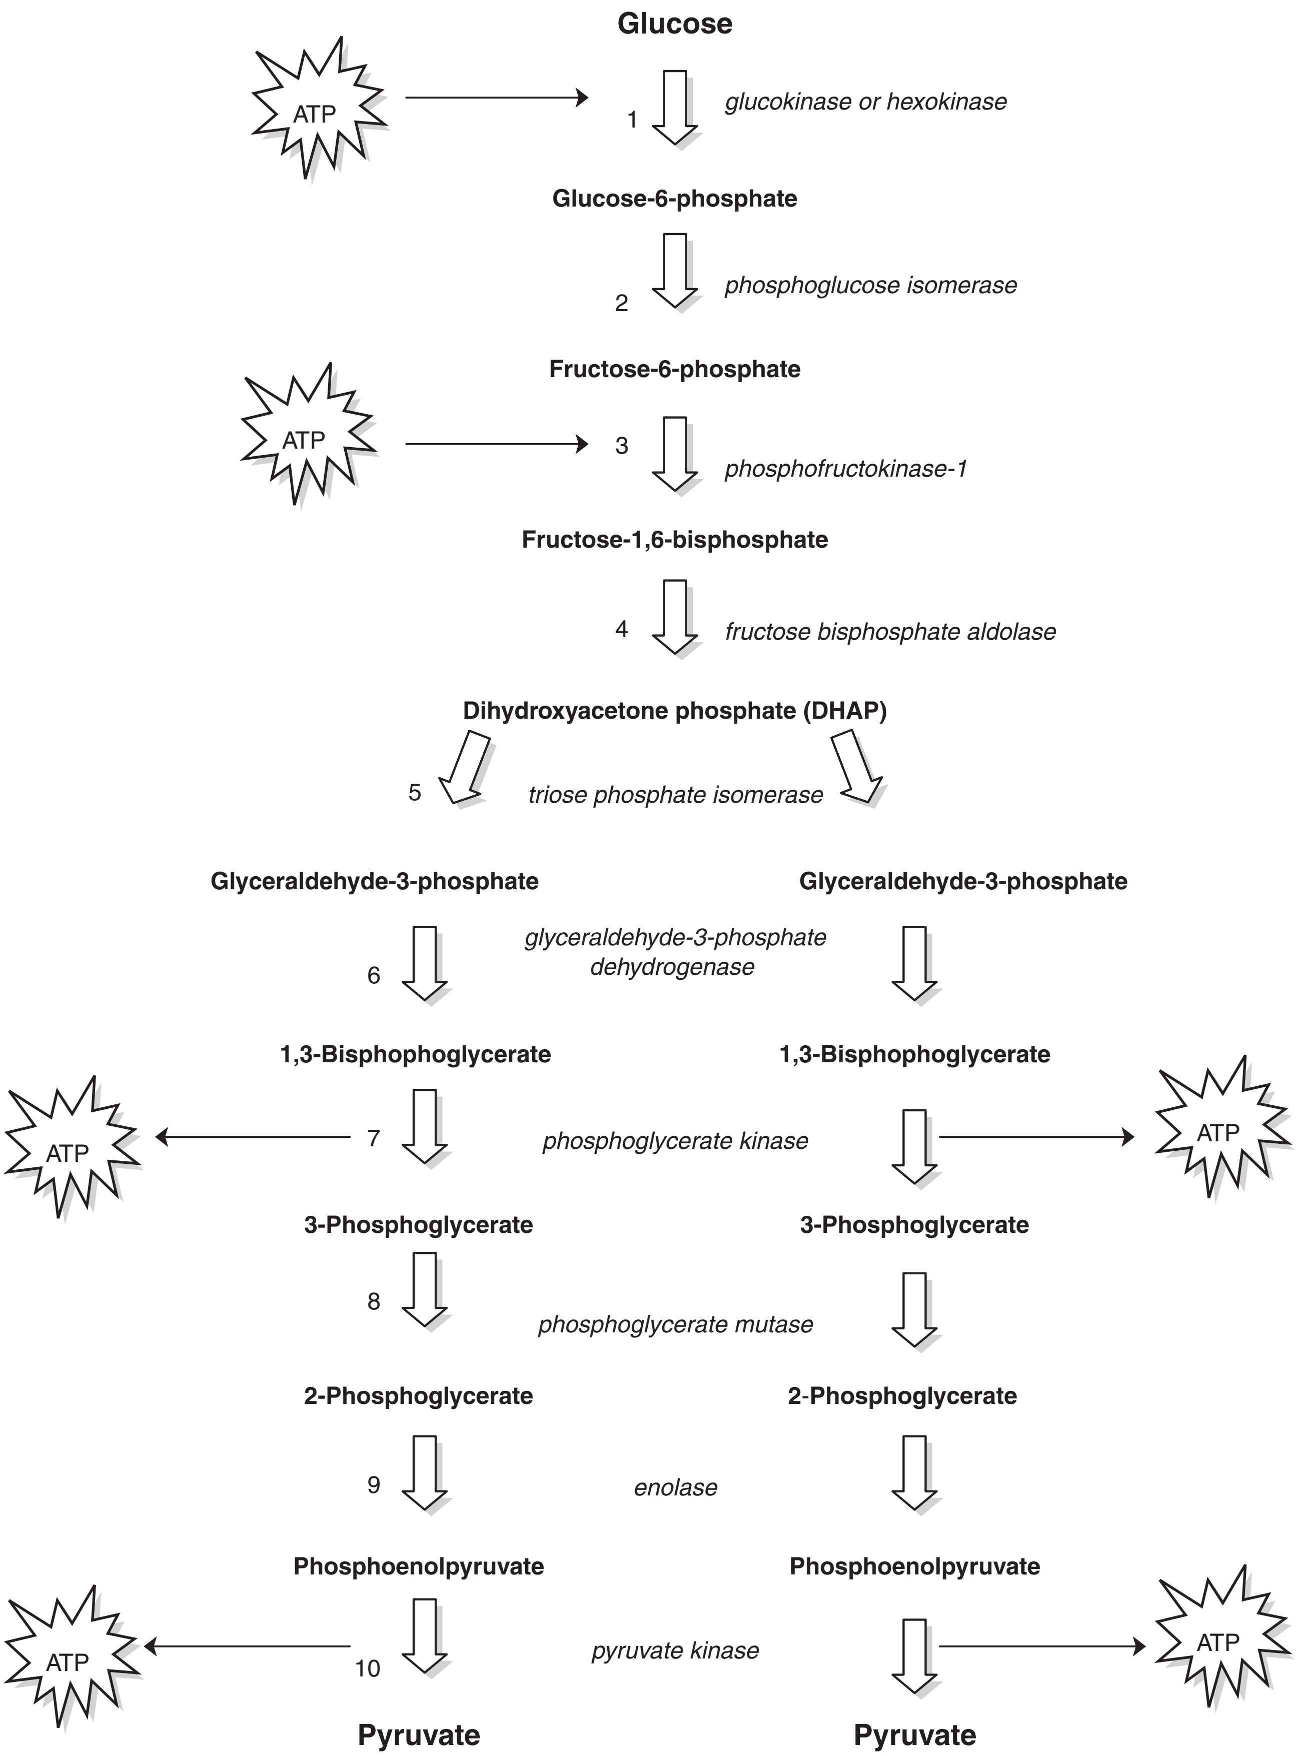

Figure 1 Glycolysis

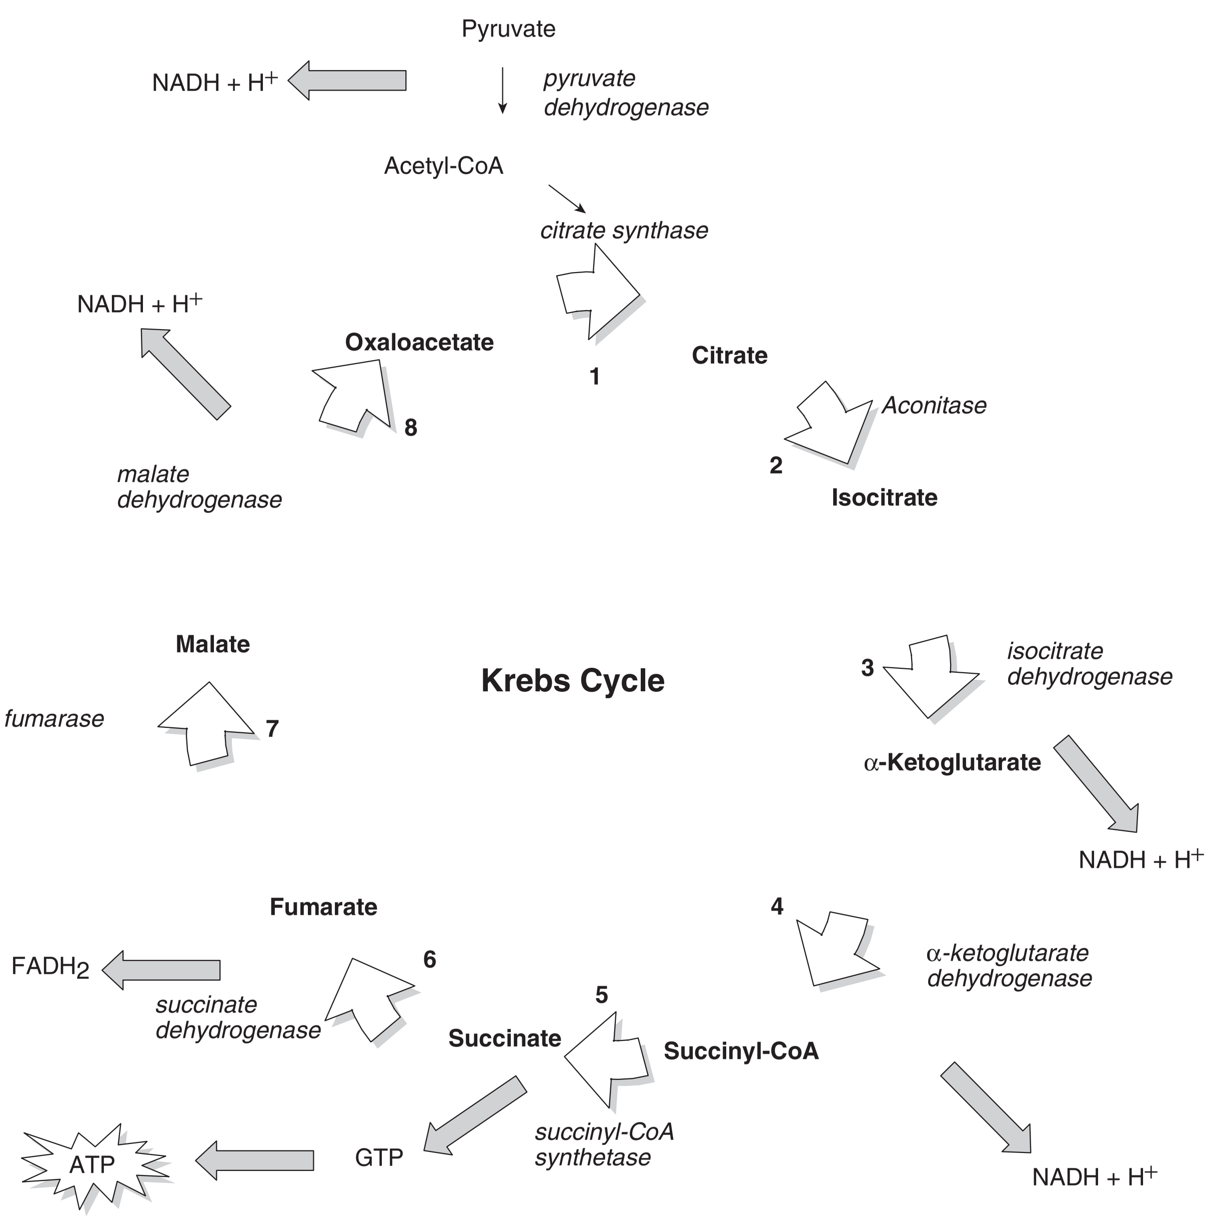

Figure 2 Krebs Cycle

periods of exercise), the body will then rely on other sources of fuel to be converted to glucose and/or acetyl-CoA directly to continue the activity. Dietary fat requires lipolysis and β-oxidation to become acetyl-CoA. Protein requires breakdown into amino acids that can be metabolized to glucose or directly to acetyl-CoA. If dietary glucose, fat, and protein are not available and the glucose stores are used up, the body will resort to using fatty acids and amino acids from the blood and tissues to eventually produce ATP.

Summary

In summary, muscle cells need energy to perform any type of exercise. Anaerobic exercise, such as weight lifting and sprinting, uses the small amount of ATP made through glycolysis. Aerobic exercise, such as light to moderate jogging and biking, uses the much larger amount of ATP made from the combination of glycolysis, the Krebs cycle, and the electron transport chain. These three processes enable cells to have a constant supply of ATP for exercise. If glucose is depleted and oral carbohydrates are not available, these three functions still occur, but less efficiently, as they use the available fatty and amino acid sources.

Leadership in Sports

Leadership refers to the behavioral process of influencing individuals and teams toward the attainment of specific goals. In sports, leadership roles can be prescribed as part of a formal role (e.g., manager, coach, team captain), or it can emerge as part of an informal role (e.g., peer leader, mentor). In the field of sport psychology, considerable attention has centered on the leadership behaviors used by coaches. In particular, research has sought to understand how these behaviors can result in or impair coaching effectiveness.

The multidimensional model of leadership, developed by Packianathan Chelladurai, represents one of the most extensively applied approaches to the study of leadership in sports. Chelladurai proposed that effective leadership is dynamic and based on a complex series of interactions between the coach, his or her athletes, and situational constraints. Specifically, Chelladurai recognized that the leadership behaviors of a coach are influenced by the personal characteristics of the coach (e.g., the experience of the coach), the characteristics of the situation or context in which the coaching takes place (e.g., the competitive level), as well as the personal characteristics of the athletes being coached (e.g., the age of the athletes). Of particular note, Chelladurai proposed that coaches will be most effective, and athletes most satisfied, when there is a direct congruence between a coach's *actual* behaviors, those behaviors *preferred* by his or her athletes, and the behaviors identified by the situation as being *required* for the athletes to perform successfully.

A recent example from the field of professional (American) football aptly describes the importance of ensuring that the actual, preferred, and required behaviors of coaches are directly aligned. After a disappointing season in 2006, Tom Coughlin, head coach of the New York Giants, became the focus of much media scrutiny as reports of player discontent and team disharmony abounded. He was considered by many observers to be an autocratic coach with an explosive temper. However, in the buildup to and during the 2007 season, Coughlin markedly adjusted his leadership style. He sat down to talk with his players to find out what they were thinking and opened up channels of communication. The previously stern coach went bowling with his players to establish rapport, and he empowered the players by involving them in the decision-making processes of the team. This approach appeared to be effective, as the New York Giants went on to defeat the heavily favored, and previously undefeated, New England Patriots at Superbowl XLII. Although several factors invariably go into determining team success, what this example clearly illustrates is that coaches can work at, and improve, their coaching behaviors to meet the needs of their team. To quote the well-known American football coach Vince Lombardi, "Leaders are made, they are not born; and they are made just like anything else, through hard work."

Relationship Quality

From a relationship-oriented perspective, the British-based psychologist Sophia Jowett has emphasized that for coaches to develop effective and mutually beneficial relationships with their athletes, three distinct relational needs require attention. The first of these, termed *closeness,* refers to the affective ties between the coach and the athlete, and it reflects the degree to which athletes and coaches like, respect, and trust one another. Second, Jowett proposed that for relationships to function effectively, both the coach and the athlete must report positive intentions to remain in the partnership. This reflects a high degree of *commitment* between the coach and the athlete. Finally, the extent to which the coach and the athlete work together to attempt to improve performance, through inclusive, responsive, and reciprocal behaviors (*complementarity*), also forms a central component of the coach–athlete relationship. A growing body of evidence has provided support for Jowett's framework, whereby the extent to which coaches and athletes report closeness, commitment, and complementarity has been found to predict outcomes such as relationship longevity and sustained athlete performance.

Coaching Efficacy

Beyond relationship quality, sport psychology researchers have also been particularly interested in understanding the extent to which the various psychological characteristics of the coach relate to athlete development. One such psychological characteristic that has received considerable attention relates to the effects of coaches' *efficacy beliefs*. Coaching efficacy corresponds to the extent to which coaches are confident in their abilities to influence the learning, development, and performance of their athletes. Deborah Feltz and her colleagues have developed a multidimensional model of coaching efficacy that has been used in numerous observational as well as intervention-based studies. In this model, Feltz suggested that coaches can display confidence in relation to different aspects of their trade, including confidence in their abilities to (a) coach during competition and lead their team to successful performance (game strategy efficacy), (b) mold the psychological skills and states of their athletes (motivation efficacy), (c) teach sport-specific skills (technique efficacy), and (d) influence the personal development of their athletes (character-building efficacy). In general, when coaches are confident in their own capabilities, they tend to make use of more positive instructional behaviors, resulting in their athletes being more satisfied with them, and ultimately, their athletes tend to perform better than athletes with inefficacious coaches. Interestingly, research on coaching efficacy also provides some support for the existence of a *Pygmalion effect,* whereby athletes internalize the cognitions of their coaches. Specifically, when coaches are confident in their capabilities, they tend to display more confidence in the abilities of their athletes. This, in turn, translates into athletes having more confidence in themselves.

Leadership: Transactional and Transformational

A noteworthy approach, and one that has only recently received sustained interest in the sports sciences, centers on the distinction between *transactional* and *transformational* leadership. Developed originally by the prominent organizational psychologist Bernard Bass, this model considers *transactional leadership* to involve the use of contingent rewards and corrective behaviors to eliminate problems and gain compliance among followers. *Transformational leadership,* on the other hand, involves actions that transcend one's own self-interests, whereby leaders influence others by elevating the goals of followers and empowering them to go beyond minimally accepted standards. According to Bass, transformational leadership is not a substitute for transactional methods. Instead, transactional leadership provides the basis for effective leadership, and transformational behaviors build on the transactional base in contributing to the extra effort and performance of individuals and teams. Transformational leadership consists of four components: (1) *idealized influence,* which involves engendering the trust and respect of others through the demonstration of personally held values and beliefs; (2) *inspirational motivation,* which involves providing a compelling vision of the future and displays of optimism about what others can accomplish; (3) *intellectual stimulation,* which involves engaging the rationality of others by encouraging them to think about old problems in new ways; and (d) *individualized consideration,* whereby leaders recognize the needs of others and display genuine care and compassion. In sports settings, transformational leadership behaviors, as displayed by coaches, have been found to result in higher levels of intrinsic motivation among athletes, increased performance, a reduced likelihood of athletes aggressing and engaging in injurious acts, as well as improved ratings of coach effectiveness. What is particularly interesting about this body of research evidence, and has particular relevance for coaching development programs, is that transformational leadership can be taught and developed through workshop-based and mentoring interventions.

Exercise Instructor Behaviors

While the majority of leadership research in the field of sports science has centred on understanding the determinants and consequences of coaching effectiveness, a growing body of enquiry has also centred on the nature of leadership behaviors within more general exercise- and health-related settings. In particular, research has examined the relationships between exercise instructor behaviors and class member adherence. Effective exercise instructors have been found to use socially enriched leadership styles, whereby the psychological needs and aspirations of group members are met. Examples of such behaviors might include using participants' names, giving frequent individual attention, providing positive feedback, and recognizing and rewarding participants' efforts.

Conclusion

Over the past few decades, several theoretical models concerned with the study of leadership have been proposed and empirically tested. However, four key features appear to pervade these diverse approaches. First, leadership happens at both an *individual* and a *group* level. Second, leadership is a *process* that can change or direct the behavior of individuals. Third, leadership is fundamentally *interpersonal,* requiring interaction and communication between the leader and individuals (or groups). Finally, leadership focuses on *achievement;* it is concerned with directing individuals toward set objectives or goals. In light of the prominent role of leaders in sports and exercise contexts and their effects on follower cognition, motivation, and behavior, the study of leadership remains a fruitful area of research.

Lean Body Weight Assessment

The muscles, bones, ligaments and tendons, tissues, and water of the body make up *lean body weight*. Conversely, the amount of fat in the body is the *fat body weight*. Muscle tissue is 18% to 20% denser than fat. A liter (L) of muscle weighs about 1.06 kilograms (kg), whereas 1 L of fat weighs about 0.9 kg.

People may of course look very different even though they have the same height and weight. While one may look soft and "pudgy," another may be thin and muscular. Thus, body composition cannot be determined accurately simply by standing on the scale and measuring one's weight. In studying body composition, body mass is usually divided into two categories: the fatfree mass (FFM) and the fat mass (FM).

Body fat decreases and muscles become more developed in a person who is exercising to get fit. Pants may become tighter and the waistband may become looser. This informal measure of lean body weight may be good enough for many people. However, a more formal test, called body fat composition test, is needed for athletes and for those who are serious about their fitness.

Body composition is determined using several methods, the four most common of which are as follows.

Skin Fold Thickness

To measure skin fold thickness, the thumb and forefinger are used to grasp the skin and the nearby underlying tissue, pulling it away and pinching it using calipers that apply a constant pressure of 10 grams per square millimeter. Each site is measured twice to get more accurate and reproducible measurements. However, the accuracy of the measurements using this method depends on the skill of the measuring person and the part that is measured. Additionally, a very large increase or decrease in the skin fold thickness can increase the error. Several equations are used to predict body FM from skin fold measurements, but certain equations are recommended.

Underwater Weighing

The first method of underwater weighing was described in 1961. This method is based on Archimedes's principle that the volume of an object submerged in water equals the volume of water displaced by the object. The difference between the weight measured in water and the weight measured in air, after correcting for the water's density, is the body volume. In this system, a stainless steel tank filled with water is used. The subject kneels on a cot on top of strain gauges at the bottom of the tank. When using this technique, it is necessary to measure the lung volume under water. This contributes approximately 1 to 2 L to the total body volume. A pneumatic valve system is used to measure this residual lung volume with the underwater weighing.

Electrical Impedance

Electrical conduction in a biological conductor (a living organism) is related to its content of electrolytes and water; the more the electrolytes and water, the better is the electrical conduction. In bioelectrical impedance, only the body's FFM is measured because fat conducts electricity poorly and the FFM holds most of the body's water and electrolytes.

The ratio of the voltage to the current flow on a pair of terminals is called impedance and is expressed in ohms. Impedance, in direct current (DC) circuits is identical to resistance, but in alternating current (AC) circuits, it is a function of resistance, capacitance, and inductance. In AC circuits, voltages from the inductors and capacitors oppose the flow of current; this is called reactance. Impedance is calculated by combining reactance with resistance. There are many theories behind the use of impedance for body mass measurement and the calculations used to measure impedance.

To measure electrical impedance, aluminum electrodes are placed in the middle of the back of the hands and feet near the knuckles, on the inside of the wrist about one third of the way out, and between the two prominent bones of the ankle. Then, 800 microamperes of current at 50 kilohertz is run through the electrodes, and the resistance and reactance values are measured. Calculating conductance using the lowest resistance value allows the prediction of FFM.

Conclusion

Age, sex, and height are taken into account in all these methods that require calculations. Lean and fat percentage is the result. A man has a normal body fat of 8% to 15% and a woman, 13% to 20%. Fat percentages below 10% may be seen in elite female athletes and as low as 3% in elite male athletes. The normal range is what most people aim for. Taking up regular aerobic exercise and decreasing the fat in one's diet helps bring the fat percentage down if a person is above the normal range.

Legal Aspects of Sports Medicine

The term *sports medicine* encompasses the activity of many individuals from a number of professions who provide a variety of services or products. It includes physicians and other health care providers such as chiropractors, physical therapists, and podiatrists, as well as product salespersons and a diverse group of service providers.

Accordingly, any review of the legal aspects of sports medicine must necessarily involve a preliminary examination of the term *sports medicine* itself, which might be succinctly and broadly defined from a legal standpoint as follows:

> The provision, primarily of medical or allied health care to athletes, exercisers, recreational enthusiasts and others and the delivery of preventive, primary or rehabilitative care related to the prevention, treatment or rehabilitation of injuries and conditions related to sport, exercise or recreational activity, as well as the rendition of service and advice for fitness and training purposes to individuals who desire to engage in the aforementioned activities, and secondarily, the provision of medically or non-medically related services or products to those who are interested or involved in sport, exercise or recreation even though in this latter sense, the use of the term "medicine" may be inherently inappropriate. (*Legal Aspects of Sports Medicine,* 1995, by D. L. Herbert, p. 8)

Commentators and organizations that have looked at this topic area have also determined to define sports medicine in such a way as to make it broader than the mere medical treatment of just injuries and more comprehensive than the treatment of injuries related solely to participation in sports since most of the definitions that have been offered include not only services provided for the treatment of injuries but also the provision of services related to illness and injury prevention as well as rehabilitation. In addition, many definitions include activities that are broader than just participation in sports and include activities related to fitness, recreational pursuits, and other similar pastimes or endeavors. Some of these definitional references for the term *sports medicine* can be located in a number of journals, magazines, and other professional publications and were nicely summarized in a 2000 publication ("Australian Sports Medicine Specialty Faces Political Hurdles," published in *The Physician and Sports Medicine*).

For the purposes of this entry, sports medicine does involve the provision primarily of health care–related services to those sports, fitness, and recreation participants in need of medical, surgical, preventive, and rehabilitative treatment or service. As such, it is primarily carried out by those who are licensed and regulated at the state level through various state-enacted health care provider practice laws and administrative regulations. However, others who are not so regulated are also involved to some degree in the provision of activities that could be included within the broad umbrella of sports medicine services. In this latter context, such individuals may include exercise physiologists, clinical exercise physiologists, personal fitness trainers, athletic trainers, and others, some of whom are licensed or otherwise regulated and some of whom are not so licensed or regulated.

Any examination of the legal aspects of sports medicine must primarily concentrate on using a medical/health care model to discuss various legal concepts that affect primarily those in the health care provider sector. Sports medicine activities in this context involve a number of functions that are carried out through those providing sports medicine services. These include pre-activity screenings; pre-activity clearance decisions based on those screenings; preventive techniques designed at increasing the strength, stamina, and athletic/fitness capacity of those about to engage in activity; maintenance of levels of minimal or even optimal sports or fitness readiness/participation, detection, treatment, and rehabilitation of a variety of injuries or conditions that affect those participating in sports; and provision of related services ancillary to any of these main functions. Some of these particular service areas involve a number of heightened legal concerns that should be briefly examined and include, among others, issues related to informed consent/screenings/clearance for participation and return-to-participation decisions as made by sports medicine health care providers. Each of these subject areas involves certain legal issues, and each has resulted in claims, lawsuits, and court decisions. These cases have in turn established certain sports medicine legal concepts and, in some cases, legal precedents. An examination of these topics should be of assistance to this overall discussion.

In this context, it is important to mention that the delivery of sports medicine services is affected in substantial part by reference to various practice guidelines, standards, position statements, or parameters of practice. A significant number of these statements have been developed and published in the medical/health care provider field since the last quarter of the 20th century. The trend has continued to this date.

There are literally hundreds of practice statements directly or indirectly applicable to the field of sports medicine. These statements have been developed by a number of professional associations, including the American Academy of Family Physicians (AAFP), the American Academy of Pediatrics (AAP), the American Academy of Podiatric Sports Medicine (AAPSM), the American Academy of Sports Physicians (AASP), the American College of Cardiology (ACC), the American College of Sports Medicine (ACSM), the American Heart Association (AHA), the American Medical Association (AMA), the American Medical Society for Sports Medicine (AMSSM), the American Orthopaedic Society for Sports Medicine (AOSSM), and the American Osteopathic Academy for Sports Medicine (AOASM), among others. Similar statements have also been promulgated by other groups involved in exercise activity, athletic training, sports, or recreation. These include the American Council on Exercise (ACE), the Aerobics and Fitness Association of America (AFAA), the American Athletic Trainers Association (AATA), the National Athletic Trainers Association (NATA), the National Strength and Conditioning Association (NSCA), the National Collegiate Athletic Association (NCAA), and many others.

All the standards statements developed by these and other groups attempt to define and delineate aspects of the care made available to client/patient populations by providers and to put forth statements defining acceptable service delivery to clients/patients in practice areas of concern (e.g., concussion recognition and treatment). Consequently, such statements also have the potential to be used as references to define the standard of care offered to patients from a legal perspective and then to be used to judge the quality of care provided by means of claims and litigation. Expert witnesses typically support their opinions as given in litigation on the basis of such statements, either to attack the care that is rendered in particular cases or to support that care.

Six sports medicine groups, the AAFP, AAP, ACSM, AMSSM, AOSSM, and AOASM, have all joined in the development and publication of a frequently cited sports medicine monograph statement titled *Preparticipation Physical Evaluation,* third edition, which is one of the principal practice statements for the delivery of specified sports medicine services. This statement is extremely important to this aspect of sports medicine service, reportedly since clearance decisions for about 12 million athletes are made per year. A fourth edition of this work was published in May 2010 (http://ppesportsevaluation.org/body.html).

A brief examination of the legal aspects of sports medicine follows.

Informed Consent

One of the very basic rights of all individuals whose rights are safeguarded through the American system of jurisprudence is the right to determine what will be done to or with one's body. As part of that right, each individual about to undergo some medical procedure is entitled to be provided with sufficient information to enable the person to determine whether he or she will choose to undergo such a procedure or treatment process.

The informed consent process involves the provision of relevant information as to the proposed treatment, the available alternatives to that treatment, and the risks and benefits associated with the treatment or with any decision to forgo treatment so as to enable the patient to make an informed decision about whether to undergo the treatment or procedure. The process is therefore a give-and-take one that involves the provision of information by a provider to a patient, who then weighs or evaluates that information and makes a decision about the care that will be provided to him or her.

In sports medicine, a number of cases have arisen in some situations as to whether or not health care providers have properly engaged in such a process with patient–athletes. In one such well-known case, a professional football player, Charles Krueger, contended in litigation that he was not provided with sufficient information to enable him to determine whether or not he should continue to participate in professional football given the injuries that he had suffered and the treatment provided to him during his many years of participation in that sport (see *Krueger v. San Francisco Forty Niners,* 1987).

Another case involved a young college basketball player (Hank Gathers) who died during participation in a collegiate basketball game. After his death, his estate filed a lawsuit contending that the athlete was not given sufficient information to enable him to determine if he should continue to participate in college basketball given his condition and the treatment provided to him, which his estate later contended was improper and led to his death (see "The Death of Hank Gathers: An Examination of The Legal Issues," 1990, by D. L. Herbert).

Screenings/Clearance for or Return to Participation

While these two cases also involved, among other things, issues related to whether the involved sports medicine practitioners should have cleared these particular patient–athletes to participate or return to participation, both cases were settled prior to full adjudication. As a consequence, no judicial rulings specifying the exact duties of sports medicine practitioners to patient–athletes in these particular cases were established as precedents. Each of these cases, however, emphasized the need for injured/ill athletes to be properly screened, evaluated, and cleared for participation or return to participation by sports medicine health care providers.

Sports medicine practitioners must provide athletes, like all patients in other contexts, with sufficient medical information to enable these athletes as patients to determine their own course of treatment and in this context also determine whether they will continue to participate or return to athletic participation. The information conveyed by the providers and the recommendations made to each athlete must be in-depth and complete and must be provided without undue interference from any other third parties, such as coaches, administrators, fans, parents, and even, in some cases, the athletes themselves, many of whom desire to participate despite injury or illness. In the course of making recommendations and clearance decisions in this regard, providers must exercise due caution and resist being influenced by the sometimes overwhelming desire of some athletes to be cleared to participate or continue to participate in sports. Sometimes, athletic awards, college scholarships, or even large financial incentives may be the motivation behind the competitive expectations and plans of these patient–athletes. However, sports medicine providers must base their decisions and recommendations solely on applicable medical standards and guidelines and the best interests of their patients. Otherwise, deficiencies in this regard can well be actionable from a legal perspective, as the previously mentioned two cases and a number of others readily demonstrate.

While the foregoing areas of sports medicine have involved a number of claims and litigations beyond merely the Krueger and Gathers cases, other factual scenarios have also resulted in legal claims and suits. These cases have arisen out of alleged improper clearance decisions based on negligence/malpractice (failure to follow the accepted standard of care); mismatching of athletic participants; improper rehabilitation; inappropriate or improper prescription of activity, exercise, rehabilitation, even preparticipation screenings; and a host of other issues.

Conclusion

Health care providers in all areas of relevant service provision, including those involved in the delivery of sports medicine services, are obligated to render competent service in accordance with the so-called standard of care. In the United States, the evaluation of the standard of care is based on a national standard and is generally determined by expert witnesses, most of whom use written statements, guidelines, or so-called *parameters of practice* to define the appropriate standard of care to be provided to patients in particular circumstances. While such statements can be used either as swords to attack the alleged substandard care that is provided to athletes or as shields to protect against claims and suits, the legal concerns related to the delivery of sports medicine care can be complex but can be properly managed through the delivery of appropriate services to athletes.

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes disease (LCPD) is a form of osteonecrosis, or dying bone, of the hip that is found only in children. It is known by other names as well, including coxa plana, ischemic necrosis of the hip, osteochondritis, and avascular necrosis of the femoral head. It is caused by a block of the blood supply to the developing femoral head, resulting in injury to the bone from lack of blood and nourishment (avascular necrosis). The disease is self-limited and usually lasts 1 to 2 years.

Cause

The cause of LCPD is not known. Some mechanism, whether it is traumatic disruption of the blood supply or injury from infection around the blood supply, causes an interruption of blood flow to the head of the femur (the leg bone that connects the hip to the knee). No known effective prevention exists for LCPD.

Who Gets Legg-Calvé-Perthes Disease?

LCPD is generally diagnosed in children between the ages of 4 and 11 years. It is a rare disease that affects approximately 1 in 1,200 children. Boys are affected more than girls; only about 1 in 4 diagnosed children is a girl. Most children with LCPD are affected only in one hip. Approximately 15% of children with LCPD have it in both hips. Children who develop the disease are generally very active and athletic. Children who are small for their age, with delayed skeletal maturity, are more likely to get LCPD.

The disease is found more often in Asians, Eskimos, and Caucasians. A much lower incidence of the disease is found in Australian aboriginals, Native Americans, Polynesians, and African Americans. Furthermore, exposure to secondhand smoke is correlated with increased risk of LCPD.

Symptoms

The onset of LCPD is often insidious. The first symptoms are usually a limp and sometimes pain in the hip, groin, or knee (pain in the groin or knee stemming from a hip problem is called "referred pain" and is common with hip problems). Parents usually notice the limping while the child is playing. The child does not remember getting hurt in any particular incident. Some children have hip pain or referred pain, and some children have no pain at all. A child with LCPD may tend to bear less weight on the involved leg while standing and may prefer to stand or lie down with the affected leg externally rotated (turned outward).

Diagnosis

A physician performs a physical exam and often orders imaging tests for children with a limp and/or leg pain. For children with LCPD, the physical exam often reveals pain and decreased range of motion when the hip is internally rotated (turned in toward the midline of the body) and when the hip is abducted (moved straight out from the midline of the body).

The physician may order X-rays, an MRI, and/or a bone scan to help determine the diagnosis. X-rays and other studies may be normal if taken early in the course of the disease. Late stages of the disease can show extensive disruption of bone in the femoral head.

Determining Disease Severity

In general, younger children usually have milder involvement of the hip bone and an easier recovery because new bone growth typically reshapes better in younger children than in older children.

Several different classification systems are used to determine the severity of the disease and the prognosis. These classifications are based on the extent of bony disruption seen on X-ray during the course of the disease, and they help physicians to determine the prognosis and appropriate treatment for patients.

Treatment

Treatment of LCPD has four primary goals:

1. To reduce hip irritability
2. To restore and maintain hip mobility
3. To prevent the ball of the femoral head from extruding or collapsing
4. To regain the spherical shape of the femoral head

For young children with minimal symptoms and X-ray findings at the time of diagnosis, doctors will often take a "watch and wait" approach. They will recommend that the child reduces his or her activity level and follow the child closely for signs of disease progression. Physical therapy to maintain good hip range of motion is often also recommended.

Nonsurgical treatments for LCPD include crutches to treat pain associated with weight bearing on the affected leg, as well as casts, traction, and braces to help with range of motion in the hip.

Patients who are diagnosed late in the disease course or who fail to respond to nonsurgical treatment will be considered for surgery.

A *tenotomy* is a surgery that is done to release a muscle that has become weak and short from limping. Once the muscle is released, a cast is placed on the leg to allow the muscle to regrow to a more natural length. The cast is usually left in place for 6 to 8 weeks.

An *osteotomy* is a surgery that involves cutting the bone and repositioning it. This surgery is done to keep the head of the femur in the normal position within the hip.

Long-Term Outcomes

Studies on the long-term results of LCPD demonstrate that the incidence of patients with LCPD who go on to develop osteoarthritis later in life depends on two factors: (1) whether or not the ball of the femoral head reshapes well and (2) whether or not the ball fits well into the hip socket. If the ball does not reshape well but the socket's shape still conforms to the ball, patients will tend to develop mild arthritis in later adulthood. If the ball of the femoral head does not reshape well and does not fit well into the hip socket, patients usually develop degenerative arthritis before the age of 50.

As stated earlier, the younger the age of onset of LCPD, the better the prognosis. In general, most patients have a favorable outcome.

Lightning Injuries

Injuries due to lightning strike constitute the most significant nature-related hazard in sport. Only floods cause more storm-related deaths in the United States. About 600 to 700 lightning strikes occur per year, with 10% of that number causing fatalities. While the likelihood of lightning strike is low, any strike should be considered a life-threatening emergency. Nearly all injuries occur outdoors, through water activities or standing under trees. Lightning injuries involve a direct current that contacts the body by direct strike, side flash, or ground current. Prevention, education, and the development of an emergency action plan are the most important methods to avoid injury.

Clinical Evaluation

Many different organ systems can be damaged by lightning strike:

Skin: Burns caused by lightning strike may range from first to third degree. There is often an entrance and exit location.

Musculoskeletal: Injuries may include fractures, compartment syndrome, muscle rupture, or extremity dislocation.

Otologic: Tympanic rupture is the most serious otologic injury. Vertigo and hearing loss are also common.

Visual: Corneal abrasion, retinal hemorrhage or detachment, hyphema, or dilated pupils may occur. Cataracts are a delayed response.

Neurologic: Neurologic system injuries may occur because nervous tissue has a low resistance to injury. Short-term memory loss, difficulty processing new information, irritability, and distractability are common. Occasionally, personality changes, poor concentration, depression, and difficulty returning to previous levels of function may lead to isolation and avoidance of previously enjoyed relationships or activities. Magnetic resonance imaging (MRI) and computed tomography (CT) scans often appear normal; therefore, clinical suspicion of neurologic changes is paramount.

Cardiovascular: Cardiac arrest is the most serious injury to the cardiovascular system. Resuscitation with an automatic external defibrillator (AED) and cardiopulmonary resuscitation (CPR) are necessary for survival. Elevated cardiac enzymes may also be present on laboratory evaluation.

Prevention of Injury

Preparation for avoidance of lightning injuries must be considered when outdoor activities are contemplated. The National Collegiate Athletic Association has recommended guidelines to prevent lightning hazards. These include the following:

1. Designate a person to monitor the weather and make decisions regarding interruption of sports activity. Make plans to shelter participants and spectators, as well as institute a lightning safety plan to announce warning signals.
2. Use www.weather.gov or the National Weather Service on a daily basis to monitor storm activity in the area.
3. Monitor thunderstorm "watches" (warning signs of severe weather) or "warnings" (reports of severe weather) and take the proper precautions.
4. Know where "safe" structures (buildings with electrically grounded facilities) are located.
5. In the absence of a "safe structure," a vehicle with a hard metal roof with the windows rolled up may prevent injury.
6. Avoid being the "highest point" in the area. Lying down in a ditch, getting out of the water, avoiding touching metal objects, and avoiding open windows and doors are all methods to limit the possibility of lightning strike.
7. If thunder is heard, consider preparing for evacuation. If lightning is seen, consider suspending activities. *The "flash-bang" method is used for measuring the lightning strike distance, which is defined as the time between seeing the lightning and hearing the thunder*

divided by 5. If the time between seeing the lightning flash and hearing the thunder is less than 30 seconds (i.e., 30/5 = 6 miles [mi; 9.66 kilometers, or km]), suspend activities, and relocate the participants.

8. Lightning may strike in the absence of rainfall and cloudy skies and may present 10 mi (16.09 km) from the rain shaft.
9. Avoid the use of landline telephones as they are a possible conduit to current. Cellular phones are safe alternatives.
10. Activities may be resumed 30 minutes after the last flash of lightning and sound of thunder.
11. It is safe to perform CPR and touch individuals who have been struck by lightning as they do not carry an electrical charge. ABCs (airway, breathing, and circulation) and notification of 911, as in all emergencies, are the hallmarks of emergency care.

Little League Elbow

The number of organized sports for children and adolescents has increased dramatically over the past few decades, with millions participating each year. In addition, year-round single-sport training has become much more commonplace among this population, leading to much longer competitive seasons and higher intensities of competition. These factors, along with conditioning and training errors, have resulted in dramatically elevated numbers of pediatric sports–related injuries, especially overuse injuries.

Classic Little League elbow (LLE) refers to an overuse injury of the medial epicondyle (inside part of the elbow), which results from repetitive throwing. The injury occurs at the apophysis, which is a bony outgrowth to which muscles attach. There are several different apophyses throughout our body, but the one associated with LLE is found on the medial epicondyle of the humerus. LLE occurs most commonly in baseball players between the ages 8 and 16 years. It has been estimated that 20% to 40% of 9- to 12-year-old adolescent baseball players suffer from elbow pain.

Repetitive throwing motions can cause an apophysitis, or inflammation of the apophysis. Since this is located on the medial epicondyle, it is also referred to as a medial epicondylitis (inflammation of the inside portion of the elbow). The apophysis is especially susceptible to injury while the growth plates are still active. Similar apophyseal injuries occur at different locations during adolescence, affecting both the heel and the knee region (commonly known as Sever and Osgood-Schlatter disease, respectively). Limiting repetitions, teaching proper mechanics, and a general understanding of skeletal development are all necessary for early recognition of this condition. Early diagnosis and treatment are important for better outcomes and for preventing long-term problems.

Anatomy

The elbow joint is where the humerus and ulna bones connect. This connection, or articulation, is surrounded by a capsule, several ligaments, and also several muscle tendons, which together form the joint. When stress is placed on the outside of the elbow, it is the bony articulation between the humerus and ulna that stabilizes the joint. When stress is placed on the inside aspect of the elbow, as in throwing, the medial collateral ligament serves as the primary stabilizer. Several muscles provide secondary support during throwing. In adult throwing athletes, elbow injuries commonly occur because the excessive forces placed on these ligaments and tendons cause them to fall, resulting in injury. In children, however, growth plates and apophyses are still active and are usually injured before tendons or ligaments. This can have serious long-term implications if the stress continues.

Mechanism of Injury

The throwing mechanism places a lot of stress on the inside of the elbow. This puts tension on the medial structures, including the ligaments and the apophysis. While stress is placed on the inside structures, a corresponding compression results on the outside structures. Overuse syndromes occur from excessive stress placed on muscles, bones, ligaments, and other soft tissue support structures. In LLE, this stress is caused by pitchers throwing at maximal effort. Under a reasonable amount of repetitive stress, the body is able to adapt. With a high number of repetitions of large amounts of force, bone or soft tissue overload will occur. This results in tissue breakdown known as microtrauma. Continuing to overload these structures without adequate recovery periods will lead to continued tissue breakdown. As this pattern continues, injury eventually results. When this occurs in a young thrower's elbow, it results in LLE (Figure 1).

Signs and Symptoms

Although LLE is most commonly found in pitchers, it is also seen in all the other baseball positions as well as in tennis players and football quarterbacks. Athletes may present with an array of symptoms that could include pulling, popping, giving out, or mild tenderness around the inside portion of the elbow. They also may have a history of decreased throwing effectiveness, velocity, or distance. However, patients often will not present until they can no longer throw because of extreme pain. On physical exam, there will likely be point tenderness over the inside elbow and pain associated with resisted flexion and resisted pronation (turning the hand with the palm facing alternately up and down). If swelling or restricted range of motion is observed, then this can be an indication of a more advanced injury.

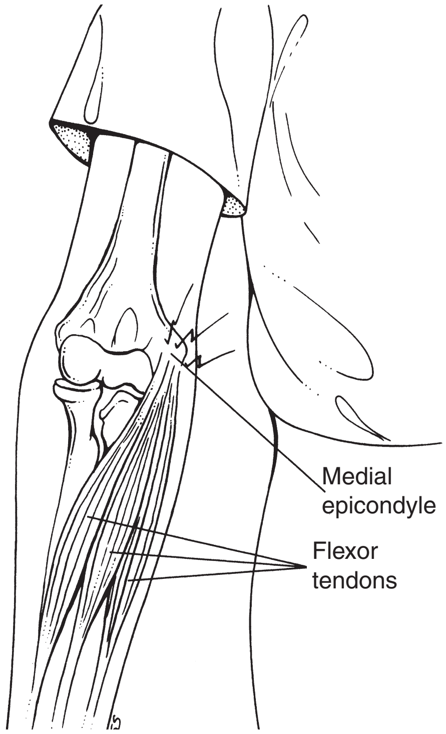

Figure 1 Little League Elbow

Notes: Little League elbow is the common term for damage to the growth cartilage on the inner aspect of the elbow of children and adolescents. If caught early enough, the separated growth cartilage can reattach.

Diagnosis

Diagnosing LLE is primarily done through the history and physical exam. The history would include when the symptoms started, what started them, and the progression until presenting to the physician. All pediatric and adolescent athletes complaining of any amount of medial elbow pain should be examined for LLE. In most instances, elbow X-rays should be taken from several different angles to make sure that there is no avulsion, loose bodies, or other bony changes. Any of these findings would complicate the injury and change the treatment plan. It is helpful to order X-rays of the opposite elbow as well so that the physician can compare the two sides, looking for abnormalities. X-ray films are found to be normal up to 85% of the time. A magnetic resonance imaging (MRI), computed tomography (CT), or bone scan of the elbow is rarely indicated in LLE but may be helpful if the patient fails to show signs of improvement after treatment.

Treatment

Treatment begins with rest from throwing that typically lasts 2 to 6 weeks. During this time, the athlete should be encouraged to begin or continue general conditioning, endurance training, and core strengthening exercises. Ice application on the area and nonsteroidal anti-inflammatory medication may also be helpful for pain and inflammation. Range-of-motion exercises followed by some stretching and strengthening exercises with resistance bands or light dumbbells are usually performed during the resting period. After the prescribed period of rest, a slow progressive throwing program should be implemented for several weeks before return to competition. During this time, the thrower's mechanics should be evaluated and corrected to decrease the chances of a recurring injury. The average time to return to unrestricted play is 12 weeks.

Complications

Most complications arise from a thrower returning to competition too soon or continuing to play while symptomatic. Continuing to throw with pain is associated with increased risks of more serious injuries that may require surgery.

Prevention

Preventing LLE should be a priority in all Little League throwing athletes. This is best achieved by first making sure that all pitchers are taught to incorporate proper form and mechanics. Next, core and muscle strengthening and stretching exercises should be implemented. This should include year-round conditioning with proper warm-ups prior to pitching. The most important aspect of prevention is monitoring the total number of competitive pitches that are being thrown both in practice and in games. The current recommendations for 8- to 14-year-olds ranges from 50 to 75 pitches in a game, 75 to 125 in a week, and a total for all age-groups of 1,000 pitches for an entire season. Although the risk of throwing breaking pitches at a young age is still not fully known with regard to Little League elbow, the USA Baseball Medical and Safety Advisory Committee currently recommends that pitchers under 13 should throw only fastball and change-ups. It further recommends that those under 10 should throw only fastballs.

As players, parents, and coaches work together, Little League elbow may in large part be prevented from becoming a problem.

Little League Shoulder

Little League shoulder is a clinical entity in which there is proximal humeral (shoulder bone) pain associated with throwing and there is radiographic evidence of a widened proximal humeral physis (growth plate). The diagnosis is typically made by history and physical exam findings. However, chronic changes such as demineralization, sclerosis, or fragmentation of the proximal humeral metaphysis (the flared end of a long bone) can also be seen on plain X-ray. It is not certain whether Little League shoulder is caused by inflammation secondary to overuse or a stress injury at the proximal humeral physis. Little League shoulder has also been described as proximal humeral epiphysitis, proximal humeral epiphyseolysis, and rotational stress fracture of the proximal humeral epiphyseal plate. If properly diagnosed and treated, Little League shoulder is a benign and self-limiting condition. However, if proper time off from throwing is not given, Little League shoulder may develop into premature closure of the proximal humeral physis and, thus, growth retardation of the humerus.

Anatomy

The shoulder joint comprises the head of the humerus as well as the glenoid fossa of the scapula (shoulder blade), hence the term *glenohumeral joint*. It is a classic ball-and-socket joint, and it is the most mobile joint in the body. The humerus is a typical long bone and like all long bones consists of a diaphysis, metaphysis, physis (growth plate), and epiphysis. The *diaphysis* is defined as the main shaft of the long bone. The *metaphysis* is considered the flared end of the long bone. The *physis* is the growth plate where expansion of the bone takes place in the skeletally immature. This appears as a radiolucent gross horizontal line on plain X-rays. The physis is not visible in adults. Last, the *epiphysis* is the end of each long bone.

The rotator cuff muscles attach at the epiphysis of the proximal humerus and aid in pulling the head of the humerus into the glenoid fossa. Little League shoulder does not involve the rotator cuff muscles. However, the condition does affect the physis and possibly epiphysis, without injury to the rotator cuff muscles of the shoulder.

Causes

Little League shoulder is a clinical entity caused by inflammation secondary to overuse or a stress injury at the proximal humeral physis. In theory, chronic overuse of the shoulder in a skeletally immature child causes strain in the weakest area of the glenohumeral joint, which happens to be the

Table 1 Recommended Maximum Number of Pitches With Respect to the Age of the Athlete

Age (years)	*Pitches per Game*	*Pitches per Week*	*Pitches per Season*	*Pitches per Year*
9–10	50	75	1,000	2,000
11–12	75	100	1,000	3,000
13–14	75	125	1,000	3,000

Source: Based on USA Baseball Medical and Safety Advisory Committee Guidelines of May 2006.

Notes: Pitch count limits pertain to pitches thrown in games only. These limits do not include throws from other positions, instructional pitching during practice sessions, and throwing drills, which are important for the development of technique and strength. Backyard pitching practice after a pitched game is strongly discouraged.

Table 2 Recommended Minimum Number of Rest Day(s) After Throwing a Certain Number of Pitches in a Game

Note: Throwing curveballs and sliders, especially with poor mechanics, puts the pitcher at an increased risk of injury.

physis. An inflammatory cascade causes pain and tenderness to the proximal physis with any overhead activity or, if severe, even at rest. The long-term sequelae of a physeal injury are the possibility of premature closure of the physis and, thus, growth retardation of the humerus.

Symptoms

Little League shoulder typically occurs in patients between the ages of 11 and 16. Although classically this clinical syndrome occurs in baseball pitchers, it can also arise in a baseball player of any position, racquet sports players (i.e., tennis, badminton), swimmers, and even gymnasts.

Symptoms typically occur over several months and consist of progressive pain and discomfort at the proximal humerus with throwing, especially with high-velocity pitches and at higher pitch counts. The symptom of pain usually worsens to the point where the child develops pain even with light throwing and at low pitch counts. Furthermore, pitch control and command are lost as symptoms advance.

In addition, the symptoms of pain and discomfort can occur at any point of the pitching motion. Initially, the symptoms of pain resolve over the course of 24 hours. However, increased recovery time is evident as the child continues to throw with this condition. An athlete who has rested a few days may not present with pain to the physician. Moreover, it is not uncommon to receive the history of a child who is on multiple baseball teams during the season and plays a throwing sport year-around.

Diagnosis

Little League shoulder should be suspected when the above symptoms are elicited from the patient and his or her parents. On physical exam, there can be tenderness to palpation of the lateral aspect of the proximal humerus. There can also be discomfort with internal or external rotation against resistance with the shoulder at 90° of abduction. Furthermore, simple abduction of the shoulder at 90° against resistance may also be distressing.

However, there is typically no effusion, muscle atrophy, or loss of active or passive range of motion. There may be some discomfort when testing the strength of the rotator cuff muscles, but this is not due to a rotator cuff injury, which is exceedingly rare in a skeletally immature child.

When Little League shoulder is suspected, plain anteroposterior radiographs of both shoulders in internal and external rotation should be taken for comparison. Classically, a widening of the proximal humeral physis will be seen, although symptoms may precede radiographic changes. On occasion, chronic changes such as demineralization, sclerosis, or fragmentation of the proximal humeral metaphysis can also be seen. Magnetic resonance imaging (MRI), computed tomography (CT), and SPECT (single-photon emission computed tomography) are not needed to make the diagnosis of Little League shoulder and should not be ordered.

Treatment

The treatment for this condition is almost always nonsurgical. The athlete should be taken out of sports that require any kind of throwing or swinging of the symptomatic shoulder. It is recommended that these activities should be avoided for a period of at least 3 months. Nonsteroidal anti-inflammatory drugs or acetoaminophen can be started briefly for acute pain relief.

Physical therapy can be started when the patient is clinically asymptomatic. Rotator cuff strength, scapular stability, and general shoulder flexibility should be emphasized during physical therapy. However, if the patient has any symptoms of discomfort at the proximal humeral physis during therapy, then shoulder rehabilitation should be temporally discontinued.

Before gradual progressive throwing can be reinstituted, the patient needs to be completely asymptomatic on physical exam. This includes testing for apprehension, range-of-motion limitations, and weakness or discomfort in the rotator cuff muscles. Gradual progressive throwing is defined as subtle increases in the number of pitches, the types of pitches, the throwing distance, and the pitching velocity over a 1- to 2-month period. Any return of symptoms during this planned pitching should warrant a return visit to a physician for a repeat physical examination. Depending on the severity of the symptoms and the physical exam findings, a decision will be made about further rest and rehabilitation or the need to back down pitch count, distance, or the types of pitches being thrown.

Last, the decision to allow the athlete to resume throwing should not be based on radiographic evidence of healing, which may take several months. In fact, proximal humeral physeal widening is possibly an adaptive change in throwing athletes and, thus, would signify a normal finding if not associated with any symptoms. Again, Little League shoulder is mostly a clinical diagnosis.

Prognosis

If properly diagnosed and treated, Little League shoulder is a benign and self-limiting condition. Greater than 90% of athletes who develop Little League shoulder are asymptomatic on return to sports. The most prominent long-term sequela of Little League shoulder is premature closure of the affected proximal humeral physis. Although not many long-term studies have been done on this condition, it appears that premature physeal closure is an extremely rare complication after proper treatment.

Pitch count limitations, the number of rest days between pitching outings, and a gradual increase in the types of pitches thrown are the keys to preventing upper extremity pathology in a young athlete. Tables 1 to 3 provide pitching recommendations for injury prevention.

Liver Conditions, Hepatitis, Hepatomegaly

The liver, which is involved in numerous bodily functions including metabolism, aiding in digestion, and removal of toxic substances, can be affected by a variety of conditions causing liver enlargement (hepatomegaly) and inflammation of the liver (hepatitis). Common causes include infection, toxins as in alcohol abuse causing cirrhosis, malignancy (cancer or tumors), steatosis (fatty liver), and trauma. It is important not to allow an athlete with an acutely enlarged or damaged liver to participate in sports because of risk of rupture and threat of further severe injury.

The liver is the largest internal organ in the body and is located in the right upper quadrant of the abdomen just below the diaphragm under the right costal margin and to the right of the stomach. Normally, the liver, soft and smooth in consistency, can be slightly palpated just below the ribs, though in certain conditions, the liver can be enlarged with a tender edge, suggesting inflammation as in hepatitis, or firm and hard with irregular borders and nodules, indicating a malignancy. Other symptoms of liver abnormalities, particularly from infection and alcohol abuse, include yellowing of the skin and eyes, called *jaundice*. A detailed history is essential for an evaluation, with attention to the use of vitamins, supplements including anabolic steroids, or medications; alcohol and drug use; sexual activity; family history; and any history of blood transfusions. Further work-up includes laboratory studies to check liver enzymes, viral hepatitis serologies (blood serum), a complete blood count, image testing such as ultrasonography, and possibly a liver biopsy. With acute hepatitis, the athlete should have no evidence of hepatomegaly, along with normal liver function tests, before safely returning to play. There is also risk of transmission of certain acute viral hepatitis infections to teammates and opponents.

Cases have been reported of vigorous and endurance exercises creating a temporary increase in liver enzymes, causing a pseudohepatitis. The levels of liver enzymes return to normal within 3 days of stopping the exercise.

Liver trauma in athletes occurs with a direct blow to the right upper quadrant of the abdomen or lower ribs or from a deceleration force seen in noncontact sports such as cycling and snowboarding. Most commonly, hepatic contusions and hematomas result though liver lacerations, and rupture can occur, causing intra-abdominal bleeding and hemodynamic instability. Fortunately, the majority of liver injuries stop bleeding spontaneously. Persistent right upper quadrant tenderness along with nausea and vomiting need further evaluation, including an abdominal ultrasound or a computed tomography (CT) scan. Treatment consists of rest, observation, intravenous fluids, and, rarely, surgery to control bleeding. Full healing of the liver injury needs to be documented before allowing the athlete to return to play.

Lower Back Contusion

In everyday life, the lower back maintains posture in sitting, standing, walking; in sports, it has a wide variety of functions. For the throwing athlete, proper transfer of forces from the lower extremity to the upper extremity requires energy transmission through the muscles. Back injuries are very common, accounting for about 10% to 15% of sports injuries. It has been estimated that about 7% of injuries involve muscle contusions. Overall, muscle contusions represent up to 55% of all sports injuries. Fortunately, they are often minimally significant, demonstrating minor bruising. However, contusions will diminish the ability to condition the core, which is often overlooked in sports.

Muscle injury may be classified as contusion, strain, or laceration. *Lacerations* of back muscles are uncommon in sports. *Strains* are common and involve tensile overload forces that are applied to the muscle tendon unit; these are discussed in other entries of this encyclopedia. *Contusions* are caused by a traumatic impact or compressive force applied to the muscle.

Anatomy

The back gets its shape from the vertebral column, which includes the cervical spine of the neck, the thoracic spine of the chest, and the lumbar spine of the lower back. The lower back includes the lumbar vertebrae and sacrum. The smaller motion muscles of the back include the multifidi, which span only a couple of segments, and the larger muscles that span the entire circumference of the lower abdomen and back. Finally, there are the larger groups that connect the upper trunk and lower trunk, such as the latissmus dorsi and gluteus maximus.

Physiologic Response

Muscle tissue injury recovers by a process of repair. It does so in three distinct phases. The first phase is the destructive phase. There is acute rupture followed by necrosis of the muscle cells. This also involves variable collection of blood called a hematoma. Inflammatory cells also participate in this phase. The second phase is the repair phase, when the muscle cells are regenerated and there is connective tissue scar formation. The concern here is contracture with extensive scar. The third phase is the remodeling phase, in which the new muscle cells mature and the scar tissue remodels.

Common bruising is a minor contusion with capillary leakage of red blood cells. Most often, bruising is indeed minor and disappears in 2 to 4 weeks. However, certain individuals are more prone to bruising, such as women, children, elderly people, those taking blood thinners, and individuals with genetic bleeding disorders. Severe contusions may lead to pain and impaired movement due to scar tissue formation. Large hematomas may further limit motion and enhance scar formation. Rarely, a contusion with hematoma may stimulate bone formation in the muscle, called *heterotopic bone formation.* This latter entity is most common in the thigh and the elbow.

Clinical Presentation and Evaluation

Athletes will present with a history of a direct-impact injury. They will manifest localized pain, tenderness, and swelling. Discoloration may occur, with typical bruising progressing through four phases. Initially, it is bluish-red, followed by reddish-blue. It then turns to greenish-yellow and, finally, brown. These represent the breakdown phases of blood cells. Most significantly, the athlete will present with decreased movement. It is important to rule out an underlying, more significant injury. This would include spinal fracture and abdominal injuries such as a kidney laceration. An X-ray or bone scan should be considered to definitively rule out fractures. Fractures will usually manifest with tenderness to direct spinal palpation. If there is a question, a plain radiograph will help distinguish a fracture. Further imaging is often not needed. Magnetic resonance imaging (MRI) may aid in ruling out muscle tearing, but its expense often does not justify its use. A simple ultrasound image is an effective tool with minimal expense in the detection of hematoma and muscle disruption.

Treatment

Rehabilitation for a lower back contusion can usually be done from home. The initial phases of care should follow the RICE pattern of *r*est, *i*ce, *c*ompression, and *e*levation. This refers only to the first couple of days. Although early mobilization is helpful in muscle regeneration, a couple of days of rest will diminish scar tissue formation and risk of rerupture. Ice and compression during this time will limit swelling.

After the first 3 to 5 days, muscle activation is done in a sequential manner. Isometric strengthening is started, whereby the muscle is kept at a constant length with progressively more resistance, provided there is no pain. This may be accomplished with a simple bridging maneuver. Once this is painfree, isotonic strengthening is started with the muscle length changing while the tension remains constant. This is often done with theraband resistance. Finally, dynamic training is done when the first two phases are painfree. It is important to warm up the muscles first in these phases to allow flexible muscle motion and shock absorption. Stretching may be combined with warming to maximize the elasticity and diminish muscle contractures. If the athlete is unable to progress after the first 3 to 5 days of rest, careful attention should be given to looking for other problems such as a large hematoma that may need ultrasound drainage or occult fractures.

Application of alternating hot packs and cold packs at this stage may be helpful. This may assist in stretching the muscles. Early aerobic activity would include walking, swimming, and biking as able. One must stop if pain persists. Elastic bands and lumbar corsets can be used to assist with lower back support. These can be quite helpful in mobilizing the athlete. Medications such as an anti-inflammatory may be recommended in severe cases. Acetaminophen has been shown to be equally effective. Injection of corticosteroids will give an initial boost to pain reduction but will diminish the effectiveness of long-term healing with more disarray of the scar tissue. Electrical stimulation has been shown to be effective in strengthening the muscle during immobilization as well as in decreasing pain. Ultrasound treatments can increase blood flow to the area. Massage is also helpful in breaking up scar tissue. This is started with light traction and advances as the athlete's recovery progresses.

Strength training for the lower back should include bilateral arm lifts, alternate arm and leg lifts, prone on elbows, prone press up, roman chair, arm lifts, and leg lifts. Once the athlete has progressed through the strengthening phases, the sport-specific or functional phase must be addressed. In this phase, the athlete gradually mimics the motions that will be required in the specific sport.

Return-to-Sports Criteria

Ideally, the athlete should be painfree with full core strength and stability prior to returning to play. This will usually start with noncontact practice drills and is followed by progressively more contact time. If there is some residual tenderness, a corset brace or pad can be very useful when returning to sports.

Lower Back Injuries and Low Back Pain

Low back pain is a very common complaint in the general population, as well as in athletes. Up to 85% of the population will experience back pain at some point in their lives. It can interfere with daily activities as well as training. Low back pain is the most common disability in those under 45 years of age. The incidence of low back pain in sports is about 10% to 15%, with certain sports having even higher incidences. Gymnastics, both artistic and rhythmic, have incidences of low back pain between 50% and 86%, whereas about 27% of college football players experience low back pain.

The causes of low back pain are significantly different between adults and youth. Bony injuries are more common in young athletes, whereas disk-related problems are relatively uncommon. Idiopathic pain is much less common among young athletes than in adults. Because structural injuries are more common in young athletes, investigations should be pursued earlier and more thoroughly in younger age-groups. The diagnosis of "back strain" in young athletes should be a diagnosis of exclusion to avoid missing serious structural injuries.

Lower back injuries occur as a result of acute trauma or from repetitive microtrauma or overuse. Acute trauma occurs most often in contact sports such as football, rugby, and hockey. Overuse injuries occur most often in sports with repetitive flexion, extension, and torsion, such as gymnastics, dance, and figure skating.

More sinister causes of low back pain should not be overlooked. Infection, neoplasm, visceral pathology, and inflammatory conditions can cause low back pain. "Red flag" symptoms such as fever, night pain, weight loss, and neurological symptoms should prompt investigation for these other serious conditions.

Risk factors for low back pain are listed in Table 1.

Anatomy

The lumbosacral or lower back spine comprises five lumbar vertebrae, the sacrum, and the coccyx. Occasionally, there may be anatomical variants, such as a sacralized fifth lumbar vertebra, a lumbarized first sacral segment, or a spina bifida occulta.

Each lumbar vertebra has both anterior and posterior elements. The vertebral body, intervertebral disks, and vertebral end plates constitute the anterior elements. The posterior elements include the facet joints and pars interarticularis. Between each pair of vertebrae is an intervertebral disk, the central core of which is the *nucleus pulposis,* a gel-like substance contained by the *annulus fibrosis,* concentric rings of fibrocartilage that enable the disk to act as a shock absorber, resilient to compressive forces. The interface between the disk and the vertebral body is formed by the cartilaginous end plates. Circumscribing the end plates is the cartilage ring apophysis, which eventually fuses with its vertebral body.

There are several bony prominences off the posterior arch that interconnect through multiple

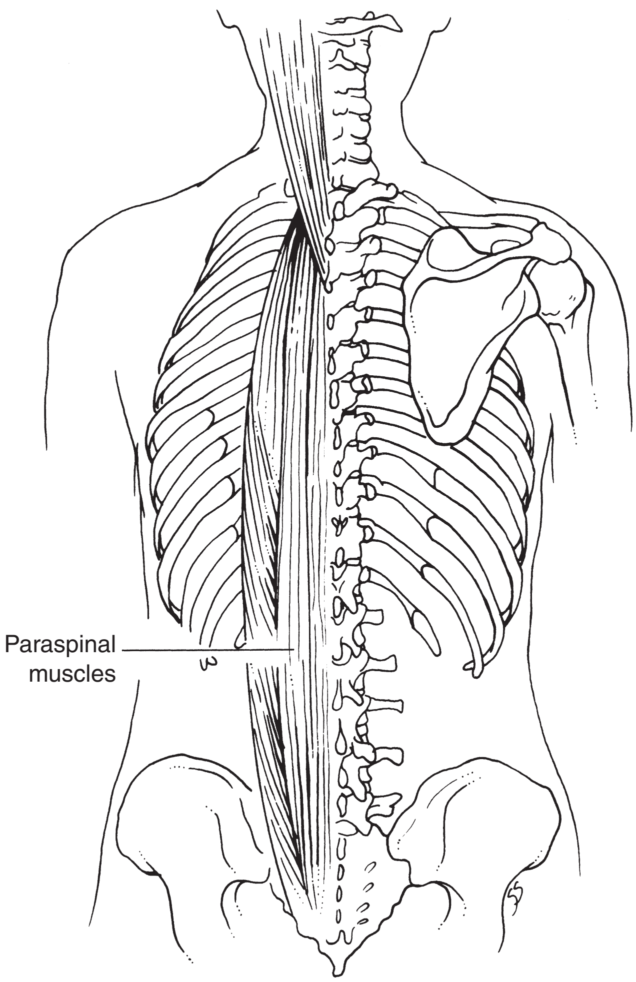

Figure 1 Paraspinal Muscles, or Erector Spinae

Notes: The paraspinal muscles both stabilize the spine and generate spinal movement. They work with a complex system of muscles in the chest, abdomen and pelvis to create spinal stability such as sitting and standing as well as bending and twisting motions.

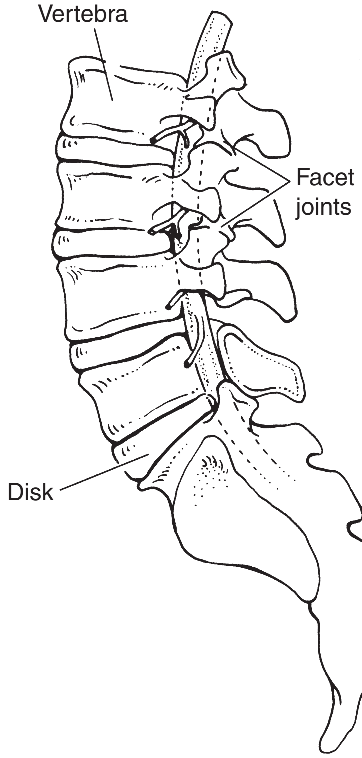

Figure 1 The Lumbar Spine

Notes: The lumbosacral spine consists of five lumbar vetebrae, the sacrum, and the coccyx. Many people associate low back– pain with the condition of the "slipped" or herniated disk, in which the a tear in the fibrocartilage around the intervertebral disk allows the soft nucleus pulposis to emerge and come into contact with nerve fibers.

ligaments. These ligaments offer stability to the spine. Furthermore, the ligaments have nerve fibers and provide a function called *proprioception*, which is the way the brain recognizes how the back is positioned at any given moment. This proprioception is critical for proper core muscle activation as the spine is subjected to various forces in sports activity.

There are a number of muscles around the spine. (Most of these are addressed in the entry Core Strength.) In short, the core muscles form a circumferential hydrostatic drum from the back round to the abdomen. These stabilize the spine and generate power to the upper and lower extremities. The pelvic muscles, such as the gluteus maximus and medius, stabilize the pelvis and aid in transfer of force. The latissimus dorsi and rectus abdominus transfer forces between the upper and lower trunk. The upper trunk refers to the shoulder girdle muscles.

The sacroiliac joints form part of the pelvic ring and have both a synovial portion and a ligamentous portion.

Physiology

Muscle injury is classified as a contusion, laceration, or strain. Contusions are discussed in the entry Lower Back Contusion. Lacerations to the lumbar muscles are exceedingly uncommon. Strains represent a shearing force to the muscle tendon unit. Every muscle transitions to a tendon at the muscle–tendon juncture. A tendon attaches from muscle to bone. The tendon crosses a joint, and muscle contraction occurs to provide joint motion. Conversely, a ligament attaches from bone to bone, and an

Table 1 Risk Factors for Low Back Pain

Risk Factors
Sedentary occupation
Heavy physical labor; jobs involving bending, twisting
Periods of growth
Muscle imbalances, inflexibility (hamstring tightness, hip flexor tightness, thoracolumbar fascia tightness)
Sports involving repetitive spinal extension, rotation
Volume of training (increased back pain with increased training hours)
Poor technique
Biomechanical abnormalities (genu recurvatum, increased femoral anteversion, increased thoracic kyphosis)

injury to it is referred to as a sprain. Muscle strains occur in the lower back when a sudden motion occurs that applies a shear force to the muscle–tendon juncture and ruptures it in this location. This is usually reflective of chronic overload, which may occur with deconditioning and postural imbalances. Muscle strains also often occur when the muscles are fatigued, such as late in a competition.

After a strain to the muscle, tissue recovery follows three sequential phases. The initial phase is the destructive phase, with muscle necrosis and inflammation. The second phase is the repair phase, with production of new muscle cells and scar tissue formation. The final, and longest, phase is the remodeling phase. Treatments are aimed at minimizing the destructive phase and enhancing the repair and remodeling phases.

Ligamentous injuries have similar repair processes of inflammation, repair, and remodeling. They are classified as Grade I, with minimal intrasubstance tear; Grade II, with a partial tear but some contiguity of the fibers; and Grade III, with a complete rupture. After a ligamentous tear, the ligaments repair with an immature Type III collagen, possibly predisposing to repetitive injury.

Evaluation of Injuries

Details of Injury

Low back pain can result from various causes. The onset of symptoms can help distinguish between acute trauma and more gradual, insidious causes. Details of the pain, including its duration, location, quality, and severity, as well as aggravating and relieving factors, and any neurological symptoms, such as numbness or shooting pain, can also help determine the cause of low back pain.

An athlete's activity, including the type of sport, position played, volume of training, and level of competition, may predispose him or her to back injuries. In particular, recent increases in the volume or intensity of training or changes in training can result in back pain. A history of menstrual irregularities, disordered eating, and previous stress fractures may indicate the presence of female athlete triad, which may predispose an athlete to stress fractures.

A family history of human leukocyte antigen B27 (HLA-B27)-associated conditions, such as inflammatory bowel disease, psoriatic arthritis, or ankylosing spondylitis, may suggest the possibility of a rheumatological cause for low back pain. The presence of any "red flag" symptoms suggests more sinister causes of low back pain, such as infection or cancer. Other causes of back pain include kidney disease, bowel disease, and gynecological disease.

Physical Findings

Athletes with low back pain may have abnormalities of gait and posture, such as a limp or unsteady gait. When looking at the back from behind, the athlete's pelvis and shoulders may not be level, and there may be asymmetry of the bony and soft tissue structures on either side of the spine. There may be skin abnormalities, such as hairy patches, skin dimples, hemangiomas, or café au lait spots, which may indicate spinal pathology. There may also be spinal abnormalities, such as scoliosis, kyphosis, or excessive lordosis. From the side, there should be a gentle lumbar lordosis. To assess for scoliosis, an Adam forward bending test can be performed to look for a rib hump. The examiner stands behind the patient as the patient bends forward with the arms hanging down.

Range of motion of the spine includes flexion, extension, lateral flexion, and rotation. Athletes should be able to flex forward, keeping their knees straight, and touch their toes, but tight hamstrings may limit forward flexion. Low back pain associated with flexion suggests injury to the anterior elements of the spine or muscle strain/spasm. Extension-related back pain suggests injury to the posterior spinal elements or the sacroiliac joint. A single-legged hyperextension test can assess for possible injury to the posterior elements. The athlete stands on one leg and extends through the spine. A positive test elicits pain in the back of the ipsilateral leg.

Palpation of the spine and sacroiliac joints may elicit areas of tenderness. Palpation of the soft tissues, such as the paraspinal muscles and buttocks, may also elicit tenderness and muscle spasm.

Special tests in the examination of the lumbar spine include the FABER (*f*lexion, *ab*duction, *e*xternal *r*otation) test, the Gaenslen sign, and the straight-leg test. The FABER test and the Gaenslen sign assess the sacroiliac joint. The FABER test is performed with the patient lying supine, with the hip flexed, abducted, and externally rotated and the foot resting on the opposite knee. The examiner then presses the flexed knee into the table while stabilizing the opposite hip. A positive test elicits pain in the back on the ipsilateral side of the flexed leg.

The Gaenslen sign is also performed with the patient in the supine position. The patient holds one leg with knee flexed to his or her chest while the opposite leg is extended over the edge of the table. The examiner applies downward pressure on the leg hanging over the table edge. A positive test elicits pain in the back on the ipsilateral side of the hanging leg.

The straight leg raise test assesses for neural tension. The patient lies supine, and the examiner raises one of the patient's legs until the patient reports severe back or buttock pain or the knee starts to bend. The examiner then dorsiflexes the ankle to determine if the pain has increased. A patient with no neural tension should be able to raise the leg close to 90° without pain.

Back injuries can sometimes involve the spinal cord and nerves. There may be abnormalities of sensation and strength, and deep tendon reflexes of the lower extremities. There may be marked tightness of the hamstring muscles. If low back pain is referred from the hip, there may be decreased range of motion of the hip or pain with hip movement. Back pain that is referred from abdominal organs may result in tenderness at the costovertebral angle (the area next to the spine below the ribs) or abdominal tenderness.

Investigations

X-rays are the most common investigation ordered for low back pain. In younger athletes with symptoms lasting more than a couple of

Table 2 Lower Back Injuries

Common	*Uncommon*	*Cannot Be Missed*
Spondylolysis (stress fracture of pars interarticularis)	Disk prolapse	Malignancy
Sacroiliac joint pathology	Spondylolisthesis	Infection (osteomyelitis, diskitis)
Disk pathology	Spinal canal stenosis	Osteoid osteoma
Hip pathology	Acute vertebral fractures	Osteoporosis
Contusion	Rheumatological	
Muscle strain/ligament sprain	Visceral pathology (gastrointestinal, genitourinary, gynecological)	

weeks, X-rays should be done to rule out structural injuries. In acute injuries where fractures are suspected, X-rays should be done.

A computed tomography (CT) scan can be helpful to diagnose bony injuries such as pars interarticularis fractures and acute fractures. This modality can be used to monitor progress of healing of fractures, although it involves a significant amount of radiation.

Bone scan with SPECT (single-photon emission computed tomography) is a very sensitive test for diagnosing structural injuries such as pars interarticularis fractures, as well as infectious processes.

Magnetic resonance imaging (MRI) can elucidate soft tissue injuries such as disk herniations. Clinical correlation is required, however, as MRI can often overcall abnormalities.

Types of Injury

A list of injuries of the lower back is given in Table 2.

Treatment

Treatment of muscle strains and ligament sprains is managed in a similar fashion. During the first few days, there is relative rest to allow for the muscle tendon unit and ligaments to start repair with minimal inflammation and muscle necrosis. During this time, the principles of RICE (*r*est, *i*ce, *c*ompression, and *e*levation) are maintained. Elevation usually refers to injury to the limbs. The ice and compression work by limiting the swelling.

After the first couple of days, early mobilization is initiated. The intense spasm is addressed with different heating mechanisms, including moist heat, ultrasound, and electrical stimulation. Another strong adjunct during this early phase is joint mobilization, which may be performed by those trained in joint mobilization, including osteopathic and chiropractic techniques. Massage may be very effective here as well. During this phase, the strengthening follows a typical pattern, starting with isometric training, where the muscle contracts with no motion, such as a bridging posture. Once this is mastered without pain, isotonic training is started, with muscle motion but constant resistance, such as theraband exercises. Once this is mastered without pain, dynamic strength training is started. Throughout these strengthening progressions, stretching is performed through the zone of comfort and enhanced by warming the muscle groups before the stretch. This warming enhances muscle viscosity and shock absorption. In the athlete who has difficulty progressing, a corset brace with a posterior molded plastic pad is helpful in giving security for increased motion.

Medications may also be considered. Although somewhat controversial, nonselective nonsteroidal anti-inflammatory medications such as ibuprofen and naprosyn appear to assist in the rehabilitative process without diminishing ligamentous healing. Other good analgesics such as acetaminophen or stronger tramadol may be considered. Muscle relaxers should be used for significant spasm. Cyclobenzaprine is useful at night to assist with sleeping.

Once the athlete has progressed with advanced strengthening, the sport-specific or functional phase of rehabilitation is addressed. Here, the athlete will start on plyometric exercises as well as drills that mimic the specific sports activity. This is a commonly missed step in rehabilitation, which may predispose the athlete to recurrent injury.

Prevention of Injury

Most back injuries and back pain in athletes can be prevented. Before each sports season, a preparticipation evaluation may identify certain risk factors, such as previous injuries that have not been fully rehabilitated, or muscle weaknesses or inflexibility. These factors can then be corrected before the season starts. Athletes should also begin general strength and fitness conditioning to get ready for the season. The frequency and intensity of training should be gradually increased to allow for safe adaptation to the demands of the sport.

In younger athletes who are still growing, loss of flexibility and muscle imbalances associated with growing can predispose them to injury. Therefore, young athletes should reduce the amount of training and the volume of repetitive motions during periods of rapid growth. Core-strengthening exercises and hamstrings and hip flexor stretches may help reduce the risk of low back pain.

Proper technique is very important to avoid injury. For all athletes, correct posture limiting excessive lordosis of the lumbar spine can help prevent injuries to the lumbar spine. In sports requiring lifting, such as dance and pairs skating, proper lifting techniques must be used to prevent back injuries.

Return to Sports

Recommendations regarding return to play for an injured athlete must take into account the diagnosis, the sport or activity, and the amount of cooperation from the athlete and coaches in allowing activity modifications during healing. As part of the rehabilitation process, risk factors such as muscle imbalances and inflexibilities should be identified and corrected.

Generally, relative rest is necessary to allow for healing. Activities causing pain should be avoided until the athlete can participate without pain. With modifications of the activity, most athletes are able to continue in their sport. Bracing is often used to allow healing while the athletes continue in their sport. Good core strength must be demonstrated by a number of tests, such as a stable single-leg squat, holding a crunch position with stability, and maintaining a neutral spine for at least 1 minute on the roman chair. As the rehabilitation program proceeds, the athlete should progress through sport-specific training prior to resuming sports activity. The athlete should demonstrate proper technique for the sport-specific activity. For instance, the crew athlete should demonstrate good pelvic posture during the catch and layback phases of the stroke. Furthermore, muscular endurance should be demonstrated by the ability to maintain this posture for prolonged periods on the erg machine. Finally, return to competition should be approached in a progressive manner by applying the general rule of increasing the amount of time in activity by about 10% per week. When the athlete has attained painfree range of motion with all activities and has regained full strength, he or she can return to full sports participation.

Lower Back Muscle Strain and Ligament Sprain

Back pain in the athlete is a common finding, and muscle injuries are one of the most common causes of back pain. Muscle injury may involve a contusion or a strain of the muscle. A contusion represents a traumatic blow to the spine. Although there is often an acute moment that the athlete recalls as the onset of pain, a strain usually represents a chronic overload with an acute episode, when it is recognized. Ligamentous sprains about the spine usually represent an acute overload to the spine. Although these are usually benign injuries, incomplete recognition and rehabilitation often lead to chronic pain and poor athletic performance. This is usually due to the reflex inhibition of the surrounding core muscles.

Anatomy

The spinal column consists of the 7 cervical vertebrae, 12 thoracic vertebrae, 5 lumbar vertebrae, and the sacrum. Low back pain refers to pain around the lumbar spine and sacrum. The spinal vertebrae are composed of the vertebral body and the posterior bony arch. This arch forms the spinal canal for the traversing spinal cord and nerves. The anterior vertebral body is separated from the level above and below by intervertebral disks. The posterior arch or canal is separated from the adjacent levels by the two facet joints. There are several bony prominences off the posterior arch, that interconnect through multiple ligaments. These ligaments offer stability to the spine. Furthermore, the ligaments have nerve fibers and provide a function called proprioception, which is the way the brain recognizes how the back is positioned at any given moment. This proprioception is critical for proper core muscle activation as the spine is subjected to various forces in sports activity. The intervertebral disk itself is a series of well-organized concentric ligament sheaths that surround the gelatinous inner substance.

There are a number of muscles around the spine; these form a circumferential hydrostatic drum from the back around to the abdomen. These stabilize the spine and generate power to the upper and lower extremities. The pelvic muscles, such as the gluteus maximus and medius, stabilize the pelvis and aid in transfer of force. The latissimus dorsi and rectus abdominus transfer forces between the upper and lower trunk. The upper trunk refers to the shoulder girdle muscles.

Physiology

Muscle injury is classified as contusion, laceration, or strain. (For a discussion of contusions, see the entry Lower Back Contusion.) Lacerations to the lumbar muscles are exceedingly uncommon. Strains represent a shearing force to the muscle tendon unit. Every muscle transitions to a tendon at the muscle-tendon juncture. A tendon attaches from muscle to bone. The tendon crosses a joint, and muscle contraction occurs to provide joint motion. Conversely, a ligament attaches from bone to bone, and an injury to the ligament is referred to as a sprain. Muscle strains occur in the low back when a sudden motion occurs that applies a shear force to the muscle-tendon juncture and causes a rupture in this location. This is usually reflective of chronic overload that may occur with deconditioning and postural imbalances. Muscle strains also often occur when the muscles are fatigued, such as late in a competition.

After a strain to the muscle, tissue recovery follows three sequential phases. The initial phase is the *destructive* phase, with muscle necrosis and inflammation. The second phase is the *repair* phase, with production of new muscle cells and scar tissue formation. The final and longest phase is the *remodeling* phase. Treatments are aimed at minimizing the destructive phase and enhancing the repair and remodeling phases.

Ligamentous injuries have similar repair processes of inflammation, repair, and remodeling. Ligamentous injuries are classified as Grade I, with minimal intrasubstance tear; Grade II, with a partial tear but some contiguity of the fibers; and Grade III, with a complete rupture. After a ligamentous tear, the ligament repairs with an immature Type III collagen, possibly predisposing to repetitive injury.

Clinical Presentation and Evaluation

Athletes with a ligamentous sprain or muscle strain will present with acute back pain. They will usually recall one moment of pain onset but may have some preceding, milder pain. The pain is very positional and worsens with activity. While swelling is a common finding with contusions, spasm is a common association with sprains and strains of the spine. This spasm may be quite debilitating. Typically, the athlete will manifest no boney spinal tenderness and will lack any neurologic symptoms such as numbness or weakness.

If there is any question of spinal tenderness or trauma, a plain X-ray should be performed. Further imaging is most often not useful. Most ligamentous sprains and muscular strains will resolve in the first couple of weeks, and advanced imaging is not needed. However, in the unusual case when pain lasts longer than 3 to 6 weeks, further imaging is indicated. If a disk problem is considered, a magnetic resonance imaging (MRI) scan is useful. A bone scan is very helpful in detecting stress fractures. This is discussed in the Lower Back Injuries and Low Back Pain entry.

Treatment

Treatment of muscle strains and ligament sprains is managed in a similar fashion. During the first few days, there is should be relative rest to allow for the muscle tendon unit and ligaments to start repair with minimal inflammation and muscle necrosis. During this time, the principles of RICE (*r*est, *i*ce, *c*ompression, and *e*levation) are maintained. Elevation usually refers to injury to the limbs. The ice and compression work by limiting the swelling.

After the first couple of days, early mobilization is followed. The intense spasm is addressed with different heating mechanisms, including moist heat, ultrasound, and electrical stimulation. Another strong adjunct during this early phase is joint mobilization, which may be performed by those trained in joint mobilization, including osteopathic and chiropractic techniques. Massage may be very effective here as well. During this phase, the strengthening follows a typical pattern, starting with isometric training, where the muscle contracts with no motion, such as a bridging posture. Once this is mastered without pain, isotonic training is started, with muscle motion but constant resistance, such as theraband exercises. Once this is mastered without pain, dynamic strength training is started. Throughout these strengthening progressions, stretching is performed through the zone of comfort and enhanced by warming the muscle groups before the stretch. This warming enhances muscle viscosity and shock absorption. If an athlete has difficulty progressing, a corset brace with a posterior molded plastic pad is helpful in giving security for increased motion.

Medications may also be considered. Although somewhat controversial, nonselective nonsteroidal anti-inflammatory medications such as ibuprofen and naprosyn appear to assist in the rehabilitative process without diminishing ligamentous healing. Other good analgesics such as acetaminophen or stronger tramadol may be considered. Muscle relaxers should be used for significant spasm. Cyclobenzaprine is useful at night to assist with sleeping.

Once the athlete has progressed with advanced strengthening, the sport-specific or functional phase of rehabilitation is addressed. Here, the athlete starts on plyometric exercises as well as drills that mimic the specific sports activity. This is a commonly missed step in rehabilitation and may predispose the athlete to recurrent injury.

Return-to-Sports Criteria

The athlete with a muscle strain or ligamentous sprain should satisfy certain criteria prior to returning to competition. First, the athlete must be relatively painfree. Occasionally, a corset-type brace may also be used in the early stages of returning to competition. Good core strength must be demonstrated by a number of tests, such as a stable single-leg squat, holding a crunch position with stability, and maintaining a neutral spine for at least 1 minute on the roman chair. Furthermore, the athlete should demonstrate proper technique for the sport-specific activity. For instance, the crew athlete should demonstrate good pelvic posture during the catch and layback phases of the stroke. Furthermore, muscular endurance should be demonstrated by the ability to maintain this posture for prolonged periods on the erg machine. Finally, return to competition should be approached in a progressive manner by applying the general rule of increasing the amount of time in activity by about 10% per week.

Lower Leg Injuries

Lower leg pain is a common complaint in athletes. Both shin and calf pain can persist for months if not appropriately managed. Injuries can be acute, such as fractures of the tibia or fibula, or chronic, resulting from repetitive microtrauma. Traumatic injuries usually occur in contact sports, such as football, rugby, and soccer, and sports such as skiing and snowboarding. Overuse injuries usually occur in sports involving a lot of running and jumping, such as cross-country running, track-and-field events, and basketball. Training errors and inappropriate equipment may contribute to the occurrence of these injuries.

Shin pain can result from acute injuries, resulting in fractures of the tibia and fibula. Nonacute, overuse injuries of the shin usually result from recurrent impact loading, leading to bone stress.

The most common causes of calf pain are injuries to the muscles and tendons. Muscle strains are very common and usually result from a sudden burst of acceleration, such as stretching for a ball in racquet sports. The calf is also a common area of contusions resulting from contact with equipment or other players. Cramping and delayed muscle soreness also frequently occur in the calf.

Anatomy

There are two bones in the lower leg: the tibia and fibula. They are covered by only a thin layer of skin and subcutaneous tissue. Most of the lower leg muscles control ankle and foot motion. The gastrocnemius muscle also flexes the knee. The gastrocnemius is the most likely muscle to be strained in the lower leg.

The muscles of the lower leg are contained in four compartments, separated by fascia. The anterior compartment contains the primary dorsiflexors of the foot: the tibialis anterior, extensor hallucis longus, extensor digitorum longus, and peroneus tertius muscles. These muscles are supplied by the deep peroneal nerve, which is also the sensory nerve for the dorsal web space between the first and second toes. The lateral compartment contains the most important evertors of the foot: the peroneus longus and brevis muscles. The superficial peroneal nerve, a sensory nerve, is also contained in the lateral compartment. The peroneal nerve bifurcates into the deep and superficial branches at the level of the fibular head. At this point, the nerve is quite superficial and is tented across the bone. The superficial peroneal nerve enters the lateral fascia of the lateral compartment at the midpoint of the lower leg and continues to the lateral ankle, where it branches to supply sensation to the distal lateral foot. The superficial posterior compartment contains the medial and lateral heads of the gastrocnemius, which originates on the femur; the soleus, which originates in the lower leg; and the plantaris muscle. The gastrocnemius and soleus have a common

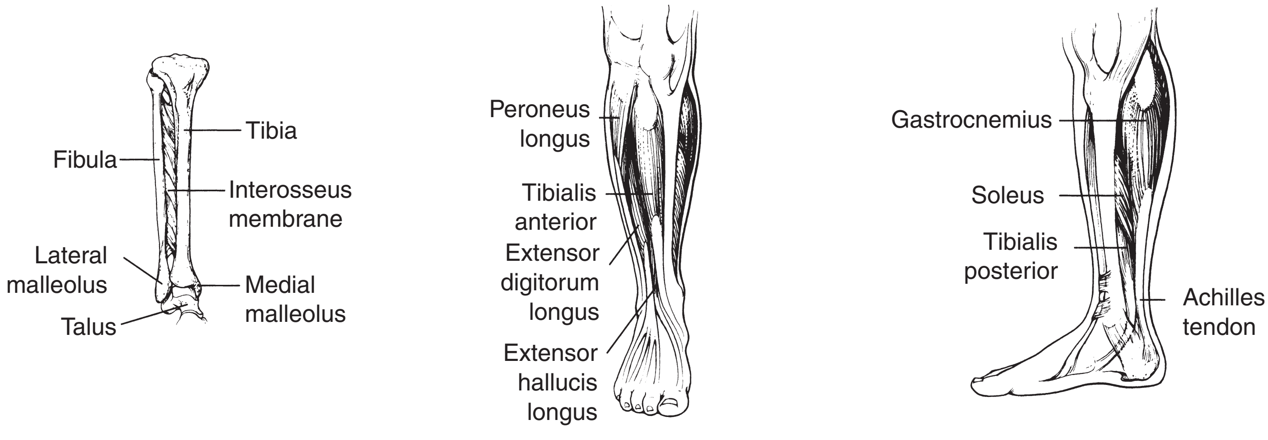

Figure 1 Lower Leg Anatomy

Notes: (a) The tibia carries almost all of the weight in the body, while the fibula acts as a stabilizing agent. The tibia is the second largest bone in the body (next to the femur). (b) The muscles of the lower leg are contained in four compartments. The calf muscle was named *gastrocnemius*, or "stomach of the leg," for its bulging shape.

tendon, the Achilles tendon, which attaches to the calcaneus. The deep posterior compartment contains the tibialis posterior, flexor hallucis longus, and flexor digitorum longus muscles. There may be a "fifth" compartment, a subcompartment of the deep posterior compartment formed by the variable fibular attachment of the flexor digitorum longus.

Blood is supplied to the lower leg mainly by the popliteal artery. It branches into the anterior and posterior tibial arteries at or just below the popliteal fossa. The anterior tibial artery travels through the anterior compartment and is palpable as the dorsalis pedis pulse. The posterior tibial artery travels through the deep posterior compartment and is palpable adjacent to the medial malleolus. The large saphenous vein runs superficially over the distal medial leg.

Evaluation of Injuries

Details of Injury

The mechanism of injury, the duration of symptoms, as well as the location and character of the pain can help differentiate the cause of lower leg pain in athletes. The timing of the pain, its relationship to different activities, and whether or not the pain resolves or recurs with activity, can help determine the cause of the pain. There may be associated symptoms, such as numbness, tingling, or muscle hernias. Sudden-onset pain usually is indicative of an acute injury, such as a fracture, muscle tear, or tendon rupture. Gradual-onset pain is more indicative of an overuse injury, such as stress fracture or chronic exertional compartment syndrome.

Previous injury to the same area may predispose the athlete to recurrent injuries, particularly if previous treatments and rehabilitation were incomplete or ineffective.

Lower leg pain may be a symptom of some other underlying concern. "Red flags" include loss of regular menses in females, excessive leanness or obesity, unusual constellations of symptoms and physical findings (night pain, loss of sensation, weakness), an athlete who does not make eye contact, or a parent who speaks for the athlete. These may indicate a systemic disorder, such as osteogenesis imperfecta or Ehlers-Danlos; a psychological disorder, such as anorexia nervosa or depression; or overtraining syndrome. Lower leg pain may also be referred from the lower back or hip.

Physical Findings

Alignment of the legs may make an athlete more prone to lower leg injuries. Bowlegs (genu varus), knock-knees (genu valgus), flat feet (pes planus), and tibial torsion (rotation of the bones) are some alignment conditions that may be seen in an athlete with a lower leg injury. There may be color changes of the skin and decreased muscle bulk, as well as swelling, bruising, or asymmetries. Comparing the injured leg with the noninjured leg can highlight the differences. Abnormal color may indicate reflex sympathetic dystrophy. Loss of muscle bulk may represent atrophy.

An athlete with a lower leg injury may walk or run with a limp or be unable to bear weight. Hopping may reproduce pain, or the athlete may not be able to hop because of weakness or pain. Pain may also be associated with activity such as calf raises and running on a treadmill or in the hall.

The bones, muscles, and tendons of the lower leg may be tender to palpation. Point tenderness of the tibia or fibula may represent a fracture or stress fracture. There may be irregularities of the skin and subcutaneous tissues, including temperature or texture changes, swelling, or edema. There may also be palpable defects in the muscles or tendons.

Range of motion of the foot and ankle may be decreased with lower leg injuries. A high-arched or cavus foot is usually somewhat rigid and has limited shock absorption, which increases the impact pressure on the bone. Excessive pronation of the foot (rolling inward) causes the superficial and deep compartment muscles to be lengthened, necessitating more forceful contraction to perform, and over time, muscle fatigue leads to decreased shock absorption. Ligament injury may result in excessive motion or decreased motion secondary to pain. Resisted muscle movements may demonstrate weakness and exacerbate pain.

Special tests in the evaluation of a lower leg injury include the stress fracture test, the Thompson test, the Homans sign, and the slump test (neural tension test). The stress fracture test involves applying a vibrating tuning fork along the tibia. In the setting of a stress fracture, this may exacerbate pain in the bone. The Thompson test involves squeezing the calf and noting whether or not ankle plantarflexion (toes pointed down) occurs. Absence of ankle plantarflexion indicates a complete tear of the Achilles tendon or musculotendinous junction. The Homans sign involves extending the knee and adding overpressure to dorsiflex (toes pointed up) the ankle.

The slump test is performed by having the patient sit on the examining table with the arms behind the back. The neck is flexed forward and then the leg is extended, with the ankle being dorsiflexed. A positive test results in reproduction of neural symptoms in the extended leg, such as shooting pain, numbness, or tingling.

Investigations

X-rays are inexpensive and are commonly performed to investigate lower leg pain; however, they are often negative or only subtly positive. Bone scans are usually performed when stress injuries are considered. Bone scans are sensitive but not specific. Stress injuries are indicated by increased uptake, which may be discrete in stress fractures or more diffuse in periostitis (inflammation of the bone).

Ultrasound imaging is beneficial for soft tissue injuries such as muscle hematomas and tears.

Magnetic resonance imaging (MRI) is advocated because of its sensitivity in diagnosing soft tissue injuries as well as bone lesions. Whereas X-ray and bone scan cannot diagnose soft tissue disorders, MRI can indicate muscle strain or herniation, as well as benign and malignant tumors.

The diagnosis of chronic exertional compartment syndrome is confirmed by intracompartmental pressure measurement, the gold standard test. Pre- and immediate postexertion measurements are essential to confirm the diagnosis.

Additional investigations that may be considered for more unusual causes of leg pain include electromyography (EMG)/nerve conduction studies (for nerve entrapments), venous Doppler ultrasound (for deep vein thrombosis), and laboratory tests such as complete blood count (CBC; for infections), erythrocyte sedimentation rate (ESR; for inflammatory or rheumatological disorders), and electrolytes (for hypokalemia [low potassium], hypocalcemia [low calcium], and hypomagnesia [low magnesium]).

Types of Injury

A list of injuries of the lower leg is given in Table 1.

Table 1 Lower Leg Injuries

Lower Leg Region	*Common*	*Less Common*
Shin	Acute fractures	Popliteal artery entrapment
	Stress fracture/stress reaction	Muscle herniations
	Medial tibial periostitis	Pes anserine bursitis
	Chronic exertional compartment syndrome	Tumors
	Muscle strains	Infection
	Tendinopathies (peroneal)	Acute compartment syndrome
Calf	Muscle strains	Deep venous thrombosis
	Gastrocnemius	Achilles tendon rupture
	Soleus	Achilles bursitis
	Muscle cramps	
	Muscle contusion	
	Delayed muscle soreness	
	Achilles tendinopathy	

Prevention of Injury

Athletes should be properly conditioned to ensure the development of sufficient strength, flexibility, and endurance to meet the demands of their sport. The athlete should gradually and progressively increase the amount of time spent doing repetitive sport skills and should learn new skills at a safe rate, allowing for sufficient motor learning as well as tissue adaptation. The appropriate protective equipment for the particular sport should be worn and properly maintained. General health should be maintained, including having proper nutrition, maintaining an appropriate body mass index, ensuring regular menses in the case of female athletes, ensuring adequate sleep, and allowing enough recovery time following sports activity.

Return to Sports

The first goal in the treatment of all injuries is to achieve painfree status. As soon as the athlete is painfree, rehabilitation can progress. Some conditions may require immobilization and non–weight bearing for a period of time. Following immobilization, a protective brace or other device may be required. As symptoms improve, the athlete can participate in more activities. Return to sports is allowed when the athlete can ambulate without a limp, pain does not recur with activity, no medications or modalities are used to mask the pain, and the athlete is able to advance through a therapeutic exercise program without increase in his or her symptoms.

Lower Leg Injuries, Surgery for

The lower leg consists of the portion of the lower extremity between the knee and ankle joints. The skeleton of the lower leg is formed by the tibia and the fibula bones. The tibia is larger than the fibula and is the major weight-bearing bone of the lower leg. The tibia articulates with the femur above to form the knee joint and with the talus below to form the ankle joint. The tibia is triangular in cross section and can easily be felt along the front portion of the lower leg.

The fibula is cylindrical in cross section and is mostly covered with muscle, but it can be felt on the outside portion of the leg at its two ends. The fibular head is just below the knee, and the lateral malleolus forms the outer aspect of the ankle. The fibula plays an important role in ankle stability through its bony articulation with the talus as well as its ligamentous connections to the foot. It does not articulate directly with the knee joint, but the lateral collateral knee ligaments do attach to the fibular head.

The tibia and fibula are connected to each other at two joints—the proximal (upper) and distal (lower) tibiofibular joints—and by a sheet of connective tissue, called the *interosseus membrane,* that spans the distance between the tibiofibular joints. The interosseus membrane transmits forces between the two bones, which can become apparent in certain ankle injuries. Rotational forces exerted on the foot can be transmitted from the lower end of the tibia, up the interosseous membrane to the top of the fibula, resulting in a fracture at the upper end of the fibula. The round fibular head sits in a shallow groove on the tibia to form the proximal tibiofibular joint. The distal tibiofibular joint is intimately associated with the ankle joint.

The muscles of the lower leg are separated into four compartments by enveloping layers of tissue called *fascia*. The anterior (front) compartment contains the muscles responsible for flexing the foot and toes upward (dorsiflexion). The muscles of the lateral (outside) compartment rotate the foot in an outward direction (eversion). The posterior (back) muscles flex the foot downward (plantarflexion). The deep posterior muscles flex the toes downward and rotate the foot in an inward direction (inversion). In general, the nerves and blood vessels travel deep in the muscular compartments, with the exception of the common peroneal nerve, which wraps around the outer aspect of the fibular head and is vulnerable to injury by a direct blow.

Lower Leg Injuries

Most athletic injuries of the lower leg are due to overuse. The tibia transmits much of the force from the foot's impact with the ground during running and jumping, making it vulnerable to injury from repetitive loading. In fact, the tibia is the most common site of stress fracture in athletes. A stress fracture is a small break in the bone that may or may not travel across the entire bone. Bone is constantly being broken down and re-formed throughout the skeleton. Stress fractures occur when microscopic injuries to the bone occur faster than the body can heal them. Inadequate nutrition for the demands of the sports activity, the training surface, changes in training intensity or regimen, the anatomic alignment of the legs and feet, bone density, and belonging to the female sex have all been associated with stress fractures. Stress fractures cause activity-related pain with tenderness over a focal area and may progress to complete fractures (see below). Stress fractures may not always be visualized on regular X-rays but can be seen on bone scans or magnetic resonance imaging (MRI). Most stress fractures can be treated by relative rest along with modification of training techniques. Immobilization in a brace may be required.

Medial tibial stress syndrome—commonly referred to as shin splints—is also related to overuse. Muscles that attach along the posteromedial (inner and back) portion of the tibia can become inflamed, causing activity-related pain in that area. Overpronation of the foot during running has been implicated as the cause of this inflammation. The area of tenderness is usually more diffuse than is the case with stress fractures. Diagnosis is usually made based on examination, but MRI or bone scan may be used to differentiate from other causes. Modifications of shoe wear or orthotics, relative rest, anti-inflammatory medications, and stretching of the lower extremity muscles typically resolve symptoms.

Chronic stress fracture of anterior tibia at risk for progression to complete fracture

Source: Children's Hospital Boston Division of Sports Medicine.

Note: The anterior tibial cortex on the left side of the figure is thickened, and a small black line is visible, extending part of the way through the cortex.

Chronic exertional compartment syndrome is caused by transient impairment of blood flow to the various compartments of the lower leg. During exercise, muscles swell. When the envelope of fascia surrounding the muscles is unable to accommodate the swelling, pressure builds up inside the compartment and limits blood flow to the tissues in the compartment. Patients usually notice aching pain in the affected compartment during exercise. The anterior and lateral compartments are most often involved. Symptoms usually begin several minutes into exercise and may persist for some time after cessation of exercise. The nerves traveling through each compartment can also be affected, causing numbness or tingling in various areas of the foot. Diagnosis is made by measuring the pressure in the compartments before and after exercise.

Intramedullary nail placement to stablilize fracture

Source: Children's Hospital Boston Division of Sports Medicine.

Muscle herniation occurs when the fascia surrounding the muscle becomes weakened, allowing an outpouching of the muscle. Hernias can be associated with compartment syndrome but can also occur independently. There are natural openings in the fascia where nerves leave the compartment and travel beneath the skin. Muscle herniation through such an opening can result in *nerve impingement,* which causes burning pain, tingling, or numbness in the area of the nerve. The common peroneal nerve can also be affected where it wraps around the fibular head.

Popliteal artery entrapment is a rare cause of leg pain in the athlete. The popliteal artery is the main artery that supplies blood to the lower leg. As it enters the lower leg, the artery can be compressed by enlarged or abnormal muscles. Cramping, aching, tingling, and numbness occur. Examination is often normal at rest, but changes in the pulses of the foot may be detected with activity or with flexion and extension of the ankle. Vascular studies or MRI are usually required to make the diagnosis. Symptoms of numbness, tingling, or weakness in the legs can also be due to nerve compression or blood vessel disease in the upper leg, pelvis, abdomen, or spine.

Gasctrocnemius-soleus (calf muscle) *strain* can cause acute pain in the athlete. Simultaneous stretching and active contraction of the muscle can cause a strain or tear, with the sensation of a pop being felt. Pain with variable amounts of bruising or defect in the muscle occurs. This injury can be mistaken for a rupture of the Achilles tendon, which connects the calf muscles to the foot, and is often treated surgically. Treatment with rest and gentle stretching usually resolves symptoms.

Acute fractures of the lower leg can occur during contact sports or in association with stress fractures. Treatment consists of either immobilization in a cast or brace, or surgery, depending on the nature of the fracture.

Most athletic injuries of the lower extremity are activity related. Pain that occurs at rest can be a sign of systemic disease, tumor, or other nonathletic causes.

Surgery for Fractures of the Tibia

Stress fractures of the tibia may require surgical fixation in cases of delayed healing—usually greater than 4 to 6 months—despite appropriate nonoperative treatment or in cases that are at high risk of progressing to a complete fracture. Stress fractures of the anterior (front) part of the midshaft of the tibia are considered high risk. Standard surgical treatment is placement of a rod down the shaft of the bone that traverses the fracture site (intramedullary nailing) and provides stability to the bone (see figure next page). Treatment of acute tibial fractures depends on the location and severity of the fracture but can include casting or surgical fixation with either intramedullary nailing or a plate and screws. Fractures of the upper and central portion of the fibula are treated nonsurgically. Fractures of the lower end of the fibula are considered to be ankle fractures and will be discussed in that section. Return to sports is allowed when the fracture has solidly healed on X-ray images, tenderness at the fracture site is resolved, and appropriate strength and range of motion have been attained, which usually takes at least 8 to 12 weeks.

Surgery for Compartment Syndrome

The unyielding fascia surrounding the leg muscles is often unresponsive to physical therapy and must be addressed surgically. Small incisions are made in the skin overlying the affected compartments, and the fascia is cut open over the majority of its length to allow the underlying muscle to expand. The anterior and lateral compartments may both be accessed through one incision, as can the superficial and deep posterior compartments. Return to sports is usually between 4 and 6 weeks.

Surgery for Nerve and Artery Entrapment

The location of entrapment must be identified based on clinical examination, imaging tests, or other studies. Surgery involves cutting a portion of the tight muscle or fascia to relieve pressure on the nerve or blood vessel. In advanced cases of popliteal artery entrapment, surgery may be required to repair damage to the vessel itself. Return to sports is variable based on the severity of damage.

Lung Injuries

Lung injuries, although rare in sports, can be serious. The basic function of the lungs is to add oxygen to the blood. This essential process depends on adequate flow of air to the air sacs (alveoli) in the lungs and adequate blood flow to the tissues surrounding the air sacs. Any injury that causes blood or fluid to leak into the alveoli, compresses the air sacs, or prevents adequate blood flow through the lungs will result in reduced oxygen supply to the blood and, ultimately, to other tissues of the body. Shortness of breath, chest pain, blue appearance to the skin (cyanosis), loss of consciousness, a rapid heart rate, or coughing up blood are all signs of possible lung damage and require immediate medical attention. The most common causes of injury to the lungs during sports are direct trauma, pressure changes, and decreased oxygen at high altitude.

Traumatic Injuries

Types of Injuries

The shearing forces of a blow to the chest can produce bruising or bleeding of the lung. Either may produce shortness of breath and coughing. If the bleeding is significant, there may be blood in the sputum. If the lung tissue is torn, air can leak into the chest cavity. This is called a *pneumothorax*. Air can leak around the lung or into the center of the chest. When it leaks into the center of the chest, it is called a *pneumomediastinum*. In this situation, air may be noted under the skin around the neck and chest. The skin feels crackly when this occurs. The medical term for this is *subcutaneous emphysema*. Occasionally, air continues to leak into the chest cavity, and this can cause the potentially life-threatening problem called a *tension pneumothorax*. In this case, air keeps entering the lung cavity, with no way to exit. As the pressure builds, the lung is compressed. In this situation, each breath a person takes will cause more air to leak into the lung, resulting in worsening shortness of breath. An opening into the chest wall must be made immediately to release the pressure and allow the lung to re-expand. Blood may collect between the lung and the chest wall. This is called a *hemothorax*. If the lung is bruised, it is called a *pulmonary contusion*.

A pneumothorax, tension pneumothrax, or hemothorax can also be caused by a puncture wound to the chest. The most common sports injury cause of this is a rib fracture, where a sharp piece of bone from the fracture tears the lung tissue.

Diagnosis

The first step in diagnosing lung injuries is to complete a history and physical exam. Signs of lung injury are decreased breath sounds, wheezing, or dullness to percussion. To percuss the lungs, the physician taps on the chest wall and listens to the difference in sounds on one side compared with the other. Normal lung tissue has a hollow sound. If fluid is present, there is dullness to percussion. Measurement of the oxygen content of the blood is often helpful. Chest X-ray is also an important diagnostic tool. The X-ray will show if there is air leaking from the lungs, if the lungs are being compressed, or if there is fluid accumulation around the lung. Occasionally, a computed tomogram of the chest is needed to see damage to lung tissue.

Treatment

The treatment depends on the size and type of injury. A small pneumothorax may be treated with observation. Once the lung tissue heals, the air leak seals and the body resorbs the air. A large pneumothorax, tension pneumothorax, or hemothorax are usually treated with a chest tube. The chest tube is inserted through the chest wall, between the ribs, and hooked up to a suction device. Air and fluid are removed from around the lung, allowing the lung to expand and heal. Once the lung has started to heal and air is no longer leaking from the lung, the chest tube can be removed. Supplemental oxygen is often needed in the early stages of treatment. Occasionally, surgery or medication placed around the lung may be needed to seal the air leak. The athlete is usually able to return to full sports participation once cleared by his or her physician. The healing time is typically 6 to 8 weeks after the injury.

A pulmonary contusion usually clears up on its own and does not require any specific intervention. However, if it is severe and the athlete's breathing is significantly impaired, a ventilator may be needed to help oxygenate the blood while the lung tissue heals.

Treatment of lung injuries due to puncture wounds from rib fractures is similar to the treatments listed above. Most often, the rib fracture will heal without the need for surgery.

Pressure Injuries

Types of Injuries

Lung tissue is sensitive to pressure changes as occurs in scuba diving. Air that is under pressure will expand when the pressure is reduced. This occurs when a diver breathes compressed air under water and then swims to the surface. Air in the lung will expand and potentially cause damage to the lungs. The diver must always exhale while coming to the surface, to allow the expanding air to escape from the lungs. Rupture of the lungs due to the expanding air can cause pneumothorax, subcutaneous emphysema, or pneumomediastinum. Another type of lung injury that can occur with diving is *air embolism*. In this case, gas bubbles suspended in the blood expand when the diver surfaces, and these bubbles, if large enough, can block the arteries in the lungs, preventing the lungs from functioning normally and providing air exchange. These bubbles can cause a blockage in any blood vessel in the body, but because of the large number of blood vessels in the lung, this is a common location for this problem to occur. This problem requires a decompression chamber for appropriate treatment.

Diagnosis and Treatment

The diagnostic and treatment steps for pneumnothorax are similar to those for traumatic injuries as outlined above.

Air embolism is a serious problem and requires immediate treatment. The usual presentation is shortness of breath and chest pain. Diagnostic tests such as chest X-ray may not be helpful. First aid is supplemental oxygen, aspirin, and hydration. Immediate transfer to a decompression chamber is the treatment of choice.

Lung Injuries Due to High Altitude

Types of Injuries

In settings where the oxygen content is relatively low, such as in high mountain regions, the lungs can become inflamed and leak fluid into the air sacs (high-altitude pulmonary edema, or

HAPE). When this occurs, the lungs' ability to provide oxygen to the blood is impaired, resulting in severe shortness of breath. These injuries occur in mountain climbers and high-altitude trekkers.

Diagnosis

The usual presentation is shortness of breath, fatigue, cough, bluish discoloration of the skin or lips, and, if severe, gurgling while breathing. Fluid in the lungs produces a characteristic sound, called rales, that the physician can hear when listening with a stethoscope. Chest X-ray will usually show fluid in the lungs. The problem is more likely to occur if the climber does not take time to let his or her body acclimatize or adjust to the lower oxygen content at higher altitudes.

Treatment

The treatment is to move the patient to a lower altitude and provide oxygen supplementation. Unfortunately, there is no preventive treatment that is 100% effective. Acclimatization rather than rapid ascent is helpful. At extremely high altitudes, climbers should use supplemental oxygen. Medications that have been used in the treatment and prevention of HAPE include salmeterol, acetazolamide, dexamethasone, and nifedipine.

M

Malignant Brain Edema Syndrome

Malignant brain edema syndrome is a rare but possibly fatal complication that can occur in the setting of a single or recurrent closed-head injury. The term *malignant brain edema syndrome* was formerly associated chiefly with infants and children but has recently been expanded to include the entity commonly referred to as the *second impact syndrome*. Second impact syndrome is thought to occur if an individual sustains a second head injury while still suffering from the effects of a previous head injury from the recent past. Sudden increases in intracranial pressure resulting from diffuse cerebral swelling lead to catastrophic deterioration hallmarked by coma, brain herniation, and death. The physiologic cause of malignant brain edema syndrome is unclear, but several theories have been proposed. Early recognition and immediate medical attention are necessary to maximize a positive outcome.

Clinical Description

Malignant brain edema syndrome was first characterized in infants. The usual scenario was that of a child who experienced a mild head trauma. The child's condition would quickly deteriorate, presenting with fixed, dilated pupils and frequently with evidence of either flexor or extensor posturing. The syndrome was notable for the fact that there was severe swelling identifiable on brain imaging studies without other significant findings such as intraventricular bleeding, subdural hematoma, or subarachnoid hemorrhage to explain the clinical progression (these findings could be present but were insufficient to explain the degree of the noted swelling). Unlike subdural or epidural hematomas, which progress over the course of minutes to hours, malignant brain edema can result in clinical deterioration in seconds to minutes. Infants, in whom closure of the fontanelle has not yet occurred, may exhibit fewer clinical symptoms, being able to better accommodate increased intracranial pressure.

From a sports perspective, the more commonly encountered scenario begins with a contact sport athlete sustaining a mild traumatic head injury during practice or competition. The resulting concussion can produce a wide variety of symptoms, such as headache, nausea, memory loss, mood changes, or balance difficulties. The severity and duration of these symptoms are highly variable. The key event that is assumed to lead to second impact syndrome is a second hit to the head that occurs while the individual is still suffering form the effects of the first injury. After several minutes and without further provocation, the athlete has a sudden change in consciousness or may collapse. Invariably, the patient is described to have pupillary abnormalities, from alternating or unilateral pupillary dilation, to prominent hippus (the condition of alternating, almost rhythmic, dilation and contraction of pupils without changes in external light stimulus), to fixed and dilated pupils. There may be evidence of flexor (decorticate) or extensor (decerebrate) posturing, and the person may quickly lapse into a coma. Given the damage to the brainstem, respiratory compromise can occur. Without immediate medical attention, death ensues, although even with aggressive measures taken to ameliorate the increases in intracranial pressure, the outcome is frequently poor.

Instances of malignant cerebral edema have been reported most commonly in contact sports such as football, rugby, boxing, and hockey and also in noncontact, high–injury risk sports such as skiing. The overall rarity of the condition has made accurate estimations of frequency difficult. Information is derived mainly from case reports and retrospective case series. While the implications are unclear, it has been noted that no clear case of second impact syndrome has been reported in anyone over 18 years of age.

Pathophysiology

The pathophysiology of malignant brain edema syndrome is poorly understood. While several hypotheses exist as to the nature of this condition, uncertainty stems in large part from the fact that the underlying mechanism of concussion is itself not fully understood. One theory of concussion states that kinetic energy from a blow to the head results in distortion or strain on the axons within the brain, resulting in abrupt neuronal depolarization and an influx of calcium and water through the damaged neuronal membrane. These changes result in disrupted neurotransmission, release of excitatory neurotransmitters, changes in glucose metabolism, and significant alteration in cerebral blood flow regulation. The transient neurologic dysfunction that results manifests as the variety of symptoms mentioned above.

The second impact syndrome occurs in the setting of the impaired cerebral blood flow regulation caused by the initial concussion. A second blow to the head then results in near-complete loss of cerebral blood supply autoregulation, resulting in rapid vascular engorgement and a sudden increase in intracranial pressure with compression of the cerebral ventricles, leading to brainstem compromise. In reported cases, the timing of the second impact has been variable. More than one boxer who had second impact syndrome was believed to have had the second impact during the same bout. In other cases, several weeks were thought to have separated the first and second impacts.

As mentioned above, second impact syndrome is thought to occur primarily in a younger population. There are several possible explanations for this phenomenon, including the fact that until adulthood, the brain is continuing to establish its internal connections through the process of myelination. Also, the head-to-body ratio is higher in this population, and neck muscles are less developed, resulting in more angular rotation of the head during impact. The skull is thinner in younger populations, perhaps adding to the risk. Finally, pediatric patients tend to experience the effects of concussion for a longer period of time than adults, increasing the possibility of a second impact occurring during this extended period of vulnerability.

Treatment

Malignant brain edema syndrome is a rapid and frequently fatal process. Given the nature of the syndrome, the best chance for survival and recovery is with immediate medical attention and transport to a facility equipped to manage elevated intracranial pressures. These measures include intubation and artificial hyperventilation of the patient; administration of hypertonic saline and/or mannitol (both concentrated osmotic agents designed to "draw" fluid out of the brain); and, in certain cases, surgery (hemicraniectomy) to remove a portion of the skull in order to allow the brain to swell without putting pressure on the brainstem, thereby avoiding herniation. With the exception of the surgical procedure, these measures are temporary, and even with aggressive management, this condition is frequently fatal.

Prevention

Given the serious nature of the possible outcomes, every reasonable step should be taken to prevent malignant brain edema syndrome from occurring. Prevention begins by first addressing the prevention of concussion in general. In contact sports, no single modifiable risk factor is as important as proper technique. Engaging an opponent by leading with the head should be, in all circumstances, clearly emphasized as improper. Ensuring the availability of properly fitted and certified equipment is also essential. The rules that govern contact sports should also be critically evaluated to minimize the number of high-impact blows to the head. Even when these steps are taken, the fact remains that many of our sports, by their nature, will continue to carry a risk of brain injury.

When a concussion does occur, prevention of malignant brain edema syndrome, or second impact syndrome, should then turn to ensuring that the athlete is not put at risk of another head injury while still suffering from the effects of the first. Practically speaking, this means keeping the athlete out of practice and competition until he or she reports no symptoms either at rest or after a controlled test of physical exertion (e.g., a 30-minute ride on a stationary bike). In addition, objective data such as a scored balance test or neuropsychological markers can be used to help determine whether an athlete has returned to his or her preconcussion baseline. Such data should only be used as part of an overall management strategy under the guidance of a health care provider.

Mallet Finger

Mallet finger is a traumatic injury to the tip of an athlete's finger. It is also called *baseball finger* due to the high occurrence of this injury in the sport. The traumatic blow, typically caused by a ball impacting the tip of a finger, may result in permanent loss of distal finger extension if not treated promptly and appropriately.

Mechanism of Injury

As described above, a ball or object forcefully contacts the tip of an athlete's finger. The trauma results in a sharp movement of the distal interphalangeal (DIP) joint or the last joint of the finger from extension to flexion. This sharp movement results in a tearing of the extensor tendon on the dorsal (top) part of the finger (see Figure 1). The extensor tendon is very thin at this point of the finger, so it is easily damaged. If the resultant force is a slower blow, then an avulsion injury (chip fracture with the tendon intact) can occur. The athlete would exhibit swelling, bruising, or inability to extend the distal part of the finger. Typically, passive extension remains, and the athlete may think it is only a sprain.

Symptoms

The athlete may experience pain at the tip of the finger; however, the main symptom remains the inability to actively extend the distal portion of the finger. Blood may be present below the nail bed. If a patient notices blood under the nail bed, he or she should seek immediate medical attention as a detached nail bed signifies an open fracture.

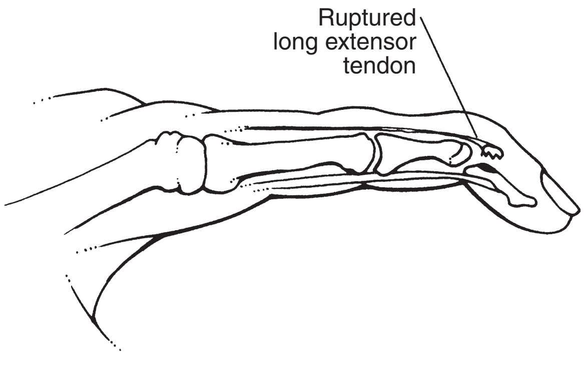

Figure 1 Mallet Finger

Notes: Mallet finger is a traumatic injury to the distal finger, resulting in tearing of the extensor tendon. Often a small portion of bone comes off, too, making it a tendon avulsion injury.

Diagnosis

A sports medicine physician will examine the finger for active and passive range of motion. In addition, palpation of the dorsal aspect of the distal finger may result in pain or a palpable defect (i.e., a hardened bump or divot). An X-ray of the finger may be taken to discern whether it is an isolated tendon injury or an avulsion injury. An avulsion injury signifies that a piece of the distal finger bone has become dislodged with the tendon.

Treatment

The majority of mallet finger injuries are treated nonoperatively. The key to healing remains early detection and compliance with the treatment. The patient should apply ice for the first 4 days after the injury to decrease the swelling. The patient needs to be splinted in full extension for 6 to 8 weeks at all times. Two types of splints exist. First, the sports medicine physician may use an aluminum splint. The aluminum splint is placed on the dorsal aspect of the finger past the DIP joint to incorporate the distal and middle phalanges. Athletic tape is used to affix the splint to the finger. The second type of splint is called a "stack" splint. The stack splint is plastic in nature and surrounds the middle and distal portions of the finger. The advantages of the stack splint include increased compliance secondary to comfort and ease of use. The splint affixes to the finger with tape and sits under the finger, as opposed to over it like the aluminum splint. (The aluminum splint can occasionally fall off due to the taping.) On follow-up visitation during the 6 weeks of splinting, a repeat X-ray may be taken. If the physician removes the splint during one of the follow-up visits, the finger should not be manipulated as this movement could reinjure the finger.

Six weeks following splinting, the physician discontinues the splint. The patient can then start a home exercise program for further strengthening the tendon. A home exercise program consists of five different exercises. First, passive range-of-motion exercises (flexing and extending the finger with the assistance of the opposite hand) afford improved range of motion of the distal portion of the finger. Second, making a fist and holding the position can improve both range of motion and strength. Third, the patient can pick up small objects such as coins, buttons, and so on, to improve dexterity and proprioception. Fourth, active distal finger extension (moving the injured finger up on its own) can slowly increase the range of motion. Fifth and foremost, the patient can improve grip strength with a grip ball. Again, these exercises should be performed *after* the 6 weeks of splinting and immobility.

Occasionally, nonsurgical treatment is ineffective. These cases typically involve large fractures attached to the tendon or those cases unresponsive to splinting. Surgery involves fixation of the fracture site followed by conservative treatment for the tendon.

Another reason why early treatment is essential is the potential development of a swan-neck deformity. Since the mallet finger results in tearing of the extensor tendon, lack of treatment places more pressure on the volar plate (the underside) of the proximal interphalangeal (PIP) joint, or the middle portion of the finger, to contract. This contracture can lead to a swan-neck deformity, in which the finger appears flexed distally and extended proximally. Once this deformity occurs, the chances of natural finger motion returning are unlikely.

Return to Sports

Typically, patients may return to noncontact sports immediately provided that they have been splinted and the splint can be maintained through the sport activity. For athletes who participate in contact sports, return to play is decided on a case-by-case basis. The sports medicine physician can be creative in maintaining a splint in full extension in a soccer goalie or linebacker. The splint would fit under the glove, and the finger could also be buddy taped for further immobilization. For sports with potential contact, such as baseball, return to play may be difficult as the athlete may have problems gripping the bat or throwing while splinted.

Manual Medicine

Manual medicine is the art of using hands-on treatments and techniques to facilitate healing and tissue recovery. Use of such treatments has been documented for over 2,500 years. Manual medicine ranges from the mainstream (physical therapy, therapeutic massage, osteopathic and chiropractic manipulation) to the alternative (acupuncture, chakra testing). In the United States, the acceptance and use of manual medicine is growing steadily as evidence of its efficacy and safety accumulates. It is widely accepted and used in athletics, where manual medicine helps athletes recover faster and return to play quicker.

Athletics

The athletic population is well suited to enjoy the benefits of manual medicine treatments. Athletes stress their bodies and joints constantly during practice and competition, which inevitably leads to tissue breakdown and injuries both acute and chronic.

The body compensates by producing an inflammatory response, which also triggers muscle spasm acutely and scar tissue formation chronically. As these injuries accumulate, they lead to alterations in the motion and stability of joints and skeletal segments. Muscles lose flexibility, firing patterns change, and functional stability can decrease. The body then develops compensatory mechanisms to handle these changes, which can lead to further breakdown.

Traditional treatment of injuries may include rest, ice, compression, elevation, and the use of anti-inflammatory medications, usually resulting in the reduction of pain. The athlete then undergoes a period of rehabilitation focused on restoring range of motion, strength, and function. Manual medicine is used as an adjunct to facilitate quicker return to play.

History and Use

The history of manual medicine in the West can be traced back to the Greek physician Hippocrates (ca. 460 BCE), who advocated using massage as a method of treating patients. More recent developments in manual medicine started when the first osteopathic, chiropractic, and physical therapy schools were established during the late 1800s. Manual medicine techniques have continued to develop throughout the past two centuries.

Manual medicine encompasses a variety of therapies and cultures. In Western Europe, North America, and Australia, manual therapy is usually practiced by members of health care professions, including chiropractors, physiotherapists/physical therapists, osteopaths, physiatrists, and massage therapists. Recent surveys estimate that Americans make 192 million visits per year to chiropractors and 114 million to massage therapists. If you have seen one of these practitioners for your sports-related injury, the chances are that you had some type of manual medicine treatment.

Common practitioners of manual medicine include the following:

- *Physical therapists* provide services to patients to restore movement and regain function in injured areas of the musculoskeletal system. They are the main practitioners of rehabilitation in the United States and are an invaluable part of sports medicine teams. They work closely with physicians in developing treatment plans for managing injury and loss of function.
- *Osteopathic physicians* are fully licensed physicians in the United States and can evaluate, diagnose, and treat medical conditions. They are trained in the understanding that structure and function are related and that the body has inherent mechanisms to correct underlying dysfunction. Their practice scope is limited in European countries and Canada to just manual medicine.
- *Chiropractic physicians* are licensed to perform manual medicine techniques and are widely consulted for musculoskeletal injuries. Chiropractors believe that your spine and your health are fundamentally related and alterations in the spine can have negative effects on the musculoskeletal and nervous systems.
- *Massage therapists* have developed various styles and forms of massage over the past 25 years. They are an accepted part of an injury recovery program, particularly for those trying to maintain function while still competing. Therapeutic

massage is well researched, and practitioners need a high level of understanding of physiology and anatomy to become licensed in the United States.
- *Athletic trainers* are often the primary source of rehabilitation and treatment for athletes, often working with them on a day-to-day basis. Their skill set includes rehabilitation, massage, first aid, basic orthopedic evaluation, splinting, and taping. Many training programs have added manual medicine skills to the curriculum.

Techniques

The goal of most manual medicine techniques is to help restore normal body function and motion. Specific goals include the following:

- Realigning the vertebral spine
- Relaxing muscle spasm
- Improving joint range of motion
- Increasing blood and lymph circulation
- Reducing myofascial restrictions and scarring
- Improving muscle firing patterns

There are different types of manual medicine techniques that involve hands-on contact for diagnostic and therapeutic purposes. These techniques are on a continuum based on the amount of force used to perform them, including the following:

- *Soft tissue articulation and mobilization:* These procedures are applied to the musculature surrounding the spine or extremities and consist of a rhythmic linear stretching (mobilization), deep-pressure massage, and traction. The purpose is to loosen tension and relax tight muscles and connective tissue. Examples of soft tissue techniques include therapeutic massage, stretching, and myofascial release.
- *Lymphatic techniques:* These methods promote the circulation and drainage of lymphatic fluids. They are used to relieve swelling and improve circulation and healing response.
- *Indirect methods:* These techniques treat restrictions and dysfunctions by moving the joint away from the restrictive barrier and facilitating release through pressure, passive movement, and respiration. Some of these techniques are strain-counterstrain, Still's technique, and functional positional release.
- *Muscle-energy technique:* In this technique, the patient is directed to use his or her muscles against a counterforce applied by the practitioner, increasing the mobility of a particular joint or muscle.
- *Articulatory or thrusting maneuver:* Here, the practitioner applies a quick force to restore normal joint motion. This technique uses long- and short-lever systems. Often, you can hear a pop when the restriction is removed. As a result, symmetry and function are improved.

History and Physical Examination

The practitioner starts by taking a medical history, including the mechanism of injury, symptoms, location of pain, treatment to date, physical activities, past medical history, family history, and psychological factors that may delay recovery.

A physical examination is then completed, which includes scrutiny of general appearance, regional orthopedic and neurological examination, assessment of aberrant movement patterns, examination of related body parts, inspection of posture, palpation, and gait analysis. The athlete will invariably show changes in muscle texture, symmetry, and joint motion. Tender points on muscle or connective tissue are also common signs of injury or dysfunction.

For example, a basic rehabilitation strategy for ankle sprains is to reduce inflammation and swelling. This is done traditionally by using *r*est, *i*ce, *c*ompression, and *e*levation (the RICE method). Manual medicine treatments can facilitate this process by performing a mobilization technique that enhances venous and lymphatic drainage from the injured extremity. This can be followed by thrust maneuvers of the foot and knee to correct the restriction caused by the ankle sprain. Once the athlete's pain has improved, he or she can begin strengthening of the injured leg/ankle and work on improving balance. Guidelines for return to play include full range of motion in the injured ankle, no swelling, and return of ankle strength to 90% of the strength of the uninjured ankle. Manual medicine techniques often speed recovery, and the athlete is able to return to competition faster.

Conclusion

Manual medicine is a hands-on approach used to facilitate rehabilitation from an injury. Manual medicine techniques correct restrictions in the body so that the body can eventually heal itself and regain its function. The various techniques, including soft tissue mobilization, muscle energy, and thrust maneuvers, promote improvement in muscle and joint motion. This allows the athlete to recover more quickly and return to play sooner. When manual medicine is used in conjunction with traditional approaches to injury and pain, the result is better patient outcomes and increased patient satisfaction. Research studies have confirmed the therapeutic benefits of manual techniques in treating neck and back pain. Further studies are needed to determine the long-term benefits of manual medicine.

Marathons, Injuries in

The marathon is a long-distance race that has boomed in world popularity since the early 1970s and is considered by many to be the ultimate challenge in physical endurance. The annual number of marathon finishes in the United States alone is nearly half a million a year. It was not until the 1970s that women became formally involved in the sport of marathon racing, and the distance was added to the Olympics in 1984. The expansion of marathon participation is due in large part to the number of women who have hit the roads, making up more than 40% of the race participants. While marathon participation has increased and the fastest runners have improved the world records for both sexes, the average popular marathon finish time has increased to 4.75 hours.

Minimum Criteria for Marathon Participation

Marathon training is rigorous, time-consuming, and certainly not for everyone. Nor is it to be taken lightly: Runners with underlying, but quiescent, coronary artery disease die of cardiovascular causes during marathon training and competition, and runners without a solid background of running and tissue toughening get injured during training and often do not make it to the starting line. Before embarking on the journey to complete the first marathon, it is prudent for a new runner to spend 2 to 4 years building up the volume of running in order to accommodate the rigors of marathon training. The preliminary running allows the muscles to strengthen and the tissues to "toughen" to meet the physical demands of the activity. There are programs that will take a "never-ever" runner to the level of marathon completion in a relatively short time, but the risks of soft tissue overuse injury and stress fracture are potentially greater than in a runner with several years of shorter-distance road running, who begins the marathon training program from a more seasoned platform.

From a cardiovascular perspective, a potential marathoner should be in good health with no known heart problems, have a clear family history (no early coronary artery disease and no unexplained sudden death, including during sleep, death by drowning, and single-car accidents), be a nonsmoker, and have a good cholesterol profile. A new marathon runner with one of the preceding conditions or risk factors, a male over age 40, or a female over age 50 should consult with a physician and consider an exercise stress test if there are risk factors for cardiovascular disease.

A lifelong running history usually produces a tested heart, but it does not guarantee that there is no risk from cardiovascular disease. Even runners who have completed several marathons have been shown to have high levels of coronary artery calcifications, beyond the expected levels. In a recent study of 108 male German marathon runners, 36% had coronary artery calcium scores >100, while only 22% of 216 men with similar heart disease risk factors who did not run at all had scores >100. In addition, there is at least one study that shows transient cardiac dysfunction and biochemical evidence of cardiac injury (release of cardiac stress markers) in healthy amateur marathoners, with the cardiac stress profile being greater in runners who train <35 miles (mi)/week (1 mi = 1.69 kilometers [km]) than in runners who train >45 mi/week. This should not discourage runners from undertaking the marathon challenge as there are no data to show that the changes noted were either detrimental to the runners' health or accelerated by participation in the marathon, but it does emphasize the need for adequate training and attention to cardiac risk factors.

Bassler's hypothesis early in the running boom suggested that a marathon runner could not get coronary artery disease and die of a heart attack. This was disproven in the Boston Marathon around the time of the statement, and the risk of sudden cardiac arrest (SCA) and sudden cardiac death (SCD) is real and has been documented in the range of 1 in 75,000 finishers. The deaths are mostly of men over age 40 with coronary artery disease. There have been deaths in every major marathon, including New York, Boston, London, Berlin, Chicago, Marine Corps, and Twin Cities. A healthy lifestyle and a keen appreciation of the symptoms of cardiovascular disease will do the most to decrease SCD in marathon runners.

To condition both the heart and the running-related musculoskeletal system, it is prudent for a potential marathon participant to have a running history of 2 to 4 years, with a training log showing 15 to 20 mi/week, some 5- to 10-km road racing experience, and at least one 10- to 15-mi race prior to ramping up the mileage for the marathon race. Training should gradually build up to 30 to 40 mi/week and culminate in several weeks of consistent running at >45 mi/week leading into the marathon. Most training programs will suggest that the runner complete at least two 20-mi runs 3 and 2 weeks prior to the race. A training program should include rest—typically 1 day/week with no exercise, with hard and easy workouts alternating on the other days of the week.

Marathon participation also takes a lot of "heart." Mental preparation is important to complete the race and must be accompanied by the "will to finish"; however, knowing when to quit if symptoms arise during the race may be the key to avoiding cardiac arrest, heat stroke, and other race-related problems.

Collapse During and After a Marathon

There are five usual causes of collapse during and after a marathon race: (1) SCA and SCD, (2) fluid balance issues including exertional hyponatremia and dehydration, (3) hyperthermia and exertional heat stroke, (4) hypothermia, and (5) exercise-associated collapse. Some of these conditions are self-limited and very common, and some can be life threatening although relatively rare.

SCA and SCD associated with marathon racing are relatively rare and most common in men. There has been a great effort on the part of race medical teams to develop rapid response teams, and a recent study showed the SCD rate in two major marathons to be 1 in 220,000 finishers, presumably due to rapid response and application of a defibrillator. An SCA during a marathon is usually an unexpected collapse, most likely due to coronary artery soft plaque rupture producing sudden occlusion of the heart artery. Unlike the large, calcified plaques that produce angina heart pain, the smaller, soft plaque does not occlude the artery blood flow and induce the growth of collateral blood vessels to protect the heart muscle from decreased or stopped blood flow. The abrupt occlusion from a soft plaque rupture produces an arrhythmia, with an unprotected collapse to the ground, often resulting in facial lacerations and fractures in addition to a stopped heart. The more rapid the response with an automatic external defibrillator, the more likely the runner will survive.

Fluid Considerations

Most marathons make fluids available along the course at 2- to 3-mi intervals, and the mega-marathons, such as Chicago, New York, and London, have fluid stations every mile to improve access in the crowded conditions. Severe dehydration is relatively rare in marathon racing, but mild to moderate dehydration occurs relatively often, is usually well tolerated, and is easily treated with oral fluid replacement. Replacing fluid during the race has the advantages of improving performance and maintaining blood volume. Keeping the blood volume near normal by replacing most sweat losses allows the most efficient transfer of muscle-generated heat to the body surface and keeps the vascular system flowing for exchange of oxygen and nutrients.

The problem associated with ingesting too much fluid is called exercise-associated hyponatremia (EAH), defined as a serum sodium (Na^+) level of <135 millimoles per liter. *Hyponatremia* can present with life-threatening cerebral and pulmonary edema and requires immediate medical attention. It is caused by too much fluid intake combined with poor kidney water clearance and is usually found in slow runners who are on course for >4 hours and ingest too much water or sports drink compared with the amount of fluid lost in sweat and urine. Affected runners tend to gain rather than lose body weight during the race, although in some cases runners maintain weight. Serum sodium losses in sweat make a minimal contribution to hyponatremia in "normal" marathon runners.

Prerace, race, and postrace hydration recommendations suggest that keeping urine pale yellow, like the color of lemonade; replacing no more than sweat losses during the race with an individualized fluid intake plan; and planning to lose a pound or two during the marathon race is the safest approach to fluid management. Lacking a fluid replacement plan, "drink when thirsty," to avoid too much fluid, but "do not ignore thirst," to avoid dehydration, is a reasonably safe option. Sports drinks may delay onset but do not prevent dilutional hyponatremia, and it is not safe to assume that having a sports drink will protect a runner from overhydration. Postrace ingestion of an initial salty drink, such as chicken broth, will help the body retain water in the rehydration process.

Recognition of hyponatremia is difficult in the early stages, when nonspecific symptoms and signs, such as lightheadedness, dizziness, headache, and nausea, may be confused with other race-related problems. As symptoms and signs progress, vomiting, dyspnea, muscle cramps, confusion, and "puffiness" may help focus the diagnosis. Late signs and symptoms of cerebral edema (prolonged seizure and obtundation), pulmonary edema (respiratory distress), and shock (ashen, gray appearance) are life threatening. The problem may be asymptomatic or minimally symptomatic for several hours, may present with "flu"-like symptoms later in the hotel or at home, and may present with muscle cramping or severe headache. Hyponatremia can deteriorate rapidly, progressing to seizure, respiratory distress, and coma due to worsening pulmonary and cerebral edema in short order.

If suspected, the medical staff at the marathon site or in the emergency room will check the serum sodium level, hematocrit, and blood urea nitrogen (BUN) to make the diagnosis. The treatment of relatively asymptomatic hyponatremia is simple: The medical team will observe the runner closely and allow natural diuresis to remove excess water via urination. Some medical teams will administer oral hypertonic solutions, such as four bouillon cubes in 4 ounces (113.65 milliliters [ml]) of water to draw water into the gut and relieve the water overload. If symptomatic, especially with encephalopathy from brain-related changes, the medical team will administer 100 ml of 3% saline intravenously over 10 minutes and repeat this until the sodium level normalizes or symptoms abate. Some medical teams choose to treat all cases in the emergency room, but that protocol has the potential to delay treatment.

Exertional heat stroke (EHS) occurs when the body temperature rises above the critical tissue levels that affect organ function, as a result of muscle heat generated by the work of running combined with inadequate heat loss usually due to exercising in hot, humid conditions. The usual definition of EHS is an elevated core body temperature >104 ºF associated with central nervous system (CNS) symptoms and other organ dysfunction (caused by heat-induced malfunction of cells and organ tissues). This is most often a problem in "short" races that are run at a faster pace than the marathon distance. The pace of the last 5 to 10 km often determines the risk of heat stroke in the marathon.

The risk is low in marathons run in cool conditions with race temperatures in the 40 to 50 ºF range, but as temperature and humidity rise, the incidence of heat stroke also rises to >1 per 1,000, even when the start temperature is a low 70 ºF, as at the Twin Cities Marathon. Heat and humidity associated with marathon-related heat stroke are often unexpectedly high for the race, and runners are not acclimatized to such conditions.

Rectal temperature measurement is required to detect heat stroke because more convenient sites such as the ear canal, tympanic membrane, forehead

(TAT), oral cavity, and axilla are in the shell and will be falsely low—missing the diagnosis and delaying life-saving cooling. Runners with heat stroke often present with "collapse," either to the ground or requiring the assistance of others to remain upright. Symptoms include fatigue, impaired judgment, weakness, flushing, chills, hyperventilation, dizziness, and intense thirst (in some). CNS depression is the most easily recognized marker of exertional heat stroke and may be simply demonstrated as bizarre behavior. Some heat stroke victims have a semilucid interval with subtle personality changes that may seem normal to a "stranger." Memory loss is common, starting at the time of critical body temperature elevation. The loss of lower limb function results in collapse and can proceed to delirium, stupor, and coma. Skin color is ashen in appearance due to circulatory collapse, and the skin is usually sweaty, wet, and even cool to the touch. Dry and hot skin is rare early in collapse from heat stroke, signifying loss of hypothalamic control of the body cooling system.

Once the diagnosis of exertional heat stroke is made, the goal is to bring the core temperature down to normal as quickly as possible. The most rapid cooling method is to place the runner in a tub of ice water to cool the body to the normal temperature range in 20 to 40 minutes. Another commonly used technique is to wrap the body in a sheet or several towels that have been dipped in ice water and then change them quickly to remove heat from the body. In an emergency situation, anything that will help remove body heat is helpful, including shade; air conditioning; ice packs to the neck, axilla, and groin; wet, cool towels; soaking with a garden hose, or using fans. However, none of these methods is as effective as immersion in ice water. If cooling is successful, the runner is either evaluated in a local emergency facility or allowed to leave the medical area with follow-up instructions.

Exercise-Associated Collapse

Exercise associated collapse is a common problem following the marathon that excludes orthopedic injuries and the problems previously outlined. A runner completing the race often requires some intervention for exhaustion and inability to continue in an upright walking posture. The reasons for this type of collapse are not fully understood but probably have to do with loss of vasovagal tone and loss of venous blood return when the leg muscles stop contracting regularly (loss of the muscle pump when running is stopped). Most runners recover rapidly by lying down and elevating the legs. In the finish area, many runners assume this position as part of their postrace recovery without reporting to the medical tent.

Marathon Race Medical Plans

The medical team for each marathon prepares protocols and equipment in advance to respond to the common, self-limited problems on the course and at the finish line, leaving the community emergency facilities open to the general public and for the rare life-threatening marathon-related problems.

The race medical team provides competitor education regarding the risks of marathon racing and the safety measures required to reduce individual risk, including much of the material discussed in the preceding section. The type and location of medical assistance along the course and at the finish should be explained in the prerace materials, along with how to identify the medical team volunteers. Often the medical team will have a standard color T shirt, jacket, or vest to make it easy to locate assistance during and after the race.

Preparticipation screening is usually not required for mass-participation marathons and is left to each individual to determine under the advice of a personal physician. Even prescreened athletes have suffered SCA, heat stroke, and hyponatremia in the course of marathon participation. Many marathons have an impaired competitor policy that allows medical evaluation without disqualification. This allows the medical staff to establish criteria for runners to continue in the event, usually including the following: The individual (a) is oriented to person, place, and time; (b) is making straight-line progress toward the finish; (c) has a good competitive posture; and (d) has a clinically fit appearance. Runners will be disqualified for any problem that appears to risk life or health or requires intravenous (IV) fluids.

Hazardous conditions that increase the risk to runner and volunteer safety during the marathon, including heat, cold, traction, windchill, and lightning, and may lead to cancellation of the event are usually published in advance of the race. Conditions that overload local emergency facilities also pose a threat to community health if the medical system is "clogged" with runners and community members cannot access care.

There are generally two types of aid stations for medical care: (1) major stations, which offer full race medical care, usually located at the finish area and in sites that historically have a high medical volume along the course and (2) minor stations, which offer comfort care and first aid. Many races have mobile aid, with teams in vans, on golf carts, and on bicycles carrying automatic external defibrillators for rapid response to possible SCA victims. Severely ill competitors along the course and at the finish area are usually transported by ambulance to the nearest hospital.

Competitor safety is always the primary goal of the race and the medical team. The medical plan should include strategies to prevent injuries, stop the progression of injuries, and relieve emergency rooms of excess admissions on the race day.

Marfan Syndrome

Marfan syndrome is an inherited problem of connective or soft tissues. It affects many parts of the body. This entry reviews the basic findings on Marfan syndrome and provides general treatment guidelines for some features.

Cause

Marfan syndrome is caused by a genetic mutation or change in the fibrillin gene. It is inherited in an autosomal-dominant fashion. This means that if a parent has the syndrome, each of the children has a 50% chance of having the syndrome. Most (about 75%) cases are inherited from affected parents, but some (about 25%) occur from chance mutations in the gene. The incidence is about 1 in every 10,000 people in the United States, with roughly 200,000 people living with this syndrome. Tissues in the body that contain fibrillin include the eye lenses, ligaments (which join bones together), and blood vessels. As a result, these areas are the most affected by this syndrome.

Features

Musculoskeletal/Muscles and Bones

People with Marfan syndrome are tall with long thin limbs and fingers, which is called arachnodactyly, or spider digits. Scoliosis or a curvature in the spine is commonly seen in up to 70% of patients. Chest wall or pectus deformities also can be seen. Another feature is hyperflexibility, which can cause extremely flat feet and dislocated joints. In the photo, a patient with Marfan syndrome is seen from the back. The features of long thin limbs and a spine curvature are visible. Other musculoskeletal problems include deep hip sockets (*protrusio acetabulae*) and abnormal growth of the lining around the spinal cord (*dural ectasia*), which can cause back pain.

(a) Marfan patient with spinal curvature and long thin limbs (b) Marfan patient bending forward showing rib hump from spinal curve

Source: Children's Orthopaedic Surgery Foundation.

Ocular/Eyes

People with Marfan syndrome often have poor vision and need glasses from a young age. A complete dislocation of the eye lens can happen.

Cardiovascular/Heart

The most serious effect of Marfan syndrome is on the blood vessels. Because the fibrillin in them is weak, they can stretch out and even rupture. The main artery that carries blood from the heart to the body, the aorta, is most at risk. It can stretch out and dilate into a balloon-like pouch (called an aneurysm) or even suddenly tear (called a dissection). Also, the valves in the heart may be too floppy to function properly. Some patients with Marfan syndrome have died suddenly from these problems. There are notable cases of tall, thin basketball players, in particular, who have died suddenly from aortic ruptures caused by undiagnosed Marfan syndrome.

Skin

Stretch marks are common and usually not a cause for concern.

Pulmonary/Lungs

In adult life, lung problems such as early emphysema are common. If severe spinal curvature or chest wall deformities are present, the lung capacity may be compromised by them. Spontaneous lung rupture (pneumothorax) can occur.

Diagnosis

Although the gene causing Marfan syndrome has been found, many different changes in it can cause the syndrome, making genetic blood tests imprecise currently. Thus, usually Marfan syndrome is diagnosed clinically after the exam by an experienced team of doctors. There are different criteria used to judge whether a patient truly has the syndrome rather than simply a few features of it. For example, few people with a spinal curvature and glasses have Marfan syndrome. The National Marfan Foundation website (http://www.marfan.org) has excellent information reviewing the diagnostic criteria that are used. Often a patient who is thought to have Marfan syndrome will see several different doctors to monitor all of the potential problems that may occur. An orthopedist will review the musculoskeletal problems. X-rays are often ordered. Before any spine surgery or in the case of back pain, magnetic resonance imaging (MRI) may be needed to assess variations from normal anatomy. An ophthalmologist will evaluate the eyes. A cardiologist will evaluate the heart; usually heart ultrasound scans called echocardiograms are used to monitor whether the aorta and heart are the proper size and working well. Computed tomography (CT) and MRI scans may be needed too. A geneticist often makes the final determination as to whether a true case of Marfan syndrome is present. Family history is very important as is counseling for patients with Marfan syndrome about their risk (50%) of passing the syndrome on to their children.

Treatment

Marfan syndrome is heterogeneous, meaning that not all patients have the same problems. Thus, treatment focuses on what problems exist in that particular person. Vision problems are treated with glasses and, occasionally, corrective surgery. The heart and aorta are monitored with echocardiogram ultrasounds and routine checkups. Some medications are available that can slow the heart and the progression of the dilation. If significant heart problems are found, strenuous physical activity must be avoided. If the dilation of the heart and/or aorta becomes severe, open heart surgery may be needed to replace the weakened areas. Some musculoskeletal problems such as flat feet may be braced. For severe deformities in the chest, spine, or limbs, surgical correction can be performed. With proper medical treatment and some lifestyle adjustments, people with Marfan syndrome can lead productive, happy lives and live as long as unaffected people. However, undiagnosed Marfan syndrome can lead to sudden death. Participation in sports depends on the severity of Marfan syndrome. Thus, some people may be able to play sports, though low-impact sports such as swimming are generally easier for their bodies. If there is heart involvement, contact sports such as basketball and football are strictly prohibited.

Medial Apophysitis of the Elbow

Medial apophysitis of the elbow is an overuse injury to the medial epicondyle growth plate. It is most commonly seen in young pitchers, generally between the ages of 9 and 14. It is sometimes called Little League elbow, but other authors use *Little League elbow* to refer to a constellation of injuries commonly seen in the skeletally immature elbow, including medial apophysitis, osteochondritis of the capitellum, overgrowth of the radial head, and premature closure of the proximal radial physis.

Anatomy

An apophysis is a bony protuberance near a physis or growth plate and serves as the insertion site of major tendons and ligaments. A physis, consisting of cartilage and new bone, is where bones actively grow during development, and as a bone matures, the physis will fuse and become all bone. However, while the physis is still open, it is weaker than all the surrounding tissues, including the formed bone, ligaments, tendons, and muscles. Therefore, *apophysitis* results when stress is applied to an apophysis.

The medial ossification center appears around the age of 5 and generally closes by age 15, forming the medial epicondyle. The medial epicondyle is the attachment site for both the flexor-pronator mass and the ulnar collateral ligament (UCL). The combination of repetitive contraction of the wrist flexors and elbow pronators and the valgus stress from the throwing motion puts the medial apophysis at increased risk for injury.

Epidemiology

The increase in organized sports participation has resulted in a similar increase in injuries among pediatric athletes. Increased specialization at a young age, year-round training, and increased intensity of training at an early age also contribute.

Surveys from Little League baseball have repeatedly shown that the elbow is the most commonly injured joint in youth baseball, with the annual incidence of elbow pain in 9- to 12-year-old players between 20% and 40%. Medial apophysitis is the most common cause of medial elbow pain in this age-group. While it is most commonly seen in pitchers, it can also be seen in other positions in baseball, as well as other overhead sports such as tennis and the quarterback position in football.

Causes

The overhead throwing motion results in valgus stress to the elbow, especially during the cocking and early acceleration phases of throwing. When this stress is repetitive, it can lead to injury to the medial structures of the elbow: medial apophysitis in the skeletally immature and UCL injury in the skeletally mature. Training errors are another common contributing factor. Common errors include sudden changes in the intensity and duration of throwing, too much throwing, inadequate preseason conditioning, poor throwing mechanics, and throwing breaking pitches at too early an age. Proper throwing mechanics depend on correct transfer of forces from the legs, through the torso, and into the arm, so strength and flexibility imbalances and injuries to other parts of the body can also lead to injuries to the elbow. Curveballs and sliders put much more stress on the elbow than fastball and change-up pitches, and they have been associated with a higher risk of medial elbow injuries.

Symptoms and Signs

The classic complaints of medial apophysitis are chronic medial elbow pain, decreased throwing velocity or distance, and decreased throwing effectiveness. Pain is generally worse during cocking and acceleration. Pain will have a gradual onset; if the patient complains of a sudden onset of pain while pitching, a medial epicondyle avulsion should be considered. Lateral pain may suggest associated injuries, such as osteochondritis of the capitellum and overgrowth of the radial head. When obtaining a history, the throwing history is very important. Ask questions about pitch counts, the types of pitches thrown, the number of practices and games per week, and recent changes in pitch types or counts.

Examination will show point tenderness over the medial epicondyle. If the patient has associated injuries to the capitellum and radial head, there may also be tenderness laterally and over the radial head. Medial swelling is common. Most patients will have full range of motion, but some may have a flexion contracture. There will usually be pain with resisted elbow pronation and wrist flexion but no pain with resisted elbow flexion or extension. On valgus stress testing, the patient will have pain but no laxity. If there is any laxity, injury to the UCL or medial epicondyle avulsion should be considered.

Diagnosis

If medial apophysitis is suspected, plain X-rays of the affected and opposite elbow should be done to detect fractures, loose bodies, and growth plate abnormalities. It is important to compare the width of the growth plate with the uninjured side. Most patients will have normal radiographs, but subtle differences in the width of the physis may be seen. If the difference is greater than 3 millimeters, the patient should be referred to a sports medicine orthopedic surgeon for consultation. Medial epicondyle fragmentation or hypertrophy is also commonly seen, but does not change the treatment. Magnetic resonance imaging (MRI) and computed tomography (CT) scans are generally not needed for medial apophysitis, but if injuries to the capitellum, radius, or UCL are suspected, an MRI scan may be considered.

When a patient presents with medial elbow pain with throwing, the other diagnoses that should be considered are avulsion fracture of the medial epicondyle and UCL sprains. Both of these will occur in patients with a history of repetitive valgus overload from throwing. Medial epicondyle avulsions present in the same age-group as medial apophysitis, but patients are more likely to complain of a sudden onset of pain while throwing, sometimes with a pop. It is not uncommon, however, for them to have a history of chronic pain before the acute onset. This is thought to be caused by preexisting medial apophysitis. There generally is more swelling than is seen in medial apophysitis; there is tenderness over the medial epicondyle, and often there is laxity with valgus stress testing. UCL sprains are more likely to occur in older throwers with fused growth plates. They may have an acute or chronic history of medial elbow pain, sometimes with a history of a pop as well. On exam, tenderness is more localized to the UCL than to the medial epicondyle. They will also have pain with valgus stress testing, with or without laxity. If either of these diagnoses is suspected, referral to a sports medicine specialist is recommended.

Treatment

The most important part of initial care for the patient with medial apophysitis is rest from throwing. Generally, 4 to 6 weeks of complete rest from any valgus stress is recommended. Ice and nonsteroidal anti-inflammatory drugs may be helpful for pain control. Occasionally, if pain is severe, immobilization for 7 to 10 days may be necessary. Initial physical therapy is focused on treating the flexion contracture, if present, and general strengthening and flexibility for the entire body.

After the rest period, if the patient is asymptomatic and has no tenderness or pain with valgus stress, a progressive return-to-throwing program can be started. The first phase is long toss, gradually increasing the velocity and then on to noncompetitive pitching, focusing on good throwing mechanics. Any return of pain will require rest for at least 2 to 3 days until the symptoms subside and then restarting at a lower level of intensity. This program should take 6 to 8 weeks, with the average time of return to pitching being 3 months from diagnosis. If these recommendations are followed, most patients will respond favorably.

Prevention

Prevention is the most important way to deal with this problem. The USA Baseball Medical and Safety Advisory Committee has made a number of recommendations to help prevent elbow injuries in young baseball players. The number of pitches thrown in practices and games and the number of innings pitched per week and season should be closely monitored. The committee has established pitch counts that vary by age and competitive level. Athletes who pitch in more than one league (e.g., on a travelling or all-star team) should follow the same guidelines, totaling the pitches for both leagues, even though each league will only monitor the pitches in its league. They have also recommended the types of pitches that should be taught at the different ages: fastball, 8; change-up, 10; curveball, 14; knuckleball, 15; slider, 16; forkball, 16; splitter, 16; and screwball, 17. Prevention can also be accomplished by educating parents, coaches, and players about the causes and symptoms of medial apophysitis. Pitchers should be taught that at the first sign of elbow pain, they should stop pitching and seek medical evaluation. Emphasis should be placed on proper throwing techniques and proper training. Overall conditioning and a good preseason program should be stressed. Pitchers should throw at the most 9 months of the year and should have at least 3 months of rest from all overhead activities annually. By following these recommendations, most cases of medial apophysitis can be prevented.

Medial Epicondyle Avulsion Fractures of the Elbow

Elbow fractures occur commonly in contact sports and constitute 10% of all fractures in children. Mechanisms of injury are usually direct trauma or a strong directional force on the elbow. In adults, it is rare to have an isolated epicondylar fracture. In children, medial epicondylar fractures are the third most common elbow fracture, after supracondylar and lateral condylar fractures. Elbow fractures and dislocations are serious injuries that can result in functional instability due to malalignment, malunion, nonunion, or concurrent soft tissue injury to stabilizing structures. Any young athlete who complains of medial elbow pain must have a thorough evaluation for injury to the growth plates or ossification centers of the elbow, with special attention to the medial epicondyle.

Anatomy and Clinical Evaluation

The elbow is one of the most complex joints in the body, consisting of three articulations: ulnotrochlear, radiocapitellar, and proximal radioulnar. The elbow is extremely congruent and stable due to the specific pattern in which the bones contact and conform to each other. Due to this configuration, anatomic alignment must be restored or maintained to decrease or minimize the functional disabilities resulting from injury. Common complications include decreased range of motion (ROM), structural instability, arthritis, nerve palsies, weakness, and heterotopic ossification. Radiographic evaluation of the pediatric elbow is particularly challenging due to the development and appearance of the six secondary ossification centers of the elbow and the relatively subtle appearance of some serious injuries. These ossification centers, or apophyses, can be remembered by the mnemonic CRITOE (*c*apitellum, *r*adius, "*i*nternal" [medial] epicondyle, *t*rochlea, *o*lecranon, "*e*xternal" [lateral] epicondyle). The ossification centers appear in order approximately every 2 years, starting from age 2 through age 12. The apophyses slowly close by ossification as the elbow matures and will be fully closed by approximately age 16. It is prior to the complete closure and ossification of the medial epicondyle that the vast majority of medial epicondyle fractures occur. The distal humeral epicondyles serve as attachment sites for the forearm flexor (medial epicondyle) and extensor (lateral epicondyle) muscle groups, the functions of which play a role in injury patterns.

Mechanism of Injury

The most common mechanism of injury to the medial epicondyle is repetitive valgus overload to the medial elbow. The stress to the flexor-pronator muscle-tendon group and/or the ulnar collateral ligament (UCL) results in a widening or separation of the medial epicondyle. This avulsion fracture can occur in the setting of an acute trauma as well. The medial epicondyle can also be injured during a traumatic elbow dislocation and become entrapped in the joint, often during a spontaneous ulnohumeral joint reduction.

Physical Examination

Physical examination includes inspection for swelling or deformities. Palpation should reveal localized tenderness and/or prominence of the medial epicondyle. Normal ROM is elbow flexion/extension 0° to 150° and forearm pronation and supination 90° in each direction. The UCL is an important stabilizer of the elbow. Multiple techniques exist for performing a valgus stress test on the medial elbow. These tests are often positive for reproducing pain as well as demonstrating signs of associated instability. Valgus stress testing at 70° to 90°, the moving valgus stress test, and the milk test are all described techniques. Any perceived laxity should be compared with the contralateral side and reevaluated at 0° of extension. It is sometimes difficult to distinguish ligamentous instability from that associated with a true medial epicondylar fracture; therefore, radiographs are essential as part of the initial evaluation. A complete neurovascular examination must be performed as associated neurovascular injuries can occur.

Imaging Studies

Standard anteroposterior (AP), oblique, and lateral views of the elbow should be sufficient to diagnose most elbow fractures. The lateral radiograph is helpful to evaluate for hemarthrosis and bony alignment. Comparison views are particularly helpful in evaluating the pediatric elbow for fractures due to the presence of the six secondary ossification centers previously described. Valgus stress views may be obtained, but they often fail to demonstrate the gross laxity detectable on physical examination. Epicondylar displacement may be seen on either the AP or the lateral view. The finding of 3 to 5 millimeters of medial epicondylar displacement is clinically significant and may serve as an indication for surgical fixation of a medial epicondylar fracture.

Advanced imaging techniques such as computed tomography may identify intraarticular fragments and assess the congruity of the articular surfaces when internal fixation is being considered. Magnetic resonance imaging (MRI) and/or MR arthrography is the most sensitive and specific imaging study to reveal injury to the medial (ulnar) collateral ligament, in addition to facilitating the identification of lateral instability, osteochondritis desiccans, intraarticular cartilaginous loose bodies, and physeal maturity. Increased signal at the medial epiphysis on an MRI scan in the absence of widening or displacement in a skeletally immature elbow indicates chronic medial injury consistent with valgus overload syndrome.

Treatment

Nonoperative treatment involves immobilization, usually a long arm cast for 3 to 4 weeks, to allow the medial epicondyle fracture to heal and prevent ongoing valgus stress to the elbow. Operative treatment may involve arthroscopic evaluation for concurrent instability, in addition to screw fixation of the medial epicondylar fracture fragment.

Rehabilitation

Rehabilitation of the injured elbow is essential to restore strength and stability whether the injury is treated operatively or nonoperatively. Usually, rehabilitation begins 4 to 6 weeks following immobilization and requires a progressive program of ROM, strength, and multiplanar exercise such as throwing so long as the activities are painfree. Even in cases of isolated medial epicondylar fractures not associated with instability, the elbow joint requires monitoring for recurrence of medial elbow pain and signs of complications such as stiffness, posteromedial osteophyte formation, ulnar neuritis/neuropathy, soft tissue/synovial hypertrophy or signs of impingement such as pain, locking, crepitus, and/or loss of extension. Serial radiographs as well as frequent physical examinations are important in the long-term treatment and monitoring of patients with medial epicondylar fractures.

Special Populations

Medial epicondylar fractures and, in general, valgus overload syndrome occur most commonly in young baseball players. As a result, much research has been conducted to identify the key risk factors for injury to the medial elbow. Pitch count limitations and proper pitch mechanics as well as general core strength and conditioning have been found to help prevent injury. The USA Baseball Medical and Safety Advisory Committee has made recommendations for guidance on appropriate pitch types and counts, which range from approximately 50 pitches per game for 10-year-olds to 100 to 110 per game for late high school–age and college-age pitchers, with season maximums of approximately 3,000 per year for young pitchers. The latest recommendations are available at http://www.usabaseball.com. Other general recommendations include not competing for more than 9 months/year, avoiding all overhead activities during the 3 months of rest, not participating in any after-game pitching practice, and playing in only one league per season. As noted, once removed, a pitcher should never return in the same game. Emphasis should be placed on year-round conditioning to promote endurance, core strength, neuromuscular control, and proper throwing mechanics. In conclusion, medial epicondylar fractures, particularly when associated with valgus overload and repetitive microtrauma, are potentially preventable injuries in athletes. When injury does occur, early intervention and proper treatment can minimize the risks of permanent injury or long term sequelae. Every athlete who experiences medial elbow pain, particularly with throwing or other overhead activities, should be referred to a sports medicine or orthopedic specialist immediately.

Medial Tibial Stress Syndrome

Medial tibial stress syndrome (MTSS) is a painful exertional condition of the lower leg that is related to exercise, specifically running. The incidence is estimated to be between 13% and 25% among active individuals, making it the most common cause of overuse injuries in runners. Many people still refer to this as "shin splints." Although running athletes most frequently present with signs and symptoms consistent with MTSS, it is not uncommon in jumping athletes.

Definition

Pain from MTSS usually occurs at the posteromedial margin of the tibia, the junction of the posterior tibialis tendon and muscle, and the gastrocnemius-soleus complex. MTSS is often confused with a tibial stress fracture or chronic exertional compartment syndrome. Pain usually occurs with running and repetitive jumping, but the athlete can usually complete the activity. Pain occurs along a broader region of the tibia, causing tenderness along a quarter or a third of the tibial shaft length. It usually improves with rest and localized treatment, but the symptoms can linger if the underlying cause is not corrected.

MTSS is thought to be related to tibial stress reactions, periostitis (inflammation of the bone surface), or tendinopathy and may be on a continuum of stress injuries to the bone. Recent high-resolution computed tomography scan studies showed that areas of the tibia affected by MTSS had lower bone mineral density in athletes than in nonathletes and athletes without MTSS, suggesting a bony reaction. One study supports inflammation of the periosteum from excessive muscle traction on the tibia as the cause of MTSS.

Causative Factors

The intrinsic and extrinsic factors related to MTSS are listed in Table 1.

Table 1 Intrinsic and Extrinsic Factors Related to Medial Tibial Stress Syndrome

Intrinsic	*Extrinsic*
Runner's build	Running surface
Bone structure and alignment	Running shoe deficiency
Gender	Changes in training program

Source: Plisky MS, Rauh MJ, Heiderscheit B, Underwood FB, Tank RT. Medial tibial stress syndrome in high school cross-country runners: incidence and risk factors. *J Orthop Sports Phys Ther*. 2007;37(2):40–47.

The most controllable factor in medial tibial stress syndrome is a *sudden change in training*. Different shoes, a different running surface, a sudden increase in mileage or intensity, or suddenly starting running after being sedentary are factors that should be considered in any case of MTSS.

Excessive pronation of the foot is associated with MTSS, likely due to the torque of the tibia generated by the pronation, causing shearing forces from the lower leg muscles along the tibial shaft. Navicular drop, or the collapsing of the medial arch, has been thought of as a cause, but evidence is not conclusive. Loss of medial longitudinal arch integrity can increase instability as the foot plants and pronates, and it should be assessed in suspected cases of MTSS.

Gender studies differ in their conclusions with respect to MTSS. One study showed that men with MTSS have significantly smaller tibial cross-sectional dimensions than their uninjured exercising counterparts and the sedentary controls. A study by J. E. Bennet et al., published in the *Journal of Orthopaedic and Sports Physical Therapy* in 2001, found that high school women were more likely to develop MTSS than their male counterparts. In a 2007 study published in the *Journal of Orthopaedic and Sports Physical Therapy*, M. S. Plisky and associates found that there was an increase in MTSS in women as well, but when controlled for orthotic usage, this finding was no longer statistically significant. However, those who used orthotics were four times more likely to have previously had symptoms consistent with MTSS. Other researchers speculate that women are more likely to report a problem than their male counterparts.

Shoe wear should be routinely evaluated by the runner. Shoe integrity breaks down as mileage of the shoe increases, and its ability to absorb impact and stabilize foot motion decreases. A prevailing theory in running was that shoes have about 300 to 400 miles (mi; 1 mi = 1.69 kilometers) in them before you need to change them. That has been amended recently, as people have different wear patterns and loads. One person's shoe may be in great shape at 400 mi of wear, while another may be broken down at 200 mi. Mileage is a good guide for assessing shoe wear, but runners and their shoes should be evaluated independently.

Higher body mass index (BMI) is linked to MTSS due to the amount of stress loaded onto the tibia from above the tibia, while harder training surfaces increase the stress loaded on the tibia from below. So running in the street may be less desirable than running on a grassy field or an asphalt track.

Treatment

Treatment of MTSS includes relative rest, physical rehabilitation, orthotics, and manual medicine techniques, with a gradual return to activity. Rest is designed to allow recuperation and recovery of the lower leg, so rest can be just from the offending activity. Athletes with MTSS can run on a softer surface, run less often, or run in a swimming pool. Sometimes, no running is allowed, but bicycling or elliptical machine training is permitted; more severe cases require complete rest and non–weight bearing. After the symptoms resolve, return to activity should be gradual and progressive. With an acute onset of pain, ice or cold compresses should be used, but for no more than 20 minutes at a time. After 3 days, heat can be applied when alternated with ice.

Rehabilitation should focus first on core stabilization and strengthening. Rehab exercises should strengthen and lengthen the gastrocnemius-soleus muscle complex and the tibialis anterior and posterior muscles. The running stance should be evaluated and treated. Medial longitudinal arch deformations should have added support. Additional interventions may include ultrasound, phonophoresis, and electrical stimulation in the skeletally mature. Addressing lower leg tender points with manual therapy can be helpful in relaxing the myofascial connections and allows for a better response to rehabilitation. In some instances, cortisone injections are also useful for soft tissue injuries.

Rarely does MTSS require surgical treatment. There is no procedure specific for MTSS, but surgery may be indicated for structural issues that lead to biomechanical running flaws, such as a collapsing arch, severe knock-knee (valgus) alignment, or other foot deformities.

Summary

In summary, medial tibial stress syndrome is a multifactorial lower leg condition that results from repetitive running and jumping. Many factors are involved, but the most controllable ones are sudden changes in a training program, equipment, or the running surface. Appropriate initial treatment can control the symptoms, and the vast majority of cases resolve without the need for surgery.

Medical Management of an Athletic Event

Large sporting events such as world and continental championships, the Olympic Games, and so on, require many years of preparation and planning. For the Olympic Games, work often starts 5 or 6 years before the event. It is important that medical personnel are involved early on in the process so that medical facilities can be incorporated into structural, staffing, and budget plans.

Other sporting events pose completely different challenges. Marathon races can attract up to 30,000 runners to a city in the hot summer. The Vasaloppet cross-country ski race attracts more than 14,000 participants for a 90-kilometer race in subzero temperatures. In the Paris-Dakar rally, motorists drive off-road across the Sahara desert into the arid lands of Mauritania. And in the Marathon des Sables, athletes run a marathon every day for 6 days in the Moroccan Sahara Desert. Planning such events requires detailed preparation to be successful; plans must be created for all eventualities and must encompass treatment of a large number of athletes and spectators with a variety of illnesses and injuries. Unfortunately, stadium disasters are not uncommon events, particularly in soccer arenas, where almost 200 spectators have died in the past 10 years in stadia around the world.

Mass participation events can take many forms. For a major track-and-field event, several hundred athletes may be localized in one stadium for a number of hours; from a medical viewpoint, these are relatively easy events to plan and cover, as many physicians have plenty of experience working in this type of environment. Things become more complicated when there are events occurring in several venues simultaneously, as in the Olympic Games, where one can have several events occurring simultaneously all day for 16 days. Imagine the amount of effort required to staff and equip the 219 medical stations at the 2008 Beijing Olympics (123 competition venue stations, 65 training venues and 31 non–competition venue stations—3,223 medical personnel—excluding the 834 doctors and 91 physiotherapists who traveled with the 204 national teams). The total number of medical encounters was more 21,000, of which approximately 15% were athletes and almost 50% were volunteers.

Outdoor Arenas

Many outdoor arenas cover large areas and are potentially difficult to "manage" medically. Cross-country running/skiing events are notoriously difficult, as the tracks often pass through areas without names or access routes, so appropriate maps are essential. There are many considerations to be taken into account; the only way to prepare for these scenarios is to develop and rehearse contingency plans, know your access routes, and know where your staff are located and what equipment and competence they possess. Everyone must have the same reference points.

All major sports events require a management team; the head of medical services is often called the chief medical officer (CMO) or medical director and should be a qualified physician with a sports medicine background. Medical services must often be provided from the time the athletes arrive for precompetition training and not just on the day of competition. For many sports, official precompetition training may start 4 or 5 days before the actual event, and services must be in place in varying degrees.

At a major event, medical services are usually available 24 hours/day and must be supplied to several different groups—athletes, spectators, and media persons (23,000 in Beijing). It is normal practice to offer 24-hour medical services to athletes and media persons. Similarly, visiting International Federation and International Olympic Committee (IOC) members usually have their own medical services, as do the tens of thousands of Games volunteers and the visiting state leaders and royalty. Considering that the Olympic Games are almost never located in one city any more, the services must be replicated in several venues, usually two or more. As the total number of spectators at an Olympics Games can reach 6,000,000, one must reckon with injuries and illnesses.

The centerpiece of the Olympic medical services is the central polyclinic, which is basically a mini hospital specifically built for the athletes and located in the Olympic Village. Satellite polyclinics may also need to be available if there are multiple Olympic sites. Emergency services are usually available all day for a whole month, with specialist services available from 8 a.m. to 11 p.m. daily. These include sports medicine, internal medicine, general surgery, orthopedics, podiatry, physiotherapy, gynecology, dermatology, dental care services, eye care services, ENT (ear/nose/throat), psychology, medical imaging (magnetic resonance imaging [MRI], computed tomography [CT], ultrasound, and X-ray, and laboratory services), blood and urine analysis services and even a pharmacy. The polyclinic alone may need a staff of 500 to 600 health professional volunteers.

Ambulances

Ambulance services must serve two separate groups—athletes (team staff are usually included) and everybody else. Many International Sports Federations (IFs) require two ambulances to be present at televised sporting events, either due to the fact that many of the athletes are participating in high-velocity sports (most winter sports, e.g., bobsled, Alpine skiing) and thus run the risk of multiple injuries or because the departure of an ambulance from the track may oblige the event organizer to stop the event due to IF regulations.

A motorized buggy for athlete transport from the field of play can be useful, particularly when treating spinal or cardiac patients. Athletes can be transferred on almost any kind of transport unit, cars, boats, ski-sleds, skidoos, surf boards, and so on.

An ambulance may be everything from a patient transport unit to a mobile intensive care unit. The right type of ambulance must be positioned at the right place, and it must be ensured that access routes are available and cleared if needed. At the 2008 Olympics, 191 ambulances were dedicated to the various venues.

Factors That Influence Medical Staffing Numbers

Certain sports are more dangerous than others. Motor sports are associated with serious injuries, and one can conclude that the higher the athlete's speed, the greater the risk of injury. Hence, injuries are to be expected in downhill skiing, ski-jumping, bobsled, and diving sports, so an adequate amount of appropriately skilled medical staff must be present. Water sports are always potentially dangerous due to the risk of drowning, particularly in open-water swimming. Head and neck injuries are to be expected in boxing, the martial arts, rugby, American football, and so on, while skating sports are associated with major cuts from blades, and serious falls can occur in equestrian sports. Athletes can collapse during endurance sports.

The number of spectators present dictates the staffing requirements in the spectator zones. Take, for example, the staffing of a major stadium with 70,000 people during the Olympic Games. The following staffing levels are not unusual and are often higher:

Spectator Medical Services

- Six to eight teams of two first aid responders—one nurse and one paramedic, two teams per tier
- Three to four event physicians (EPs), one for each tier of the arena or stadium
- Medical tent/cabin/room—two EPs, four nurses, and four paramedics—to treat spectators and also act as a backup in case of an emergency (the room doctors and paramedics can rotate with the stadium staff so that they can watch some of the games)
- Reserve medical and paramedical staff, in case of fallout—sickness, and so on
- Ambulances—a minimum of two, often four, staffed by two ambulance personnel each
- Ambulance standard—Europe: CEN 1/2, United States: basic life support/advanced life support (BLS/ALS)

Athlete Medical Services

- Athletics arena—two medical teams, one team at each end of the stadium by the track, composed of one EP, one anaesthetic nurse, and two paramedics (different sports have different requirements, e.g., boxing, judo, wrestling, etc., have the medical staff on the ringside)
- Athletes' medical room—two EPs, two nurses, and one physiotherapist/sports masseur
- Ambulances—two, manned by two ambulance paramedics each

Other Tasks for the Medical Director

In addition to recruiting the right number of staff, the CMO must also choose the right number of specialists and, not the least, the right people. Keeping all of these volunteers happy for a month is no easy task, and the CMO needs to have sophisticated personnel management skills.

When working with a large number of new staff, it is important to develop and distribute predetermined medical care protocols well before the start of the competition. These protocols should include topics such as emergency on-site care, the level of care to be given at various stations, where and how athletes are to be transported, who should accompany the athlete to other medical facilities, and return-to-play decisions. To help structure acceptable protocols, it is a good idea to liaise with the IF physicians, who have in-depth knowledge of the various sports and their federation requirements.

Similarly, good contact with the visiting national team physicians is important.

Staff rotation between various venues can have its advantages but also its disadvantages; familiarity with a stadium is vitally important for effective medical intervention, and frequent change of venue can cause location disorientation, particularly at the time of a crisis. However, if boredom and tedium (due to being overworked or underemployed) are becoming an issue, and there is a danger of losing volunteer medical staff, then venue rotation may be a valuable option.

Medical Log

During a large sports event, it is important to keep a log, not only as a statistical tool after the event but also to keep track of individual incidents. It is important to know where the athlete is in the treatment chain; it allows one to give information to the coach, the family, and so on. One can also have a documented chain of response in case of later review.

Athlete Injury Forms

Computer-based medical records are essential. It can take some time for the medical staff to learn and be proficient in the new medical software, so allow time for this in the precompetition period. Security issues for journalists must be addressed. All medical personnel must be made to sign confidentiality agreements.

Daily Venue Reports

During the competition, the day's event should be concluded by having a staff meeting. Each team should deliver a report on the number and severity of injuries, any hospital admissions or referrals, and special situations. There should be a short review of staffing and staff location plans. A list of used equipment should be prepared, and supplies should be replenished before the next day's event. Staff rotas for the next day should be confirmed and start time agreed on. Radios must be delivered so that batteries can be charged. The venue reports should be sent to the CMO.

Availability of Medical Services

Staff should be present at least 60 minutes before the event starts. After the event is over, keep athlete services available for 30 minutes after the award ceremony. Spectator services should be available until all spectators have left the venue. Conclude the service by having a 5- to 10-minute meeting with all medical staff to collect reports, logs and statistics, and equipment lists and to confirm that all staff will be returning the next day.

Traffic Control

A major concern is that ambulance access and exit routes can be blocked by either spectators or traffic. At larger events, there should be a dedicated road for venue vehicles, and cooperation with the police and traffic authorities is a prerequisite.

Prevention

The medical director will be intimately involved in race day planning and must be prepared to make difficult decisions in order to reduce the potential for athlete injury. In extraordinary circumstances, the CMO may recommend altering or even cancelling an event if there are severe environmental risk factors present—for example, extreme heat at a marathon, lightning, and so on. It must be emphasized that a doctor has no right to stop a race or competition; these decisions are made by the sports authorities. Major work and effort are being put into discovering the causes of injury, and huge resources are being used to prevent athletes from being injured. In many sports, certain injuries are more common—for example, back problems in divers—and one can take preventative steps by encouraging specific training programs to help protect against these conditions.

It is also vital to remind participants to wear, if pertinent to the individual, medical alert wrist braces (e.g., "I have diabetes").

Cooperation with the local health authorities in the prevention of contagious infectious diseases is another important task. Plans must be developed to combat food poisoning, water poisoning, airways diseases, and so on.

Medical Staff Clothing and Visibility

You can have the best equipment and staff in the world, but without adequate footwear and good-quality gloves when working in water or freezing weather, your ability to perform in cold, wet climates is extremely reduced. Particularly if patients have to be lifted and carried out of ditches or steep hills, rescue work can become exhausting for the medical staff. Similarly, staff working in extreme heat and sun should be supplied with appropriate, loose-fitting clothing. Sunblock cream, sunglasses, and caps are vital. Remember also that staff may have to work both indoors and outdoors, and correct clothing has to be available. It is not unusual to have a 20 to 30 °C temperature difference between indoor and outdoor conditions. Medical staff should wear similar clothes so that they are easily identifiable.

Accreditation

Access to various zones of a sports arena during a major event is extremely restricted, with good reason. It is important to allow medical personnel access to all parts of an arena, at the same time ensuring that this access is not abused. Different zones are letter or number coded, thus allowing the bearer access. Before an event, all medical staff must receive an accreditation card; they will usually have to go through a registration process weeks or months beforehand and then collect their cards at a designated accreditation center before being allowed access to any arena. It is imperative to keep your accreditation card hanging round your neck at all times so that you do not lose it!

Temporary Medical Licenses

During large sporting events, it is usual to issue licences for visiting nonnational physicians in order to allow them to practice medicine legally on their own nationals before and during an event. Visiting physicians must apply for these licences from the host nation's national health authorities many months in advance. Insurance matters must be addressed, and the visiting physicians must receive information well in advance of the competition about what rights and facilities they will have on entering the host nation. As a rule, foreign physicians are only allowed to treat athletes from their own country; they may issue prescriptions, which can be delivered to a specific pharmacy. A meeting between the host medical staff and visiting physicians is usually arranged just before commencement of the sporting event.

Language and Cultural Difficulties

Language differences do not usually create great difficulties as a rule; if you have seen the injury, then the path to diagnosis is usually clear. If not, then one can usually get some kind of history through physical demonstration. The problem gets worse when nontraumatic conditions have to be diagnosed and becomes almost impossible if there are psychiatric problems present.

Translators are necessary in certain instances. During smaller events, you can ask other volunteers, the ground staff, athlete team members, and so on, for assistance. In today's multinational world, it is not unusual to find someone who speaks the injured athlete's language. It is also advisable to have both male and female doctors available.

Equipment

Ordered equipment should be delivered in crates that have built-in shelves and should be packed in such a way that the crates, when opened, are actually stand-alone units ready for use, thus doing away with the need for extensive packing and unpacking of medical equipment.

The contents of the crates and their placement in the medical rooms should be standardized to facilitate ease of use. Sealed equipment and medications should not be used unless absolutely necessary.

Equipment that is not used can be resold or returned to the supplier after the event.

All disposable materials and medications used should be compiled on a list. This list of used and required items can be sent daily (or less frequently) by fax or e-mail to the central warehouse, and refills can thus be ordered.

At large events, it is important to have a store of disposable materials and medications. Refill orders should be sent in by a particular time each day, thus allowing refills to be delivered to the stadium during the night. Refilling, thus, will be done before the start of competition the next day.

Always test vital equipment before the start of an event. In particular, check whether the oxygen tanks are working and full, check all equipment containing batteries and bulbs, make sure there are no leakages from splints and ensure that the right pumps are available, make sure that all medications are available and are not outdated, and ensure that infusion fluids are intact and have the correct temperature.

Outfit doctors, nurses, paramedics, and first aid responders with backpacks/fanny packs containing lightweight portable equipment. The contents of the backpacks will vary according to the individual skill levels, location, number of potential patients, and so on.

Belt packs and fanny packs are usually standard and can contain items for personal use, for example, water bottles, snacks, sunglasses, gloves, and so on.

De-Rigging and Resale

After an event has been completed, a major de-rigging operation is initiated, and rooms are literally stripped bare of all equipment, including telephones and other electronic equipment. This process can begin 1 hour after the final event. The urgency and speed with which these de-rigging exercises occur is often quite staggering, and one often wonders why it takes months to outfit rooms but only hours to empty them! One motive for this haste is to prevent theft.

Although this program may appear somewhat excessive and overdimensioned for minor sporting events, the issues addressed are often equally relevant for smaller sports events, though on a much reduced scale.

In conclusion, planning the medical aspects of a sports event can be quite challenging but also most rewarding. Careful and detailed planning is always essential to ensure a quality service.

Meniscus Injuries

One of the most commonly injured parts of the knee, the *meniscus* is a wedgelike, rubbery cushion where the major bones of the leg connect. Meniscal cartilage curves like the letter C at the inside and outside of each knee. A strong stabilizing tissue, the meniscus helps the knee joint carry weight, glide, and turn in many directions. It also keeps the femur (thigh bone) and tibia (shin bone) from grinding against each other.

Football players and others in contact sports may tear the meniscus by twisting the knee, pivoting, cutting, or decelerating. In athletes, meniscal tears often occur in combination with other injuries, such as a torn anterior cruciate ligament (ACL). Older people can injure the meniscus without any trauma as the cartilage weakens and wears thin over time, setting the stage for a degenerative tear.

Anatomy

The knee menisci are C-shaped pieces of fibrocartilage that serve as shock absorbers in the knee. Their triangular cross section serves to increase the contact area between the rounded end of the distal femur and the relatively flat tibial plateau, thus allowing for load to be transferred over a greater surface area between the two bones. The menisci also contribute to knee joint stability, joint lubrication, and proprioception. The menisci are able to slide to the front and the back of the knee as the knee flexes and rotates, with the less constrained lateral menisci (outer menisci) moving to a greater extent than the medial meniscus (inner menisci). The more limited range of motion of the medial meniscus makes it more vulnerable to tearing and injury.

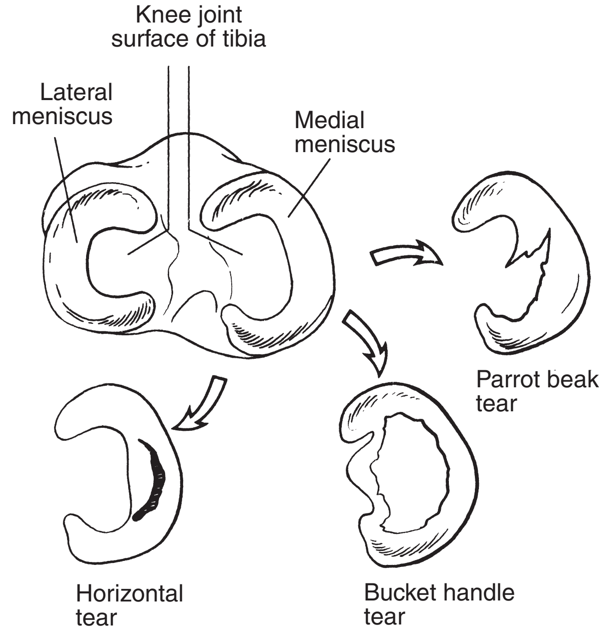

Figure 1 Meniscus Injuries

Note: Meniscus tears are named according to the shape of the tear: *bucket handle, horizontal,* and *parrot beak,* to name three.

Causes

Menisci tear in a number of ways:

Young athletes often get longitudinal or "bucket handle" tears if the femur and tibia trap the meniscus when the knee turns.

Less commonly, young athletes get a combination of tears called radial or "parrot beak," in which the meniscus splits in two directions due to repetitive stress activities such as running.

In older people, cartilage degeneration that starts at the inner edge causes a horizontal tear as it works its way back (Figure 1).

Symptoms

The athlete might experience a "popping" sensation when a tear of the meniscus occurs. Most people can still walk on the injured knee, and many athletes continue to play. When symptoms of inflammation set in, the knee feels painful and tight. For several days, the athlete has

- stiffness and swelling,
- tenderness in the joint line, and
- collection of fluid ("water on the knee").

Without treatment, a fragment of the meniscus may loosen and drift into the joint, causing it to slip, pop, or lock; the knee gets stuck, often at a 45° angle, until it is manually moved or otherwise manipulated. The athlete suspected to have a meniscal tear should see a physician promptly for diagnosis and individualized treatment.

Diagnosis

The history and physical examination are probably the most important ways to diagnose a meniscal tear. In an acute (sudden) injury, joint swelling is a good indicator. Swelling that occurs within the first few hours of an injury can be especially indicative of the injury causing bleeding in the joint, while swelling that occurs the next day may be due to the inflammatory response. In addition, examination of the knee with specific tests may be helpful in determining whether the injury is to a meniscus or another structure within the knee, such as a ligament or the cartilage.

Imaging of the knee may also be recommended. X-rays can be used to rule out a fracture, but the menisci themselves will not be visible on these studies. To assess the meniscus, a magnetic resonance imaging (MRI) scan may be ordered. In some cases, arthroscopy (putting a small camera into the joint) may be required to determine whether there is a tear in the meniscus. If this is needed, treatment of the tear can usually be accomplished at the same time.

Treatment

Nonoperative Approach

Initial treatment of a meniscal tear follows the basic RICE formula (*r*est, *i*ce, *c*ompression, and *e*levation), combined with nonsteroidal anti-inflammatory drugs (NSAIDs) for pain. If the patient's knee is stable and does not lock, this conservative treatment may be all that is needed. Blood vessels feed the outer edges of the meniscus, giving that part the potential to heal on its own. Small tears on the outer edges often heal with rest.

Surgical Repair

If a meniscal tear does not heal on its own and the knee becomes painful, stiff, or locked, surgical repair may be needed. Depending on the patient's age, the type of tear, whether there is also an injured ACL, and other factors, the surgeon may recommend arthroscopic surgery to either place sutures to repair the meniscus or to use small instruments to trim off damaged pieces of cartilage.

Orthopedic surgeons who are specialists in meniscal injury treatment have spent many years developing highly specialized arthroscopic techniques to repair tears in the meniscus. This experience has enabled repair of not only small, "simple" tears but also complex, multicomponent tears, which most physicians elect to remove, particularly in young patients. Although the success rate is lower for complex tears than for simple tears, it is felt to be worth the time and effort to try to save the meniscus in order to keep as much of the normal shock absorber in the knee as possible, especially for young patients.

In some cases, the torn part of the meniscus is either so small that it would be impractical to repair or so damaged that the repair would have a high likelihood of failure. In these cases, this tissue is simply trimmed out to leave a stable rim of meniscus and to minimize further damage within the knee.

The goal of meniscal surgery is to obtain a stable, smooth rim of meniscal tissue that does not rub abnormally on the cartilage surfaces of the knee. Patients may still have a slightly increased risk of arthritis in the knee after a meniscal tear, even if surgery is performed.

Alternatives to Surgery

Surgical treatment is usually advised for patients with symptoms of unstable meniscal tears, including pain, locking, giving way, or catching in the knee. However, deciding against surgery is reasonable for select patients. Nonoperative management of isolated meniscal tears is likely to be successful or may be indicated in patients with

- small, stable tears located in the outer third of the meniscus,
- low-demand lifestyles, and
- no effusion or swelling of the knee and no symptoms of locking or catching in the knee.

Preoperative Care

If arthroscopic surgery is elected, the patient should have a complete physical examination with the family physician before surgery to assess general health and to rule out any conditions that could interfere with surgery. Tests including blood samples and a cardiogram may be ordered.

Preoperatively, the patient must be informed which medications to discontinue prior to surgery. These typically include aspirin and anti-inflammatory medications such as ibuprofen, which should be stopped 10 days before surgery.

Rehabilitation

Nonsurgical Rehabilitation

Nonsurgical rehabilitation for a meniscal injury will typically last 6 to 12 weeks if no mechanical symptoms are present (symptoms such as locking, catching, or giving way). This will consist of exercises to strengthen the muscles around the knee, avoidance of high-impact activities, and possibly use of a brace to stabilize the knee during the healing process. The patient can return to full activities when there is no more swelling in the knee, the pain subsides, and the patient has regained complete strength and control of the knee.

After Surgery

A cast or brace immobilizes the knee after surgery. The patient must complete a course of rehabilitation exercises before gradually resuming normal activity.

Most patients will take part in formal physical therapy after meniscal surgery. In cases where only a small trimming was needed, many patients find that gradually resuming their normal activities as their knee strength and control return is effective and safe. Patients who have had a repair of the meniscus will often need formal physical therapy to regain strength and motion within the knee as the meniscus heals.

Menstrual Cycle and Sports Performance

The female menstrual cycle (MC), with its alternating levels of sex steroid hormones, affects exercise capacity and performance through numerous mechanisms, such as substrate metabolism, cardiorespiratory function, thermoregulation, psychological factors, and injury rates. Female athletes and their coaches should be aware of both positive and negative influences of the MC on overall performance, on an individual basis. Athletes negatively affected by their MC can consider the use of oral contraceptives to provide a stable and controllable hormonal milieu for training and competition. It should be noted that this is a very complex field, and future research will undoubtedly shed more light on the mechanisms and outcomes detailed below.

The Menstrual Cycle

The MC can be divided into three phases based on ovarian function—follicular, ovulatory, and luteal—all of which are controlled by pituitary hormonal signals. The *follicular phase* begins on the first day of menses, lasts about 9 days, and is the period when the follicle (soon to be an ovum) grows. Estrogen is secreted from the cells surrounding the follicle to the circulation. As estrogen levels increase, ovulation occurs, and an ovum is released and starts to migrate to the uterus. This marks the beginning of the *ovulatory phase*, which lasts about 5 days. After the follicle has released the ovum, it transforms into a progesterone-secreting corpus luteum, marking the beginning of the *luteal phase*, which normally lasts 14 days. At the end of the luteal phase, progesterone secretion from the corpus luteum ceases, and menstrual bleeding occurs. The three phases of the cycle are therefore differentiated from one another by estrogen and progesterone levels: Both are low in the follicular phase, estrogen is high and progesterone is low in the ovulatory phase, and both are high in the luteal phase. The sex hormones have several physiological functions, which can affect exercise performance through several mechanisms.

Physiological Effects of the Sex Steroid Hormones

Cardiovascular System

Estrogen enhances arterial vasodilatation, which in turn can increase blood supply to the heart and muscles. Estrogen and progesterone (high in the end-luteal phase, i.e., premenstruation) can cause fluid retention and increase in body weight, which might hinder performance. Additional effects on heart function have been documented, but not enough research has been done in this field.

Respiration and Ventilation

Sex hormones are involved in the central neural control of breathing, also affecting the lungs and the airways. Furthermore, premenstrual and perimenstrual aggravation of asthma can be seen in up to 40% of asthmatic women, even though they may not be aware of it.

Thermoregulation

Progesterone causes an increase in basal body temperature of 0.3 to 0.5 °C during the luteal phase (and during pregnancy). The major mechanisms of this phenomenon are altered skin blood flow, a higher threshold for cutaneous vasodilatation, and delayed onset of sweating. A higher core body temperature may increase the risk for heat accumulation when exercising in hot weather, thus decreasing time to fatigue.

Substrate Metabolism and Energy Sources

Estrogen promotes glycogen uptake and storage in both liver and muscle. During exercise, higher levels of estrogen (and progesterone to a lesser extent) tend to spare glycogen stores by shifting metabolism toward free fatty acids. This may be an advantage during ultraendurance exercise. Estrogen can also act in concert with additional hormones regulating glucose metabolism, such as growth hormone, catecholamines, and insulin. Progesterone is probably responsible for the relative glucose intolerance and insulin resistance during the luteal phase and pregnancy.

Psychological Factors: Estrogen and the Brain

There is evidence that estrogen mediates different aspects of cognition, alertness, and mood, possibly through changes in the availability of neurotransmitters such as serotonin in the brain. The importance of these effects is mainly during competition, where peak mental functions are required.

Menstrual Cycle and Physical Performance

The physiological changes throughout the MC may affect physical performance. The main factors for discussion are strength and aerobic and anaerobic capacities. Since there is great variation between individuals, it is essential for each woman to monitor her own response.

Strength

Estradiol can promote growth hormone secretion, a hormone known for its anabolic effects. Some research suggests that estrogen increases the ability of muscles to contract by about 10%, with a peak in strength just before ovulation. Others show that maximal muscle contraction is significantly higher during the ovulatory phase but there are no significant changes in muscle strength, fatigability, or electrically stimulated contractile properties. To date, there is no consensus on this matter.

Aerobic Capacity

Some studies suggest a slight decrement in aerobic capacity and exercise efficiency during high-intensity exercise in the luteal phase, paralleling an increase in oxygen consumption and metabolic rate. However, these results are not consistent. Aerobic endurance is also a matter of controversy, with some studies suggesting improvement during the luteal phase. However, it is more likely that nutritional status, glycogen stores, and other hormonal effects on substrate utilization contribute more to enhancement of performance than the MC phase itself.

Anaerobic Capacity

The few studies conducted in this area have found either no difference in anaerobic power output during the different phases of the MC or greater anaerobic capacity and peak power during the luteal phase.

Menstrual Cycle and Overall Sport Performance

While the MC can affect physiological and metabolic responses to exercise, optimal performance in a specific sport type is the ultimate goal of the female athlete. The aerobic effects of the hormonal fluctuations may be more relevant to a long-distance runner or biker, whereas strength is important for the weight lifter, fluid retention for the high jumper, and so on. Because maximal function in a sports event depends on a combination of physiological and psychological factors, it is very difficult to isolate the effects of the MC on overall performance. Most of the early studies on athletic performance were based on subjective feelings, without measuring the hormone levels. Many athletes reported a decrease in performance during the premenstrual and menstrual phases, whereas others reported improved performance, winning gold medals and breaking world records. When asked which symptoms of the MC hinder their performance, athletes reported abdominal or low back pain, fatigue, or nervousness during menstruation, yet most did not feel that these symptoms affected their ability. Gold medals were won throughout the female cycle, emphasizing that menstrual phase effects are individual.

Very few studies have intentionally addressed MC and performance in specific sports. For example, swimming speed was found to be highest during menstruation and lowest during the premenstrual period; cross-country skiers performed better in the early luteal and in the late follicular phases; in runners, no effect of MC phase on aerobic parameters or perceived exertion was identified. However, these kinds of studies usually involve only a few athletes, and a menstrual phase is not verifiable by blood tests, only through self-report or body temperature changes. Hence, the influence of the MC on the "end result" of performance in a particular sport type per se is not known, so every athlete should examine the effects of her own MC on her sports performance.

Menstrual Cycle and Sports Injuries

Females have nearly 10-fold the rate of sports injuries as males. This has been found in playing ball games, running, biking, military training, and other activities. Suggested mechanisms that may be affected by the female hormones include anatomical and biomechanical factors, neuromuscular control, ligament laxity, and others. Most studies focus on knee injuries and the changes in laxity of the anterior cruciate ligament (ACL) throughout the MC.

Recent studies, which use measurements of hormone levels, show a clustering of ACL injuries in the ovulatory phase, that is, Days 10 to 14 of the MC, with a lower than expected rate of events during the luteal phase. Suggested mechanisms for the higher rate of ACL injury in females in general and during the ovulatory phase in particular include changes in neuromuscular control, muscle strength and fatigability, and the intensity of the premenstrual syndrome and its effects on balance and motion perception. Much attention has been given to the increased laxity of the ACL during the luteal phase, which is associated with higher hormone levels.

Oral Contraceptives

Oral contraceptive pills (OCPs), which provide a steady level of high estrogen and progesterone, are increasingly being used by female athletes. They allow manipulation of the timing of menses; it is possible to even completely withhold menstruation with the use of new pills such as Seasonale®, which is administered for 3 months continuously, allowing only four "periods" of withdrawal bleeds per year. The latter method abolishes premenstrual syndrome and menstrual discomfort and pain, decreases blood loss and iron deficiency, and, of course, prevents unwanted pregnancies.

As discussed so far, research indicates that regularly menstruating female athletes do not need to adjust their MC to maximize performance, as hormonal changes during the MC and any physiological and psychological effects they may inflict differ greatly from one woman to another. If OCPs are used to minimize the identified negative effects of menstruation on sports performance, then regular use of OCPs will give a stable hormonal milieu and predictable onset of menstrual bleeding. Hormonal manipulation of the MC should be restricted to mature, elite athletes and reserved only for critical competitions in cases where there is a clear deleterious effect of the menstrual phase on performance.

Conclusion

The changes in estrogen and progesterone levels throughout the MC cause several biochemical, anatomical, physiological, and psychological effects on a female's body, which in turn may affect sports performance. The paucity of research in this field, and the varied methodologies used, prevents us from drawing distinct conclusions other than the following: The net sum of these changes may bring about positive or negative effects on sports performance *on an individual basis,* so athletes and coaches should "listen to the body" and act accordingly. Use of hormones can be considered in specific cases where the MC is shown to negatively affect sports performance. For those who need contraception, continuous pills can be a new, promising option.

Menstrual Irregularities

The average age for girls to first have a period (undergo menarche) is 12 years. However, it is normal to experience menarche between the ages of 8 and 15. Menopause, when a woman has her last menstrual cycle, occurs at an average age of 51 but is normal between the early 40s and late 50s. Genetics, diet, and activity level all affect the age of menarche and menopause.

The Menstrual Cycle

The normal cycle is about 28 days (±7 days), and it is common for the cycle to be of slightly different lengths from month to month. In the first year or two after menarche, it is common to have even more variability, as the body adjusts to menstruation. When a woman experiences cycles within the normal range, it is called *eumenorrhea.*

The first day of the menstrual bleed is considered Day 1 of the cycle and begins the *follicular phase.* Normal menstrual bleeding, the shedding of the endometrial lining of the uterus, usually lasts from 3 to 5 days. As menses ceases, hormonal changes lead to the buildup of the endometrial lining again and the growing of follicles in the ovaries. While still part of the follicular phase, this subphase after menses is considered the *proliferative phase,* when the endometrial lining is thickening and the follicles are growing. Eventually, one follicle dominates, and around Day 14, it releases what becomes a mature ovum, or egg, from the ovary. This is ovulation.

The ovum travels into the fallopian tube, awaiting fertilization, while the endometrial lining develops secretory glands to prepare for implantation. The corpus luteum, what remains of the dominant follicle after the ovum is released, grows and secretes hormones to help maintain the endometrial lining. This is the beginning of the luteal phase or secretory phase, the second half of the menstrual cycle. If the ovum is not fertilized, it disintegrates, as does the corpus luteum; hormone levels fall, and eventually, the endometrial lining is shed (menstruation and Day 1 of the next menstrual cycle).

There are a variety of hormonal changes that occur during the menstrual cycle. Pulsatile secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus (an organ in the brain) stimulates the production of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in the pituitary gland (another organ in the brain), which affects the levels of important hormones involved in the menstrual cycle, including estrogen and progesterone. The menstrual cycle is a complex positive and negative feedback system of an array of hormones and endocrine glands.

Importance of Normal Menstrual Function

Normal hormone levels are important for bone health, fertility, cardiovascular health, and other biological functions. For example, women attain 90% of their peak bone density by the time they are 18 years of age. If menstrual cycles do not occur during adolescence, a significant opportunity for bone building will be lost, putting the individual at much higher risk for fractures immediately and later in life. Thus, abnormal menstrual cycles should always be investigated. First and foremost, they may signify pregnancy! But they may also signify lack of nutrition, excessive exercise, polycystic ovarian syndrome, a thyroid disorder, uterine polyps, fibroids, endometrial fibroids, diabetes, a drug effect, infection, or other health problems. The following are signs that a female should see her doctor about her menstrual cycle:

- She has not started menstruating by the age of 15 even though she has secondary sex characteristics (e.g., breast development, axillary and pubic hair). This is known as *delayed menarche* or *primary amenorrhea*.
- She has not had breast growth by the age of 13 (*delayed puberty*) or hasn't started menstruating within 3 years of breast development (also *delayed menarche*).
- She has experienced menarche but suddenly has no menstrual cycles for >90 days (*secondary amenorrhea*).
- She has menstrual cycles that are >35 days (*oligomenorrhea*).
- She has menstrual cycles that are <21 days (*polymenorrhea).*
- She has breakthrough bleeding during her cycle at unexpected intervals (*metrorrhagia*).
- She bleeds for >7 days (*menorrhagia*).
- She bleeds more heavily than usual or is using more than one pad or tampon every 1 to 2 hours (also *menorrhagia*).
- She has severe pain during menses (*dysmenorrhea*).
- She suddenly gets a fever and feels ill after using tampons.

If a woman has testing done that determines that she has *luteal suppression* (menstrual cycles with a luteal phase shorter than 11 days or with a low concentration of progesterone) or if she has *anovulatory* cycles (no ovulation), these should also be further evaluated.

Menstrual Irregularities in Athletes

Female athletes, often in weight-restricted sports, aesthetic sports, and/or endurance sports, are at higher risk for menstrual irregularities. This is because of the *female athlete triad* (the interrelationship of poor bone health, menstrual dysfunction, and disordered eating). Oligomenorrhea or amenorrhea may be the first sign that an athlete has the triad. A fracture, stress fracture, or stress reaction may be a sign that an athlete is missing periods and has disordered eating (not enough calories, poor nutritional choices, or pathologic eating patterns such as anorexia or bulimia).

Because estrogen and other hormones involved in the menstrual cycle are so important for bone health, skipping periods should not be accepted as "normal" among athletes. Menstrual irregularities can compromise long-term health as well as athletic performance. Some women will take an oral contraceptive pill (OCP) to ensure that they do get menstrual bleeds, but the hormones in "the pill" do not mimic the hormonal fluctuations of a normal menstrual cycle. Thus, while OCPs may help with dysmenorrhea, menorrhagia, metrorrhagia, acne improvement, pregnancy prevention, and other health issues, they have not been proven to be helpful in maintaining or improving bone density as well as they have in retaining or regaining regular periods. Ongoing studies are being conducted to determine the short- and long-term effects of OCPs on bone and other health parameters. For now, OCPs should be used with caution in athletes who have experienced menstrual irregularity, and a bone density test may be warranted in these athletes before routine use of OCPs.

Summary

There are many types of menstrual irregularities, all of which should be evaluated by a doctor. Some may be easily managed with changes in diet, exercise, or medication, but the abnormality could mask a more severe disorder, and ignoring it may put a woman at risk for further health problems.

Mental Health Benefits of Sports and Exercise

Mental health can be broadly defined as how we feel, think, and behave. Exercise is believed to boost mental health, enable us to cope better with stress, and also help in treating a number of mental disorders. Mental disorders include conditions such as depressed mood and anxiety, dementia and cognitive decline, and various psychoses, such as schizophrenia. Since poor mental health not only reduces a person's quality of life but also increases the risk for various physical diseases, this is an important topic in sports medicine.

Depression and Mood State

Mood describes a set of affective states—such as fatigue, vigor, or anger—that we experience on a daily basis. Mood is generally assessed using questionnaires that ask people to rate how they are feeling on a scale. There are a large number of studies that have examined the association between exercise and mood. Acute effects refer to the mood response from a single bout of exercise, while chronic effects describe how mood alters with involvement in regular exercise over time. Following a single bout of exercise, mood is generally enhanced. Immediately after vigorously exercising, there may be a short period of increased negative mood state, such as fatigue, but positive mood is still enhanced some time later. The positive mood response to acute exercise is potentially important because it provides the motivation to maintain regular exercise habits. When people who exercise regularly are forced to stop their normal physical activity, it is known to be a powerful and stressful stimulus that can induce depressive and fatigue-like symptoms. This is an important factor to consider when injury prevents athletes from continuing with their normal exercise training.

Depression is a common mental disorder and has gained a lot of interest in relation to exercise. Depression is recognized from various symptoms that include depressed mood, loss of interest and pleasure, feelings of guilt and low self-worth, disturbed sleep and appetite, low energy, and poor concentration. Research in large populations suggests that people who exercise regularly are less likely to suffer from depression throughout their lives. These results are observed when other factors are also taken into account, such as social class, education, employment, marital status, smoking, and alcohol intake. Nevertheless, it remains unclear whether exercise is a cause of better mental health or whether regular exercisers have a particular genetic makeup that makes them less prone to depression in the first place. To resolve some of these issues, researchers have attempted to see if exercise can reduce levels of depression when individuals are randomly allocated to exercise training or control treatments.

Results from these studies suggest that exercise can consistently reduce symptoms of depression in both adults and children. The present research, however, has not been able to establish if the antidepressant effects of exercise can be maintained over a long period of time. This information will be important if exercise is to become an established treatment for depression.

Depression has been strongly linked with premature death, and cardiovascular disease, in particular. Physical illness, especially chronic or severe diseases, is associated with a substantially higher prevalence of depression than good physical health. It is therefore important to consider the use of exercise to improve physical health outcomes in clinical populations with existing mental health disorders such as depression. For example, among cardiac patients with depression, those who exercise regularly have been shown to have a lower risk of subsequent death and heart attack. Therefore, treating depression with exercise appears to have additional benefits over and above medication.

Age-Related Cognitive Decline

Cognitive decline, which refers to loss of memory and the ability to concentrate and make decisions, presents a major problem in aging communities. Dementia is a common disease and is characterized by a decline in memory. Various longitudinal studies have shown that people who exercise regularly are less likely to develop dementia at a future time point. Walking for a minimum of 1.5 hours/week is associated with better cognitive performance in older women, although reducing physical activity levels over a period of 10 years might result in cognitive decline. In studies where individuals are randomly allocated to exercise training or control treatments, exercise has been shown to consistently improve cognitive function. These benefits are seen both in healthy people and in older people with existing cognitive impairment. For example, individuals with Alzheimer disease who exercise show improved function on activities of daily living, better cognitive performance and physical function, and decreased depressive symptoms, in comparison with nonexercisers, who show continued decline. However, in most of these studies, exercise training interventions have been conducted for 6 months or less, and longer-duration studies are therefore required to confirm the long-term benefits.

Stress Buffering

Stress is a common aspect of everyday life, and although a certain degree of stress is beneficial to stimulate mental and physical performance, the inability to cope with excessive psychological demands may be detrimental. People who are physically fit or engage in regular physical activity show reduced responses to stress. Such responses include lower blood pressure, lower immune activation, and reduced release of various stress hormones, such as adrenaline and cortisol. Exercise might be particularly beneficial for people who are already suffering from mental health problems because these individuals display heightened responses to stress. And exaggerated responses to stress may further contribute to a worsening of their condition.

The beta endorphins, which are produced during exercise, have often been related to the positive affective states observed following exercise and have also been associated with stress-buffering characteristics. In addition to various exercise-induced adaptations to the central and peripheral nervous system, this may form the basis for the mental health benefits of exercise. It is, however, possible that the additional benefits gained from participating in sports may have a psychological component, such as fostering social support networks and developing mastery and better coping abilities.

Prescribing Exercise

It is important to define the amount and type of activity required to achieve mental health benefits. The current recommendations for physical activity for preventing chronic disease are at least 30 minutes of moderate to vigorous exercise on 5 or more days per week. However, the existing evidence suggests that mental health benefits can be gained from lower amounts of physical activity. A minimum of one session (of at least 20 minutes) per week of any type of activity, including domestic work, walking, and sports, can be beneficial. However, exercising vigorously (e.g., sports participation) and more frequently (everyday) seems to give the most benefit. From a practical standpoint, several components of mental disorders, such as fatigue, low self-esteem, and other physical ailments, might make it difficult for people with poor mental health to begin and sustain an exercise program. Indeed, patients with depressive symptoms appear to be the least likely to take up regular exercise. Therefore, a key aspect is not only prescribing exercise but also motivating and supporting people with mental disorders to become physically active.

Another important aspect to consider is the relative benefits of structured compared with lifestyle exercise programs. Structured exercise is usually supervised and performed in an exercise facility, whereas lifestyle interventions might encourage people to use more exercise in their daily lives, such as walking instead of taking the car. Both approaches have advantages and disadvantages. For example, structured exercise ensures a safe environment to exercise in, appropriate exercise levels can be easily monitored, and exercise professionals can provide motivation and support. On the other hand, individuals with mental health problems might feel particularly self-conscious about exercising in this type of environment. A home-based exercise program may therefore be more appealing and give greater flexibility, although self-motivation and self-monitoring of physical activity goals are major difficulties with this approach. Taking all of these factors into consideration, when prescribing exercise for mental health, programs that are tailored to the individual are most likely to prove successful.

Metatarsalgia

Metatarsalgia is defined as pain at the ball or forefoot, usually associated with increased stress over the metatarsal head area.

It is a relatively common problem seen in primary care but is very common in some sports, especially in running. It can be seen in athletes of all ages, with Freiberg disease more specific to adolescents and fat pad atrophy to the elderly. Metatarsalgia also occurs in patients of all shapes and sizes, with obesity contributing to pressure-related pain on one end of the spectrum and overly thin ultraendurance athletes developing stress fractures on the other.

The metatarsals take up to 275% body weight during running, with the first metatarsal usually bearing half the weight. Biomechanical deficits involving the entire kinetic chain, whether it is genu valgus, tight heel cord, or severe pronation, all contribute to metatarsalgia.

There are many causes of metatarsalgia, and thus, a thorough history and physical and judicious imaging are critical for proper diagnosis. Treatment can vary from simply rest to, rarely, surgical management.

Symptoms

The pain of metatarsalgia is usually described as sharp, although sometimes it may be a burning or tingling sensation at the ball of the foot. The most common areas are usually the second, third, or fourth metatarsals. Patients may complain of worsening of the pain with walking or running, usually during the midstance or push off phase. The pain may improve with rest or non–weight bearing. There may also be pain with just standing. Pain is usually worse when associated with barefoot walking on hard surfaces.

Usually, the pain develops gradually and is not necessarily associated with any trauma. Sometimes, if a neuroma is involved, there may be numbness of one or multiple toes.

The history should also include a thorough training history, either increases in mileage or intensity. The type of terrain can play a role if the athlete mostly trains on hard surfaces such as concrete. Age of training footwear (generally recommended to be replaced every 300–500 miles [mi; 1 mi = 1.61 kilometers]) can definitely play a role. A new shoe that may not be appropriate to the athlete's foot mechanics can also contribute to the pain; for instance, a motion control shoe on an athlete with pes cavus and supinates may not provide enough shock absorption.

Causes

Metatarsalgia is often seen in the context of increases in training. Increased training increases the repetitive load, increasing the risk for stress fracture, fat pad atrophy/contusion, sesamoiditis, and breakdown of shoe cushioning.

Certain physical characteristics also increase the risk for metatarsalgia. A longer second toe than the first one shifts more weight to the second metatarsal head. Weight gain can obviously increase the load on the metatarsals. Hammertoes (flexed, curled toes) due to high heels or shoes that are too small cause depression of the metatarsal heads. Bunions (hallux valgus) result in a hypermobile and weak first toe, which offloads pressure to the second metatarsal. Fat atrophy from aging can be a risk for the elderly.

Shoe wear can definitely play a role in the development of metatarsalgia. As previously stated, old shoes that have lost their cushioning ability will more directly transmit shock. Toe boxes that are too narrow can irritate a neuroma due to constant compression. Daily wearing of high heels will place extra load on the metatarsals. Shoes that are too small can be a common problem, especially in new marathoners who do not take into account the swelling caused by long hours of running.

Metatarsal stress fractures are usually found in the setting of a runner with increased levels of training. Commonly, it will involve the second, third, or fourth metatarsals, in that order.

Morton or interdigital neuromas are perineural fibrosis of the intermetatarsal plantar digital nerves causing a mechanical entrapment neuropathy. They usually occur in the third and second interdigital spaces as a result of overly narrow shoes. Besides pain, often there is a sensation of numbness, tingling, and burning.

Freiberg disease is a condition where microtrauma at the metaphysis and growth plate in adolescents results in avascular necrosis of the second metatarsal.

Pain can also come from the sesamoids—the two semilunar-shaped bones. The medial sesamoid is known as the tibial, and the lateral is known as the fibular. They are usually embedded in flexor hallucis brevis, which inserts into the base of the first proximal phalanx. They can fracture acutely or as stress fractures, or they can be inflamed from repetitive trauma. A bunion deformity (hallux valgus) can also rotate the sesamoids laterally into a greater weight-bearing position. The pain from a sesamoid injury is typically beneath the head of the first metatarsal.

Other causes of metatarsal pain include gout, infection, capsulitis, osteoarthritis, rheumatoid arthritis, and radicular or referred pain from the lumbar spine.

Physical Examination

Physical exam in the evaluation of metatarsalgia begins with inspection. This includes basic evaluation of gait and the entire kinetic chain to evaluate for risk factors and causes of the pain. On inspection of the foot, one should note not only signs of obvious deformity from trauma but also hallux valgus, pes cavus or planus, excessive pronation, and hammer toes. The examiner should also look for signs of infection or inflammation (i.e., gout or cellulitis) if there is erythema or warmth.

Generally, there will be tenderness to palpation over the affected metatarsal.

Range of motion may be increased at the first metatarsal phalangeal joint. Range of motion may be reduced at the ankle with a tight Achilles tendon, resulting in greater weight transfer to the forefoot.

There may be pain with squeezing the metatarsals together (the "squeeze test") if there is a neuroma. A severely affected neuroma may also cause paresthesias or numbness reproducible on exam.

The diagnostic procedure includes a local digital nerve block with a few milliliters of 1% or 2% lidocaine block just below the transverse tarsal ligament to diagnose neuroma.

Diagnostic Testing

Radiographs are usually obtained because they evaluate bony causes of metatarsalgia fairly quickly and at a low cost. Usually, anterior-posterior and lateral views of the foot are sufficient to detect signs of an acute or stress fracture, osteoarthritis, or a widened and flattened second metatarsal and sclerotic/irregular joint in Freiberg disease.

No further imaging study is usually needed. If there is a high suspicion of stress fracture, a bone scan or magnetic resonance imaging (MRI) study may be helpful. An MRI scan may also help in the case of atypical presenting symptoms or exam findings with persistent pain to evaluate for stress fractures, neuromas, sesamoiditis, or lumbar radicular pain.

Treatment

The initial treatment for metatarsalgia generally involves rest, ice, and elevation, as with most sports-related injuries. Non–weight bearing should be considered if there is any pain with walking. Nonsteroidal anti-inflammatories may be helpful, especially if the metatarsalgia is due to capsulitis or gout.

Subsequent treatments should be geared to the causes and risk factors associated with the injury. It may require adjusting of training schedules and goals, cross-training to reduce higher-impact activities, modifying the terrain the athlete trains on (i.e., grass instead of concrete), or recommending new footwear. Weight loss may be a critical factor if obesity or recent weight gain is the primary cause.

If there are biomechanical deficits, they need to be addressed. For example, the athlete may need to focus on stretching the Achilles tendon or correcting pronation either through posterior tibialis strengthening or through improved shoe selection.

Shoes may need to be more supportive in athletes with metatarsalgia who have pes cavus (high arches) and should have more motion control features for athletes who have pes planus and tend to overpronate. All patients who suffer from metatarsalgia should avoid high heels and shoes that have narrow toe boxes or are obviously too small.

Over-the-counter or custom orthotics can be helpful to address pronation as well. And metatarsal pads can be a quick and low-cost method to unload pressure from the metatarsal heads by spreading them apart. They can be applied in numerous shoes and adjusted easily as needed. A hypermobile first toe may be controlled with taping to minimize movement, specifically dorsiflexion, to relieve pressure on the metatarsals and sesamoids.

Generally, callus does not need to be debrided as it is a consequence of biomechanical problems and not the primary cause of pain. Debridement risks infection without significant benefit.

As mentioned above, an injection that includes an anesthetic with some long-acting steroids can be not only diagnostic but also therapeutic for Morton neuroma.

Rarely is surgery indicated in the treatment of metatarsalgia, but if it is necessary either in the form of excision of a neuroma or as a metatarsal osteotomy, a board-certified orthopedic surgeon trained in foot and ankle injuries would be best qualified.

Methicillin-Resistant *Staphylococcus Aureus* Infections

Among the many bacterial skin infections that affect athletes, none have gained as much recognition or public awareness in recent years as the methicillin-resistant *Staphylococcus aureus* (MRSA) infections. There have been numerous reports of serious infection and even death from these bacteria, and the public and health care system are now in a state of alert to tackle this relatively new threat. The vast majority of MRSA infections in athletes are skin infections, although any organ system can be affected. Athletes, parents, coaches, athletic trainers, and other medical providers all have a responsibility to minimize the impact that these infections have on the affected individual and other athletes around that person.

Microbiology

Staphylococcus bacteria species are common skin bacteria present in a large proportion of the population. Under normal circumstances, they do not cause infection. Risk factors that may lead to infection, however, are unfortunately common among athletes and include skin abrasions and wet environments. The majority of these *Staphylococcus* bacteria are susceptible to penicillin-type antibiotics (methicillin has become the standard marker antibiotic of this type) and are called methicillin-sensitive *Staphylococcus aureus* (MSSA). Those strains that are resistant to methicillin are also resistant to most penicillin-type antibiotics and are called methicillin-resistant *Staphylococcus aureus* (MRSA) strains.

It is important to further distinguish between hospital-acquired methicillin-resistant *Staphylococcus aureus* (HA-MRSA) and community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) strains. The former has been identified for decades, and it is associated with risk factors of recent hospitalization, significant immunocompromisation, and recent antibiotic use. These infections are usually limited to hospitals and nursing homes. In contrast, CA-MRSA has been a recognized problem in the athletic community only since the 1990s and can affect individuals regardless of these risk factors. We will focus in this entry on CA-MRSA due to its impact on athletes.

There are numerous strains of CA-MRSA bacteria identified throughout the world, and microbiologists are continuing to search for the specific factors that affect the virulence (severity) of the bacteria. This is of particular importance since the impact of infections range from a simple abscess, such as a pimple, to sepsis (blood infection with organ involvement) and even death.

Epidemiology

The prevalence of CA-MRSA in any given community varies widely. Among athletic teams, there have been reports of more than 25% carrier status, although most of the carriers did not have active infections. Identical strains of CA-MRSA have been found among teammates and competitors, indicating close contact as a high risk factor for transmission. Other risk factors for transmission include skin-to-skin contact, shared athletic equipment, and perhaps even shared artificial turf. These factors make quarantine, appropriate hygiene, and prompt identification of the problem essential in prevention strategies, as discussed below.

Clinical Presentation

Any skin or soft tissue infection (SSTI) characterized by warmth, redness, pain, pustules, or boils should be suspected for *Staphylococcus* infection and thus, by extension, CA-MRSA infection. This includes erysipelas (superficial redness of the skin from infection), cellulitis, folliculitis, impetigo, furuncles, and abscesses. Any athlete who has such symptoms should report them immediately to his or her coach or to medical personnel. Likewise, coaches or trainers of such athletes should facilitate medical evaluation.

MRSA infections are more likely than MSSA infections to form abscesses or other "closed" infections, although this is by no means an accurate method of diagnosis since there are a wide range of presentations of both. The only definitive way of differentiating an MRSA infection from an MSSA infection is by obtaining a culture and testing it in the lab for antibiotic sensitivity. Because of the potential rapid progression of symptoms that can be associated with MRSA infections, any skin infection in an athlete that is accompanied by fever, chills, malaise, or other systemic signs of illness warrants urgent evaluation in an emergency room or hospital setting.

Treatment

Treatment options for a skin infection in an athlete will vary somewhat based on the severity and type of infection, the overall health of the individual, how closely he or she can be monitored by a health professional, and the prevalence of CA-MRSA in an area. In areas with high prevalence of CA-MRSA or for athletes with known contacts with a CA-MRSA strain, treatment should be initiated with the assumption that a resistant organism is causative. There is ongoing discussion and research on optimal treatment strategies, which keep changing frequently.

For an athlete with a simple "closed" infection, such as an abscess or furuncle, who is otherwise healthy and has good medical follow-up, sterile incision and drainage by a medical provider may be the only needed intervention. Antibiotics, however, are often also prescribed. A larger lesion may need to have a surgical wick inserted to continue to drain the infection. If the medical provider has any question about whether the infection is CA-MRSA, he or she may take a sample and send it for evaluation for a definitive answer.

For diffuse CA-MRSA infections such as erysipelas, cellulitis, or any infection affecting a sensitive area (groin, hands, or face), antibiotics are almost always prescribed. Oral antibiotics most commonly recommended are trimethoprim/sulfamethoxazole, doxycycline, clindamycin, or linezolid. Some providers combine two of the above antibiotics, particularly in more serious infections. The duration of treatment is usually 10 to 14 days. Medications traditionally used for MSSA infections are not effective against MRSA and include cephalexin, amoxicillin, methicillin, azithromycin, clarithromycin, or quinolones (ciprofloxacin, levofloxacin). These antibiotics may, however, be used initially to treat an infection, with close monitoring to see if the patients are responding; if not, these antibiotics are stopped, and an antibiotic that treats CA-MRSA infections is given instead.

Severe MRSA infections include those with widespread or deep infections, involvement of a joint, or any associated systemic involvement (fever, chills, or malaise). These infections can be life threatening and require urgent hospital or emergency room evaluation. Any athlete presenting with these symptoms should proceed to an emergency room without delay. Intervention in this case usually involves hospitalization and use of intravenous antibiotics such as vancomycin.

Athletes who have had an infection or have been exposed to someone with MRSA may carry the bacteria in their noses, groins, or elsewhere on their skin, even if they have no active infection. Such people are termed *carriers*. There is conflicting evidence on the effectiveness of trying to eradicate MRSA from such carriers. The majority of studies show that attempts at eradication using a topical antibiotic such as mupirocin with or without oral antibiotics are usually not effective in removing the bacteria for any extended period.

Return to Sports

No athlete with a skin infection should play if there are also any systemic signs of illness. In the absence of systemic infection, coaches, trainers, and doctors need to consider the risk of contagion as well as the risk to the affected individual. There are no universal guidelines for return to play for MRSA, and established guidelines such as those from the National Collegiate Athletic Association (NCAA) or the National Federation of High Schools for bacterial skin infections and return to wrestling should be used as a conservative baseline. These guidelines prohibit an athlete from competing in contact or collision sports with an open, draining infection, and they also recommend being on antibiotics for 2 to 3 days prior to return to play. It is unclear as to whether these guidelines are applicable to individual or noncontact sports such as track events. With regard to MRSA infections, institutional and local guidelines are under constant review and change.

Prevention

Good personal and institutional hygiene are essential in preventing spread of the disease among teams and competitors. Measures such as simple hand washing are very effective in cutting down on infection and carrier rates. Athletes should not share personal equipment or personal hygiene items (towels, razors, deodorant, etc.) and, as discussed above, should let a coach or trainer know immediately if they have a skin infection. Strict quarantine of an infected athlete from competition, other team members, and facilities should be followed without exception. Appropriate disinfectant procedures of gym equipment or other shared equipment should be completed. Although there are many commercially available synthetic turf disinfectants, none has been conclusively shown to decrease MRSA transmission.

Miserable Malalignment Syndrome

Anterior knee pain in children and adolescents, often assigned the vague diagnosis of "patellofemoral syndrome," may have a number of different causes. Subtle anatomic abnormalities in the alignment of an adolescent's hips, knees, or legs can contribute to anterior knee pain. *Miserable malalignment syndrome* (MMS) is a term used to describe a triad of anatomic findings—excessive femoral anteversion (inward rotation of the knee, relative to the hip), increased knee Q angle (alignment that creates an outward pull on the kneecap by the connecting tendons), and external tibial torsion (outward rotation of the leg)—which are more frequently found in females and are associated with anterior knee pain.

Anatomy

At birth, there is a normal rotational alignment of the femurs (thighbone) and the tibias (shinbones) from top to bottom, which changes throughout the process of skeletal development. The bottom portions of both the femur, near the knee, and the tibia, near the ankle joint, begin by being rotated inward slightly, relative to the tops of the bones, and slowly rotate outward with increasing growth. When this process does not progress to a normal degree in the femur, the patient is said to have abnormally high "femoral anteversion." Notably, females normally have higher anteversion than males, which puts them at greater risk of having this abnormal condition. When this occurs too much in the tibia, the patient is said to have external tibial torsion, which can leave the feet splayed outward to some degree.

When abnormal femoral anteversion and external tibial torsion occur together, patellofemoral pain and other problems, such as patellar instability, can develop because of the effect on the Q angle of the knee. The Q angle is the angle formed by a line drawn from the anterior superior iliac spine (ASIS; a point on either side of the front of the pelvis) to the middle of the top of the patella (kneecap) and a second line drawn from the middle of the bottom of the patella to the tibial tubercle (the prominence at the top of the shinbone, which serves as the insertion of the patellar tendon). Because the knee and patella are rotated inward with femoral anteversion and the tibial tubercle is rotated outward with external tibial torsion, this combination creates an abnormally high Q angle. As a result, the patella has an abnormally high vector of force pulling it laterally to the outside of the knee.

Causes

Femoral anteversion and external tibial torsion are generally thought to be extremes of the physiologic spectrum of rotational development during skeletal maturation. Increased knee Q angle can be caused by other factors, such as a tight lateral retinaculum (connective tissue that runs from the patella to the side of the femur, along with the joint capsule) or genu valgum (knock-knees), but femoral anteversion and external tibial torsion are among the most common causes.

Symptoms

The primary symptom of MMS is patellofemoral, or anterior, knee pain. Patellar instability, in which the kneecap partially slides (subluxes) or dislocates out of its normal groove to the outside of the knee, can also occur in a small number of patients.

Diagnosis

Diagnosis of MMS is made primarily with a comprehensive physical examination focused on measuring the rotation of a patient's hips keep to assess femoral anteversion, and measuring the position of the feet relative to the knees (thigh-foot angle measurements) keep to assess tibial torsion. Evaluation of patellofemoral tracking, or the way in which the kneecap slides in its groove during knee flexion and extension, can reveal signs associated with MMS, such as patellar tilt (in which the kneecap tilts inward), or lateral subluxation. The appearance of "squinting patellas" or "patella alta" (high-appearing kneecap) is also a feature of MMS.

Full-length, standing lower extremity radiographs should be obtained to assess alignment and perform Q-angle measurements. Special techniques with computed tomography (CT) scans have been described for evaluating femoral anteversion and may have a role in preoperative planning.

Treatment

Nonsurgical Treatment

Patellofemoral knee pain is usually treated with physical therapy aimed at quadriceps strengthening and hamstring stretching. Some patients may benefit from selected patellar bracing or taping as well.

If femoral anteversion is detected before a child reaches skeletal maturity, it may spontaneously resolve as the child grows. However, external tibial torsion tends to worsen with age, so interventions should be planned with the patient's age and this natural history in mind. Braces and other devices have not been shown to be effective in treating either type of rotational deformity.

Surgery

If anterior knee pain persists despite aggressive physical therapy and the adolescent's rotational abnormalities are severe, rotational osteotomy surgery may be beneficial in select cases. Such a surgery involves making a transverse bone cut straight across either the femur or the tibia and rotating one end of the bone relative to the other, so as to improve the rotational alignment at the knee joint. A metal nail or plate and screws are used to facilitate healing of the bone in its new position.

After Surgery

When patients receive osteotomy surgery for MMS, there is generally a short period of recovery involving protection of weight bearing with crutches. An additional procedure to remove the hardware placed at the time of osteotomy may be pursued, but this is usually performed several months to years later.

Mixed Martial Arts, Injuries in

Mixed martial arts, also known as MMA, is a hybrid system composed of several practical aspects of multiple martial arts. MMA may include cross-training in the areas of boxing, jiujitsu, karate, muay thai, wrestling, judo, and other traditional martial arts. In recent years, MMA has become more popular, rivaling the financial success and popularity of boxing. It has undergone a dramatic evolution from the early days of "no-holds-barred" fighting to a commissioned sport with weight classes, rounds, and rules. Due to the nature of MMA fighting, it plays host to numerous injuries because of its blend of ground fighting and striking. And similar to boxing, it also has its share of controversy and debate within the sports medicine community.

History

It is generally recognized that martial arts developed not in one particular place but all over the world as a means of defense or military development. MMA-style competitions can be traced back to the Olympic Games themselves, when Greek pankration was introduced in 648 BCE. Pankration was a mix of boxing and wrestling, with minimal rules. With the rise of the Roman Empire, interest in Greek pankration waned, which led to the rise of other martial arts systems. The idea of integrating well-defined, "traditional" martial arts would be up to the individual practitioner.

The idea of integration became more popularized through the art of Jeet Kune Do, created by the martial artist/actor Bruce Lee, whom many consider to be one of the early developers of the idea of MMA. Although Lee was influential in martial arts, the evolution of modern MMA did not truly begin until the Ultimate Fighting Championship (UFC) was introduced to North American audiences in 1993. Although no-holds-barred fighting events had been held for many years in other countries, they did not become popular until the UFC held its first event. The UFC was an eight-man tournament with minimal rules, no time limits, and no weight classes, pitting different martial arts against one another. The tournament winner, Royce Gracie, was a 183-pound (lb; 1 lb = 0.45 kilograms) Brazilian jiujitsu practitioner who had defeated fighters and at times outweighed the smaller fighter by as much as 100 lb. Royce Gracie would continue his success by becoming a champion again in the UFC 2 event, demonstrating the effectiveness of grappling and submission fighting. Many would argue that it was Gracie's success that motivated "striking" martial artists around the world to incorporate "ground-fighting" skills into their armamentarium to make them more complete fighters. As the UFC's popularity grew, Japan would also play host to other similar events through its Pancrase Hybrid Wrestling, Shooto, and PRIDE Fighting Championships. And as the field of MMA's popularity grew, the idea of no-holds-barred fighting was given up in North America and replaced by a new set of rules and regulations known as the Unified Rules of Mixed Martial Arts, originally commissioned by the New Jersey State Athletic Commission in 2000. By the end of the century, a new type of martial artist arose, one who would be successful by cross-training in the areas of boxing, jiujitsu, muay thai, wrestling, karate, judo, and other traditional martial arts.

Rules

Although many rules exist for MMA competition, the most commonly used are the guidelines set by the New Jersey State Athletic Commission. Below are some basic competition rules set by the commission.

- Weight classes should be maintained.
- Gloves are to be 4-, 5-, or 6-ounce (oz; 1 oz = 28.35 grams) gloves supplied by the promoter and approved by the commission.
- No Gi (traditional martial arts shirt) shoes or shirts should be used.
- Nonchampionship contests are of three rounds, each round being of 5 minutes' duration.
- Championship contests are of five rounds, each round being of 5 minutes' duration.
- All bouts are scored by three judges based on a 10-Point Must System and evaluated on the basis of effective striking, grappling, control, aggressiveness, and defense.
- Warnings are issued for holding or grabbing the fence (or ropes) and holding the opponent's shorts or gloves; penalties may result in a deduction of points or disqualification if the infractions mentioned continue.
- Basic fouls that will result in penalties include, but are not limited to, head butting, eye gouging, biting, hair pulling, fish hooking, groin attacks, strikes to the spine or the back of the head, kicking or kneeing the head of a downed fighter, throat strikes, or stomping of a grounded fighter.

Sports Medicine Issues in Mixed Martial Arts

Because of its cross-training nature, MMA practitioners are susceptible to many types of injuries. Below is a description of the more common types of injuries sustained.

Takedown Injuries

Common MMA takedown techniques include the hip toss, suplex, souplesse (a variant of the suplex), and the guillotine drop. The hip toss is generally a throw of an opponent using the hip as the fulcrum. The suplex is a technique using the back hyperextension of the technician to throw an opponent, with the souplesse differing in how much extension is performed. The guillotine drop is a type of takedown that includes first having an opponent in a front-facing choke and then having the technicians throw their legs around the opponent's body, using gravity to take down their opponent while still maintaining the choke. Due to the nature of the techniques, the suplex and souplesse techniques can lead to back hyperextension injuries such as spondylolysis or spondylolisthesis, which are commonly seen in wrestlers or gymnasts. The guillotine drop also places the neck in flexion, which, in addition to the gravity of the practitioner applying it, can lead to further cervical flexion injuries.

Head and Facial Injuries

A high proportion of MMA matches are stopped due to either head injury or facial laceration. Although traumatic brain injury has been a topic of discussion among the fighting arts, the knockout proportion is lower than in boxing. This may be the result of allowing the fighters to use a "tap out" mechanism to end the competition at any time due to a submission or strikes. The most common result of matches is actually either a technical knockout (TKO) or a tap out. Facial lacerations are the most common injury sustained in MMA competition.

Other Health Issues

Because MMA involves grappling and submission techniques, many practitioners are also susceptible, though relatively rarely, to anoxic brain damage due to frequent strangulation or to joint strains due to its manipulation for submission. Blood-borne diseases caused by human immunodeficiency virus (HIV) and hepatitis virus are also considered, as well as skin conditions such as tinea and herpes gladiatorum.

Ergogenic Aids

Ergogenic aids, or supplement enhancers, have been an issue for many athletes. Steroid supplements have been the most popular enhancer for MMA practitioners, with claims of maximizing the response to resistance training, improving the immune system, and increasing fat metabolism. Although there are numerous anecdotal claims for their use, steroids have not been scientifically shown to improve athletic performance.

Ethical Considerations: Should MMA Be Banned?

The British Medical Association calls for a complete ban on MMA on the grounds of what it characterizes as excessively violent behavior. Many comparisons have been made with boxing, which is banned in many countries, including Norway, Iceland, and North Korea. As a comparison, there have been two documented deaths in MMA competition (one sanctioned, one nonsanctioned), whereas at least 140 boxers worldwide have died since 1990. Some of the counterarguments to banning both boxing and MMA are that freedom of choice should not be denied, training develops discipline, and, as a whole, boxing and MMA are safer today due to stricter rules and regulations. Another contentious issue is the participation of children, which recently has been fueled by allowing children to take part in MMA competitions (with protective headgear). These issues will continue to be a part of any full-contact, fighting-based competition.

Morton Neuroma

A *Morton neuroma,* also known as an *interdigital neuroma,* is a benign enlargement of a nerve in the foot, most likely caused by repetitive irritation of the nerve, which can lead to pain, a burning sensation, numbness, and/or tingling in the foot and toes. It classically occurs between the third and fourth toes (the area known as the third web space of the foot), but also may occasionally form between the second and third toes (the second web space). It is a common condition in athletes, especially those who wear restrictive footwear for their sport (e.g., ballet dancers) or those involved in high-impact activities (e.g., distance runners).

Anatomy

Two main nerves are responsible for sensation in the sole of the foot: the medial and lateral plantar nerves, both of which originate from the tibial nerve in the leg. The medial plantar nerve supplies sensation to the first, second, and third toes, as well as part of the fourth toe; the lateral plantar nerve supplies sensation to the fifth toe and part of the fourth toe. Branches from these nerves run in between the metatarsals in the web spaces of the foot; for this reason, they are also called the interdigital nerves. The branches from the medial plantar nerve run in between the metatarsals in the first and second web spaces; the branches from the lateral plantar nerve run in between the metatarsals in the fourth and fifth web spaces. In the third web space, a branch from the medial plantar nerve and a branch from the lateral plantar nerve join together, and the combination then runs between the third and fourth metatarsals. Due to this confluence of nerves, there is believed to be an increase in the thickness of the nerve branch that runs in the third web space; this may play a role in this location being the most common site of occurrence of Morton neuroma (see Figure 1).

Pathology

A Morton neuroma is a benign outgrowth of one of the branches of the medial or lateral plantar nerves. This outgrowth is due to perineural fibrosis—the formation of fibrous tissue around the nerve itself; it is not, in fact, a tumor of nerve cells, as the name *neuroma* would indicate. The perineural fibrosis in Morton neuroma occurs in response to repetitive trauma and/or stress to the nerve. A number of factors have been found to contribute to the increased susceptibility of the interdigital nerves to this fibrosis. Due to the limited space

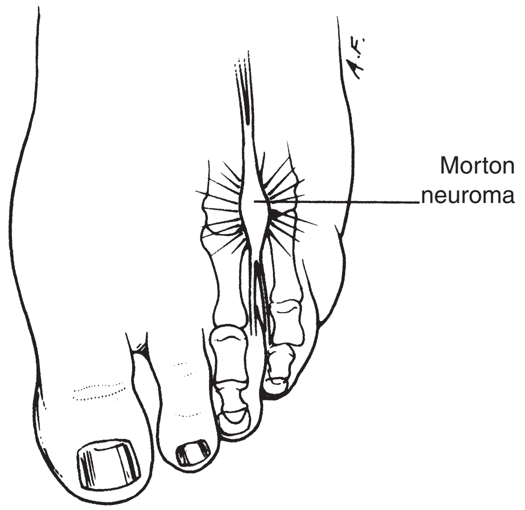

Figure 1 Morton Neuroma

Note: This benign outgrowth of a branch of the medial or lateral plantar nerve is a response to stress or repetitive trauma to the nerve.

between the metatarsal heads, the nerves are vulnerable to compression at that point; this effect is heightened by shoes with a small toe box, which further decreases the space between the metatarsals. Additionally, the interdigital nerves travel over a ligament that runs between the metatarsals, and during ambulation, the nerve can be pressed against this structure; specific foot types (pronated and pes planus) exaggerate this effect. Furthermore, in the third web space, branches of the medial and lateral plantar nerves join together near a muscle of the foot (the flexor digitorum brevis) and are therefore exposed to increased pulling forces when the toes are extended (dorsiflexed), as occurs during walking. Finally, the fourth metatarsal has more mobility than the third; this may result in the interdigital nerve becoming wedged against the third metatarsal and being subjected to repeated pressure from the fourth metatarsal as it moves with ambulation.

Certain foot types may also be predisposed to the formation of Morton neuroma. As noted briefly, both pronated and pes planus foot types increase the forces from the flexor digitorum brevis muscle on the interdigital nerve in the third web space and can thus elicit irritation in that nerve. Additionally, any abnormal positioning of the toes, including bunions (hallux valgus deformity) and the hammertoe deformity, may alter the distance between the metatarsal heads and, thereby, increase the likelihood of Morton neuroma formation.

The restrictive footwear used in some sports, especially ballet, decreases the distance between the metatarsal heads and can lead to nerve compression. Furthermore, athletes who are involved in sports that invoke repetitive trauma on the foot or excessive extension/dorsiflexion of the toes are especially prone to the development of Morton neuroma; examples of these sports are running, basketball, ballet, and racquet sports.

Due to all of these factors, the interdigital nerves can be exposed to repetitive trauma, which leads to irritation and inflammation of the nerve. This continued irritation then initiates the process of perineural fibrosis. Once the nerve starts to fibrose, it enlarges in size, which amplifies its susceptibility to irritation, thus creating a cycle of worsening irritation and fibrosis.

Symptoms

The nerve irritation that is the hallmark of Morton neuroma can manifest in a number of different symptoms. Pain in the sole of the forefoot is common and, once the condition has advanced significantly, is often described as similar to the feeling of walking on a marble. Alternately, there may be the feeling of burning, cramping, or numbness and/or tingling in the forefoot. All of these symptoms may radiate down into the toes as well. Symptoms are typically made worse with walking, especially on hard surfaces and while wearing tight shoes or high heels; conversely, symptoms often improve with cessation of walking, removal of the tight or high-heeled shoe, and massage of the affected area.

Initially, the symptoms only occur intermittently, with even weeks to months between episodes, and are mild. However, with the progression of neuroma formation, the symptoms occur more often and last for longer periods; they may become continual once the damage is severe enough.

Epidemiology

Morton neuromas are of significantly higher prevalence in women than in men. The vast majority occur in people 15 to 50 years old; however, patients either younger or older than this may also develop one. The most common site for a Morton neuroma is in between the third and fourth metatarsals (third web space); about 80% to 85% of these injuries occur in this location The remaining 15% to 20% occur in between the second and third metatarsals (second web space). Morton neuromas do not occur in the first or fifth web spaces.

Diagnosis

A careful history of the symptoms and physical examination of the foot are the mainstays of Morton neuroma diagnosis. As occasionally a patient with Morton neuroma may not have any findings on physical exam, a description of the symptoms outlined above can be enough to make the diagnosis. In general, the diagnosis of Morton neuroma does not need any confirmatory imaging studies such as an X-ray or magnetic resonance imaging (MRI).

A number of physical exam findings have been associated with Morton neuroma. The two most common findings are tenderness with palpation of the web space that is affected and pain with horizontal compression of the forefoot, also known as the "squeeze test." In some instances, a painful "click" underneath the affected web space may be felt and heard by the examiner during the squeeze test; this is known as a *Mulder sign,* or *Mulder click,* and is thought to be due to the enlarged area of the affected nerve passing over a ligament.

Additional findings may include a decrease in sensation in the involved web space and toes and reproduction of the patient's symptoms with extension (dorsiflexion) of the toes.

Treatment

The initial approach to treatment of Morton neuroma is to take steps to lessen the nerve irritation, including shoe modification, adjustment of activity, and oral anti-inflammatory medications. Shoes with a wide toebox help decrease the compression of the interdigital nerve by the metatarsal heads; furthermore, the placement of a metatarsal pad in the shoe can increase the space between the metatarsal heads. In instances where the patient has a foot type that may contribute to the development of Morton neuroma (as in pes planus or pronated foot type), custom orthotics may be of benefit. Additionally, activities that expose the foot to repetitive trauma, such as prolonged running or jumping, should be avoided for a period of time until the nerve inflammation subsides. Finally, a course of oral nonsteroidal anti-inflammatory drugs (NSAIDs) may be tried as well.

The success rate of these conservative measures has not been satisfactorily established in the literature, but a general approximation is that about 20% to 30% get complete or acceptable relief. This proportion of success decreases with the length of time of the patient's symptoms.

If these interventions fail to provide adequate relief, an injection of the combination of a local anesthetic and a corticosteroid into the affected web space has been shown to be effective in decreasing symptoms in some cases.

Occasionally, all of these therapies may not sufficiently mitigate the symptoms of Morton neuroma. In these cases, surgical excision of the neuroma has been shown to have about an 80% rate of success in the relief of symptoms. However, the patient is left with a permanent loss of sensation in the area supplied by the affected nerve.

Motivation

The word *motivation* comes from the Latin word for "to move." In other words, motivation means to get something or someone from one place to another. Motivation is essential in achieving one's goal, no matter how near or far-reaching. One area of life during which motivation plays a more obvious role is sports and athletic participation. Athletes, young and old, amateur and professional, require something to get them to that next place. Motivation is what gets the couch potato off the couch and into the gym. It provides the incentive for the high school athlete to work toward an athletic scholarship. Motivation helps the injured, professional athlete do what is necessary to recover completely and return to the field of play. Motivation has social benefits as well, including increased self-esteem, improved academic achievement, and decreased high-risk youth behaviors and school attrition. This entry discusses the process of providing healthy motivation to athletes as they strive to achieve their goals.

Motivation is not one moment in time. It does not suddenly come to an individual aspiring to athletic success. Motivation is a process. Although motivated and positive coaches, parents, family, friends, and fellow athletes are important, most of the motivation process comes from within the athlete.

The Motivation Process

Define a Vision

The motivation process consists of three basic parts. The athlete must first define his or her vision. An athlete's vision answers the question of why participating in that sport or learning that new skill is important. A vision provides a picture of the "after" and the inspiration to attain it. In creating a vision, an athlete must first focus on what he or she wants (i.e., I want to improve my fitness level), instead of on what he or she does not want (i.e., I do not want to get hurt while running). The vision should be something the athlete feels passionate about and truly wants for himself or herself. The vision should be as specific and detailed as possible. As the process of determining what he or she may truly want and feel passionate about can be difficult, athletes should allow time to define their vision.

Determine the Current Level

Once an athlete has defined his or her vision, the next step is to determine his or her current standing in relationship to that vision. To move someone or something from one place to another, there must be a starting point from which to determine the necessary distance and effort it will take to achieve the goal. This step requires a realistic assessment of the athlete's physical and mental strengths and weaknesses. It is essential that the athlete remain positive and constructive during this process.

Determine Methods for Achieving Goals

Once an athlete has a vision and understands his or her current level in relation to achieving that vision, he or she must determine how to move toward that vision. Just as defining the vision and assessing the current level can take time, this "how to" process can also be challenging and can be divided into two general parts: specific goal setting and focusing.

When beginning a cross-country driving trip, we often break down our drive into shorter segments (e.g., state by state, 200 miles [mi; 1 mi = 1.60 kilometers] driving and then rest), so as to quiet the sometimes silent question, "Are we there yet?" Staying motivated to achieve an athletic vision also includes the creation of short-term, intermediate-term, and long-term goals. Goals can be divided into four general categories: athletic/physical, academic/professional, social, and spiritual. These goals should be identifiable and realistic, in addition to being challenging. Goals should be performance related (e.g., running a mile without walking) instead of result based (e.g., running a mile in 8 minutes). Athletes should periodically reevaluate their goals and reassess their progress toward their vision. Frequent feedback and positive reinforcement, such as a review of recent past successes, can keep an athlete on track to achieve his or her vision.

Good mental skills are also important in achieving an athlete's vision. One important mental skill is focusing, in which an athlete should concentrate on things within his or her control. For example, the athlete should concentrate on skill and fitness development, instead of on the chance that it might rain during his or her run. In general, we tend to move toward that on which we focus, so it is important that our focus be not only something we can control but also something positive. Another important aspect of focus is maintaining it. This maintenance may include remaining in the moment (e.g., thinking about one's form during a run instead of about one's upcoming project deadline) or persevering despite adversity (e.g., continuing to play despite an earlier disappointing performance). To keep their focus, athletes can ask themselves a few basic questions about their current activity, whether their thoughts support that current activity, and whether their thoughts are about something they can control.

Other mental skills useful in achieving an athlete's vision include self-talk, mental imagery, and relaxation. Self-talk should always be positive, with a focus on the athlete's strengths and possibilities. Each affirmation should be brief and easy to repeat; thus, the athlete can retrieve these positive thoughts quickly and easily during practice or competition. Mental imagery involves creating an image of the athlete's vision and/or short-term goals (e.g., a new skill) and using all of his or her senses to imagine performing that new skill correctly from beginning to end. For example, a platform diver might imagine the smell of the pool, the coolness of the air on his or her skin, the view from high above the ground, and the quietness associated with that high perch. To be effective, mental imagery should be performed in a quiet place free from distraction (internal and external), should be practiced regularly, and should be positive. As the athlete becomes more adept at mental imagery, he or she may be able to increase the complexity of his or her imagery sessions (e.g., from a skill to a set of skills to a whole performance). With all of the activity, physical and mental, involved in achieving an athlete's vision, the athlete must also learn to relax. This type of relaxation does not refer to reclining by the pool with an iced drink. This relaxation involves using only those muscles necessary to perform a particular skill. This relaxation ability stems from an increased ability to perform the skill, as well as an increased ability to use imagery and focus. This can be seen in the simple example of handwriting. When first learning to write, children often hunch over their desks with a death grip on their pencils, making faces as they practice writing their letters. Adult writing appears to be effortless, with only those muscles necessary to keep the pen on the paper and make the words legible being moved. Adults have mastered the skill of relaxation while writing. Athletes work to master the skill of relaxation while achieving their vision.

Summary

Motivation can affect an athlete's participation in a sport, as well as the quality of that participation, whether in the initial stages of training, at the elite levels, or in recovery. It can also improve an individual's mental fitness and behavior. The process of motivation includes defining a vision, determining the current level of skill in relation to the vision, and determining the methods for achieving that vision. Athletes should set challenging and realistic goals, think optimistically, reinforce positive behavior patterns, and obtain frequent constructive feedback. Using the mental skills of imagery, focus, and relaxation can help them reach their goals.

Mountain Bike Racing, Injuries in

Mountain bike racing takes place at Olympic, collegiate, professional, and community levels. It involves a wide variety of race styles and bike designs. Mountain bike races often take place in rural areas and place unique demands on emergency services due to increases in local emergency department visits and the challenges of transporting injured athletes from remote areas. Athletes expect race organizers to have a plan for providing medical assistance to the injured racers. Basic knowledge of equipment, competition demands, and common injuries in mountain bike racing is crucial for medical personnel in charge of race coverage. This information is also important to physicians and allied health care providers who take care of these athletes in their outpatient practices.

The Mountain Bike

A mountain bike is designed for off-road use. Mountain bikes were invented in the 1970s in northern California. Mountain bikes are designed to ride on rough and varied terrain. Compared with road bikes, mountain bikes have a more upright riding posture, wider tires with an aggressive tread, and beefier frames. The modern mountain bike has evolved to suit the different styles of riding. In general, mountain bike design attempts to strike a balance between terrain handling and pedaling efficiency. Bikes designed for more difficult terrain will be heavier, with geometries and suspension systems that make them less efficient at transferring pedaling effort into forward motion. Mountain bikes designed for cross-country racing will be lighter but less forgiving in difficult terrain.

Demographics of Mountain Bike Racing

Mountain biking has seen a rapid rise in popularity and economic importance in the past 20 years. Mountain biking is now a widespread activity most popular in the west and north central United States. As interest in mountain biking as recreation has increased, so has participation in mountain bike racing. By 2000, almost 1 million U.S. adults had participated in a mountain bike race. The most rapid increase has been in the participation in community races. The vast majority of racers are men in their 20s and 30s; however, participation of women in racing is also increasing. Notably, the riders in community races tend to be older and female (both risk factors for injury) compared with other forms of racing.

Classifications of Mountain Bike Racing

With the variety in disciplines and levels of competition, the taxonomy of mountain bike racing remains elusive. Mountain bike racing achieved full Olympic status in 1996 when the first medals were handed out in Atlanta. It is also a collegiate sport administered by the National Collegiate Athletic Association (NCAA) with competition and national championships at the Division 1 and 2 levels. The National Off Road Biking Association (NORBA) holds yearly national championships at the professional, collegiate, masters, and junior levels. At the 2006 NORBA national championships, race categories included the following:

Cross-country: a mass start race over varied terrain that averages about 48 kilometers (km) or 30 miles (mi)

Downhill: gravity-assisted time trial event that lasts about 10 minutes

Short track: groups of riders repetitively completing short loops for about 30 minutes

Mountain cross: small groups of riders competing on a gravity-assisted course

Marathon: mass start point-to-point races of 60 to 100 km

Cross-Country Racing

Cross-country racing deserves special mention. This type of racing closely mimics recreational trail riding. It is the most established style of racing and almost the exclusive form of community racing. Cross-country races are typically mass start events with start position determined by expected finish time. The race can be a point-to-point or a repeated-loop–style course. The terrain is often varied, including sharp ascents, descents, and occasional technical sections. Cross-country races vary in distance but usually are about 30 mi (48 km). The duration of the race varies greatly depending on the skill of the rider and the terrain. A typical finishing time could range from 1.5 to 4 hours. Cross-country style races place unique physiologic demands on the riders. Due to the diversity of terrain, race duration, and need for frequent changes in riding positions, these races require a mix of aerobic endurance, anaerobic power, and muscular strength. Technical skill and strategy also become important in high-level competition.

Injury Epidemiology

Injuries are common in mountain biking. The cause of injuries can be rider related, such as errors in judgment or technique, riding beyond one's ability, intoxication, or lack of a helmet. They can also be bike related and caused by mechanical failure or improper bike fit. Terrain-related risks have also been identified, including unfamiliarity, downhill sections, and unique surfaces such as soft sand or wet, slippery conditions. Data show that a fall over the handlebars poses the great risk of serious injury. Admirably, the mountain biking literature shows a very high use of helmets compared with other cyclists and a corresponding decrease in serious head injuries.

As a whole, mountain biking is thought to be responsible for 10 million injuries per year. Surveys of riders reveal that the vast majority had been injured in the previous year. Most of these injuries would be considered minor; however, about 20% of riders reported a significant injury in the last year. Despite the high rate of injuries in those who participate in mountain biking, the rates of significant injury in competition are actually quite low (0.45%–0.6% in cross-country races).

Some studies suggest that advancing age is a risk factor for injury. The literature also repeatedly shows that women are at greater risk of injury than are men. The reason remains unclear, but suggested explanations include less experience or general gender-related physiologic differences, such as lesser upper body strength. In general, studies suggest that experience does not preclude injury. Rather, injuries increased with increased exposure; that is, the more you ride the more likely you are to get injured. And riders who race have a fourfold increased injury rate per year. This suggests that competitive, experienced women riders are at the greatest risk for significant injury.

Types of Specific Mountain Biking Injuries

Acute Traumatic Injuries

Blunt and penetrating trauma make up the vast majority of injuries seen in mountain bike racing. Skin and soft tissue abrasions, contusion, and laceration are ubiquitous. Fractures represent the second most common type of injury observed during racing. Most fractures are noted in the upper extremity, with clavicle fractures being the clear leader. However, rare lower extremity, trunk, pelvic, and cervical fractures have been reported. Joint injuries are also frequently seen, particularly sprains of the acromioclavicular joint, wrist, and knee. Injuries to the head and face are notable for a high rate of concussion (3–13% of injuries in some studies) and dentoalveolar trauma. Trauma to the abdomen and chest poses unique risks, including rib fractures and injury of the internal organs. Curved handlebar ends have been implicated as an increased risk for abdominal injury. Genital injuries can result from forceful straddling of the top tube, causing lacerations and blunt trauma. Fatalities are rare, especially when compared with road biking.

Overuse Injuries

Survey-based studies show that 45% to 90% of respondents had experienced overuse injuries due to mountain biking. Hand and wrist, neck, low back, knee, and genitourinary complaints were all common. Causative factors include excessive training, bike fit, technique, and terrain.

Environmental Injuries

Races often take place in rugged areas, where quick changes in the weather are common, leading to concerns about hyperthermia, hypothermia, and frostbite, depending on the conditions. High altitudes, exposure, and long race durations increase the risk of clinically significant sunburn. Altitude-related illness is often a concern as many races take place at clinically significant elevations. An extreme example is the renowned Leadville, Colorado, mountain bike race that covers 100 mi

(160.9 km), all between 10,000 and 12,000 feet (3048–3657.6 meters).

Medical Illnesses

Although most racers are healthy, some may have underlying medical problems that present as acute emergencies during a race, including asthma, heart disease, diabetes, and allergies. There are also specific medical illnesses that are potentially induced by mountain bike racing, including dehydration, hyponatremia, and rhabdomyolysis.

Prevention of Injury

General evidence-based recommendations to prevent injury in mountain bike racing include wearing of a helmet, familiarization with the course, mechanical bike check prior to the race, and evaluation to ensure proper bike fit. Riders would also likely benefit from a mountain bike skills–development program and fitness program that encourages upper body strength and endurance training for women.

MOUTHGUARDS

Mouthguards are pliable plastic devices used in sports to protect the oral cavity, including the lips, teeth, jaw, and gums. Mouthguards are also known as gum shields, mouth protectors, and mouth shields. Mouthguards are used to avoid and reduce trauma to the mouth during collision sports, such as American football, boxing, rugby, lacrosse, and ice hockey, and during contact sports, such as basketball and soccer.

Injuries

The risk of injury is greater in collision sports than in contact sports. Oral cavity trauma is not life threatening, but associated maxillofacial injuries and fractures can compromise the airway. Soft tissue injuries include cuts and lacerations of the lip and tongue. Swelling of gums and other oral parts is also associated with collision sport trauma. Almost 80% of dental injuries are to maxillary teeth, the most frequent injury being crown fractures of the central incisor teeth, usually affecting a single tooth. Chipping, cracking, fracturing, or displacement of teeth is possible, as well as teeth being knocked out by falls or collisions with another player or object. Tooth injury varies in degree and type with age. In children, the primary teeth are commonly displaced, whereas in adults, the permanent teeth are often fractured. In children, injury usually results in primary teeth failing to continue eruption or in color changes, infection, abscess, loss of space in the dental arch, ankylosis, injury to the permanent teeth, and/or abnormal exfoliation. In the case of permanent teeth, the injury can result in discoloration, infection, abscess, loss of space in the dental arch, ankylosis, reabsorption of root structure, and/or abnormal tooth development.

Causes

The common cause of oral injury is severe impact to the mouth and teeth. This can be the result of a fall, collision with a fellow player, or collision with sports equipment and hard objects (stick or ball). The damage can be sufficient to cause lacerations of the lip and disruption of the enamel and/or dentin of a tooth.

Prevention

Mouthguards reduce the risk of broken or lost teeth and other jaw and mouth injuries during contact sports by cushioning a blow to the face that otherwise might result in an oral injury. A mouthguard decreases the intensity of force to the mouth during a powerful collision, which can cause injury to the lips, cheek lining, tongue, alveolar arches, and teeth. A misdirected elbow in a one-on-one basketball game or a fall from a bicycle (noncontact) can result in chipped or broken teeth, nerve damage to a tooth, or even tooth loss. A mouth protector can reduce the risk of such injuries as well as protect the soft tissues of the tongue, lips, and cheek lining. Mouthguards have also been shown to reduce the risk of mandibular fracture and brain injury.

Types

Three types of mouthguards are available.

Over the Counter. These mouthguards, which are readily available at most sporting goods stores, are inexpensive but come only in limited sizes (small, medium, large). They are ready-made and require no preparation; simply remove from the cover and put in the mouth. Over-the-counter mouthguards are often bulky and lack any retention; they need to be held in place by constantly biting down. The bulky mouthguard may interfere with breathing and talking, making them the least comfortable type. The athlete usually tries to alter or even cut this mouth shield in order to make it more comfortable. This decreases the protectiveness of the mouthguard. The lack of retention and protection makes these mouthguards the least recommended.

Boil and Bite/Mouth Formed. These mouthguards are also readily available in sporting goods stores and are inexpensive. They are most frequently used because of better fit than over-the-counter mouthguards. These mouthguards are made from a thermoplastic material that is softened by immersion in boiling water and then adapted to the mouth by using finger, tongue, and biting pressure. A good fit can be achieved if the instructions are followed with care. Otherwise, one can end up with an ill-fitting mouthguard. However, mouth-formed devices are available only in limited sizes. They sometimes lack proper extensions and do not cover the posterior teeth.

Custom. These mouthguards are made by a dentist; as is the case with many custom-made items, they are expensive. Custom mouthguards are well adapted to individual mouth shapes, have greater retention, and are comfortable. They have no effect on breathing and hardly interfere with talking. The dentist takes many issues into consideration to ensure a proper fit of the mouthguard. The aspects addressed are the sport being played, the age of the athlete, the compliance of the mouthguard with the sport, and any other dental conditions particular to the athlete, such as cavities or missing teeth.

There are two categories of custom mouth guards: vacuum mouthguard and pressure-laminated mouthguard. The vacuum mouthguards are made from stone casts of the athlete's mouth using an impression made by a dentist. A thermoplastic mouthguard material is tailored over the cast with a special vacuum machine. The pressure-laminated mouthguard consists of multiple layers that are chemically fused together under high heat and pressure. The multiple layers make this second category more protective.

Mouth Guard Care

The following precautions should be taken:

- Brush the mouthguard after every use. Washing with mouthwash is also recommended.
- Frequently used mouthguards should be washed with a solution of soap and water once a week.
- Store the mouthguard in a container that lets air in.
- Do not expose the mouthguard to sunlight and heat as these can alter the mouthguard's shape and, therefore, reduce its protective power.

- Replace the mouthguard if it has tears, holes, or fraying.
- Children need regular checkups to see if refitting is required.

Recommendations

The use of mouthguards in sports is highly recommended by dentists and experts to avoid oral/facial injury. It should be noted that 10% of sports injuries are on the face and mouth. Mouthguards help avoid and reduce the severity of trauma. In sports, both collision and contact, at both professional and recreational levels, mouthguards are adapted for use to prevent injury to the anterior teeth and parts of the face and jaw. Mouthguards also help protect the athlete from concussions. The use of mouthguards is especially recommended in people who wear braces because mouth trauma can damage orthodontic brackets or other fixed appliances; a properly fitted mouthguard may be particularly important for people who wear braces or have fixed bridge work.

Muscle Cramps

A muscle cramp is considered a minor heat-related illness, but the athlete or exerciser who is experiencing one would argue that this involuntary muscle spasm is anything but minor. Cramps are very common and very painful among both elite and recreational athletes, and they are most likely to occur in hot, humid weather conditions.

For most people, a cramp is not a long-term problem. It usually subsides within a few minutes but may recur several times during an event after the initial muscle spasm has disappeared. Although a cramp can affect any muscle or muscle group, more than 90% of them involve the quadriceps (the muscles on top of the upper legs), hamstrings (the muscles behind the upper legs), or calves (backside, lower leg muscles). According to the American Academy of Orthopaedic Surgeons, muscles that span two joints are the most prone to cramping.

On rare occasions, muscle cramps may be an indication of a more serious problem associated with blood circulation, the nervous system, body metabolism, hormonal imbalance, or medications. The person who has severe cramps, frequent cramps, or cramps that do not respond to simple, conservative treatments should see a physician.

Causes

There are several theories regarding the exact cause of cramps but very little absolute proof. Physicians, trainers, researchers, and exercise scientists generally agree that cramps are likely to involve a combination of factors and that they may occur in different people for different reasons. Among the possible causes are muscle fatigue, vigorous exercise (especially in hot, humid conditions), exercising while in poor physical condition, dehydration, and dietary deficiencies, including not enough salt intake. “Salty sweating,” according to one prominent sports medicine physician, seems to be the common denominator for all exercise-related cramps.

A common scenario for developing a cramp would be: (a) a football player, (b) early in the season, (c) playing in hot weather, (d) late in a game or practice session, (e) not acclimatized to playing conditions, and (f) not well hydrated during the period leading up to the event. A similar combination of factors could happen in tennis, soccer, lacrosse, basketball (in gyms that are not air-conditioned), or long-distance running events, among others.

Symptoms

The most common symptom of a cramp is also the definition—a sudden, involuntary contraction or spasm of a muscle. A hard knot of muscle tissue may be palpable or visible beneath the skin, and as any athlete who has had a cramp can attest, the muscle spasm causes extreme pain.

Treatment

Cramps usually subside without medical attention, but there are steps the athlete can take to deal with the immediate crisis. First, stop the activity that triggers the cramp, which is something that usually happens anyway. Continuing the activity may simply be impossible.

If the athlete is alone, self-treatment is almost as involuntary as the injury. Quickly massage, squeeze, or put pressure on the muscle until it relaxes. Gently stretching the muscle or muscle group might also relax the muscle and relieve the pain. For a quadriceps spasm, pull the toes and the forward part of the foot back toward the shin. For a cramp in the calf, try putting the weight of the body on the affected leg and slightly bending the knee.

If a cramp recurs for a period of several days, apply cold packs for 15 to 20 minutes, three to four times a day. If the muscle still feels tight, use moist heat or take warm baths for 20 to 30 minutes at a time, three to four times a day.

Prevention

There are no guarantees that any single measure will prevent cramps, but all of the suggestions that follow may lower the risk.

- Warm up before stretching. Muscles that are overstretched before body temperature has been raised are vulnerable to cramps and other sports-related injuries. Pay particular attention to quadriceps, hamstrings, and calf muscles. Do not stretch to the point of pain or bounce during a stretch.
- An increasing body of evidence shows that the best stretches for performance (but not necessarily related to cramps) are those dynamic movements that mimic the actions taken in a sport—not traditional, static stretches in which the muscle is stretched and held for 20 seconds or more.
- Cool down after intensive exercise sessions. Walking several hundred yards after running and slowly swimming one or two laps after a swim event are examples of cooldowns.
- Follow these hydration and acclimatization guidelines:
    - Drink a sports beverage that contains 6% to 8% carbohydrate and small amounts of sodium (110 milligrams [mg]/8 ounces [oz]; 1 oz = 28.35 grams) and other electrolytes (potassium and chloride) to prepare for intense or long training sessions.
    - Drink 10 to 16 oz (two cups; 1 oz = 29.57 ml) of cold fluid approximately 15 to 30 minutes before practice sessions or athletic events.
    - Drink 4 to 8 oz of cold fluid during exercise bouts every 10 to 15 minutes.
    - Use a trial-and-error strategy with cold fluids during periods of training to find the type of drink and quantities that work for you. Do not wait until the day before or day of an event to find out.
    - If possible, allow 1 or 2 weeks for acclimatization to the competitive environment.

Musculoskeletal Tests, Ankle

The ankle is one of the most commonly injured joints in the body, especially with activities involving jumping or running. Ankle sprains are the most common sports-related injury seen in physicians' offices. They can pose a problem because many individuals incur permanent ligament laxity and recurrent sprains and may acquire residual symptoms of pain, swelling, weakness, and decreased proprioception (joint position sense). Any of these symptoms may affect an athlete's sports performance.

The ankle joint acts as a hinge between the foot and the lower leg and functions to help propel the body in addition to providing support and shock absorption. Problems arising in the ankle can create biomechanical deviations during gait, which may cause other maladies to develop in the joints above and below the ankle. As such, tendon problems can occur around the ankle since sports activities involve high motion and stresses. With trauma at the extremities from falls and sprains, fractures in the bones of the ankle can also occur.

Examination of the patient's past history is important in establishing the nature of the ankle injury. The clinician should ask the patient about the onset of symptoms and his or her chief complaint, which may include pain, instability, weakness, or loss of range of motion. The mechanism of injury is particularly valuable in determining the injury. Patients should report any prior history of ankle injuries or disorders and what type of treatment or rehabilitation they received. The most common ankle injury is lateral ankle sprains. Usually, this involves a rolling mechanism inward of the foot and ankle, followed by immediate pain and swelling. The athlete may or may not be able to weight bear depending on the degree of the injury. If the athlete cannot weight bear, there is a greater chance that the athlete may have a fracture in the ankle or foot. Following an initial sprain, many patients will go on to have repetitive ankle sprains and will commonly complain of ankle weakness and giving out.

Acute ankle sprain

Source: University of California, San Francisco, Sports Medicine.

Examination of the Ankle

Examination of the ankle should also include a thorough evaluation of the foot (see the entry Musculoskeletal Tests, Foot). When the patient enters the room, the clinician should evaluate his or her gait pattern, standing posture, and the wear on the soles of his or her shoes. The clinician should assess the ankle for any gross deformity, malalignment, or atrophy. Acute injuries to the ankle commonly result in swelling and the development of ecchymosis. Accumulation of swelling occurs around the lateral and/or medial malleoli, in addition to moving distally into the foot.

Palpation

Palpation of the ankle is important in identifying which structure is injured. Bony structures to palpate should include the shaft of the tibia and fibula traveling down to the borders of the medial and lateral malleoli. Palpation of the neck and dome of the talus can be performed by inverting and everting the foot while palpating just anterior to the medial and lateral malleoli. Soft tissue palpation should include the ligamentous structures: the anterior talofibular ligament, posterior talofibular ligament, calcaneofibular ligament, deltoid ligament complex, and anterior tibiofibular syndesmosis. The clinician should also palpate the muscle tendons that cross the ankle joint. The peroneus longus and brevis tendon are palpable as they pass posterior to the lateral malleolus and as they course below the distal pole of the lateral malleolus toward the base of the fifth metatarsal. On the medial aspect of the ankle, the clinician should palpate "Tom, Dick, and Harry," which is a mnemonic for the posterior tibialis, flexor digitorum longus, and flexor hallucis longus. These three tendons pass posterior to the medial malleolus; the posterior tibial artery and nerve can also be palpated here. Along the anterior aspect of the ankle, the body and tendon of the tibialis anterior, extensor hallucis longus, and extensor digitorum longus can be palpated.

Specifically following an acute sprain, if the athlete is unable to weight bear four steps due to pain, the Ottawa Ankle Rules for getting an X-ray for the ankle apply. The rules indicate that if there is tenderness that is elicited on palpation over the distal 10 centimeters (cm) of the lateral or medial malleolus, then an X-ray of the ankle is indicated. These areas are typically where an ankle fracture would occur following an inversion injury of the ankle. Studies demonstrate that using the Ottawa Ankle Rules properly identifies all fractures in those locations and helps avoid taking unnecessary X-rays in the emergency room.

Range of Motion

Assessment for ankle range of motion typically begins by evaluating active, passive, and then resistive range of motion. For the ankle, there are four motions that occur at the ankle joint: dorsiflexion, plantarflexion, inversion, and eversion. To assess the passive range of motion, the patient should be seated with his or her foot off the exam table. While stabilizing the lower leg, the clinician passively applies pressure to assess soft tissue mobility. Range of motion should always be compared bilaterally, and any deficits should be noted. The normal motion for passive dorsiflexion is 10° to 15°; for plantarflexion, 50° to 70°; for inversion, approximately 40°; and for eversion, around 10°. Pain during passive movement may be musculotendinous or ligamentous. Motion may be limited due to pain, swelling, or scar tissue from a chronic injury. Finally, resistive range of motion should be conducted to assess for any muscular weaknesses or injuries.

Special Tests

Talar Tilt Test

The talar tilt test is a ligamentous stress test that examines the integrity of the lateral ankle ligaments, primarily the calcaneofibular ligament.

Description of the Maneuver. With the patient seated, knee bent, and foot in neutral or slightly dorsiflexed position, the clinician stabilizes the distal tibia with one hand while applying an inversion force to the foot.

Positive Findings. There is pain or increased joint laxity in the involved ankle. Pain may be over the calcaneofibular ligament or the anterior talofibular ligament, depending on the positioning of the ankle.

Talar tilt test

Source: University of California, San Francisco, Sports Medicine.

How good is the test? No studies have examined the validity of the talar tilt test.

Anterior Drawer Test

The anterior drawer test is a test used to examine the integrity of the anterior talofibular ligament, which is frequently injured during an inversion ankle sprain.

Description of the Maneuver. The patient should be seated with his or her knee bent, and the ankle should be typically in the neutral position at 0° or 90° to the leg. The clinician stabilizes the distal tibia with one hand while grasping the heel with the other hand and applying an anterior force to the heel. This test should be performed bilaterally to compare for differences in anterior translation.

Anterior drawer test

Source: University of California, San Francisco, Sports Medicine.

Positive Findings. Pain or increased joint laxity in the injured ankle indicates disruption of the anterior talofibular ligament. Visually, a dimple may be seen by the clinician while performing this test.

How Good Is the Test? The validity testing demonstrates the anterior drawer test to have high sensitivity, moderate specificity, high positive predictive value, and moderate negative predictive value.

Special Tips for Improving Accuracy. The examiner's index finger can be placed behind the heel with the thumb over the front of the ankle to better feel the translation of the foot in relation to the lower leg. A firm, steady load during testing can be more sensitive than a higher, quick load.

External Rotation or Kleiger Test

The test was first described by Barnard Kleiger and is used to identify syndesmotic injuries.

Description of the Maneuver. The patient is seated with his or her knee bent on an exam table. The clinician stabilizes the distal tibia while externally rotating the foot.

Positive Findings. Pain in the anterolateral ankle joint is felt, or there is an increased external rotation

External rotation test

Source: University of California, San Francisco, Sports Medicine.

of the foot when compared bilaterally. External rotation of the talus applies pressure to the lateral malleolus, widening the tibiofibular joint.

How Good Is the Test? To date, no studies have examined the validity of the external rotation test.

Special Tips for Improving Accuracy. The examiner may be able to feel the talus displace from the medial malleolus, which may indicate disruption of the deltoid ligament.

Thompson Test

There is controversy over who first described this test; regardless, the test was described in the 1950s to assess the integrity of the heel cord.

Description of the Maneuver. The patient is positioned prone on a table with his or her foot extended to the edge of the table. The clinician squeezes the calf muscle just distal to the place of widest girth and examines the movement at the foot. Negative squeeze test is indicated when plantar movement of the foot occurs.

Positive Findings. Positive test occurs when the calf is squeezed and no plantar movement occurs at the foot, which indicates a heel cord rupture.

How Good Is the Test? The Thompson test has been shown to have high sensitivity and specificity for evaluating heel cord rupture.

Squeeze Test

This test not only examines the integrity of the distal tibiofibular joint but also can assess for fractures of the tibia and fibula.

Description of the Maneuver. With the patient sitting supine with his or her foot on the table, the clinician grasps the midcalf and squeezes the tibia and fibula together. The clinician continues applying the same amount of pressure while moving distally toward the ankle.

Positive Findings. Pain in the lower leg may be indicative of a fracture or syndesmosis sprain.

Squeeze test

Source: University of California, San Francisco, Sports Medicine.

How Good Is the Test? To date, no studies have examined the validity of this test.

Bump Test

The bump test assists in the identification of fractures in the lower leg, talus, and calcaneus.

Description of the Maneuver. The patient should be seated with his or her injured leg hanging off the table. The examiner extends the knee with one hand and, using the palm of the other hand, bumps the calcaneus with increasing force until pain is elicited.

Bump test

Source: University of California, San Francisco, Sports Medicine.

Positive Findings. A positive test occurs when pain emanates from a fracture of the calcaneus, talus, fibula, or tibia.

How Good Is the Test? To date, no studies have examined the validity of this test.

Peroneal Tendon Subluxation Test

The peroneal tendon subluxation test is used to assess the integrity of the inferior peroneal retinaculum.

Description of the Maneuver. With the patient seated, the clinician instructs the patient to actively dorsiflex and evert the foot, while gently palpating over the peroneal tubercle. This test can also be performed passively.

Positive Findings. Positive findings occur when subluxation of the peroneal tendon over the tubercle is either visualized or palpated.

How Good Is the Test? To date, no studies have examined the validity of this test.

Musculoskeletal Tests, Elbow

These musculoskeletal tests are used to diagnose common injuries around the elbow. The most common problems around the elbow include atraumatic, repetitive, overuse injuries such as lateral epicondylosis, medial epicondylosis, or ulnar neuropathy, usually caused by traction, friction, or compression of the nerve. Traumatic injuries usually involve a fall on the outstretched hand and include fractures and dislocations or the elbow. The radial head fracture is the most common. The elbow typically dislocates posteriorly. Finally, the disorder known as thrower's elbow presents a specific complex of injuries, including ulnar collateral ligament (UCL) sprains and damage to the joint surfaces. Following a trauma, it is not uncommon for people to develop a flexion contracture of the elbow, as loss of terminal extension is the most common complication following an elbow injury.

Examination of the Elbow

Observation

The examination of the elbow begins by first examining the elbow for skin changes such as bruising or discoloration as well as swelling. Swelling in the elbow joint itself, referred to as *effusion,* is checked by examining the back of the elbow for absence of the dimples of the joint. Soft tissue swelling directly at the tip of the elbow can be consistent with olecranon bursitis. Localized swelling near the medial or lateral epicondyles may suggest local tendon injury or ligament injuries, for example, to the ulnar collateral ligament.

One should also observe for normal bony and soft tissue contours anteriorly and posteriorly. In traumatic injuries, the elbow should be checked for bony deformity. The carrying angle of the elbow is the angle formed by the long axis of the humerus and ulna when the elbow is straight and the forearm is fully supinated. The normal carrying angle in males is 5° to 10°, while in females it is greater, approximately 10° to 15°. If the angle is less than this, the elbow is said to be in *cubitus varus,* and if the angle is greater than this, the position is referred to as *cubitus valgus*.

Atrophy of muscles around the elbow and more distally in the forearm should be noted. Chronic ulnar nerve problems may weaken and atrophy the ulnarly innervated muscles of the hand, which are located in the palm and dorsum of the hand.

Palpation

The examiner can palpate the bony landmarks of the elbow, in particular the lateral and medial epicondyles and the olecranon. These should make an isosceles triangle. When the arm is extended, these three points normally form a straight line across the elbow. This can be lost due to trauma, deformity, or arthritic conditions. Another bony landmark is the radial head, which can be felt over the lateral or outside portion of the elbow. Palpation of the radial head can be confirmed by feeling the rotation at the head when rotating the forearm in supination and pronation.

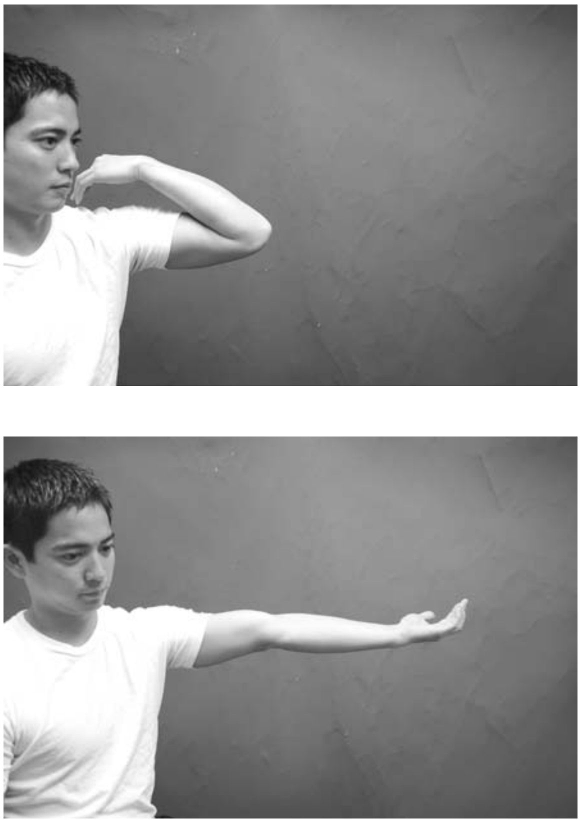
The ulnar nerve feels similar to a ropelike structure behind the medial epicondyle. It passes behind the medial epicondyle, within the cubital tunnel. It may subluxate over the medial epicondyle with flexion and extension of the elbow. Patients can develop *ulnar neuropathy* (numbness, tingling, and/or weakness), which most commonly affects the ulnar-most digits (ring and small fingers) as a consequence of elbow deformity or trauma.

One should palpate the antecubital fossa, including the flexor-pronator mass and the brachioradialis muscles, which form the distal contour of the antecubital fossa. Proximally, the contour is formed by the biceps. One should palpate the distal biceps tendon within the antecubital fossa as it inserts into the proximal radius. Loss of this structure indicates rupture to the distal biceps tendon. The brachial artery can be felt within the antecubital fossa as well.

The examiner can palpate the olecranon fossa along the superior aspect of the olecranon. This is a common location for osteophyte formation in posttraumatic arthropathy as well as for loose bodies that can affect terminal extension. Also, the medial and lateral gutters of the olecranon as it articulates with the humerus can be palpated for osteophyte formation and/or loose bodies. Synovial inflammation can also occur in this region and will present as bogginess and warmth.

Range of Motion

The examiner should observe the total *range of motion* of the elbow with regard to flexion, extension, pronation, and supination. The examination can be performed with the patient sitting, standing, or supine. The examiner should also examine the opposite side for comparison. Normal range of motion of the elbow is from 0° to 145° ± 10°, while the functional range of motion (motion required for normal daily activities) is from 30° to 130°. It is common for some individuals to hyperextend at the elbow up to 10°. Supination and pronation of the elbow should be checked. They are usually in the range of 85° ± 5° in each direction. Placing a pen or pencil in the hand can help estimate the amount of pronation and supination bilaterally. At least



Elbow flexion

Source: University of California, San Francisco, Sports Medicine.

50° of supination and pronation is required to perform the tasks of daily living.

Special Tests

Muscle/Tendon Tests

The lateral and medial tendons are the most common atraumatic elbow problems. These represent a majority of the elbow problems that will present, especially when there is no clear mechanism of injury.

Resisted Third-Digit Extension for Lateral Epicondylosis

This resisted strength test is performed to evaluate for lateral epicondylosis, or what is commonly labeled as tennis elbow. Lateral epicondylitis, or more appropriately lateral epicondylosis, mainly affects the extensor carpi radialis brevis tendon, with degenerative changes developing within the tendon origin just distal to the lateral epicondyle.

Description of the Maneuver. The maneuver is performed by extending the elbow fully, pronating the forearm, and then extending the wrist. The patient is then asked to fully extend all of the digits. The patient is then asked to keep his or her fingers extended against resistance, particularly the third or middle finger.

Positive Findings. A positive test will reproduce pain in the area of the lateral epicondyle.

How Good Is the Test? The test is reliable for evaluating for lateral epicondylosis, with a high sensitivity and moderate specificity.

Special Tips for Improving Accuracy. The examiner should focus on keeping the elbow fully extended, forearm fully pronated, and digits fully extended. Flexion at the elbow will reduce tension within the extensor carpi radialis brevis and reduce the accuracy of the test. The examiner should be aware of other potential causes of pain along the lateral epicondyle, such as radial tunnel syndrome, that could potentially be confused with lateral epicondylitis.

Resisted Wrist Extension for Lateral Epicondylosis

This test is classically performed for lateral epicondylosis, or what is commonly labeled as tennis elbow. Lateral epicondylitis, or more appropriately lateral epicondylosis, mainly affects the

Resisted third-digit extension for lateral epicondylosis

Source: University of California, San Francisco, Sports Medicine.

Resisted wrist extension for lateral epicondylosis

Source: University of California, San Francisco, Sports Medicine.

extensor carpi radialis brevis tendon, with degenerative changes developing within the tendon origin just distal to the lateral epicondyle.

Description of the Maneuver. The test is performed by asking the athlete to extend the wrist against resistance, with the elbow fully extended and the forearm maximally pronated.

Positive Findings. A positive test is reproduction of pain at the lateral epicondyle.

How Good Is the Test? The test is not as reliable as resisted digital extension because resisted wrist extension recruits other extensors, such as the extensor digitorum and extensor carpi radialis longus. It has a high sensitivity but reduced accuracy compared with resisted digital extension.

Resisted Wrist Flexion for Medial Epicondylosis

This test is employed to evaluate for medial epicondylosis or tendinopathy within the flexor-pronator mass. This condition is commonly called golfer's elbow. This is a degenerative tendinopathy rather than an inflammatory condition, making *epicondylosis* a more appropriate terminology than *epicondylitis*.

Resisted wrist flexion for medial epicondylosis

Source: University of California, San Francisco, Sports Medicine.

Description of the Maneuver. The maneuver is performed by having the patient extend and supinate the forearm. Next, the patient is asked to flex the wrist against resistance.

Positive Findings. Resisted flexion will elicit pain along the medial epicondyle and more specifically within the flexor pronator mass.

How Good Is the Test? The test has a high sensitivity and reproducibility.

Special Tips for Improving Accuracy. One should be aware of other potential causes of medial-sided elbow pain, such as ulnar collateral ligament disorders or ulnar neuropathy, which could also elicit pain with this condition. The examiner should fully examine the medial aspect of the elbow, in particular the medial collateral ligament and the ulnar nerve, to evaluate for any potential confounding conditions.

Resisted Pronation for Medial Epicondylosis

This test is employed to evaluate for medial epicondylitis or tendinopathy ("golfer's elbow") within the flexor-pronator mass, most commonly within the pronator teres.

Description of the Maneuver. The maneuver is performed by having the patient extend and supinate the forearm. Next, the patient is asked to pronate the wrist and forearm against resistance or turn the hand palm down.

Positive Findings. Resisted pronation testing will elicit pain along the medial epicondyle and more specifically within the flexor-pronator mass.

How Good Is the Test? The test has a high sensitivity and reproducibility.

Special Tips for Improving Accuracy. One should be aware of other potential causes of medial-sided elbow pain, such as ulnar collateral ligament disorders or ulnar neuropathy, which could also elicit pain with this condition. The examiner should fully examine the medial aspect of the elbow, in particular the medial collateral ligament and the ulnar nerve, to evaluate for any potential confounding conditions.

Distal Biceps Tendon Assessment

The examiner can assess for pain along the distal biceps tendon, which inserts into the proximal radius. Tendon injury is often tender on direct palpation of the tendon insertion. Resisted supination can reproduce the athlete's symptoms. Similarly resisted elbow flexion can be painful, though the biceps' primary role is as a supinator for the forearm.

Ligament Stress Tests

The ulnar collateral ligament is the most important stabilizer for the medial elbow and is the primary stabilizer for valgus stress. During overhead sports such as baseball pitching, a large valgus force is applied to the elbow, which makes the ligament vulnerable to overload. Also, a fall on an outstretched arm with a resultant valgus force with rotation can lead to injury of the ligament and sometimes even dislocation of the elbow. The lateral ligament complex of the elbow is more commonly injured in elbow trauma, particularly elbow dislocations. Injury to this structure can lead to varus instability of the elbow, as it is the primary stabilizer to varus stress at the elbow. In children under 6 years of age, the annular ligament may be naturally loose, leading to dislocation of the radial head when the arm is axially pulled, resulting in "nursemaid's elbow."

Valgus stress test

Source: University of California, San Francisco, Sports Medicine.

Valgus Stress Test

The elbow valgus stress test is commonly employed to evaluate for ulnar collateral ligament injury. Injuries to the ulnar collateral ligament are typically seen in throwing and overhead athletes when a valgus stress is applied acutely or in a repetitive fashion during sports.

Description of the Maneuver. The humerus should be maximally externally rotated; the forearm should be in maximal supination, with the patient's wrist and hand fixed; and a valgus stress should be applied toward the inside portion of the elbow, with the patient's arm flexed at 30°.

Positive Findings. Positive findings will elicit pain and opening of the ulno-humeral articulation with valgus stress.

How Good Is the Test? The test has a moderate sensitivity (not as sensitive as the milking maneuver) and high specificity.

Special Tips for Improving Accuracy. The examiner should keep the arm at 30° when evaluating the ligament, as this contributes the most to valgus stability. At higher degrees of flexion, the conformity of the elbow joint (ulno-humeral articulation) provides stability in addition to the ligament, making it less accurate. Also, concomitant conditions of the ulnar nerve can reduce the specificity of this condition as the test also places traction on the ulnar nerve and falsely creates a positive finding.

Milking Maneuver

This test was originally described as a more sensitive and specific test for ulnar collateral ligament conditions. The test evaluates for injury to the ulnar collateral ligament. It simulates a position for the elbow similar to throwing.

Description of the Maneuver. The "milking maneuver" is performed with the arm at 70°, with the valgus force applied by supporting the elbow and tractioning the thumb, similar to milking a cow.

Positive Findings. Positive findings will be elicited by pain along the ulnar collateral ligament.

How Good Is the Test? The test is more specific and accurate than the valgus stress test.

Special Tips for Improving Accuracy. The examiner should keep the arm positioned at 70° of flexion and apply a constant traction force on the abducted thumb.

Moving Valgus Stress Test

The moving valgus stress test evaluates for injury or laxity of the ulnar collateral ligament. The movement and stress on the elbow simulate positions for the elbow similar to throwing.

Description of the Maneuver. With the patient sitting with the shoulder abducted to 90°, the examiner applies a valgus force to the elbow until the shoulder is fully externally rotated. While maintaining the valgus torque, the examiner quickly extends the elbow to approximately 30°.

Positive Findings. A positive test reproduces pain at the ulnar collateral ligament, typically occurring maximally between 70° and 120° of flexion.

How Good Is the Test? The test has been described to be extremely sensitive in diagnosing conditions of the ulnar collateral ligament and has a high specificity as well.

Special Tips for Improving Accuracy. One must maintain a constant valgus torque to the fully flexed elbow by placing traction on the thumb while extending the elbow quickly.

Pivot Shift Test for the Elbow

This test is designed to evaluate for ligamentous injury to the lateral collateral complex of the elbow. The pivot shift test evaluates for injury to the lateral ulnar collateral ligament.

Description of the Maneuver. With the athlete lying supine with the arm overhead, the elbow is supinated, and valgus and axial forces are applied to it. The athlete may complain of pain or apprehension. Starting in extension, the elbow is flexed, with a reduction "clunk" occurring typically at 40° to 70° of flexion. Starting in flexion, the elbow can be subluxated with a constant valgus force as the arm is gradually brought into extension.

Positive Findings. A positive test indicates apprehension or instability as the arm is brought into extension with a constant valgus force.

Pivot shift test for the elbow

Source: University of California, San Francisco, Sports Medicine.

How Good Is the Test? The test has a high sensitivity and specificity in the willing patient.

Special Tips for Improving Accuracy. This test is difficult to conduct reliably in the patient who is awake. It is more reliably performed with the patient under anesthesia.

Neurovascular Tests

The ulnar nerve is often referred to as "the funny bone."

Tinel Sign or Tinel Test (Ulnar Nerve)

The Tinel sign can be used to evaluate for any number of compressive neuropathies, most commonly the median nerve at the wrist but also for the ulnar nerve at the elbow.

The ulnar nerve passes behind the medial epicondyle and courses into the forearm.

Description of the Maneuver. The test is performed by percussing with the index and middle fingers on the ulnar nerve along the posteromedial aspect of the elbow as it passes behind the medial epicondyle and courses into the forearm.

Positive Findings. A positive finding is elicited by pain and paresthesias that extend distally along the course of the ulnar nerve into the forearm.

Tinel test

Source: University of California, San Francisco, Sports Medicine.

How Good Is the Test? The Tinel sign has a moderate sensitivity and specificity for ulnar neuropathy.

Special Tips for Improving Accuracy. The examiner can evaluate the patient for subtle signs of neuropathy, including sensory testing with two-point discrimination, which has a higher sensitivity in detecting neuropathy than the Tinel test alone.

Ulnar Nerve Subluxation Test

The test evaluates for mobility and subluxation of the ulnar nerve when the elbow is brought from flexion into extension.

Description of the Maneuver. The elbow is passively moved from flexion into extension by the examiner. The examiner can place his or her fingers behind the medial epicondyle of the elbow.

Positive Findings. Subluxation of the ulnar nerve over the medial epicondyle is a positive finding as the elbow is brought into extension.

How Good Is the Test? The test is highly sensitive in detecting subluxation of the nerve but does not necessarily indicate that the patient has neuropathy.

Elbow Flexion Test

This test evaluates for ulnar nerve entrapment at the cubital tunnel, which is located along the posteromedial aspect of the elbow behind the medial epicondyle. Possible entrapment of the nerve at the cubital tunnel syndrome can be caused by various etiologies such as rheumatoid arthritis or posttraumatic arthritis.

Description of the Maneuver. The elbow flexion test is performed by having the patient fully flex the elbow with extension of the wrist and hold this position for 3 to 5 minutes.

Positive Findings. A positive finding is indicated by tingling and paresthesias along the ulnar nerve distribution.

How Good Is the Test? The test is sensitive and reliable in diagnosing ulnar nerve entrapment.

Special Tips for Improving Accuracy. The examiner must make sure that the patient holds this position for the specified time.

Median Nerve Compression at Pronator Teres

The median nerve can be compressed as it passes between the two heads of the pronator teres as it enters the forearm. This condition is referred to as *pronator syndrome*.

Description of the Maneuver. The test is performed by flexing the elbow to 90° and having the examiner strongly resist pronation as the elbow is gradually extended.

Positive Findings. A positive finding will be elicited by paresthesias along the median nerve distribution.

How Good Is the Test? The test has a high sensitivity with good reproducibility.

Special Tips for Improving Accuracy. Local tenderness in this condition can be observed over the medial nerve approximately 4 to 5 centimeters (cm) from the elbow distally. Resisted pronation with the elbow in the flexed position tests for pronator quadratus syndrome. It is important to evaluate for pronator teres syndrome by having the patient extend the elbow.

Allen test

Source: University of California, San Francisco, Sports Medicine.

Allen Test

This test evaluates for circulatory competence from the radial and ulnar arteries into the hand.

Description of the Maneuver. The Allen test is performed by having the patient open and close the hand several times as rapidly as possible and then squeezing the hand tightly. The examiner's thumb and index finger are then placed on the radial and ulnar arteries, respectively, compressing them. The patient then opens the hand while pressure is kept on the radial and ulnar arteries. Each artery is then sequentially tested by releasing pressure over the artery to see if the hand perfuses. Both hands should be tested for comparison.

Positive Findings. A positive finding is indicated if the hand fails to perfuse from either artery or if the circulation is sluggish from either the radial or the ulnar artery. It is also used to determine vascular dominance to the hand.

How Good Is the Test? The test has a good sensitivity and accuracy in diagnosing vascular disorders of the hand and forearm.

Special Tips for Improving Accuracy. The examiner should make sure to hold pressure over both arteries equally and that the patient rapidly opens and closes the hand at the beginning of the examination.

Check the Shoulder and the Neck

The examiner should consider problems at the shoulder and the neck, since they sometimes affect the elbow. Quick screening tests for shoulder problems include the Neer impingement test, where the shoulder is forward flexed maximally. If the test is positive, pain will be elicited at terminal forward flexion. A second test, referred to as the *Hawkins impingement test* (or sometimes only as the Hawkins test), can also be performed. The shoulder is abducted in the scapular plane to 90° and then internally rotated. If the test is positive, pain is elicited when the arm is internally rotated.

To screen for neck problems, the examiner can evaluate for the athlete's neck range of motion, including forward flexion, extension, rotation, and lateral bending. The Spurling sign is performed by turning and extending the head toward the ipsilateral arm with any symptoms and then applying an axial stress with the examiner's hand on top of the forehead. A positive test will elicit pain in the neck.

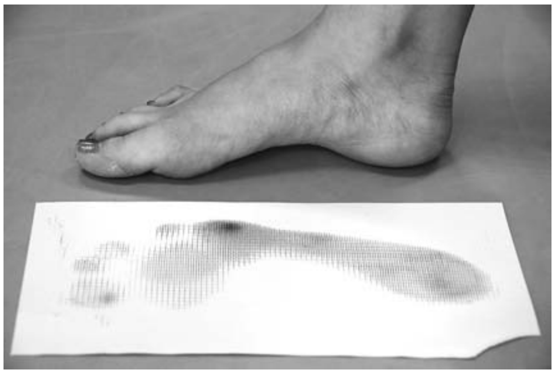
Musculoskeletal Tests, Foot

The foot provides the body's base of support, as it is the part of the body that comes into physical contact with the ground during gait. It provides stability to stand and move upright, acts in shock absorption, adapts to uneven surfaces or terrain, and acts as a lever for propulsion to enable the body to move in all directions. The foot is composed of 26 bones, which create 33 different joints. Due to the many bones and joints and the different roles the foot plays in locomotion, it is prone to injury, especially in activities or sports that require a significant amount of running or jumping. Walking forces increase to 1.2 times the body weight and can increase to twice the body weight while running. Jumping substantially increases the forces on the foot and lower extremities further to around five times the body weight. Therefore, it is not surprising that the foot often has problems with pressure points causing calluses or irregular deformities such as bunions. With repetitive stress, stress fractures can occur in several areas of the foot. Ligament sprains, acute fractures, and tendon and soft tissue problems can all occur. The foot is indeed a puzzle of bones, working together to produce complex movements that allow ambulation and make running, jumping, and other sports maneuvers possible.

In the foot itself, typically the location where the person feels the pain is the location of the problems. However, it is important when evaluating individuals with other joint problems to also examine their feet. Many problems occurring further up the kinetic chain can be attributed in some part to imbalances at the feet. When patients have biomechanical imbalances occurring at their feet, the body compensates in other joints of the body to maintain balance and function, which in turn can result in undue stress on the other joints. For individuals with foot problems, the clinician needs to establish when the patient has the pain. Morning pain at the heel when a person first gets out of bed is suggestive of plantar fasciitis. Does the pain increase with activities such as walking, exercising, and standing? What is the patient's occupation? Did the foot swell or bruise following the injury? Have the symptoms improved, worsened, or remained the same? What type of footwear does the patient wear to work, to workout, or during leisure activities, and has he or she recently changed the type of footwear that he or she normally wears? It is important to thoroughly evaluate the type of footwear that patients wear to ensure that they have the correct type for their foot posture. The average person takes between 3,000 and 5,000 steps per day; however, many people advocate 10,000 steps of activity per day for health. With those numbers expected, if the patient is wearing the wrong type of footwear, those steps can cumulatively add up to cause significant foot dysfunction.

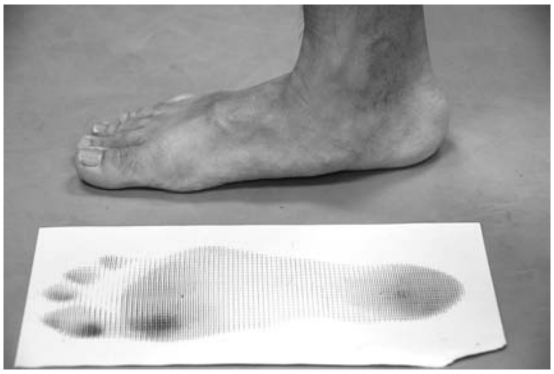
Examination of the Foot

Assessment of the foot begins when the patient first enters the room. The clinician should take note of the patient's gait pattern, his or her standing



Pes planus

Source: University of California, San Francisco, Sports Medicine.



Pes cavus

Source: University of California, San Francisco, Sports Medicine.

posture, the type of shoes the patient is wearing, and the wear on the soles of the shoes. The clinician should then evaluate the patient's standing posture with his or her shoes and socks removed.

Posture and Alignment

With the patient standing in a naturally comfortable position, the clinician can examine from the front and note the height of the arches (*pes cavus*—high arch; *pes planus*—flat feet). Functionally, one can observe the dynamic motion at the arch by asking the patient to go up on his or her toes and then return back to the standing position, to look for any collapse at the arch. From the posterior view, the clinician evaluates the position of the calcaneus and hindfoot region relative to the lower leg during weight bearing to determine the presence of hindfoot *varus* (heel deviated inward) or *valgus* (heel directed outward). Further evaluation of the feet out can be made by looking to see how many toes can be observed pointing inward or outward from the posterior view that relates to *in-toeing* ("pigeon toed") or *out-toeing*, respectively. It is normal to see two or three of the lateral toes from behind when the patient is standing relaxed. From a lateral perspective, the clinician should evaluate the alignment of the toes and nail deformities. The toes are examined for flexion abnormalities at the joints, referred to as *claw toe*, *hammertoe*, or *mallet toe* deformities. Excessive valgus positioning of the first metacarpal phalangeal joint more than 20° results in the development

Anterior foot view

Source: University of California, San Francisco, Sports Medicine.

of a “bunion” (*hallux valgus*). Similarly, a bunionette can develop on the fifth metatarsal head, with the fifth toe pointing inward. During the postural assessment, any differences observed bilaterally as well as any signs of injury should be noted: inflammation, redness, or discoloration. A detailed evaluation of the other joints of the patient’s lower extremity is important to ensure a thorough assessment of his or her posture.

Footwear

For all lower extremity injuries, it is important to examine the footwear of patients, not only for clues of foot dysfunction but also because the type of footwear can play a major role in the development of foot pathologies. Normal wear to the shoes should be seen below the ball of the foot, lateral side, and the posterolateral corner of the heel. Old shoes can break down and lose their support for the feet. Wearing of the sole decreases its shock absorption properties. Patients who often wear high-heeled or platform shoes are at increased risk of developing foot pathologies. Individuals who wear high-heeled shoes continuously may also be prone to developing knee injuries and back pain, because to maintain an upright posture, there is an increase in the (lordotic) curve of the lumbar spine. A narrow toe box in the shoe can lead to additional foot pathologies such as bunions, foot fractures, interdigital neuromas, and mechanical foot pain (*metatarsalgia*) for an individual with a wide ball of the foot.

Palpation

With 26 bones constituting the foot, there are many structures in which injuries can occur. During the examination, it is important to thoroughly palpate the bony and soft tissue structures, starting with the hindfoot and moving on the midfoot and forefoot. The hindfoot consists of the talus, calcaneus, and Achilles tendon. Palpate along the Achilles tendon as it inserts onto the calcaneus. Note any tenderness along the tendon and insertion site. During puberty, adolescents may develop calcaneal pain due to the development of a *traction apophysis*; this is known as Sever disease. The insertion of the Achilles tendon is over a growth plate in the calcaneus, and excessive activity can lead to irritation of the calcaneus. Symptoms usually include pain with activity and palpation and usually diminish once the individual has reached maturity.

Palpate the lateral aspect of the foot that includes the lateral malleolus, calcaneus, and talus. Palpate over the anterior talofibular ligament and calcaneofibular ligaments. Feel along the entire course of the fibularis longus and brevis as they run posterior to the fibular and course around the lateral malleolus. Palpate the insertion of the fibularis brevis on the base of the fifth metatarsal. Ankle sprains can lead to several different structure injuries in the foot and ankle. Commonly, lateral ankle sprains cause injury to the lateral ligaments; however, they can also cause an avulsion fracture at the base of the fifth metatarsal due to the involvement of the fibularis brevis in counteracting the inversion moment. Other sites of possible injury include fracturing of the lateral malleolus or injury to the distal tibiofibular syndesmosis, but these usually involve some type of rotary moment.

On the anterior aspect of the foot, palpate bony structures that include the distal tibia, talus, navicular cuneiforms, cuboid, metatarsals, and phalanges, in addition to palpating the joint spaces between each. Stress fractures to the tarsal and metatarsal bones are common among runners and other highly active individuals. *Stress fractures* are caused by repetitive microtrauma to the structure of the bone, most commonly seen in running sports, dancing, and high-impact activities. Individuals with a stress fracture will have localized point tenderness on the bone and often have an area of soft tissue swelling immediately surrounding the painful spot.

On the medial aspect of the foot, palpate along the medial malleolus and calcaneus, over the navicular tubercle, and along the metatarsals. Palpate the first metatarsalphalangeal joint, as individuals with hallux valgus can develop a bunion over this area that may be tender, especially medially. Soft tissue structures to feel include the deltoid ligament and spring ligament, which are located between the navicular tubercle and the sustenaculum tali.

The plantar aspect of the foot can be palpated at the calcaneus and at the medial portion of the heel, where the calcaneal tubercle is located. This insertion site for the plantar fascia can be tender in individuals with *plantar fasciitis*. In long-standing cases, a bone spur can develop in this area. Other bony structures to feel are the metatarsal heads, especially the first metatarsal head because two sesamoid bones are located here and are prone to fracture. Soft tissue palpation should include the plantar fascia along its length, which is more pronounced when the foot is dorsiflexed. Tenderness between the metatarsals distally between the heads can be indicative of an *interdigital neuroma,* which most commonly occurs between the third and fourth toes. In some cases of neuroma, a small, tender soft tissue nodule may be palpable. Assess the fat pads of the foot that are located over the base of the calcaneus and the metatarsal heads. Also, note any callus development in the sole of the foot, which can indicate poor footwear selection.

Range of Motion

The first movement to assess at the foot is active range of motion. With patients seated with their foot hangingoff the table, they can actively perform plantarflexion, dorsiflexion, supination, and pronation of the foot, as well as toe extension, flexion, abduction, and adduction. For normal gait to occur, individuals must have at least 20° of plantarflexion and 10° of dorsiflexion. *Supination* is the combination of inversion, adduction, and plantarflexion of the foot, while *pronation* involves eversion, abduction, and dorsiflexion of the foot. If no inversion occurs, the foot is considered to be unstable or there is weakness of the tibialis posterior.

Passive range of motion of the joints is also important to examine the soft tissue and if there is any joint arthritis present. Bilateral comparison of the passive movements is important. The clinician should examine any limitations in dorsiflexion, plantarflexion, supination, and pronation seen on active motion. In addition, gliding of the midfoot and forefoot joints should be performed to examine adequate movement of each. Restricted movements at one joint tend to cause increased movement and undue stress to the surrounding joints.

The toes should be examined as well. Painful hyperextension of the first metatarsal phalangeal joint is known as *turf toe,* essentially a sprain of the joint ligaments. It can be a debilitating injury and is commonly caused when the hallux is placed under excessive loads. Shoes with a flexible forefoot or activities played on artificial turf are common causes of turf toe. Limited motion at the big toe can be suggestive of osteoarthritis of the first metatarsal phalangeal joint, known as *hallux rigidus*.

Palpation of the dorsal pedal pulse

Source: University of California, San Francisco, Sports Medicine.

Palpation of the tibialis posterior pulse

Source: University of California, San Francisco, Sports Medicine.

Resistive range of motion should be performed to examine the contractile tissues of the foot and lower extremity. With the patient in a seated position, the clinician should perform an isometric strength test for dorsiflexion, plantarflexion, supination, pronation, toe extension, and toe flexion. These tests should be performed *bilaterally,* and the strength results depend on the individual's age and sex.

Neurovascular Exam

Evaluation of the neurovascular systems of the lower extremity is an important step to complete a thorough examination. To evaluate circulation in the foot, the dorsal pedal pulse can be palpated over the dorsal aspect of the foot, and the posterior tibial artery is best felt immediately posterior to the medial malleolus. The capillary refill of the toes is checked by pressing firmly for 5 seconds over the tip of one of the toes and then releasing the pressure, which causes the skin to blanch and then return back to its normal color. Normal capillary refill occurs in 2 to 3 seconds.

Testing of the peripheral nerves in the lower extremity should not be overlooked because pathologies higher up in the lower extremity of the spinal column can result in muscle weakness and atrophy and sensory deficits. The lower extremity screen should include manual muscle testing, deep tendon reflexes, and sensory testing. *Manual muscle testing* should include the hip flexors, quadriceps, anterior tibialis, extensor hallucis longus, and gastrocnemius. *Deep tendon reflexes* include the patellar tendon and Achilles tendon. *Sensory testing* involves seven different nerve root dermatomes: L1 is located over the anterior hip and lateral gluteal region, L2 over the anterior and lateral thigh, L3 over the distal thigh, L4 over the medial aspect of the lower leg and foot, L5 over the anterior aspect of the lower leg and foot, S1 over the lateral aspect of the lower leg and foot, and S2 over the calf and bottom of the foot. The neurological exam should be equal bilaterally, and any differences may suggest trauma to the peripheral or spinal nerve roots.

Special Tests

Navicular Drop Test

The test is used to assess the arch shape of the foot and quantify midfoot mobility.

Description of the Maneuver. With the patient weight bearing, the foot is placed in a neutral talus position. To find the neutral talus position, the clinician palpates the medial and lateral aspects of the talus with his or her thumb and forefinger. The patient is then asked to rotate his or her trunk to the right and left. The neutral talus position is found when the clinician cannot feel the head of the talus bulge on either side. To perform the navicular drop, the clinician positions the foot in a neutral talus position, then measures the height of the navicular turbercle using a ruler. Then the patient is asked to relax in his or her standing position, and the measurement is taken again. The difference in the two numbers indicates the amount of foot pronation or flattening of the medial longitudinal arch.

Positive Findings. A difference greater than 10 millimeters (mm) is considered abnormal.

How Good Is the Test? To date, no studies have examined the validity of the navicular drop test.

Special Tips for Improving Accuracy. This test depends on the experience of the clinician and finding the neutral talus position.

Homans Sign

This test is used to diagnose the presence of a blood clot in the veins of the leg, known as *deep vein thrombophlebitis.*

Description of the Maneuver. With the patient seated, the clinician quickly dorsiflexes the foot with the knee extended and holds the ankle in dorsiflexion. The clinician can palpate the calf muscle.

Positive Findings. Pain when the foot is dorsiflexed and tenderness when the clinician palpates the calf are indicative of a positive finding.

How Good Is the Test? To date, no studies have examined the validity of the Homans sign.

Special Tips for Improving Accuracy. Other symptoms include swelling of the leg, a diminished or absent dorsal pedal pulse, and changes in skin pallor. An individual suspected of having a deep vein thrombosis should be immediately referred to the emergency room for further evaluation.

Homans sign

Source: University of California, San Francisco, Sports Medicine.

Anterior Drawer Test

The anterior drawer test is a test used to examine the integrity of the anterior talofibular ligament, which is frequently injured during an inversion ankle sprain.

Description of the Maneuver. The patient should be seated with his or her knee bent and ankle at 20°. The clinician stabilizes the distal tibia with one hand while grasping the heel with the other hand and applying an anterior force to the heel. This test should be performed bilaterally to compare for differences in anterior translation.

Positive Findings. Pain or increased joint laxity in the injured ankle indicates disruption of the anterior talofibular ligament. Visually, a dimple may be seen by the clinician while performing this test.

How Good Is the Test? The validity testing demonstrates that the anterior drawer test has high sensitivity, moderate specificity, high positive predictive value, and moderate negative predictive value.

Anterior drawer test

Source: University of California, San Francisco, Sports Medicine.

Talar tilt test

Source: University of California, San Francisco, Sports Medicine.

Talar Tilt Test

The talar tilt test is a ligamentous stress test that examines the integrity of the lateral ankle ligaments, primarily the calcaneofibular ligament.

Description of the Maneuver. With the patient seated, knee bent, and foot in neutral or slightly dorsiflexed position, the clinician stabilizes the distal tibia with one hand while applying an inversion force to the foot.

Positive Findings. Pain or increased joint laxity in the involved ankle. Pain may be over the calcaneofibular ligament or the anterior talofibular ligament, depending on the positioning of the ankle.

How Good Is the Test? To date, no studies have examined the validity of the talar tilt test.

External Rotation Stress Test or Kleiger Test

The test was first described by Barnard Kleiger and is used to identify syndesmotic injuries.

Description of the Maneuver. The patient is seated with his or her knee bent on an exam table. The clinician stabilizes the distal tibia while externally rotating the foot.

Positive Findings. Pain in the anterolateral ankle joint is felt, or there is an increased external rotation of the foot when compared bilaterally. External rotation of the talus applies pressure to the lateral malleolus, widening the tibiofibular joint.

How Good Is the Test? To date, no studies have examined the validity of the external rotation stress test.

External rotation stress test or Kleiger test

Source: University of California, San Francisco, Sports Medicine.

Special Tips for Improving Accuracy. The examiner may be able to feel the talus displace from the medial malleolus, which may indicate disruption of the deltoid ligament.

Thompson Test or Squeeze Test

There is controversy over who first described this test; regardless, the test was described in the 1950s to assess the integrity of the heel cord.

Description of the Maneuver. The patient is prone on a table with his or her foot extended off the edge of the table. The clinician squeezes the calf muscle just distal to the place of widest girth and examines the movement at the foot. Negative squeeze test occurs when plantar movement of the foot occurs.

Thompson test or squeeze test

Source: University of California, San Francisco, Sports Medicine.

Positive Findings. Positive test occurs when the calf is squeezed and no plantar movement occurs at the foot, which indicates a heel cord rupture.

How Good Is the Test? The squeeze test has been shown to have high sensitivity and specificity for evaluating heel cord rupture.

Ottawa Ankle Rules

The Ottawa Ankle Rules were developed to assist physicians in determining whether individuals with foot or ankle pain require X-rays to rule out the possibility of a fracture. Prior to the development of these rules, many individuals received unnecessary X-ray imaging. Testing of the Ottawa Ankle Rules have demonstrated high sensitivity in identifying individuals with foot and ankle fractures, which has resulted in significant reduction of unnecessary X-rays. According to the ankle rules, X-rays are required if there is

- any bony pain in the malleolar region,
- bone tenderness in the distal 6 centimeters (cm) of the posterior edge of the tibia or tip of the medial malleolus,
- bone tenderness in the distal 6 cm of the posterior edge of the fibula or tip of the lateral malleolus, and
- inability to walk immediately and four steps in the emergency department.

Additionally, X-rays are indicated for individuals with foot pain if there is

- any bony pain in the midfoot region,
- bone tenderness over the base of the fifth metatarsal,
- bone tenderness over the navicular bone, and
- inability to walk immediately and four steps in the emergency department.

Musculoskeletal Tests, Hand and Wrist

The tests in this entry are used to diagnose common injuries in the hand and wrist. Injuries of the hand and wrist are some of the most common conditions observed by sports medicine physicians. The wrist and hand are particularly complex joints since the joints themselves are small and perform extremely fine, complicated movements. The most common problems of the hand and wrist include carpal instability, triangular fibrocartilage complex (TFCC) tears, de Quervain tenosynovitis, ulnar collateral ligament injury of the thumb (gamekeeper's thumb), arthritis of the CMC (carpometacarpal joint) of the thumb, and carpal tunnel syndrome. Fractures of the wrist, in particular the distal radius, are the most common type of fractures in the upper extremity and are caused by falls on an outstretched hand (commonly known as FOOSH).

Examination of the Hand and Wrist

Observation

The examination of the hand and wrist should commence with an observation of the digits and wrist for any evidence of masses or deformity as well as the patient's willingness to use the hand. Observe for symmetry between both hands and wrists with regard to color, atrophy, hair patterns, and position of the wrist and digits. Presence of the digital cascade should be noted (see the first image). Asymmetry can indicate evidence of pathology. Of note, the dominant hand tends to be slightly larger than the nondominant hand. Lack of use or avoidance of a particular portion of the hand with regard to grasping or holding objects can indicate pathology as well as neuromuscular dysfunction. Nodules or ganglions on the wrist and digits are common as well and should be noted if present. Bouchard and Heberden nodes are present on the proximal interphalangeal and distal interphalangeal joints, respectively, and are found in the setting of osteoarthritis of the interphalangeal joints. The examiner should also take note of the scars present as they may indicate prior surgery or trauma. Fingernails should also be inspected for color and shape. Various pathological conditions can affect the appearance of the fingernails, such as anemia, psoriasis, or vascular insufficiency.

Palpation

Palpation of the hand and wrist is an important aspect of the examination of the hand and wrist.

The digital cascade

Source: University of California, San Francisco, Sports Medicine.

One should take note of the skin temperature of both hands. As with visualization, asymmetry can indicate pathology. One should take note of the texture of both hands. Increased dryness of one hand could indicate neurologic dysfunction. Palpation of both the radial and ulnar pulses is important as well. Asymmetry could indicate vascular disorders such as thrombosis or aneurysm.

Palpation of the hand and wrist is important as there are a number of anatomical landmarks of which the clinician must be aware. Palpation of the *anatomical snuffbox* along the radial aspect of the wrist evaluates the scaphoid. The snuffbox is marked by the abductor pollicis longus and extensor pollicis brevis on the radial aspect and the extensor pollicis longus along the ulnar aspect of the snuffbox.

Palpation of another bony landmark is the *Lister tubercle*. This is a tubercle (bony prominence) present along the dorsal aspect of the wrist. It is an important landmark as this is where the extensor pollicis longus tendon courses as it passes along the dorsum of the wrist. Distal to this landmark is the lunate fossa of the distal radius, where the wrist can be aspirated if necessary. The lunate can also be palpated in this location. Pain on palpation can indicate pathology of the lunate, such as in *Kienbock disease* (osteonecrosis of the lunate). The ulnar snuffbox is the soft area just distal to the ulna. It contains the *triangular fibrocartilage complex,* which is a fibrocartilaginous disk that aids in load transmission across the radioulnar joint. Palpation of the ulnar styloid is important as well, along with the extensor carpi ulnaris that lies along the ulnar aspect of the wrist. Palpation of the metacarpals and carpometacarpal joints is important to evaluate for deformity that can indicate prior trauma. Boxer's fractures are common, as are fractures of the head-neck junction of the small finger metacarpal. Range of motion of the metacarpophalangeal and interphalangeal joints should be noted as well, and any asymmetry should be documented.

Scaphoid palpation in the anatomical snuffbox

Source: University of California, San Francisco, Sports Medicine.

Palpation of the triangular fibrocartilage complex (TFCC)

Source: University of California, San Francisco, Sports Medicine.

Range of Motion

Range of motion at the wrist is approximately 60° to 70° of wrist extension and 70° to 90° of wrist flexion. Radial deviation at the wrist is 15° to 20°, while ulnar deviation is around 35°. Range of motion at the metacarpophalangeal (MCP) joints includes 100° of flexion and 60° range of motion in the abduction-adduction plane. The proximal interphalangeal (PIP) joints have approximately 100° of flexion (range of motion from 0° to 100°), while the distal interphalangeal (DIP) joints have approximately 80° of flexion.

Special Tests: Muscle/Tendon Tests

Intrinsic Tightness Test for Contracture of the Lumbricals and Interossei Muscles of the Hand

This test is used to evaluate for contracture of the intrinsic muscles (interossei and lumbricals), which can occur in neurological conditions, most commonly with brachial plexus injuries or stroke.

Description of the Maneuver. The test is performed by positioning the MCP joints initially in extension and the PIP joints in extension. PIP flexion is then evaluated in this position. The MCP joints are then flexed, and the PIP joints are again held in an extended position. PIP flexion is again evaluated.

Positive Findings. A positive test result for intrinsic tightness is demonstrated when there is less PIP flexion with the MCP joints hyperextended than when they are flexed.

How Good Is the Test? This test is reliable for evaluating intrinsic tightness.

Special Tips for Improving Accuracy. Evaluate the MCP joints in extension first, and then bring them into flexion. Positioning the wrist in neutral position with regard to extension and flexion is also beneficial. This will remove any chance of the extrinsic flexors and extensors affecting motion at the MCP joints.

Elson Test

This test evaluates for a *boutonniere deformity*, which occurs when there is injury to the central slip of the extensor mechanism. The resulting deformity is a PIP flexion contracture and a compensatory DIP hyperextension.

Description of the Maneuver. The test is performed by bending the PIP joint 90° over the table. The examiner then places a finger on the middle phalanx. The patient is then asked to extend the digit against resistance.

Positive Findings. A positive test result is indicated by the DIP joint going into rigid extension due to all forces being distributed to the terminal tendon through intact lateral bands. A negative test result is demonstrated by the DIP joint remaining floppy.

Special Tips for Improving Accuracy. The patient should be in a seated position. Flex the injured digit over the edge of a table. This is the best way of isolating and testing the PIP joint.

Finklestein test

Source: University of California, San Francisco, Sports Medicine.

Finklestein Test

This is a test that evaluates for *de Quervain disease*, or *tenosynovitis*, which is an inflammation of the first dorsal compartment of the wrist. The first dorsal compartment of the wrist includes the abductor pollicis longus and extensor pollicis brevis tendons. It is most common in women 30 to 50 years old.

Description of the Maneuver. The test is performed by placing the patient's thumb within the patient's clenched fist. The wrist is then positioned in ulnar deviation, placing the first dorsal compartment under tension.

Positive Findings. A positive test result is indicated by pain along the involved compartment with this maneuver.

How Good Is the Test? This test is highly sensitive for evaluating de Quervain tensosynovitis.

Special Tips for Improving Accuracy. Place the patient's thumb within the palm of his or her hand, and then have the patient clench a fist.

Neurovascular Tests

Tinel Sign

The Tinel sign or Tinel test can be used to evaluate for any number of compressive neuropathies

Tinel sign

Source: University of California, San Francisco, Sports Medicine.

Dirkin compression test

Source: University of California, San Francisco, Sports Medicine.

but most commonly for the ulnar nerve about the elbow and the median nerve at the wrist.

Description of the Maneuver. The test evaluates for median neuropathy at the wrist by percussing along the median nerve as it courses under the flexor retinaculum at the wrist.

Positive Findings. A positive test result is indicated by numbness and tingling within the thumb, index finger, and middle digits.

How Good Is the Test? This test is moderately sensitive in diagnosing carpal tunnel syndrome.

Dirkin Compression Test

The Dirkin compression test can also be used to evaluate for carpal tunnel syndrome.

Description of the Maneuver. The test is performed by the examiner placing his or her thumb directly on the carpal tunnel and exerting compression on the median nerve within the carpal tunnel for a period of 1 minute.

Positive Findings. A positive test result is indicated by numbness and tingling within the thumb, index finger, and middle digits.

How Good Is the Test? This test has better sensitivity in diagnosing carpal tunnel syndrome than the Tinel sign—approximately 90% sensitivity.

Phalen Test

This test is also used to evaluate for carpal tunnel syndrome.

Description of the Maneuver. Position the patient's wrist in maximal flexion, and have him or her maintain this position for 1 minute.

Positive Findings. Pain and paresthesias can be felt along the median nerve distribution (thumb, index finger, and middle digits). It is often present when carpal tunnel syndrome is in the advanced stages.

Phalen test

Source: University of California, San Francisco, Sports Medicine.

How Good Is the Test? This test is not as sensitive as the Dirkin compression test as the test is often positive once the condition has become more advanced.

Special Tips for Improving Accuracy. Have the patient flex both wrists at the same time and hold in position for 1 minute. This will allow a comparison with the contralateral side.

Ligament Stress Tests

Watson Test for Carpal Instability

Carpal instability can affect the individual carpal articulations and also the midcarpal articulation. Dorsal intercalated instability refers to a disruption of the scapholunate ligament. The Watson test is the best method for evaluating for dorsal intercalated instability.

Description of the Maneuver. The best way of evaluating this is to place the examiner's thumb along the scaphoid tubercle and bring the wrist from ulnar deviation to radial deviation. This will cause a palpable click of the proximal aspect of the scaphoid over the dorsal rim of the distal radius.

Positive Findings. A palpable click will be elicited as the proximal aspect of the scaphoid goes over the dorsal rim of the distal radius as the wrist is brought from ulnar deviation into radial deviation. This can also be accompanied by pain.

How Good Is the Test? This test has moderate sensitivity and specificity in diagnosing scapholunate instability.

Special Tips for Improving Accuracy. Maintain constant pressure on the scaphoid tubercle as the wrist is brought into radial deviation. Place an index finger over the scaphoid dorsally to evaluate the position of the proximal aspect of the scaphoid.

Lunotriquetral Ballottement Test

This test is used to evaluate for sprains of the lunotriquetral ligament.

Description of the Maneuver. This test is performed by fixing the lunate in position with the thumb and index finger of one hand while using the thumb and index finger of the opposite hand to displace the triquetrum dorsally and then plantarly.

Positive Findings. Patients with injury to this ligament will complain of pain and instability.

How Good Is the Test? This test has moderate sensitivity and specificity in diagnosing injury to the lunotriquetral ligament.

Special Tips for Improving Accuracy. It is best for both the clinician and the patient to be seated for this examination. Have the patient flex the elbow as well for more optimal positioning of the wrist prior to evaluation.

Ulnocarpal Stress Test

This test is used to evaluate for injuries to the triangular fibrocartilage complex (TFCC).

Description of the Maneuver. This test is performed by positioning the wrist in maximal ulnar deviation while passively bringing the wrist from maximal pronation to supination.

Positive Findings. Patients with an injury to the TFCC will experience pain and clicking in the setting of a TFCC tear.

Special Tips for Improving Accuracy. One must compare both the injured and uninjured wrists as clicking can be present at baseline.

Ulnar Ligament of the Thumb MCP Joint

Stress tests of this ligament are used to evaluate for an injury to the ulnar collateral ligament of the thumb (gamekeeper's thumb).

Description of the Maneuver. This test is performed by first positioning the thumb MCP joint in 30° flexion and then applying a valgus load to the joint. The thumb must be held along the metacarpal shaft as well to prevent rotation at the MCP joint. The thumb MCP joint is then positioned in extension (0°), and the test is repeated.

Positive Findings. A positive test result with the MCP joint in 30° of flexion is indicated by greater

Ulnar collateral ligament stress test

Source: University of California, San Francisco, Sports Medicine.

than 30° of opening at the MCP joint with a valgus stress or greater than 15° compared with the contralateral side. If there is greater than 30° of opening or greater than 15° compared with the contralateral side with the thumb in extension, then there is injury to the accessory collateral ligament as well.

Special Tips for Improving Accuracy. This test is more accurately performed under fluoroscopy to properly estimate the degree of laxity.

Thumb CMC Grind Test

This test is used to evaluate for arthritis of the basal joint (carpal-metacarpal) articulation. Arthritis of the basal joint of the thumb results in attenuation of the volar beak ligament, which is the primary ligamentous stabilizer of the thumb CMC articulation.

Description of the Maneuver. The test is performed by stabilizing the trapezium with one hand and then forcefully dorsally attempting to subluxate the thumb metacarpal on the trapezium while simultaneously compressing the metacarpal against the trapezium.

Positive Findings. Patients with arthritis at the CMC joint have pain and instability with this test.

Special Tips for Improving Accuracy. One must differentiate this from arthritis within the wrist itself at the scaphoid-trapezial-trapezoid (STT) articulation. Palpation along this articulation and along the thumb CMC articulation can differentiate the two conditions.

Other Points to Consider in Examination of the Wrist and Hand

The examiner should be careful to also inspect the elbow for deformity and total range of motion. Injury to the elbow can be reflected in loss of the carrying angle or loss of range of motion that can affect the ability to position the hand and wrist in space. Evaluate the neck with regard to range of motion and pain with range of motion. Cervical radiculopathy can lead to numbness, tingling, and/or weakness within the hand and wrist. Evaluate for the Spurling sign, which is performed by tilting the neck to the ipsilateral shoulder and then applying an axial stress with the examiner's hand on top of the forehead. A positive test will elicit pain in the neck.

Musculoskeletal Tests, Hip

Musculoskeletal tests are used to diagnose common injuries around the hip and the pelvis. During activities, the hips link the lower extremities to the central skeleton. Many people consider the pelvis a portion of the hip when they describe their pain, though it is also an extension of the lumbar spine. The hip joint provides significant contact between the ball and the socket, making it a very secure and stable joint. Whenever hip problems are suspected, it is prudent to always check the back and vice versa.

Many sports require extreme motion in the hip, for example, jumping in track-and-field events; kicking in dance, martial arts, and soccer; and performing tumbling maneuvers in gymnastics. Because there is a lot of motion around the hip, there are frequent muscle strains and tendon strains. External problems of the hip typically involve the tendons surrounding the hip, namely, the iliopsoas anteriorly, or the tensor fascia lata, which is joined to the iliotibial band laterally. These can snap over bony prominences and become painful from mechanical friction or eccentric load. Lateral hip pain often presents due to greater trochanteric bursitis or gluteal tendinopathy as the tendons insert into the greater trochanter. An important diagnosis not to miss is a stress fracture of the hip, which can affect athletes subjected to repetitive impact. These occur typically on the inferior aspect of the neck of the femur but can also occur on the shaft or the superior aspect of the neck. These fractures are dangerous and can lead to displacement.

In some individuals, the neck of the femur bumps against the rim of the socket (acetabulum) during the extreme range of motion that occurs with hip flexion and internal rotation. This can occur because the hip socket is shallow (hip dysplasia), allowing increased motion and less bony support for the joint, or because there is bony overgrowth, resulting in more bony impingement with movement. These problems are often referred to as femeroacetabular impingement. Degenerative changes in the cartilage surface of the joint or involving the cartilage rim or labrum can occur, causing internal derangements in the joint. Since much of the forces during sports and daily activity are transmitted from the leg to the spine through the hip, arthritis in the hip can occur in older athletes.

Examination of the Hip and Pelvis

Observation: Posture and Alignment

Lower Extremity Alignment. The examination of the hip includes assessment of posture and lower extremity alignment. The alignment at the knees can be quickly screened by asking the athlete to stand with the ankles together, observing the knees. If there is a wide space between the knees when the athlete stands with the feet together and the athlete appears to be "bowlegged," the athlete has *genu varum,* indicating that the lower leg angles medially after the knee. Similarly, if the athlete appears "knock-kneed" and has difficulty putting the feet together due to the proximity of the knees, it is called *genu valgus* alignment. With the feet together pointing forward, if the kneecaps point inward, it is called "squinting patellae" and often represents a rotational malalignment at the hips called *femoral anteversion,* where the hips are angled such that the knees and lower legs rotate inward. Femoral anteversion is one reason for in-toeing or "pigeon-toed" alignment.

Femoral Anteversion. Femoral anteversion is a common malalignment at the hip that can result in subtle rotational deformity in the lower extremities. The underlying cause is a forward angulation of the femoral neck in relation to the shaft and coronal plane of the pelvis. Normally, this angle is approximately 12° to 15°. An increased anterior angle results in more femoral anteversion, causing functional internal rotation at the knees during gait.

Gait. The athletes can be observed performing functional activities such as walking, hopping, squatting, walking on their heels, and walking on their toes to test the function of the knees and other joints in the lower extremities. A "lurching gait" typically suggests that the individual has a hip problem. As the patient walks, he or she bends laterally toward the affected side during weight bearing. Leaning toward the problem side helps decrease the forces of gravity directly on the head of the hip, resulting in less pain and stress on the hip. This is typical for someone with a history of arthritis in the hip or previous trauma.

Back Examination. For patients with chronic pelvic or hip pain, it is helpful to perform an appropriate back exam. During the assessment, look for *scoliosis* or anterior-posterior asymmetries in posture (e.g., head forward, shoulder forward, or increased curvature at the low back, known as *lordosis*).

Tests: Posture and Alignment

Trendelenburg Test

The Trendelenburg test examines for weakness or instability of the hip abductors, primarily the gluteus medius.

Description of the Maneuver. The patient balances first on one leg, raising the nonstanding knee toward the chest. The examiner can stand behind the athlete and observe for any misalignment and dropping of the pelvis or buttock on the nonstance side.

Positive Findings. If the pelvis on the side of the nonstance leg rises, the test is negative. If the pelvis on the side of the nonstance leg falls, the test is positive, indicating weakness or instability of the hip abductors, primarily the gluteus medius, on the stance side.

How Good Is the Test? The Trendelenburg test has moderate to good sensitivity and specificity for detecting a tear in the gluteus medius muscle.

Trendelenburg test (negative)

Source: University of California, San Francisco, Sports Medicine.

Functional Squat

The athlete can be asked to quickly squat, fully flexing at the hips, knees, and ankles. This can help quickly screen for any limitations in range of motion at any of these joints.

Leg Length Discrepancy

The leg length testing in the supine position can assess for both true and apparent leg length discrepancies. A true leg length discrepancy occurs when there is an actual difference in the femur and/or tibia between the two legs. An apparent leg length discrepancy occurs when one leg appears shorter than the other. However, there is no true difference in the length of the bones; rather, there is a functional or structural pelvic, spinal, or foot asymmetry.

Description of the Maneuver. With the patient lying supine, the examiner can assess for a true leg length difference by measuring the distance from the

Trendelenburg test (positive)

Source: University of California, San Francisco, Sports Medicine.

palpated anterior superior iliac supine to the medial or lateral malleolus on the same leg using a tape measure. Similarly, the opposite side can be measured and the measured lengths on both sides compared.

An apparent leg length difference can be assessed with the patient in the supine position by measuring the distance from the xiphisternum (the prominence immediately below the breastbone or sternum) to the medial malleolus.

Positive Findings. A difference of more than 1 centimeter is considered of concern for a leg length discrepancy. There may be some error in measurement.

How Good Is the Test? There is no sensitivity and specificity for these measurement tests for leg length discrepancy. The reliability of the measurements between examiners is excellent, though within-examiner reliability is only very good.

Special Tips for Improving Accuracy. If there is suspicion about a leg length discrepancy, especially a true leg length discrepancy, the best test to verify it is a standing anteroposterior (AP) X-ray of the lower extremities from the hip to the ankles, referred to as a scanogram. If there is concern about scoliosis or pelvic asymmetry, scoliosis or pelvis X-rays can be ordered.

Palpation

During the examination of the hip, it is important to feel the anatomical strucutures around the hip and pelvis to see if there are any symptoms. Typically, structures around the hip are tender to direct pressure if they are injured or subject to overuse or overload, often in compensation for problems at the knee, ankle, or the spine. Important landmarks to palpate on the pelvis include the anterior superior iliac spine (ASIS), the posterior superior iliac spine (PSIS), and the pubic symphysis. The examiner should be familiar with the anatomy to be able to isolate specific structures while palpating. The sacroiliac joints and the lumbar spine should be routinely checked in patients with hip complaints.

Palpation of the anterior superior iliac spine

Source: University of California, San Francisco, Sports Medicine.

Anterior Structures

Bony landmarks to palpate on the pelvis anteriorly include the ASIS, the pubic rami (superior and inferior), and the pubic symphysis. The hip joint must be palpated deep in the anterior femoral triangle. It is very difficult to palpate the actual bony structures of the hip since there are other soft tissue structures overlying the joint itself.

The hip flexor is a common cause of anterior hip pain and will typically present with pain deep in the anterior femoral triangle. At times, a click or clunk can be palpated in the front of the hip, especially when the patient flexes and then extends the hip, referred to as an "internal snapping hip" because of its proximity to the hip joint.

Lateral Structures

The lateral greater trochanter is a common area for complaint. In this area, several structures can cause pain, including the gluteus medius and minimus tendon insertions and the greater trochanteric bursa, often resulting in chronic symptoms when they are inflamed. The tensor fascia lata is also another soft tissue structure that is palpable over the greater trochanteric area. Some patients have a clicking sensation laterally when they walk that occurs when the tensor fascia lata snaps over the greater trochanter, referred to as an "external snapping hip."

Palpation of the greater trochanter

Source: University of California, San Francisco, Sports Medicine.

Posterior Structures

Posteriorly, common areas of tenderness include the sacroiliac joints, the coccyx, and the ischial tuberosities, where the hamstring tendons insert. The piriformis is another muscle that can present with activity-related buttock pain. There may be signs of pain or spasm involving the piriformis, which runs from the sacrum to the greater trochanter. Firm pressure needs to be applied when palpating these structures since they lie deep to the soft tissues.

Standing Flexion Test

The standing flexion test assesses the movement between the lumbar spine, pelvis, and hips, specifically focusing on the movement near the sacroiliac joints.

Description of the Maneuver. The examiner is positioned behind the standing athlete. Using the thumbs, the PSIS of each ilium is palpated. These are found at the end of the iliac crest, close to the superior aspect of the sacrum. Oftentimes, there is a dimple overlying the PSIS on each side that is visible on inspection. With the thumbs positioned in a relaxed manner over the PSIS and applying light pressure, the examiner asks the athlete to slowly flex forward or reach toward his or her toes without bending at the knees. The examiner's thumbs will move along with the PSIS. The amount of movement is subjectively determined and compared from side to side.

Standing flexion test

Source: University of California, San Francisco, Sports Medicine.

Positive Findings. Unequal movement of the thumbs during full flexion of the spine suggests abnormal movement at the sacroiliac joints. The thumbs are expected to move superiorly and forward as the iliums rotate forward (nutate).

How Good Is the Test? The reliability of this test is poor between observers. The test displays low sensitivity and moderate specificity.

Special Tips for Improving Accuracy. The presence of scoliosis can affect the motion of the sacroiliac joints due to rotational abnormalities at the lumbar spine.

The "dimples of Venus," similar to the dimples near the buttocks of the famous statue, are usually above the PSIS.

Range of Motion

The examination of the range of motion at the hip is most easily performed with the patient in a lying position. The typical range of motion of the hip with the patient lying on his or her back during the exam, or supine, includes flexion 120° to 130°, extension 15° to 30°, adduction 25° to 30°, and abduction 30° to 50°. Restricted movement in one direction, especially internal rotation, is usually related to the presence of osteoarthritis. Loss of motion in three directions is indicative of osteoarthritis of the hip or other hip joint problem.

To check the range of motion in the hip in the supine position, the examiner can flex the athlete's hip and knee to 90° each. Grasping the heel, the hip can be rotated on the axis of the femur either clockwise or counterclockwise. When the foot is turned out laterally, the hip is internally rotated. When the foot is turned inward, as when crossing one's leg while sitting, the hip is externally rotated. Typical range of motion of the hip with external

Staheli method (internal rotation)

Source: University of California, San Francisco, Sports Medicine.

rotation is approximately 40° to 60°, and internal rotation is around 30° to 40° from the neutral (midline). Checking passive internal rotation of the hip is almost always the best range-of-motion test to assess for significant problems involving the hip joint.

Staheli Method (Prone)

A very good way to assess rotational hip range of motion is to examine the patient in the prone position, lying face down. This immobilizes the pelvis while checking range of motion of the hips. The examiner asks the athlete to lie face down on the table, keeping the knees together. The examiner then can bend each knee to 90° and then allow the lower leg to rotate inward (external rotation) or outward (internal rotation). Typical range of motion of the hip with external rotation is approximately 40° to 60°, and internal rotation is around 30° to 40° from the neutral (midline). The reproducibility of this measurement is high. This is also referred to as the *Craig test*.

Special Tests: Labral Tests

The examiner should perform enough tests to confirm suspected injuries. Examiners should master at least one or two tests from each group and learn how to do them well before making the diagnosis.

Labral Impingement Test

The labral impingement test for the hip is a provocative maneuver to assess for a labral tear of the hip or other internal derangement in the joint.

Description of the Maneuver. The examiner has the athlete lie supine on the examination table. The examiner passively flexes the hip to 90° with the knee at 90° of flexion (see image part A) and fully rotates the hip internally (see image part B). The

Labral impingement test part A

Source: University of California, San Francisco, Sports Medicine.

Labral impingement test part B

Source: University of California, San Francisco, Sports Medicine.

hip is then returned to the neutral position of rotation and adducted. It is then internally rotated again in the adducted position.

Positive Findings. This test is positive if the pain is reproduced deep in the groin with either maneuver. Typically, the test is more painful with the hip adducted and internally rotated than with the hip at neutral, 0° adduction, and internally rotated.

How Good Is the Test? For the labral impingement test, sensitivity was moderate, specificity was high, and interrater reliability was moderate.

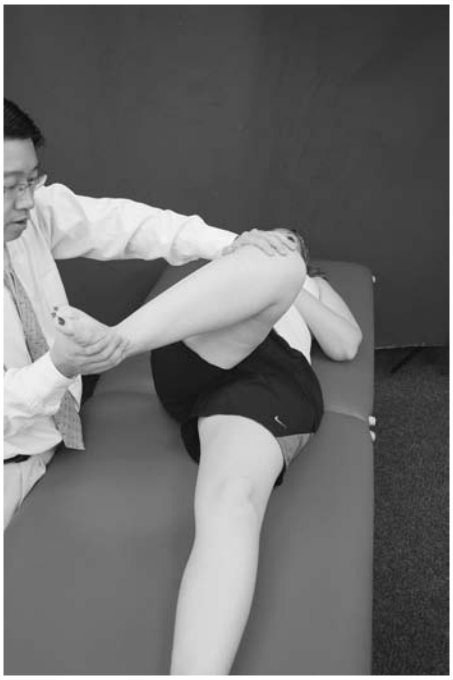
Special Tips for Improving Accuracy. Many patients complain of pain near the gluteal muscle insertions with internal rotation of the hip. The pain associated with the hip joint is classically in the groin area and occasionally deep in the buttock if the posterior aspect of the joint is affected.

Labral Stress Test (Hip Scour Test)

This test checks for a labral tear of the hip or other internal derangement in the joint.

Description of the Maneuver. The examiner has the athlete lie supine on the examination table. The examiner passively flexes the hip to 90° with the knee at 90° of flexion. The hip is then slowly, passively circumducted, first in the clockwise and then in the counterclockwise direction, taking the hip fully into internal and external rotation.

Positive Findings. This test is positive if the pain is reproduced deep in the groin with any of these maneuvers. Typically, the test is more painful with the hip adducted and internally rotated than with the hip at neutral, 0° adduction and internally rotated, though posterior hip pain can be painful often with abduction and external rotation of the hip.



Labral stress test part A

Source: University of California, San Francisco, Sports Medicine.

Labral stress test part B

Source: University of California, San Francisco, Sports Medicine.

Labral stress test part C

Source: University of California, San Francisco, Sports Medicine.

How Good Is the Test? There are minimal data on the sensitivity, specificity, and reproducibility of this test.

Flexibility Tests

Thomas Test (Snapping Hip Test)

The Thomas test assesses for flexibility of the hip flexor or iliopsoas. This test can identify a hip flexor contracture or snapping hip flexor tendon.

Description of the Maneuver. The examiner has the athlete lie in the supine position at the end or side of the table so that the patient's leg can drop off the table. Both knees are flexed toward the chest, and the nontested leg is held by the patient to immobilize the pelvis and the lumbar spine. The tested leg is then allowed to passively extend at the hip.

Positive Findings. If the leg cannot reach the table and remains in a flexed position at the end of the

Thomas test

Source: University of California, San Francisco, Sports Medicine.

test, it suggests a tight hip flexor tendon/muscle. Normally, the leg can be brought down to the table level or extended beyond.

How Good Is the Test? The Thomas test had moderate intra- and interrater reliability.

Special Tips for Improving Accuracy. The examiner can keep his or her thumb palpating the anterior iliac spine during the test for motion at the pelvis when the hip flexor is being stretched.

Ely Prone Knee Flexion Test

The Ely test assesses the flexibility of the quadriceps muscle and tendons, specifically the rectus femoris.

Description of the Maneuver. The athlete lies prone on the examination table. Keeping the leg in the neutral position without adduction and abduction, the examiner passively flexes the athlete's knee. The angle of knee flexion is measured and compared on both knees.

How Good Is the Test? The Ely test was shown to have moderate sensitivity and moderate to high specificity. Intra- and interrater reliability was moderate.

Ely test

Source: University of California, San Francisco, Sports Medicine.

Ober Test

This test assesses the tightness of the tensor fascia lata and iliotibial band, located at the lateral hip and knee, respectively.

Description of the Maneuver. The athlete lies on his or her side on the examination table. Keeping the leg relaxed and slightly flexed forward at the hip, the examiner passively abducts the athlete's leg with the knee bent no more than 90°. Some examiners keep the knee extended straight. The abducted leg is then slowly extended and then allowed to passively fall in adduction. The spine should remain perpendicular to the exam table at all times.

What Is a Positive Test? Normally, the knee will drop toward the table. A positive test occurs when the leg cannot reach a level that is at least parallel to the table. Often, the leg will remain abducted due to tightness or a contracture of the tensor fascia lata and iliotibial band.

Reliability. Interrater ICC (intraclass correlation coefficients) = 0.90.

Ober test

Source: University of California, San Francisco, Sports Medicine.

Special Tips for Improving Accuracy. The test cannot be performed accurately when the knee is flexed too far, for example, past 90°, as tightness of the quadriceps and hip flexor can affect the tightness observed.

Piriformis Test

The piriformis test assesses pain that is associated either with the piriformis muscle or with the adjacent sciatic nerve.

Description of the Maneuver. The athlete lies on the side with the upper leg flexed forward across his or her body. The examiner can support the body with one hand while applying a downward pressure to the knee. Symptoms can be further aggravated by asking the athlete to externally rotate the hip in this position against resistance.

What Is a Positive Test? Piriformis syndrome can present with pain in the buttock with radiating pain down the leg if the sciatic nerve is affected by the piriformis muscle.

Gaenslen test part A

Source: University of California, San Francisco, Sports Medicine.

Gaenslen test part B

Source: University of California, San Francisco, Sports Medicine.

Provocative Tests

Gaenslen Test

The Gaenslen test is a provocative test for hip flexor tendinopathy or sacroiliac joint pathology. This test can help identify a hip flexor contracture or snapping hip flexor tendon, or it can stress the sacroiliac joint.

Description of the Maneuver. The examiner positions the athlete in the supine position at the end or side of the table so that the patient's leg can drop off the table. Both knees are flexed toward the chest, and the nontested leg is held by the patient to immobilize the pelvis and the lumbar spine. The tested leg is then allowed to passively extend at the hip. By placing one hand on each knee, the examiner then passively hyperextends the hip and hyperflexes the opposite hip. The hip strength can be recorded on a scale of 1 to 5.

Positive Findings. Reproduction of the patient's hip pain deep to the anterior aspect of the hip predominantly suggests a hip flexor tendinopathy or a primary joint pathology.

How Good Is the Test? The test is moderately sensitive and has low to moderate specificity for sacroiliac joint pain.

Reliability. Test-retest kappa statistic (k) = 0.58; specificity: right 71%, left 77%; sensitivity: right 53%, left 50%; odds ratio: positive likelihood ratios, right 1.84, left 2.21; negative likelihood ratios, right 0.66, left 0.65.

Special Tips for Improving Accuracy. The examiner can keep his or her thumb palpating the anterior iliac spine during the test for motion at the pelvis when the hip flexor is being stretched.

FABER Test (Patrick Test or Figure-Four Test)

The FABER (*f*lexion, *ab*duction, *e*xternal *r*otation) test is a provocative stress test that reproduces symptoms of intraarticular hip pathology, such as osteoarthritis, articular cartilage injuries, or labral tears.

Description of the Maneuver. The athlete is supine on the examination table, and the hip is placed in flexion, abduction, and external rotation (FABER), which is referred to as the figure-four position. The patient ends up crossing his or her leg with the foot just above the opposite knee. The examiner then applies a downward force to the crossed leg at the knee, externally rotating the hip further.

FABER test

Source: University of California, San Francisco, Sports Medicine.

Positive Findings. A positive test is reproduction of the athlete's hip pain, which is typically in the anterior groin or deep posterior buttock.

How Good Is the Test? The FABER test is highly sensitive for intraarticular pathology. It has high reliability on retesting.

Slump Test

The slump test is a neurodynamic test, placing mechanical stress, traction, or compression on neurologic tissues in the lumbar spine. This test looks for sciatica and can be performed in conjunction with the straight leg raise (SLR) test and indirect straight leg raise test. For these tests to be positive, they must reproduce the patient's symptoms regardless of discomfort and pain.

Description of the Maneuver. The athlete sits on the table with his or her hands behind the back. The patient is asked to "slump forward" at the lumbar and thoracic spine while keeping the head in a neutral position. The examiner can apply pressure across the shoulders to maintain thoracolumbar spine flexion. The patient is then asked to fully flex the neck, "chin to chest." The examiner applies overpressure to the cervical spine to maintain cervicothoracolumbar flexion. The examiner then holds the foot in dorsiflexion, and the patient is asked to actively straighten his or her knee, or the examiner passively extends it. The test is then repeated with other leg.

Positive Findings. The test is positive if the patient's symptoms are reproduced at any stage, including shooting pain from increased tension in the spinal cord and sciatic nerve. The patient's symptoms often decrease with neck extension. The athlete may become apprehensive about being placed in the slump test position and may lean backward to avoid further flexion of the spine.

How Good Is the Test? The reliability between examiners for this test is high.

Slump test

Source: University of California, San Francisco, Sports Medicine.

Special Tips for Improving Accuracy. If the patient is unable to fully extend the knee because of pain, he or she is allowed to actively extend the neck for relief, allowing further knee extension.

Musculoskeletal Tests, Knee

The musculoskeletal tests in this entry are used to diagnose common injuries around the knee. The knee is one of the most commonly injured joints, especially in sports that involve a lot of running and jumping. The most common knee complaints typically involve the patellofemoral joint. The knee takes a lot of stress, especially when bending. Studies have shown that the forces at the knee joint can reach three times the body weight when the knee is bent, such as when going upstairs, and up to six to seven times the body weight when the person is in a full squat position. Internal derangement of the knee refers to a variety of damaged structures that can be injured within the knee, for example, meniscal cartilage tears or loose bodies. Ligament tears often present with pain and instability during function. A higher degree of tearing of the ligament typically results in more instability symptoms. The knee serves as an important point of transmission between the ankle and the hip. As such, knee injuries are among the most common complaints encountered in sports medicine.

Examination of the Knee

Observation: Knee Alignment

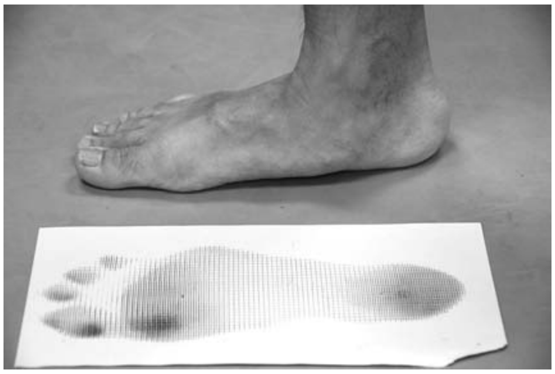
The examination of the knee includes assessment of posture and lower extremity alignment. The alignment at the knees can be quickly screened by asking the athlete to stand with the ankles together, observing the knees. If there is a wide space between the knees when the athlete stands with the feet together and the athlete appears to be "bowlegged," the athlete has *genu*

Genu varum

Source: University of California, San Francisco, Sports Medicine.

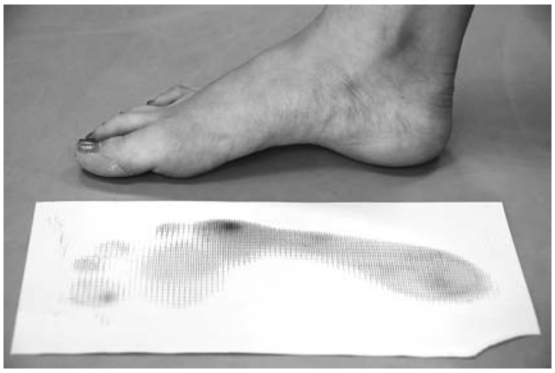
Femoral anteversion

Source: University of California, San Francisco, Sports Medicine.



Pes planus

Source: University of California, San Francisco, Sports Medicine.



Pes cavus.

Source: University of California, San Francisco, Sports Medicine.

varum, indicating that the lower leg angles inward after the knee (toward the midline). Similarly, if the athlete appears "knock-kneed" and has difficulty putting the feet together due to the proximity of the knees, it is called *genu valgus* alignment. With the feet together pointing forward, if the kneecaps point inward, it is called "squinting patellae" and often represents a rotational malalignment at the hips called *femoral anteversion,* where the hips are angled such that the knees and lower leg rotate inward. It is important to always check the hip joint when evaluating knee injuries. The hip may refer pain to the knee.

Observation: Foot Arch Alignment

The athlete can then stand with the ankles a shoulder width apart. When the athlete goes on his or her toes, the arch of the foot can be assessed. Typically, with individuals who have a flexible foot arch, the arch becomes maximal as they go on their toes. As the athlete comes down, the arch can be observed to see if it collapses. If the arch is lost, the athlete's foot is termed *pronated*. If this is severe, it may create a completely flat foot, which is termed *pes planus*. A very high-arched foot is referred to as *pes cavus*.

The athletes can be observed performing functional activities such as walking, hopping, squatting, walking on their heels, and walking on their toes to test the function of the knees and other joints in the lower extremities.

Observation: Kneecap Position and Swelling

Milk or Bulge Sign

The knee is observed easily when the athlete is lying down. Swelling inside the knee joint, referred to as *effusion*, can be observed over the medial and lateral aspects of the kneecap, especially near the top area of the knee, known as the suprapatellar pouch. It is useful to compare both knees. When one has swelling in the knee, it is difficult to see the normal indentations or "dimples" around the kneecaps. To palpate for swelling in the knee, one can stroke the medial aspect of the knee, pushing the fluid inside the knee into the suprapatellar pouch above the knee. By pushing on the lateral aspect from a superior to inferior direction, one can *milk* fluid back into the knee from above. If a *bulge* of fluid forms on the medial aspect of the knee causing a fluid wave, suspect a joint effusion, which suggests a problem causing swelling within the knee joint.

Medial milking sign

Source: University of California, San Francisco, Sports Medicine.

Lateral milking sign

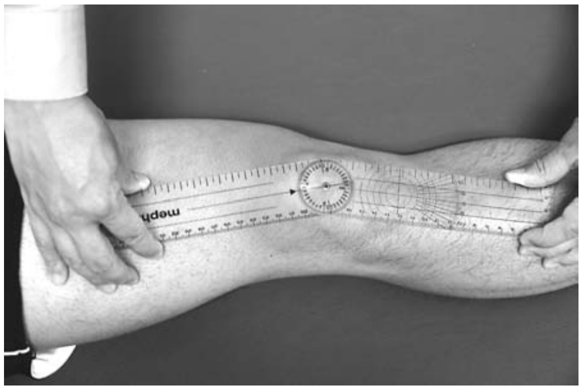
Source: University of California, San Francisco, Sports Medicine.

Patellar Tap

A method to assess for fluid in the knee involves using one hand to push the fluid in the superior pouch or capsule of the knee. If there is more joint fluid under kneecap the, by using the other hand, you can feel that the kneecap is floating on the fluid. Normally, the kneecap rests on the femur (thigh) bone, and there is no movement when pushing directly posterior on the kneecap.

Bursal Swelling

There are several bursas around the knee. These serve to provide protection of soft tissues near an area of bony prominence, which can lead to excessive friction during activity, resulting in pain and swelling. Two common areas for swelling around the knee include the prepatellar bursa, usually found immediately on top of the kneecap, as well as the pes anserine bursa, usually found over the medial aspect of the proximal tibia (shinbone). These swellings can be mild or, in some cases, very large. Fortunately, they often resolve without any medical intervention.



Q angle

Source: University of California, San Francisco, Sports Medicine.

Q Angle

The *Q angle* is the angle measured from the front of the pelvis, center of the kneecap and the tibial tubercle (front bump on the proximal tibia/shin). After puberty, the Q angle normally ranges between 13° and 18°. A Q angle less than 13° is often associated with patella alta (see below). An angle greater than 18° is associated with femoral anteversion. A high Q angle may be found in individuals who complain of kneecap pain.

Patella Alta

Patella alta means a high-riding kneecap. Some individuals naturally have a high position for the kneecap, which may make the kneecap fairly loose side to side during examination. If the kneecap is positioned higher after an acute injury where the joint is hyperflexed, then a patellar tendon rupture may be suggested. From the side view of the knee, a patella alta may demonstrate the "camel" sign, where there are two bumps seen involving the kneecap and the proximal tibia, with the gap being the area of the patellar tendon rupture.

Patella Baja or Infera

Patella baja or *infera* means low kneecap. The kneecap is positioned lower in these athletes, which may result in pain symptoms. Following an acute trauma where the knee is hyperflexed, if a new patella baja is seen, the potential injury that the athlete has sustained is a quadriceps tendon tear.

Palpation

During the examination of the knee, it is important to feel the anatomical structures of the knee to see if they have been injured. Typically, tenderness on application of direct pressure suggests damage to the structures around the knee, such as the joint surfaces of the kneecap, femur (thigh), and tibia (shin), as well as the muscles and tendons around the knee.

Patellar Mobility

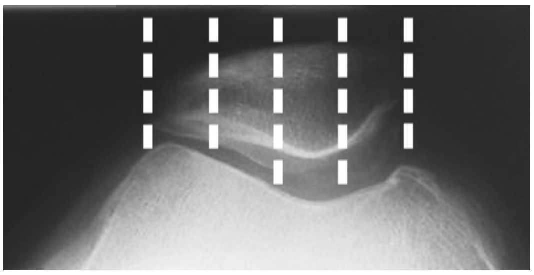
Patellar mobility is determined by passive medial and lateral movement. The patella can be divided into quadrants. A patella is hypomobile when it moves less than one quadrant on medial or lateral glide. A hypermobile patella is illustrated by glide of more than two quadrants (one half of the patellar width).

Patellar Tilt

It should also be noted whether the patella tilts or rotates when it is pushed medially or laterally.

Lateral patellar glide

Source: University of California, San Francisco, Sports Medicine.



X-ray of knee with quadrants

Source: University of California, San Francisco, Sports Medicine.

If the medial structures are too tight, the patella will tilt up when pushed laterally. If the lateral structures are too tight, the patella will tilt up when pushed medially.

Patellar Crepitus

A crunching sensation, or *crepitus,* can be felt under the kneecap while flexing and extending the knee. This can represent degenerative changes in the joint surfaces or maltracking of the kneecap with movement.

Joint Line Tenderness

The joint line can be felt using one's index finger. The joint line can be felt at the top of the shin, where one's finger drops onto a soft area between the bones. One can extend and flex the knee to confirm the presence of the joint line. The meniscal cartilage and articular cartilages are felt when palpating the joint line. Local tenderness may suggest injury to these cartilage structures.

Range of Motion

The examination of range of motion at the knee is most easily performed with the patient in a lying position. Full knee flexion is approximately 135° (range 120°–150°). Hyperextension may occur, especially in women (range 0°–15°). A goniometer is a joint angle–measuring tool that can measure range of motion. The greater trochanter (hip reference), lateral joint line (knee), and lateral malleolus (ankle) are used as reference landmarks to check range of motion in the knee.

The "Locked" Knee

Worrisome signs include a "locked" knee that lacks full extension compared with the other side because it suggests an internal derangement in the knee, for example, large meniscus tears, a ligament tear, or a loose body/bone chip.

Extensor Mechanism Disruption

The inability to extend the knee against gravity in the lying down position suggests an injury to the extensor mechanism of the knee, for example, quadriceps tendon tear, patellar fracture, or patellar tendon injuries.

Special Tests: Ligament Tests

The examiner should perform enough tests to confirm suspected injuries. Examiners should master

Knee flexion

Source: University of California, San Francisco, Sports Medicine.

Knee extension

Source: University of California, San Francisco, Sports Medicine.

at least one or two tests from each group and learn how to do them well in order to make a correct diagnosis.

Ligaments are located between two bones to provide stability to joints. Following injury to a ligament, athletes may complain of joint instability and giving way symptoms. The examiner should test the normal knee first to establish the baseline stability inherent to the athlete's joint. It is important for clinicians to use the same starting position and the same amount of force for both limbs while performing stress tests on ligaments. The muscles must be relaxed throughout the ligament tests. If the ligament is intact, there should be an abrupt end point when it is tested. A soft end point usually represents injury.

Lachman Test

The Lachman test examines for a tear or laxity of the anterior cruciate ligament (ACL).

Description of the Maneuver. The patient is placed in a supine position. The examiner performs the test on the same side of the affected knee with the knee at 20° to 30° of flexion. Fixing the femur with one hand, the examiner lifts the tibia forward with the other hand. The foot should be slightly externally rotated, with the anterior force applied near the posteromedial aspect of the proximal tibia. One lifts the shin forward with approximately 15 lb (pounds) of force (i.e., to lift a 15-lb weight).

Positive Findings. A positive finding is increased anterior movement of the tibia on the femur compared with the normal side. This is typically more than 3 millimeters (mm) of movement.

How Good Is the Test? A summary of the literature suggests that the Lachman test has high sensitivity, high specificity, and moderate reproducibility.

Special Tips for Improving Accuracy. ACL testing is ideally done at 20° to 30° of knee flexion because that is the position where the joint capsule and its attachments give the least resistance. For large legs and small hands, the examiner can cup one hand and fix the femur while using the other hand and wrist wrapped behind the tibia to pull the tibia forward. The examiner should make sure the pulling force applied to the leg is perpendicular to the plane of the tibia.

Lachman technique

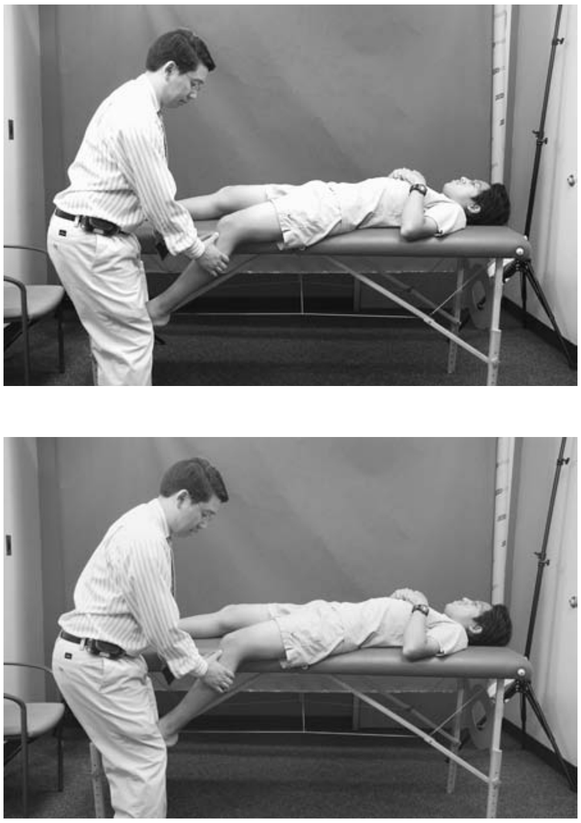
Source: University of California, San Francisco, Sports Medicine.

Drop Lachman Test

The drop Lachman test is a variant of the Lachman test and examines for a tear or laxity of the ACL.

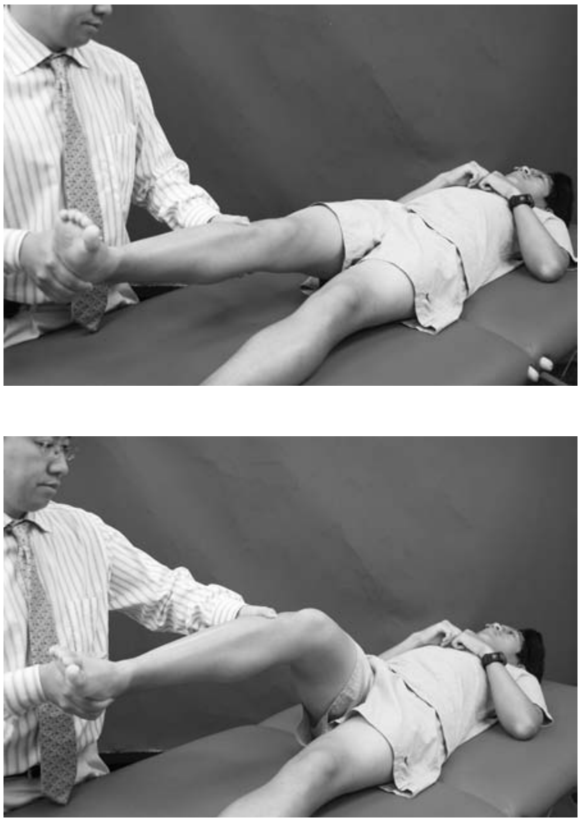
Description of the Maneuver. The patient lies supine with the leg abducted off the side of the table and flexed to 20° to 30°. The foot is stabilized between the examiner's legs. Both hands can be used to pull the tibia forward, or one can use the free hand to anteriorly direct the tibia.

Positive Findings. A positive finding is increased anterior movement of the tibia on the femur compared with the normal side. This is typically more than 3 mm of movement.



Drop Lachman technique

Source: University of California, San Francisco, Sports Medicine.



Pivot shift

Source: University of California, San Francisco, Sports Medicine.

How Good Is the Test? The drop Lachman test has high sensitivity, better than the classic Lachman test.

Special Tips for Improving Accuracy. The athlete's thigh is stabilized by the table as the leg drops off, reducing muscle spasm and making the leg more relaxed during the examination.

Pivot Shift Test (Test of MacIntosh)

The pivot shift test checks for functional instability of the ACL. The test aims to recreate the "giving way" instability at the knee that athletes describe during sports activity. This test was originally described by Galway, Beaupre, and MacIntosh in 1972.

Description of the Maneuver. To perform the pivot shift exam, the knee is placed at 10° to 20° of flexion. The tibia is internally rotated, and valgus stress is applied over the lateral aspect of the proximal femur. The knee is slowly flexed under stress.

Positive Findings. The knee spontaneously reduces when flexed, usually around 40°, often with a noticeable clunk.

How Good Is the Test? The sensitivity for the pivot shift is moderate (though the range is from low to high in the literature), and the specificity is high.

Special Tips for Improving Accuracy. A grading system from 1 to 3 can be used to describe the movement that is seen at the knee during the pivot shift test. A Grade 1+ suggests a slight slide, associated at times with a sense of grinding in the lateral compartment. A Grade 2+ test demonstrates a distinct jump. A Grade 3+ test shows gross instability on testing, with locking occurring during the movement. It is unlikely that a patient with a 2+ or 3+ pivot shift will be able to return to unlimited sports activity. Athletes with a negative or 1+ pivot shift and the presence of an end point on Lachman testing rarely complain of giving way symptoms.

Anterior Drawer Test

The anterior drawer test examines for a tear or laxity of the ACL.

Description of the Maneuver. With the athlete lying on his or her back, the knee is bent as close to 90° as possible with the foot resting on the table. The examiner places both hands behind the tibia and pulls the tibia forward, using a force between 15 and 20 lb. The test can also be performed with the foot externally rotated (turned out) to 15°.

Positive Findings. A positive test is increased anterior movement of the tibia on the injured side compared with the noninjured side. Up to 3 mm of forward movement of the tibia is considered normal. The grading for the test is as follows: Grade 1 = 5 mm, Grade 2 = 5 to 10 mm, and Grade 3 > 10 mm.

How Good Is the Test? A summary of the literature suggests that this test has moderate sensitivity and high specificity. The test is not as sensitive a test as the Lachman or as specific as the pivot shift.

Special Tips for Improving Accuracy. The anterior drawer test has reduced sensitivity, especially after an acute injury, due to the protective spasm of the hamstring muscles, any large swelling in the knee, and any effects of the posterior horn of the medial meniscus.

Anterior drawer test

Source: University of California, San Francisco, Sports Medicine.

Valgus Stress Test

The valgus stress test checks for medial joint laxity, which usually indicates an injury to the medial collateral ligament (MCL).

Description of the Maneuver. The athlete lies on his or her back. The examiner positions one hand at the joint line on the outside part of the knee while the other fixes the ankle on the affected side. The examiner flexes the knee between 20° and 30° and applies a medial or valgus force to the knee. Approximately 15 to 20 lb of force is applied during the test. The test can be repeated at 0° with the knee in full extension to test the MCL as well as the posterior medial capsule.

Positive Findings. A positive test demonstrates increased medial joint laxity compared with the unaffected side. A grading system from 1 to 3 can be used that is based on the amount of joint space opening (Grade 1 = 5 mm, Grade 2 = 5–10 mm, and Grade 3 >10 mm).

How Good Is the Test? The reproducibility between observers (Kappa) is moderate to high.

Special Tips for Improving Accuracy. Fixing the ankle and pushing medially with the hand at the knee allows the examiner to apply the force to the knee easily due to the leverage of the long bone of the shin. In an acute MCL injury, there may be substantial loss of motion and pain so that the athlete may not wish to move the leg in extension or flexion. These are usually higher-grade MCL tears. This appearance of an acute knee injury, referred to as "pseudolocking," can be confused with more damage within the knee, though it is only the MCL.

Valgus stress test

Source: University of California, San Francisco, Sports Medicine.

Varus stress test

Source: University of California, San Francisco, Sports Medicine.

Varus Stress Test

The varus stress test checks for joint laxity on the outside of the knee, which usually represents an injury to the lateral collateral ligament (LCL).

Description of the Maneuver. The athlete lies on his or her back. The examiner positions one hand at the joint line on the outside part of the knee while the other fixes the ankle on the affected side. The examiner flexes the knee between 20° and 30° and applies a lateral or varus force to the knee. This can be done either by reaching over the top of the knee or by approaching the patient from the inside aspect of the knee with the leg out to the side. Approximately 15 to 20 lb of force is applied during the test. The test can be repeated at 0° with the knee in full extension.

Positive Findings. A positive test demonstrates increased lateral joint laxity compared with the unaffected side. A grading system from 1 to 3 can be used that is based on the amount of joint space opening (Grade 1 = 5 mm, Grade 2 = 5–10 mm, and Grade 3 > 10 mm).

How Good Is the Test? The sensitivity of the varus stress test is low, though there are no studies on its efficacy.

Special Tips for Improving Accuracy. Fixing the ankle and pushing laterally with the hand at the knee allows the examiner to apply force to the knee easily due to the leverage of the long bone of the shin. If the leg opens on varus stress testing, check the ACL, PCL, and posterolateral corner tests very carefully as the LCL is not commonly torn in isolation.

Posterior Sag Sign

The posterior sag sign is an observational test looking for a tear in the posterior cruciate ligament (PCL). When the PCL is torn, the shin appears to sag back on one side due to posterior shift of the tibia/shin.

Description of the Maneuver. The athlete lies on his or her back with both hips flexed to 45° and knees to 90°. The examiner then looks perpendicularly across the knees at the front of the shins.

Positive Findings. A positive sag sign occurs when there is an absent tibial tubercle or the prominence at the top of the shin is more obvious on one side than on the other.

How Good Is the Test? The posterior sag sign has a moderate to high sensitivity and a high specificity.

Special Tips for Improving Accuracy. This test should be considered with special attention to the history, because the PCL needs to have the anterior to posterior force and trauma to the knee either directly or by falling directly on the shin. Pulling forward on the shin can often reduce the sag, placing the knee in its original position.

Posterior Drawer Test

The posterior drawer test is a stress test looking for a tear in the posterior cruciate ligament (PCL).

Description of the Maneuver. With the athlete lying on his or her back, the knee is bent as close to 90° as possible with the foot resting on the table. The examiner places both hands behind the tibia and pushes backward on the proximal shin/tibia, looking for instability backward, using a force between 15 and 20 lb.

Positive Findings. A positive posterior drawer test involves further backward motion when a force is applied posteriorly on the upper shin on one side rather than on the other (posterior translation of the tibia).

How Good Is the Test? The posterior drawer test has moderate to high sensistivity.

Posterior sag sign

Source: University of California, San Francisco, Sports Medicine.

Posterior drawer test

Source: University of California, San Francisco, Sports Medicine.

Special Tips for Improving Accuracy. A PCL injury can give false-positive ACL laxity because pulling the leg forward may actually reduce the knee from its new posterior position. Therefore, one should take special notice of any posterior sag sign in the knee before the test is performed. Applying a posterior force to the tibia with the knee flexed 80° and the tibia externally rotated 15° can also stress the posterolateral corner of the knee.

Dial Test (Posterolateral Drawer Test)

The dial test assesses for laxity in the posterolateral structures of the knee (also known as the posterolateral corner [PLC]).

Description of the Maneuver. The athlete lies face down on the exam table. The examiner positions the athlete with both knees together and places the knees at 30° of flexion. Grasping the heels on both sides, the examiner turns both feet outward (external rotation), turning the shins outward like a dial. The test is then performed with the knees at 90°, again turning the shins outward. The examiner takes note of the angle of the foot in relation to the midline, before and after turning the feet.

Positive Findings. A positive dial test occurs when one foot turns 10° more than the opposite side. When a positive test occurs at 30°, it suggests that the structures of the PLC have been damaged. If the test is positive at 90°, it suggests that the structures of the PLC as well as the PCL have been damaged.

Meniscal Tests

Because menisci are avascular and have no nerve supply on their inner two thirds, there can be little or no pain or swelling with injury. The history is often very useful, with reports of clicking or locking, especially in deep squats. Joint line pain or tenderness may also be present. Most tears occur in the posterior aspects of the menisci.

Joint Line Tenderness

Description of the Maneuver. The athlete's knee is passively placed in maximal flexion by the examiner while the athlete is lying on his or her back. The knee is flexed to 90°. The tibia is felt and then dropped into the joint space. The finger or thumb is moved sequentially along the joint line medially and laterally.

Positive Findings. A positive sign is reproduction of the patient's localized pain over the joint line.

How Good Is the Test? The sensitivity in palpating the joint line is high, and the specificity is low.

Special Tips for Improving Accuracy. Fractures that are positioned near the joint line of the knee can be painful with the application of direct pressure

(e.g., MCL/LCL injury, osteoarthritis of the joint surface, and bone bruise). If an area of swelling is noted along the joint line, it can suggest the presence of a meniscal cyst.

Hyperflexion

Description of the Maneuver. The athlete's knee is passively placed in maximal flexion by the examiner.

Positive Findings. A positive sign is reproduction of the patient's localized pain over the joint line.

Knee hyperflexion

Source: University of California, San Francisco, Sports Medicine.

How Good Is the Test? The sensitivity and specificity are moderate.

Extension Block Hyperextension

Description of the Maneuver. The athlete's knee is passively placed in maximal extension by the examiner. The examiner can grasp the knee with one hand above the patella and push the knee gently into extension.

Positive Findings. A positive sign is reproduction of the patient's localized pain in the joint line.

How Good Is the Test? The sensitivity was moderate, and the specificity was high.

McMurray Test, Classic

The classic McMurray test checks for meniscal tears or other internal derangement in the knee.

Description of the Maneuver. The athlete lies on his or her back, and the examiner grasps the heel with his or her hand (i.e., the right hand and right heel). The other hand can be placed on the athlete's knee with the thumb and fingers over the joint line. The leg is then moved from full, acute flexion to full extension with the foot in full internal and then

McMurray test part A

McMurray test part B

Source: University of California, San Francisco, Sports Medicine.

Modified McMurray test part B

Source: University of California, San Francisco, Sports Medicine.

full external rotation. In the classic McMurray test, no valgus or varus stress is applied to the knee. Typically, internal rotation of the tibia/shin tests the lateral compartment, and external rotation of the tibia tests the medial compartment (think of the direction of the heel).

Positive Findings. A palpable thud is a positive sign, as well as pain localized to the joint line. When there is a tear in the posterior meniscal cartilage with a loose fragment, the piece will snap when the knee is brought from full flexion and extended.

How Good Is the Test? The test has low to moderate sensitivity, high specificity, and high reproducibility (Kappa), especially when looking for a thud or click, in particular on the medial side.

Special Tips for Improving Accuracy. The laterality of the test is nonspecific, which means that the test can bother a meniscal tear on either side of the knee when rotation occurs. There is no strong association between the rotation, the side on which the symptoms occur, and the side of the tear.

Modified McMurray Test

This is presently the more common way in which the McMurray test is performed to check for a meniscus tear.

Description of the Maneuver. With the patient supine, the hip and knee are bent to 90°. Grasping the heel in one hand and with the other hand over the knee with the thumb and fingers on the joint line, the examiner gently rotates the tibia, with the heel internally rotated and exerting a mild valgus force (for the lateral compartment) and externally rotated and exerting a mild varus force (for the medial compartment).

Positive Findings. A positive sign is pain over the joint line reproducing the patient's symptoms or a painful click along the joint line.

How Good Is the Test? This test has high specificity but low to moderate sensitivity, especially when looking for a thud or click, in particular on the medial side.

Special Tips for Improving Accuracy. The laterality of the test is nonspecific, which means that the test can bother a mensical tear on either side of the knee when rotation occurs.

Thessaly Test

The Thessaly test is a functional test for meniscus tears in the standing position. As bending and twisting movements while weight bearing often reproduce pain from meniscus tears, this test recreates the exacerbating movements.

Description of the Maneuver. The athlete stands on one foot with the foot flat on the floor. The examiner holds the athlete's hands to give support. First, the patient bends on the standing knee to 5° of flexion. The patient then is asked to twist on the knee, internally and externally rotating at the knee rather than at the pelvis or back, checking for reproduction of the pain symptoms. The patient then bends the knee deeper to 20° and again actively twists on his or her knee.

Positive Findings. The twisting movement will reproduce pain in meniscal injury. The pain is typically localized to the joint line. Patients usually have more pain with knee bent at 20° rather than at 5°.

Thessaly test (side view with knee at 20° flexion)

Source: University of California, San Francisco, Sports Medicine.

Thessaly test (patient asked to internally and externally rotate on the flexed knee)

Source: University of California, San Francisco, Sports Medicine.

How Good Is the Test? The sensitivity and specificity of the Thessaly test are high for both medial and lateral meniscus tears. The Thessaly is one of the most useful tests for checking for meniscus tears.

Steinmann Sign

This checks for internal derangement problems in the knee, such as meniscal tears or loose bodies. In children, one can consider osteochondritis dissecans in the differential diagnosis if the patient complains of internal pain.

Description of the Maneuver. With the patient sitting, the examiner internally and externally rotates the tibia with the knee flexed to 90° and dangling off the table. The examiner can do so by grasping the ankle and internally and externally rotating the tibia.

Positive Findings. A positive sign is reproduction of pain over the joint line.

Apley (Grind) Test

The Apley test checks for meniscus tears or other knee internal derangement.

Apley test part A

Source: University of California, San Francisco, Sports Medicine.

Steinmann sign

Source: University of California, San Francisco, Sports Medicine.

Apley test part B

Source: University of California, San Francisco, Sports Medicine.

Description of the Maneuver. The athlete lies face down on the table, and the knee is flexed to 90°. The examiner grasps the ankle and first lifts vertically to distract the knee joint. The lower leg is then internally or externally rotated (distraction). The second part of the test is then holding the heel and pushing down on the shin. Again, the lower leg is then internally or externally rotated (compression).

Positive Findings. A positive Apley test involves reproducing the patient's pain or mechanical catching within the knee.

How Good Is the Test? This test is still commonly taught and practiced, though there are other tests that are better based on sensitivity and specificity. The test has low sensitivity with both compression and distraction maneuvers. The specificity has been shown to be high in some studies.

Special Tips for Improving Accuracy. If the test is used, it should be correlated to the history and the findings of other physical exam maneuvers.

Patellofemoral Tests

Patellar Apprehension Test

The patellar apprehension test checks for side-to-side instability of the kneecap.

Instructions. The examiner has to assess patellar glide at 20° flexion.

Description of the Maneuver. With the athlete lying flat on his or her back, the examiner can grasp the kneecap and push laterally, trying to displace it as far as possible without hurting the patient or causing a dislocation of the kneecap.

Positive Findings. The athlete may contract the quadriceps to avoid subluxation of the patella, or he or she will express apprehension that the kneecap is slipping out of joint.

Patellar apprehension test

Source: University of California, San Francisco, Sports Medicine.

Quadriceps Inhibition Test or Active Compression Test (Clarke Sign)

The Clarke sign reproduces the pain associated with patellofemoral syndrome.

Description of the Maneuver. With the athlete supine, the examiner places one hand over the superior aspect of the patella, holding the kneecap in place with the web space between the thumb and the index finger. The athlete should then contract the quadriceps.

Positive Findings. The pain under the kneecap will be reproduced with the maneuver. The athlete may not be able to sustain the contraction due to pain. The patient may not wish to perform the maneuver due to apprehension of pain.

How Good Is the Test? This test has a high specificity.

Special Tips for Improving Accuracy. If positive, this is often a painful maneuver, thus it is better to perform at the end of the knee examination.

Quadriceps inhibition test

Source: University of California, San Francisco, Sports Medicine.

Functional Tests

One-Leg Hop Test

One-leg hop test is a functional test to check the general functioning of the knee. It is done to test how the athlete can perform a jumping motion on one foot and also to find out if there is any pain while landing. Athletes with significant painful injuries will usually be apprehensive about performing this test, or they may lose their balance or complain of pain during the test.

One-leg hop test

Musculoskeletal Tests, Shoulder

These musculoskeletal tests are used to diagnose common injuries around the shoulder girdle. The glenohumeral joint is the most mobile joint in the body, but the large, multidirectional range of motion is a trade-off for joint stability. Lack of stability makes the shoulder more susceptible to a large spectrum of injuries, especially with overhead sports such as baseball, volleyball, swimming, and weight lifting. The shoulder girdle is important because it not only serves as the connecting joint between the arm and the axial skeleton but also serves as the base of support for movements occurring at the elbow, wrist, and hand.

Taking a thorough history is as important as the physical exam itself. The clinician should establish the patient's hand dominance and his or her occupation and recreational activities. It is important to establish the patient's chief complaint, which may include pain, instability, weakness, or loss of range of motion. Complaints of numbness and tingling may be associated with neurovascular disorders, stiffness suggests adhesive capsulitis and/or arthritis, and crepitus may indicate a bursa, osteoarthritis, or rotator cuff pathology. Patients should be able to establish a time line for when the injury occurred and what event or mechanism, if any, led to the injury or onset of symptoms. For patients reporting a dislocation, the clinician should ask what position the arm was in at the time of the dislocation and the frequency of dislocations or subluxations. Finally, it is important to establish what type of activities of daily living the patient can and cannot perform. Such activities include getting dressed, lifting an object overhead, sleeping on the shoulder, brushing the teeth, combing the hair, putting on shoes, or carrying or lifting objects such as groceries.

Examination of the Shoulder

To inspect the shoulder, the athlete must be gowned appropriately. Ideally, females should be dressed in a sports bra and shorts. A gown can be used so long as it can be opened to see the back and shoulder.

Posture

The patient's posture should be assessed from multiple positions. Much of what people do on a daily basis can affect their posture and ultimately lead to injury if abnormal mechanics are adopted. When examining a patient from the side, determine if he or she has a forward head position. Ideally, the ears should be in line with middle of the shoulder. Next, assess the position of the patient's shoulders. A high percentage of people will have their shoulders rolled forward. This is commonly an adaptation in individuals who sit at a desk or work on a computer for extended periods of time, but it can also occur from poor posture or muscular imbalances. From the front and back, examine the patient's muscular development. Typically, the height of the dominant shoulder is lower than that of the nondominant shoulder. Inspect the patient for scars, atrophy, swelling, ecchymosis, erythema, rashes, deformity, and scapula positioning. Clavicle deformity may suggest a fracture, whereas a step-off deformity at the acromioclavicular joint may indicate a shoulder "separation."

After assessing the patient's posture when seated, it is important to observe his or her posture during motion. When the patient actively abducts the arms above the head, note any jerky motions that occur at the scapulothoracic region. Ideally, the two sides should be a mirror image of one another. The glenohumeral and scapulothoracic joints should move at a 2:1 ratio during shoulder abduction. It is also important to assess the positioning of the scapula during this movement. Movement of the scapula should be symmetrical when compared bilaterally. Any "winging" or lifting off of the medial border of the scapular shoulder should be noted (see the first image). This can also be assessed by asking the patient to perform a wall push-up or repetitive shoulder flexion. Winging of the scapula may indicate atrophy of the serratus anterior due to disuse or an injury of the long thoracic nerve. The majority of abnormal winging that is seen in athletes, known as *scapular dyskinesis*, is secondary to inhibited function of the scapular stabilizers, usually due to pain from other areas in the shoulder.

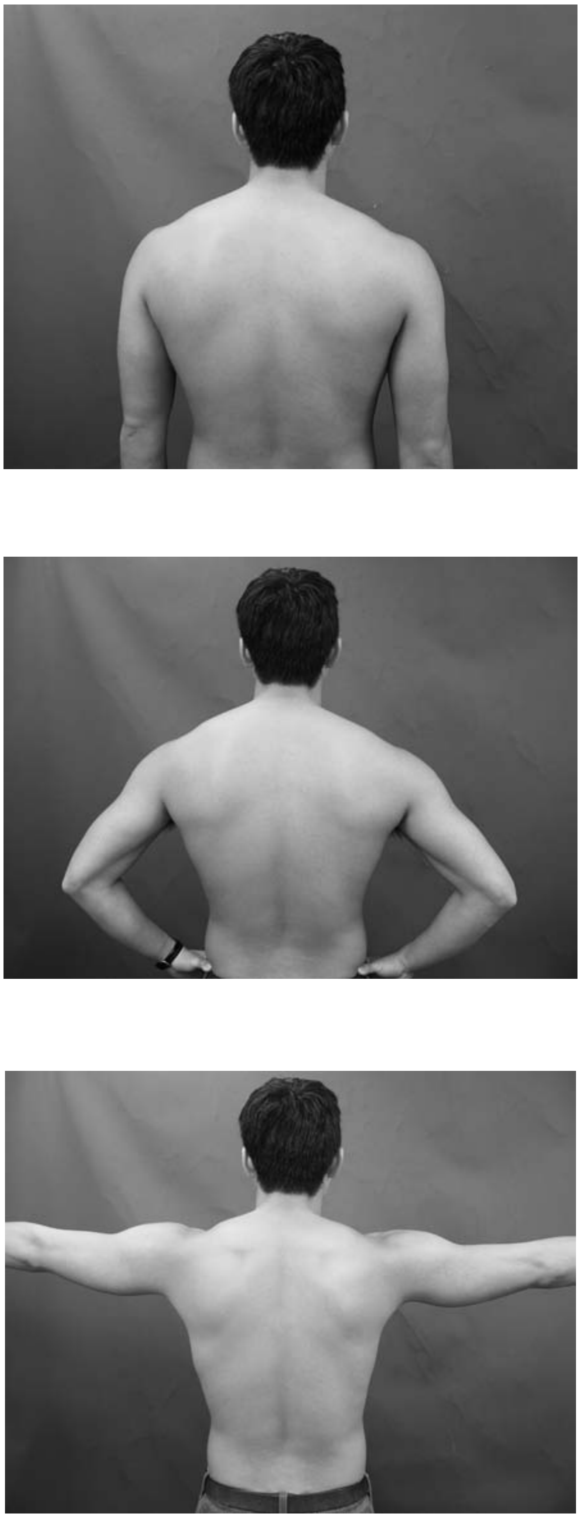
Palpation

Several important bony and soft tissue structures need to be palpated during the physical exam (see images right column, p. 943). The bony structures

Winging scapula

Source: University of California, San Francisco, Sports Medicine.

should include the sternoclavicular joint, the clavicle, the acromioclavicular joint, the coracoid process, the borders of the scapula, and the greater and lesser tuberosities of the humerus. Soft tissue landmarks include the subacromial bursae, the supraclavicular fossa, the long head of the biceps tendon, the trapezius, and other associated muscles and tendons. Starting at the sternoclavicular joint, slowly palpate the joint, and move laterally along the clavicle. Compare the "S" shape and contours of the clavicle bilaterally. Next, assess the acromioclavicular joint located at the distal end of the clavicle, where it meets the acromion process. A step-off deformity may be present if the individual has suffered an acromioclavicular sprain (separated shoulder). The coracoid process can be palpated inferior to the clavicle and medial to the long head of the biceps tendon. For palpation of the scapula, the superior angle of the scapula should be adjacent to the second rib, the spine of the scapula should be adjacent to the spinous process



Scapular function

Source: University of California, San Francisco, Sports Medicine.

of the third thoracic vertebra (T3), and the inferior border should correspond to the seven spinous processes of the thoracic vertebra (T7).

For assessment of proper scapula function, Kibler has developed a measurement test in which the examiner measures the distance from the medial border of the scapula to the spinous process of the seventh thoracic vertebra (T7). The measurement should be performed with the arm at the patient's side, hands on the hips, and arms abducted to 90° and compared bilaterally. Differences seen in these measurements may be suggestive of scapular dyskinesis (sick scapula).

In addition, the axilla should be evaluated. The anterior border of the axilla comprises the pectoralis major, the medial border being the thorax, the posterior border being the latissimus dorsi, and the lateral border being the bicep and tricep. The axilla should be assessed for masses and enlarged lymph nodes.

Range of Motion

Active range of motion performed by the athlete is typically assessed first and can be affected by pain and motor function. The patient can be either

Shoulder abduction

Source: University of California, San Francisco, Sports Medicine.

Shoulder external rotation

Source: University of California, San Francisco, Sports Medicine.

Shoulder flexion

Source: University of California, San Francisco, Sports Medicine.

seated or standing. The movements to be assessed include forward flexion, extension, internal/external rotation, and abduction/adduction. Passive range of motion is performed by the clinician with the patient seated or supine in the same planes noted

Shoulder internal rotation

Source: University of California, San Francisco, Sports Medicine.

before and is used to isolate motion for accurate evaluation of soft tissue.

Normal motion for forward flexion is 0° to 170°–180°, and extension is 60°. To accurately measure internal and external rotation, the arm should be abducted to 90°. Normal internal rotation is 90°, and external rotation is 60° to 70°. The values can vary greatly in overhead athletes such as baseball or softball players. Adduction assessment is limited due to the trunk, but typically, 30° is normal. Abduction motion is from 0° to 180°.

Apley Scratch Test

The Apley scratch test is a general test that examines the patient's active internal rotation range of motion of the shoulder.

Description of the Maneuver. The examiner stands behind the patient and instructs the patient to reach as far as possible behind the back in internal rotation and behind the neck in adduction and external rotation. Typically, the examiner can make a general assessment of the patient's ability to touch his or her fingertips. For a more formal measurement, the level of the spinous process that can be reached is documented, or the distance between the fingertips is measured. This test should be conducted bilaterally to compare differences in motion.

Positive Findings. Any bilateral differences noted in the measurements.

Apley scratch test

Source: University of California, San Francisco, Sports Medicine.

How Good Is the Test? Despite this test being widely used for assessing shoulder motion, no studies have examined the sensitivity or specificity of this test.

Rotator Cuff Strength Testing

Empty Can Test (Supraspinatus)

First described by Jobe, the empty can test is used to evaluate the strength and integrity of the supraspinatus muscle and tendon.

Description of the Maneuver. For the empty can test, the shoulder is abducted to 90° and horizontally adducted forward 30° with the thumbs pointing down toward the floor, as if pouring out something from a can. The patient is asked to maintain this position while the examiner applies downward resistance to the patient's forearm. A variation of

Empty can test

Source: University of California, San Francisco, Sports Medicine.

External rotation test

Source: University of California, San Francisco, Sports Medicine.

this test can be done at 30° abduction instead of 90°, where the supraspinatus should function in relative isolation.

Positive Findings. A positive test shows decreased strength or pain on resisted testing.

How Good Is the Test? A review of the literature indicates that the empty can test has moderate sensitivity and moderate to high specificity for detecting supraspinatus lesions and tendinitis. For supraspinatus tears, it has low sensitivity and high specificity.

External Rotation Test (Infraspinatus and Teres Minor)

The external rotation test examines the strength of the infraspinatus and teres minor.

Description of the Maneuver. With the patient's arms at his or her side, externally rotated 45° and elbow flexed to 90°, the examiner applies an internal rotation movement to assess the strength of the external rotators.

Positive Findings. Decreased strength or pain on resisted testing indicates a positive test. Significant weakness of the infraspinatus may be indicative of suprascapular nerve palsy, where the infraspinatus becomes denervated. This can be due to trauma, a ganglion cyst, or illness.

How Good Is the Test? A review of the literature reveals that the external rotation test demonstrates low sensitivity and moderate specificity for detecting tendinitis and bursitis, while it has moderate sensitivity and high specificity for detecting partial to complete rotator cuff tears.

Lift-Off Test (Lower Subscapularis)

The lift-off test, described by Gerber and Krushell, evaluates the muscular strength of the subscapularis.

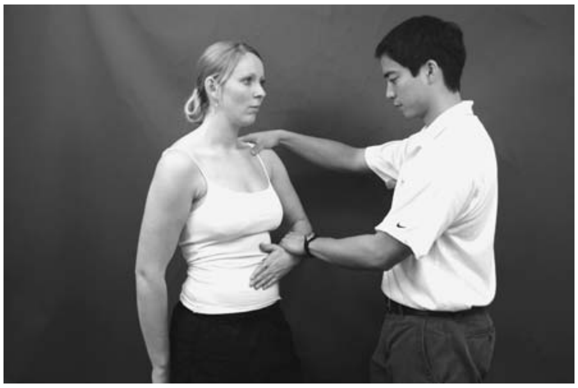
Description of the Maneuver. With the patient seated or standing, the arm of the patient is internally rotated behind his or her back. The patient is asked to lift the back of the hand off the lower back. If the patient is able to the complete this task, the clinician then applies resistance to the palm to assess the strength of the subscapularis.

Positive Findings. Inability of the athlete to lift the dorsum of the hand off the back indicates a positive test.

How Good Is the Test? The literature indicates that the lift-off test has moderate sensitivity and high specificity for detecting subscapularis lesions, such as tendinitis and tears.

Lift-off test

Source: University of California, San Francisco, Sports Medicine.



Belly press test

Source: University of California, San Francisco, Sports Medicine.

Belly Press Test (Upper Subscapularis)

The belly press test examines the strength of the subscapularis.

Description of the Maneuver. The patient places his or her hand on his or her belly. The clinician attempts to lift the hand off the abdomen while the patient resists.

Positive Findings. The athlete complains of decreased strength or inability to hold the hand against the abdomen.

How Good Is the Test? There are no studies examining the sensitivity or specificity of this test.

Impingement/Rotator Cuff Special Tests

Impingement can occur when the soft tissue structures (rotator cuff, bursa, biceps, and tendon) that lie within the subacromial space become compromised or pinched between the acromion and the greater tuberosity, typically with overhead motions and internal rotation maneuvers.

Neer Impingement Test

The Neer impingement test assesses the presence of impingement of the rotator cuff, primarily the supraspinatus, as it passes under the subacromial arch during forward flexion. Dr. Charles Neer first described this test in 1972.

Description of the Maneuver. With the patient standing, the clinician stabilizes the scapula with one hand while applying passive force for flexion of the arm.

Positive Findings. Pain in the anterior shoulder or reproduction of the patient's symptoms signifies a positive test.

How Good Is the Test? The literature suggests that this test has high sensitivity and moderate specificity.

Neer impingement test

Source: University of California, San Francisco, Sports Medicine.

In addition, it has moderate positive predictive value and moderate negative predictive value.

Hawkins Test

The Hawkins test, described by Drs. Hawkins and Schutte, is used to evaluate impingement of the rotator cuff and subacromial bursa.

Description of the Maneuver. The patient is seated or standing with the arm forward flexed to 90° and the elbow bent at 90°. The clinician stabilizes the top of the shoulder while internally rotating the arm at the forearm.

Positive Findings. Pain in the anterior shoulder or reproduction of the patient's symptoms with the test indicates a positive test.

How Good Is the Test? Several studies examining the efficacy of this test demonstrate moderate to high sensitivity and low to moderate specificity. In addition, the test has shown moderate positive predictive value and moderate negative predictive value.

Special Tips for Improving Accuracy. The clinician can stand at the side of the athlete with one hand on top of the shoulder, keeping the patient from elevating the shoulder. The other hand is positioned close to the elbow with the thumb down, making it more comfortable for the examiner to internally rotate the arm. The test should not be done with the arm abducted.

Drop Arm Test

The drop arm test examines for rotator cuff tears, most specifically in the supraspinatus.

Description of the Maneuver. With the patient standing, the clinician abducts the arm to 90° and instructs the patient to slowly lower his or her arm to the side.

Positive Findings. Severe pain or an inability to slowly lower the arm to the patient's side is a positive finding. The arm typically drops suddenly at approximately 90°.

How Good Is the Test? A review of the literature indicates that the drop arm test has low sensitivity and high specificity in identifying both tendinitis and rotator cuff tears.

Patte "Dropping" Test

The Patte test, developed by Patte in 1995, evaluates the integrity of the infraspinatus or teres minor.

Description of the Maneuver. With the arm flexed to 90° in the plane of the scapula and the elbow

Hawkins test

Source: University of California, San Francisco, Sports Medicine.

Patte test

Source: University of California, San Francisco, Sports Medicine.

flexed to 90°, the patient is instructed to externally rotate the arm while the clinician applies resistance to the forearm.

Positive Findings. Pain, decreased strength, or inability to externally rotate the forearm when compared bilaterally indicates a positive test.

How Good Is the Test? The Patte test demonstrates moderate sensitivity and moderate to high specificity in detecting infraspinatus lesions, tendinitis, and tears. In addition, the test has also shown high positive predictive value and moderate negative predictive value for detecting these pathologies.

Yocum Test

The Yocum test assesses impingement of the rotator cuff.

Description of the Maneuver. The patient is instructed to place the hand on the opposite shoulder and then raise the elbow while keeping the hand on the shoulder.

Positive Findings. A positive test is pain in the anterior shoulder or reproduction of symptoms.

How Good Is the Test? The literature has shown the Yocum test to possess moderate sensitivity and moderate specificity when performed in combination with the Hawkins and the Neer test.

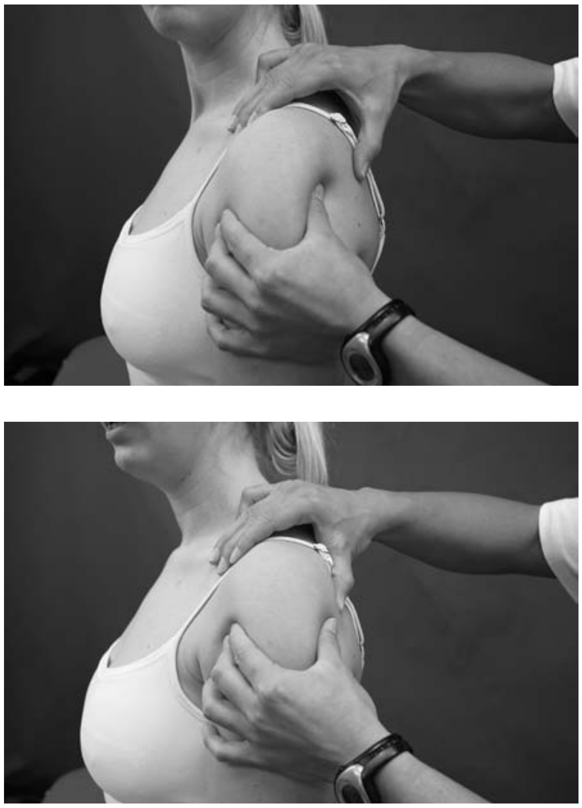
Special Tests to Examine Shoulder Instability

Load and Shift Test

The load and shift test examines the integrity of shoulder stability in the anterior and posterior directions.

Yocum test

Source: University of California, San Francisco, Sports Medicine.



Load and shift test

Source: University of California, San Francisco, Sports Medicine.

Description of the Maneuver. The patient is seated or supine with his or her arm relaxed and resting at the side. The clinician grasps the head of the humerus between his or her thumb and fingers and applies anterior and posterior glide from the resting position.

Positive Findings. A positive sign is excessive gliding of the humeral head. The degree of stability can be graded: Grade 0 stability means no gliding from the center of the glenoid, Grade 1 equals translation to the glenoid rim, Grade 2 stability leads to translation of the head over the glenoid rim but no locking, and Grade 3 stability results in the head of the humerus locking over the glenoid rim.

How Good Is the Test? Research has shown high sensitivity and specificity for the load and shift, as well as high positive predictive value in diagnosing Bankart lesions. However, there is no good correlation between examiners because the measurement of translation is somewhat subjective.

Apprehension Test

The apprehension test, described by Row and Zarin, examines for anterior instability of the shoulder.

Description of the Maneuver. The patient is supine on the table, and his or her arm is abducted with the elbow flexed to 90°. The clinician gently rotates the arm externally. The test is often performed in conjunction with the relocation and surprise tests.

Positive Findings. The patient may complain of pain or be apprehensive that his or her arm may dislocate as the arm is externally rotated.

How Good Is the Test? The literature indicates that the apprehension test has moderate sensitivity and moderate specificity in detecting labral pathology that often leads to instability of the joint.

Relocation Test

The relocation test, described by Jobe, is used in conjunction with the apprehension test to distinguish between anterior instability and primary impingement of the shoulder.

Description of the Maneuver. The apprehension test is performed first, and when the patient becomes apprehensive or complains of pain, the clinician applies a posterior force to the humeral head.

Apprehension test

Source: University of California, San Francisco, Sports Medicine.

Relocation test

Source: University of California, San Francisco, Sports Medicine.

Positive Findings. The relocation test is positive if the symptoms of apprehension reduce or if the clinician is able to externally rotate the shoulder further without increase in pain or apprehension. If the symptoms persist following the posterior-directed force, the pain is associated with primary impingement and not anterior shoulder instability.

How Good Is the Test? A review of the research suggests that the relocation test has moderate sensitivity and moderate to high specificity in detecting labral pathology.

Sulcus Sign

The sulcus sign tests for inferior instability caused by laxity of the inferior glenohumeral ligament complex.

Description of the Maneuver. The patient is seated with his or her arm resting at the side. The clinician grasps the upper arm and applies a distal force to the arm.

Positive Findings. A positive sign is increased inferior movement of the humeral head or the visible development of a sulcus at the glenohumeral joint. A positive test often suggests that the athlete has multidirectional instability if there are other signs of join instability.

Sulcus sign

Source: University of California, San Francisco, Sports Medicine.

How Good Is the Test? So far no studies have examined the validity of the sulcus sign as it pertains to inferior instability.

Labral Special Tests

Active Compression/O'Brien Test

The active compression test, developed by O'Brien and Pagnani, assesses the integrity of the glenoid labrum and the acromioclavicular (AC) joint.

O'Brien test

Source: University of California, San Francisco, Sports Medicine.

Description of the Maneuver. With the patient seated or standing, the patient is instructed to raise his or her arm into 90° of forward flexion with the elbow extended and then adduct the arm to 10° to 15°. The patient internally rotates the arm and points the thumb down to the ground. The clinician applies a downward force to the arm. Afterward, the patient is instructed to externally rotate the arm and point the thumb toward the ceiling, and the clinician again applies a downward force.

Positive Findings. Positive findings for labral pathology occur when the first test reproduces pain while the second test decreases or eliminates pain. The pain associated with labral tears is described deep in the shoulder. Pain situated over the AC joint is associated with AC joint pathology, such as osteoarthritis or a shoulder separation, rather than labral pathology. Pain in the AC joint is usually equal with the palm down or the palm up.

How Good Is the Test? Several studies have reported validity data regarding the active compression test. A review of the literature has shown the test to have moderate to high sensitivity and low to high specificity for detecting labral tears and AC joint pathology and high positive predictive value and high negative predictive value.

Crank Test

Liu and Henry first described the crank test to assist clinicians in determining the presence of a labral tear.

Crank test

Source: University of California, San Francisco, Sports Medicine.

Description of the Maneuver. The patient is seated or supine with his or her arm flexed to 60° in the scapular plane. The clinician applies a load across the axis of the humerus while the other hand rotates the arm.

Positive Findings. Pain during external rotation or reproduction of symptoms, which usually consist of pain or clicking, is a positive sign.

How Good Is the Test? The literature suggests the crank test to have high sensitivity and high specificity with high positive predictive value and high negative predictive value.

Compression-Rotation Test

The compression-rotation test checks for the integrity of the labrum.

Description of the Maneuver. With the patient supine, the arm is abducted to 90° with the elbow flexed to 90°. The clinician applies an axial force to the humerus and attempts to push the humeral head against the torn part of the labrum.

Positive Findings. Pain or catching of the labrum signifies a positive test.

How Good Is the Test? The validity examination has shown the compression-rotation test to have high sensitivity and low specificity in detecting labral pathology.

Special Tests to Examine Thoracic Outlet Syndrome

A less common diagnosis for shoulder and diffuse upper extremity pain is thoracic outlet syndrome. The symptoms include weakness, pain, and numbness of the upper extremity and pain that radiates from the shoulder into the hand and fingers. The symptoms occur when the neurovascular structures around the neck and clavicle are compromised when the arm is in an overhead position.

Adson Maneuver

Adson and Coffey first described this maneuver to assist clinicians in examining possible compression

Adson maneuver

Source: University of California, San Francisco, Sports Medicine.

of the subclavian artery between the scalene anticus and the cervical rib.

Description of the Maneuver. In a seated position, the patient extends the neck and turns the head toward the shoulder being tested while that shoulder is slightly abducted and extended. The patient inhales while the examiner palpates the ipsilateral radial pulse.

Positive Findings. Diminution or elimination of the pulse and reproduction of the paresthesias indicate a positive test, provided that they do not occur on the asymptomatic, contralateral side.

How Good Is the Test? Studies have documented the Adson maneuver to have poor to good specificity and good sensitivity.

Wright Hyperabduction Test

Wright originally described this maneuver in 1945 and suggested that the neurovascular symptoms in the upper extremity were attributed to compression by the pectoralis minor.

Description of the Maneuver. With the patient seated, the clinician progressively hyperabducts and externally rotates the patient's arm while assessing for ipsilateral radial pulse.

Positive Findings. Diminution or elimination of the radial pulse and reproduction of the paresthesias is indicative of a positive test.

Wright hyperabduction test

Source: University of California, San Francisco, Sports Medicine.

How Good Is the Test? No studies have examined the validity of the Wright hyperabduction test as it pertains to thoracic outlet syndrome.

Roos Stress Test

This test was first described by Roos to assess entrapment of the neurovascular bundle in the upper extremity.

Roos stress test.

Source: University of California, San Francisco, Sports Medicine.

Description of the Maneuver. The Roos stress test is performed with the patient holding his or her shoulders in abduction and external rotation of 90° while maintaining elbow flexion at 90°. The patient is instructed to repeatedly open and close his or her hands for 3 minutes.

Positive Findings. Reproduction of these symptoms or a sensation of heaviness and fatigue is consistent with a positive finding and a diagnosis of thoracic outlet syndrome.

How Good Is the Test? No studies have examined the validity of the Roos stress test as it pertains to thoracic outlet syndrome.

Musculoskeletal Tests, Spine

These musculoskeletal tests are used to diagnose common injuries around the spine. Back pain ranks second only to the common cold as a symptomatic reason to visit the doctor's office. Approximately 70% of adults have one or several significant bouts of low back pain at some time in their lives. Fortunately, most causes of back pain respond to conservative treatment measures early on. However, following recurrent episodes of back pain, the natural history is typically progressive degenerative change as one ages.

The spine plays a central role in achieving the maneuvers involved in sports. The axial skeleton allows the peripheral limbs to perform functional sports movements while the spine transmits energy and forces. Sports that use the upper extremities often involve twisting motions, which lead to more athletic-related injuries in the back than sports that use the lower extremities predominantly. Because the back functions integrally with the pelvis and hips, patients may complain of pain in the spine or pelvic area, with problems affecting function in the other sites, especially the hips and lower extremities. The clinician should evaluate the spine as well as the hip during the examination.

Lumbar Spine

Common injuries include muscle and ligament strains, degenerative disk disease (i.e., herniated disk), scoliosis (curved spine), and osteoarthritis. The physical exam of the spine and associated systems is important to determine that back pain is coming from the spine and not from a systemic disease such as cancer or an internal organ pain referring to the back.

The most common cause of back pain in the adult population involves *degenerative disks leading to disk herniation.* The most common areas of disk herniation are at the lowest part of the lumbar spine, L4-L5 or L5-S1 level, as well as the lower part of the neck. If the disk herniation in the lower back is large, it can cause nerve impingement, leading to radiating pain down the leg, known as *sciatica.* Sciatica is typically a pain that radiates from the spine in typical nerve distribution, affecting the sciatic nerve that runs down the back of the leg to the foot. When the sciatic nerve is compressed, usually by a lumbar disk herniation at the L4-L5 or L5-S1 level, the patient experiences pain, weakness, and numbness in the leg, often below the level of the knee. The pain is usually reproduced with back flexion.

Cauda equina, seen in 1% to 2% of lumbar disk herniations, is a surgical emergency. A large disk herniation can compromise the spinal cord and put pressure on it. The most consistent finding is urinary retention, though numbness around the buttocks and anus, known as saddle anesthesia, is a danger sign. Osteoarthritis can also cause problems in the lower back, especially if there is narrowing of the spinal canal due to the arthritis changes, referred to as *spinal stenosis*. Patients with spinal stenosis may report neurogenic claudication, complaining of leg pain, weakness, and gait unsteadiness after walking. Symptoms of spinal stenosis typically worsen with standing and back extension and may improve with sitting and flexion.

Examination of the Spine

The back exam is more easily performed using an approach based on the position of the patient, specifically standing, sitting, supine, and prone, instead of using a LOOK (inspection), FEEL (palpation), MOVE (range of motion), and special tests that can be used to examine many of the peripheral joints. By combining the exam and positioning of the patient, elements of the inspection, palpation, movement, and special tests are involved, making the exam more efficient.

Standing

To inspect the back, the athlete must be gowned appropriately, in shorts without socks and shoes. Females should be dressed in a sports bra and shorts. A gown may be used as long as it can be opened to see the back.

Skin and Muscles

The musculature and skin can be quickly examined by exposing the back. The examiner can check for muscle spasm, which is often more obvious when standing and moving the spine. Any atrophy of the muscles should be noted since it may suggest a long-standing problem. Skin lesions are documented, especially any irregular spots and rashes.

Posture

Posture is an important factor in back conditions. The athlete's alignment can be assessed from the side. Using a plumbline, general landmarks that should line up include the earlobe, acromioclavicular joint, lateral hip (greater trochanter), and outside ankle (lateral malleolus). Excessive curvature at the upper back is referred to as *kyphosis*. From the back, the shoulders, pelvis, and skin folds at the buttocks and behind the knees can be grossly checked to make sure they are at similar levels. Asymmetries can be examined more closely to see what the underlying cause is. Postural abnormalities that are frequently seen include head forward posture, rolled forward shoulder posture, and hyperextension at the lower back (*hyperlordosis*).

Scoliosis

Scoliosis refers to side-to-side curvature of the spine greater than 10°. The curve is best seen when the athlete bends forward. Because there are rotational changes with a lateral curve, when the athlete bends forward, there is a hump that is higher on the side the curve it is pointing toward. A curve at the upper spine toward the right is the most common type of scoliosis. When there is one curve, a second corrective curve can occur. Less commonly, there can be a triple or quadruple curve.

Kyphosis

Source: University of California, San Francisco, Sports Medicine.

Scoliosis

Source: University of California, San Francisco, Sports Medicine.

Walking/Gait

The athlete's mechanics should be observed while walking, looking for limited movement at the spine, asymmetries of gait, and signs of muscle weakness. Specifically, difficulty walking on one's heels suggests an L5 nerve root problem, while difficulty walking on one's toes suggests S1 nerve root weakness.

Peripheral Joint–Scanning Exam

If the athlete has abnormal biomechanics and signs of asymmetry, it is obviously important to rule out any pathology in the extremities that may be influencing the spine. A functional maneuver, such as asking the athlete to squat and take a few steps in the squatted position (duck walk), can quickly screen for problems at the hips, knees, ankles, and feet.

Special Tests (Standing)

Schober Test

The Schober test checks for flexion range of motion at the lumbar spine. When it is reduced, it may suggest conditions that cause stiffness at the lumbar spine.

Description of the Maneuver. With the examiner standing behind the patient, the top of the tailbone (sacrum) is palpated, and a mark is made at 10 centimeters (cm) higher from this point. The athlete then bends as far forward as possible without bending at the knees, and the distance is measured.

Positive Findings. The increased distance between the top of the tailbone should measure more than 14 cm. A positive test means that the distance in flexion is less than 14 cm, suggesting limited movement.

How Good Is the Test? The reproducibility of the test is moderate.

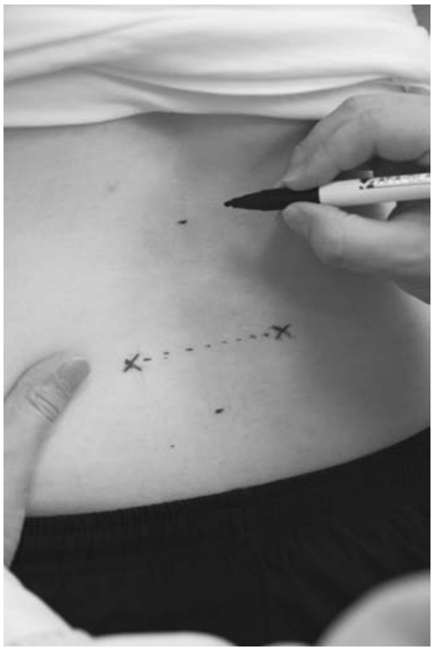
Modified Schober Test

The modified Schober test checks for flexion range of motion at the lumbar spine. When it is reduced, it may suggest conditions that cause stiffness at the lumbar spine.

Description of the Maneuver. From behind the standing patient, the posterior superior iliac spines of the pelvis are palpated (there are dimples typically visible in this area), and a line is drawn across. A mark is made 10 cm above the line, and another mark is made at 5 cm higher from this point. The athlete then bends as far forward as possible without bending at the knees, and the distance between the two marks is measured.

Positive Findings. The distance between the marks should normally increase 5 cm or more with flexion (e.g., the distance between the marks increased from 15 cm to more than 20 cm in 90% of the population.

How Good Is the Test? The sensitivity of the modified Schober test is low, the specificity is high, and the reproducibility of the test is good.



Modified Schober test

Source: University of California, San Francisco, Sports Medicine.

Trendelenburg Test

The Trendelenburg test examines for *weakness or instability of the hip abductors,* primarily the gluteus medius.

Trendelenburg test (negative)

Source: University of California, San Francisco, Sports Medicine.

Trendelenburg test (positive)

Source: University of California, San Francisco, Sports Medicine.

Description of the Maneuver. The patient balances first on one leg, raising the nonstanding knee toward the chest. The examiner can stand behind the athlete and observe for any misalignment and dropping of the pelvis or buttock on the nonstance side.

Positive Findings. If the pelvis on the side of the nonstance leg rises, the test is negative. If the pelvis of the nonstance leg falls, the test is positive, indicating weakness or instability of the hip abductors, primarily the gluteus medius, on the stance side.

How Good Is the Test? The Trendelenburg test has moderate to good sensitivity and specificity for detecting a tear in the gluteus medius muscle.

Gillet Test (March Test)

The Gillet test assesses for asymmetric movement around the sacroiliac (SI) joints, suggesting biomechanical dysfunctions. The test is done in a similar fashion to the Trendelenburg test.

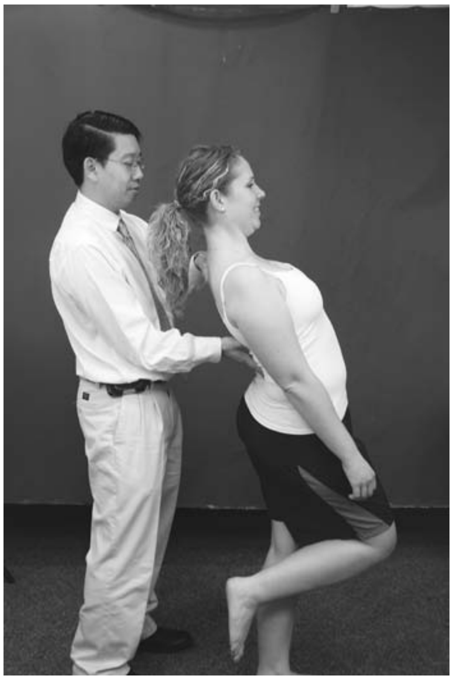
Description of the Maneuver. The examiner palpates the posterior superior iliac spine (PSIS) on one side with the thumb and the horizontal sacral spine with the other thumb while the athlete is standing. The patient then pulls the non–weight-bearing knee up toward the chest. The examiner keeps a thumb gently over the PSIS to assess the movement that occurs at the joint. Normally, the thumb and joint will move laterally and downward. Upward movement of the thumb and SI joint is abnormal. The test can also be repeated with one thumb over the ischial tuberosity and the other over the apex of the sacrum. Repeat on the other side.

Positive Findings. Normally, PSIS will drop downward and move laterally. If the PSIS moves minimally or in an upward direction, it is a positive test, suggesting SI fixation, hypomobility, or dysfunction.

How Good Is the Test? This test has poor reliability among examiners and is very subjective.

One-Leg Standing Hyperextension (Stork) Test

The one-leg standing extension test assesses for pain in the back on extension, which can be associated with pars interarticularis fractures (spondylolysis or spondylolisthesis).



One-leg standing hyperextension test

Source: University of California, San Francisco, Sports Medicine.

Description of the Maneuver. The athlete stands on one leg while extending the spine. The examiner stands behind, supporting the athlete to allow him or her to extend fully on one leg.

Positive Findings. A positive test is indicated by pain in the back, usually in the lowest lumbar vertebrae (L5 or L4), when the athlete is extended. The pain is usually on the side of the stance leg.

How Good Is the Test? This test has poor sensitivity and specificity for detecting spondylolysis.

Special Tips for Improving Accuracy. The examiner can stand directly behind the athlete and place one hand on the athlete's shoulder and the other hand with the (examiner's) arm extended on the patient's lower back. This can help unload some of the individual's weight as the athlete extends backward, allowing him or her to balance more easily.

Range of Motion

The examiner can ask the athlete to actively move to check the motion at the spine. The common directions include flexion, extension, and rotation. Passive movements, with the examiner assisting the athlete to move, are sometimes difficult to perform because of the weight of the athlete's body. If active movements are full and painfree, overpressure can be attempted with care. Avoid exacerbating suspected painful movements during the exam if possible.

Though the spine motion flexes almost 90° to 100°, the forward flexion actually occurs at both the spine and the pelvis and hips. The lumbar spine flexes approximately 40° to 60° and extends around 20° to 35°. When the spine bends forward, it is locked in flexion so that lateral bending and rotation do not occur and the back can receive axial loading. Motion can be limited by ligament tightness, pathology in the spinal elements such as osteoarthritis, or anatomical variants including scoliosis.

Lateral bending of the lumbar spine can occur when the spine is in extension, while almost no bending occurs in flexion. Lateral bending of the lumbar spine ranges from 15° to 20°. With lateral bending, the spine also rotates; for example, as the spine bends laterally to the left, it also rotates toward the right. Similarly, axial rotation can occur in the extended position with motion averaging approximately 15° to 20°. Minimal rotation occurs in full flexion.

Sitting

The athlete can now be asked to sit on the exam table. Observe how the patient gets on the table, especially if he or she has to use a step to get on the table. The neurological exam for the lower extremities can easily be performed with the patient in the sitting position. Alternatively, the neurological exam can be done with the patient supine.

Lateral rotation

Source: University of California, San Francisco, Sports Medicine.

Strength Testing (Myotomes)

The examiner can check for weakness by eliciting a resisted isometric contraction for approximately 5 seconds in major muscles in the lower extremities. It is important to compare the strength bilaterally to detect subtle weaknesses. The strength

Ankle plantarflexion, S1

Source: University of California, San Francisco, Sports Medicine.

can be graded from 1 (*no muscle activitation*) to 5 (*full strength*). The following muscle groups should be tested. The associated primary nerve roots are indicated in brackets: hip flexors (L1-L2), knee extensors or quadriceps (L3), ankle dorsiflexors (L4-L5), first toe extensor or extensor hallucis longus (L5), knee flexors or hamstrings (S1), ankle plantarflexors or calf muscles (S1), and hip extensors (S1).

Sensation (Dermatomes)

Dermatomes are areas of skin where the sensation is supplied by specific nerve roots in the spine. These dermatomes can vary subtly from person to person. The approximate distributions for common areas in the lower extremity and their nerve roots are as follows: groin (L1), thigh (L2), knee (L3), lateral shin and medial ankle (L4), first dorsal web space of the foot between the first and second toes (L5), lateral foot (S1), back of the thigh (S2), and perianal area (S3, S4, S5).

Reflexes

Using a reflex hammer, the reflexes of the lower extremity can be assessed. These are typically graded as +2 = *normal reflexes*, +3 = *hyperreflexic (increased) reflexes*, +1 = *hyporeflexic (decreased) reflexes*, and 0 = *absent reflexes*.

The knee reflex is elicited by tapping the patellar tendon over the anterior knee while the athlete is relaxed, causing contraction of the quadriceps and subsequent extension of the knee. The knee reflex tests the L3 and L4 nerve roots.

The ankle reflexes can be tested by tapping the posterior aspects of the Achilles tendon with the foot resting in the neutral position, which causes a reflex plantarflexion of the foot. The ankle reflex tests the S1 nerve root.

The Babinski reflex is elicited by quickly brushing the sole of the foot from the heel to the big toe on each side. The normal response to this maneuver is dorsiflexion of the first toe. Patients with central spinal cord or brain lesions involving the upper motor neurons may have an abnormal response such as flexion of the big toe downward. Some patients do not demonstrate any movement on either side, which is normal as long as the reflexes are symmetric on both sides.

Special Tests (Sitting)

Modified or "Indirect" Straight Leg Raise Test

The modified or "indirect" straight leg raise (SLR) is a test that puts traction and compression forces on the lower lumbar nerve roots, reproducing the mechanism of compression of the nerve root usually caused by disk herniation. This is performed in a seated position, whereas the classic SLR test is performed with the patient lying supine. Both tests should be done during the exam to check if the findings are consistent (see also Straight Leg Raise Test and Waddell Tests).

Description of the Maneuver. With the patient sitting, the examiner passively extends the knee. The examiner explains that he or she is checking the patient's ankle or the Babinski reflex, so as not to reveal what the examiner is looking for.

Positive Findings. The test is positive if pain extends from the back down the leg in a sciatic nerve distribution.

Modified straight leg raise

Source: University of California, San Francisco, Sports Medicine.

Slump test

Source: University of California, San Francisco, Sports Medicine.

Slump Test

The slump test is a neurodynamic test, placing mechanical stress, traction, or compression on neurologic tissues in the lumbar spine. This test looks for sciatica and can be performed in conjunction with the SLR test and indirect SLR test. For these tests to be positive, they must reproduce the patient's symptoms regardless of discomfort and pain.

Description of the Maneuver. The athlete sits on the table with his or her hands behind the back. The patient is asked to "slump forward" at the lumbar and thoracic spine while keeping the head in a neutral position. The examiner can apply pressure across the shoulders to maintain thoracolumbar spine flexion. The patient is then asked to fully flex the neck, "chin to chest." The examiner applies overpressure to the cervical spine to maintain cervicothoracolumbar flexion. The examiner then holds the foot in dorsiflexion, and the patient is asked to actively straighten his or her knee, or the examiner passively extends it. The test is then repeated with the other leg.

Positive Findings. A positive test is if the patient's symptoms are reproduced at any stage, with shooting pain from increased tension in the spinal cord and sciatic nerve. The patient's symptoms often decrease with neck extension. The athlete may become apprehensive about being placed in the slump test position and may lean backward to avoid further flexion of the spine.

How Good Is the Test? The reliability of this test between examiners is high.

Special Tips for Improving Accuracy. If the patient is unable to fully extend the knee because of pain, the patient is allowed to actively extend the neck for relief, allowing further knee extension.

Supine Tests (Hip)

The hip is examined while the patient is in the supine position. To screen for intraarticular hip pathology, the range of motion in the hip can be checked by moving the hip in full internal and external rotation. If the patient is suspected to have significant trauma or discomfort in the hip, the leg can be "logrolled" in extension to perform gentle internal and external rotation at the hip.

Straight Leg Raise Test or Lasegue Test

The SLR test is the classic test for identifying symptoms of sciatica. The test puts traction and compression forces on the lower lumbar nerve roots, reproducing the mechanism of compression of the nerve root usually caused by disk herniation.

Description of the Maneuver. The examiner flexes the patient's hip while maintaining knee extension until the end of the range of motion is reached passively or the patient has painful symptoms. Most individuals can be flexed at the hip to 80° or 90° unless they have symptoms of pain or tight hamstrings. Very flexible individuals, such as dancers, may flex more than 90°.

Straight leg raise

Source: University of California, San Francisco, Sports Medicine.

Positive Findings. The SLR test is positive if the patient complains of pain extending from the back down the leg in the sciatic nerve distribution (primarily L4, L5, or S1-S2 sciatic nerve roots). A positive test should occur when the leg is flexed between 30° and 70° while the sciatic nerve root stretches from 30° to 70°.

How Good Is the Test? Sensitivity of sciatica for herniated disk is high, with moderate specificity. The reliability is high if the test is negative; however, it is only moderate if the test is positive. The maneuver may cause mechanical loading on the lumbar spine, which can be a positive sign for low back pain but not the classic positive sign for sciatica.

Special Tips for Improving Accuracy. To confirm symptoms based on stretching of the sciatic nerve, the examiner can drop the leg back down approximately 10° until the symptoms disappear. The examiner can then passively dorsiflex the foot, which will provoke the sciatica symptoms in a similar fashion.

If the patient shows symptoms of pain between 0° and 30° of flexion at the hip or at greater than 70°, suspect that it originates from the sacroiliac joints, the facet joints, or a tight hamstring.

Crossed Leg/Straight Leg Raise Test

The crossed leg/straight leg raise test is another neurodynamic test that is usually indicative of a large intervertebral disk protrusion.

Description of the Maneuver. The examiner flexes the hip while maintaining knee extension until the end of the range of motion is reached passively or the patient has symptoms of pain. The test is similar to the SLR test except that pain is noticed in the nonlifted leg.

Positive Findings. A positive test reproduces the patient's sciatic pain in the nonlifted leg, which suggests that the disk herniation is large and is compressing the opposite nerve root.

How Good Is the Test? The test has low to moderate sensitivity but high specificity.

Spine palpation

Source: University of California, San Francisco, Sports Medicine.

Prone (Lying Face Down)

Palpation of the Spine

Palpation of the spine is easiest in the prone position. With the athlete face down on the exam table, the examiner can palpate many of the underlying muscles and structures of the spine. The spinous processes, facet joints, and transverse processes may be palpable if the individual does not have much overlying soft tissues. The examiner can identify the levels of vertebral point tenderness. General percussion can identify other areas of tenderness, including kidney pain near the lower areas of the rib cage posteriorly. Spasms involving the paraspinal muscles can be noted. Other bony landmarks including the ischial tuberosity and greater trochanter can be palpated.

Femoral Nerve Traction Test

The femoral nerve traction test is a neurodynamic test that stretches the femoral nerve and its corresponding nerve roots (L2, L3, L4).

Description of the Maneuver. The patient lies face down with the knee bent. While holding the foot with one or two hands, the examiner lifts the leg toward the ceiling, extending the hip to 15°. A variation of the test can be performed in a similar fashion with the athlete lying on his or her side with the back straight and neck slightly flexed. The examiner can extend the hip to 15° with the knee extended. The examiner then flexes the knee.

Positive Findings. Pain radiating down the anterior thigh is a positive test for the femoral nerve stretch test.

Rectal Exam

If there is concern regarding serious compression of the spinal cord, a physician should perform a rectal exam. Early symptoms suggesting cauda equina include saddle area or perianal sensory changes or paresthesias. The individual may also have lower extremity neurological weakness or deficits, or incontinence symptoms. Cauda equina syndrome is a surgical emergency, and the athlete should be treated immediately.

Special Tests of Malingering

Malingering refers to a behavior where the patient exaggerates or creates fake symptoms, usually for secondary gain purposes, such as financial gain, drugs, or avoidance of work/school. Back pain is a very common complaint used by individuals who are malingering.

Femoral nerve stretch test

Source: University of California, San Francisco, Sports Medicine.

Waddell Tests

Waddell tests are a series of maneuvers used to differentiate between physical and nonphysical back pain. These maneuvers do not typically affect the lumbar spine sufficiently to produce mechanical load leading to exacerbation of back pain symptoms. If the patient complains of significant back pain, these would be inconsistent with the usual causes of mechanical back pain. The examiner needs to consider other medical or nonorganic causes of back pain or secondary gain issues for the patient.

Description of the Maneuver. There are six maneuvers for the Waddell signs. Each of the following can be tested to see how the patient reacts:

1. Superficial skin tenderness to a light pinch over a wide area of the lumbar spine
2. Deep tenderness over a wide area, often extending to the thoracic spine, sacrum, and/or pelvis
3. Low back pain on axial loading of the spine in standing
4. A positive SLR test in the supine position but not with the indirect SLR (The examiner can test the patient when seated and extend the knee to test the Babinski reflex, so that the patient does not know what the examiner is looking for)
5. Abnormal or inconsistent neurological (motor and/or sensory) patterns
6. Overreaction to maneuvers in the regular back exam

Positive Findings. Each test counts +1 if positive or 0 if negative. Positive findings of +3 or more should be investigated for nonorganic causes.

Hoover Test

The Hoover test assesses for inconsistent effort during the examination when asking the patient to actively flex his or her hip. This test can be performed to check whether the patient is putting in genuine effort during strength testing of the hip flexors. When flexing the hip on one side, the individual must extend the hip actively on the opposite side, stabilizing the pelvis.

Hoover test

Source: University of California, San Francisco, Sports Medicine.

Description of the Maneuver. With the patient lying supine, the examiner places his or her hands under each heel (calcaneus). The patient is asked to lift one leg off the table keeping the knee straight. The test is repeated on the opposite leg.

Positive Findings. If the patient does not lift the leg or the examiner does not feel pressure under the opposite hand, the patient is probably not trying. If the lifted limb is weaker, normally the pressure under the normal heel increases because of the increased effort to lift the weak leg.

Narcotic Analgesics

Narcotic analgesics are strong pain relievers. As such, they are strictly controlled substances, and a prescription is needed to obtain or possess them. When used appropriately, athletes may take narcotics when recovering from serious injuries or surgery. However, narcotics have also been exploited by athletes, who may abuse them to train harder and longer with less perceived effort. Athletes have also used narcotics to mask the pain of nagging injuries in order to avoid taking time off from training or missing competitions. Unfortunately, this type of use can hinder recovery, create an opportunity for more serious injury, and theoretically lead to a cycle of narcotic dependence.

Opium, the original narcotic analgesic, is extracted from a species of the poppy flower and has been used for centuries. Opium and its derivative heroin currently do not have medicinal applications. Heroin is extremely addictive in all forms. People who abuse heroin may smoke, snort, or inject it.

Morphine is another derivative of opium (i.e., an opioid) that has been modified and refined for appropriate medical use. Today, there are many natural, semisynthetic, and synthetic derivatives of morphine that are used as injections, pills, liquids, and even slow-release transdermal patches. These preparations vary in their onset, duration, and safety profile. There are many options for effective pain control, but the potential for tolerance, dependence, and abuse always exists with narcotics.

Narcotic analgesics work by stimulating receptors in the central nervous system (CNS). They also affect receptors in the intestinal tract, which is why they can cause nausea, vomiting, and constipation when they are used. Narcotics also affect the breathing center in the brain. For example, medications such as codeine are effective cough suppressants, but at higher doses, they can depress the respiratory drive. In fact, the reason people die from overdose is because they stop breathing. Stimulation of CNS opioid receptors by narcotics gives relief from severe pain. In addition, it can give a powerful feeling of euphoria. Illicit narcotics are designed to target this euphoric effect.

Narcotic drugs, such as heroin and morphine, are very effective in producing this effect early in their use. However, very quickly, the euphoric effects dissipate, and the user needs more of the substance to get the same effect (tolerance). There are behavioral effects and social conditions that push the user to seek the drug again (psychological dependence), but there is also an extremely powerful physical dependence that develops rapidly.

There are sensitive receptors and chemical neurotransmitters in the body, especially in the brain and gastrointestinal tract, that exist in a delicate balance. Narcotic analgesics can affect the sensitivity and the number of receptors, as well as deplete the neurotransmitters. This explains why withdrawal symptoms are so severe and wide-ranging. Acute withdrawal symptoms include profuse sweating, shaking, chills, rhinorrhea (runny nose), vomiting, and diarrhea. A dependent user in withdrawal will have hyperalgesia (severe diffuse pain and decreased pain tolerance) and hyperesthesia (sensitivity to benign stimuli such as noise and light). The hyperalgesia and depression symptoms can last for several months until the normal balance of receptor sensitivity and neurotransmitters is restored.

Withdrawal symptoms vary according to the medication used, its half-life, and the length of time it is used. Morphine and heroin have short half-lives and so have a rapid onset and relatively short duration. Withdrawal symptoms appear within a few hours after an addict's last fix. On the other hand, methadone has a very long half-life, and this is why methadone is used to wean people off narcotic dependence slowly. Withdrawal is gradual, and the symptoms do not appear early or rapidly.

Methadone binds opioid receptors in the body without producing intoxication. This not only prevents physical withdrawal symptoms but also prevents methadone from being used as a recreational drug of abuse. Because the opioid receptors are bound, a person who has taken methadone and then takes another narcotic will not experience the effect from the second drug. These characteristics allow methadone to be used to treat chronic pain and still allow people to function effectively. Medications such as methadone are considered partial opioid agonists.

Most narcotics are what the federal government calls Schedule II drugs. This means they are strictly regulated by the Drug Enforcement Agency (DEA). No more than a 30-day supply is given with any prescription, and automatic refills are not allowed. Possession of these substances without a prescription is a federal offense punishable by fines and a jail term. Of note, heroin is a Schedule I drug. This means heroin has no therapeutic benefit, and possession is only permitted in special, tightly controlled, and rare circumstances, such as scientific research. Some codeine preparations are available over the counter in Canada, Mexico, and some European countries.

Many common oral narcotics are a combination of medications. Narcotics are prepared with other analgesics such as acetaminophen (brand name when used alone: Tylenol, commonly abbreviated as APAP), aspirin (acetylsalicylic acid, or ASA), or ibuprofen (common brand names when used alone: Motrin, Advil). Oxycodone, a narcotic, plus acetaminophen is known by the brand name Percocet. Hydrocodone, a different narcotic, plus acetaminophen is marketed as Vicodin. These medications deliver their effects in about 15 minutes and last around 6 hours. They are commonly used in the treatment of fractures or in postoperative care. Abusing these medications can not only have the side effects of narcotic abuse, but there can be toxicity from the other medications in the pills. Acetaminophen toxicity causes liver failure, aspirin toxicity can cause bleeding and tinnitus (permanent ringing in the ear), and ibuprofen toxicity can cause kidney failure.

Oxycontin has made news in recent years because of increasing abuse and the aggressive efforts by addicts to get the medication, including pharmacy robberies. This medication is designed to give effective pain relief, with a slow release of narcotics over a 12-hour period. It is very helpful in conditions of chronic severe pain, such as certain kinds of cancer. Recreational drug abusers crush the pills and get the narcotic's concentrated effect all at once by ingesting, snorting, or injecting it.

Athletes are sometimes prescribed narcotic medications when recovering from injuries or surgeries. Interestingly, real pain has been found to be fairly protective in preventing tolerance or dependence when using narcotics. For the vast majority of patients, as the injury heals, the medication is used less and less and discontinued appropriately. For a very small percentage of people, personality, body chemistry, or indiscriminate prescribing by their doctor can contribute to dependence or abuse. Sometimes, athletes continue to use narcotics to train or compete through ongoing pain or as a mechanism to deal with stress.

If narcotic abuse is suspected or discovered, a caring, multidisciplinary team is needed to assist in recovery. This often includes a physician skilled in pain management, a psychologist and/or psychiatrist, and family and friends.

Neck and Upper Back Injuries

Injuries to the neck (cervical spine) are not uncommon in contact sports, including rugby, hockey, and football. Up to 15% of athletes participating in football sustain some cervical spine injury. Unfortunately, a large majority of neck injuries result in catastrophic injury (death or permanent disability). Upper back (thoracic spine) injuries occur less often and are seen in sports such as gymnastics, wrestling, hockey, and football, as well as other contact sports.

Overuse injuries of the cervical and thoracic spine occur in noncontact sports. In children and adolescents, these overuse injuries may produce spinal deformity such as kyphosis (forward curvature of the back). Sports such as dancing, swimming, and diving appear to have a higher incidence of spinal deformities in young athletes. A possible explanation for this is that the immature spine is more susceptible to injury from the forces generated by sporting activity.

Anatomy

The neck and upper back play an important role in motion and support of the upper body and head. The neck, or cervical spine, provides motion and support for the skull. The upper back, or thoracic spine, allows for the transfer of forces between the upper and lower extremities. Together, the cervical spine and thoracic spine contain the spinal cord.

The flexible cervical spine is at greater risk of injury to the disks and bony structures because of its inherent mobility. The thoracic spine, however, is more rigid and isprotected by the rib attachments. The lower two ribs are unattached ("floating") and allow increased motion in the lower thoracic spine. Traumatic and overuse injuries of the spine are more common in the transition zones of flexibility at the lower cervical and thoracic spine.

The cervical vertebrae can be divided into the upper and lower cervical spine. The upper cervical spine consists of the occiput to C1 and the C1-C2 articulation. The atlas, C1, has a smaller arch in the front and a larger arch in the back, which are connected by the lateral masses. The axis, C2, contains the odontoid process, which articulates with the anterior arch of C1. It is held in place by the transverse ligament. Forty percent of cervical flexion and extension and 60% of rotation occur between the occiput to C1 and C1-C2 articulations.

The lower cervical spine is principally responsible for flexion and extension. The lower cervical spine consists of the C3-C7 vertebral bodies, separated by the intervertebral disks. The facet joints form the posterior border of the foramina and lie in a horizontal plane, allowing for rotation. In the thoracic spine, the facet joints are more vertical. The transverse process contains the vertebral artery foramen.

The size of the thoracic vertebrae gradually increases from T1 through T12. The heads of the ribs articulate with the facets on the vertebral bodies. The tubercles of the ribs articulate with the facets on the transverse processes. The thoracic facet joints are in a coronal orientation that allows for lateral flexion of the thoracic spine. There is a transition between the upper and lower thoracic vertebrae. The upper vertebrae resemble cervical vertebrae, whereas the lower thoracic vertebrae more closely resemble lumbar (lower back) vertebrae. An additional structure unique to the thoracic spine is the scapula (shoulder blade). The scapula is a triangular bone that lies between the second and the seventh ribs and projects 30° to 40° to the frontal plane. There are several fluid-filled sacs called *bursae,* which help in the movement of the shoulder blade over the posterior ribs.

From C3 through T12, each functional unit of motion acts as a tripod. The tripod consists of the disk anteriorly and the facet joints posteriorly. The intervertebral disk is composed of the annulus and ligamentous layers enclosing the gelatinous nucleus pulposus. The annulus consists of 10 to 20 layers of concentric, obliquely oriented ligamentous lamellae and provides torsional stability.

There are important anatomical differences in the spines of growing children. The annulus of the disk is attached to the growth cartilage of the epiphysis and apophyseal ring of the vertebral body. The epiphyseal growth plate forms the superior and inferior borders of the vertebral body. The epiphyseal growth plate consists of a cartilaginous end plate and the contiguous ring apophysis. This growth cartilage is susceptible to injury, particularly with repeated flexion and extension.

There are many paraspinal muscles associated with the cervical and thoracic spine. The anterior and middle scalene muscles are functionally important as they originate from the anterolateral cervical spine and attach to the first rib. The brachial plexus travels between the scalene muscles as it passes through the thoracic outlet. The brachial plexus can be impinged in the thoracic outlet as well as between the first rib and the clavicle.

Evaluation of Injuries

Injuries to the neck and back can be catastrophic injuries and should be considered as medical emergencies. If an athlete sustains a neck or upper back injury, he or she should not be moved until paramedics arrive. Paramedics should put a neck collar on the athlete and put the injured athlete on a rigid backboard for transportation to a hospital for further assessment. It is important to make sure that the athlete's airway and breathing are not affected by the injury. This should be assessed by qualified health care personnel (doctor, nurse, trainer, paramedic). If the athlete is unconscious, it must be assumed that there is a cervical spine injury, and the athlete's neck should be protected from any movement to avoid further injury.

Details of Injury

It is extremely important to obtain details of the mechanism of injury and associated symptoms when an athlete presents with a neck or back injury. Injuries may be acute or may have a more insidious onset. Details regarding age, gender, and sport/occupation are important to ascertain. Younger athletes are at risk for growth cartilage injuries, whereas older athletes are more prone to disk injuries. Certain conditions are associated with gender; for example, spondyloarthropathies are more common in males. Patterns of injury are associated with particular sports. For instance, disk and end plate injuries are common in gymnasts.

The mechanism of injury, the onset of pain (whether it was sudden or insidious), the location of the pain, as well as the quality of the pain and whether the pain radiates anywhere else are important to help determine the type of injury. Neck and back injuries may be associated with neurological symptoms, such as weakness, paralysis, or paresthesias (tingling sensation, numbness). Things that make the pain better or worse, such as body position and activities, can help suggest the type of injury. The quality of the pain can also suggest the type of injury. For instance, severe pain that shoots down the leg suggests compression of a nerve root.

With traumatic injuries, knowledge of the mechanism of injury and position of the head at the time of injury can help determine the location of injury. The most common injuries are hyperflexion injuries, which can cause compression fractures of the anterior vertebral body and tears of the posterior spinal ligaments. Hyperextension injuries can result in compression of the posterior spinal elements and tears of the anterior longitudinal ligament. Axial loading of the spine can result in compression or burst fractures of the vertebrae. Rotational forces may result in facet joint injuries.

Pain originating from the cervical spine may radiate into the arms or the shoulder blade region, whereas thoracic pain may radiate to the chest or to the legs. The presence of myelopathic symptoms, such as bowel or bladder incontinence, unstable gait, or weak hands, indicates an injury to the nerves or spinal cord. Some medical conditions, such as Down syndrome, can be associated with neck problems and may predispose athletes to neck injuries. It is important to know details of previous evaluation and treatment of neck and back injuries.

The presence of "red flag" symptoms should be elicited. These symptoms include night pain, weight loss, fever, structural deformity, gait disturbance, and inflammatory symptoms, such as morning stiffness. The presence of cauda equina syndrome, characterized by incontinence of bowel or bladder, loss of anal sphincter control, and saddle anesthesia, is a surgical emergency.

Physical Findings

An athlete with a neck or back injury may have bruising, swelling, or deformity of the spine. There is usually tenderness to palpation of the bony structures injured. The surrounding muscles in the neck and upper back may also be tender to the touch and may be in spasm.

Range of motion of the spine may be decreased, both actively and passively. Flexion and extension of the neck can be assessed by asking the athletes to put their chin to their chest and to look up at the ceiling. Lateral rotation of the neck can be assessed by asking the athletes to turn their chin to the right and left. Normal range of rotation of the neck is 60° to 80°. Side-to-side flexion is assessed by asking the athletes to put their right ear to their right shoulder and then their left ear to their left shoulder. Normal range of motion of lateral bending is 40°.

Range of motion of the thoracic spine is assessed with the athlete standing. The athletes are asked to bend forward and touch their toes. If pain is exacerbated by forward flexion, or if movement is limited secondary to pain, it may indicate injury to the anterior spinal elements, such as a vertebral body fracture or disk injury. Extension of the thoracic spine is assessed by having the patient bend backward with the examiner stabilizing the patient's hips. Pain that is exacerbated by extension suggests injury to the posterior spinal elements, such as the facet joints.

Certain provocative maneuvers of the neck can help identify the etiology of neck or upper extremity symptoms. The Spurling test elicits cervical root compression resulting from root pathology or narrowing of the exiting foramen. The Spurling test is performed by extending and rotating the athlete's neck toward the symptomatic side while applying an axial load. This position causes narrowing of the exiting foramen; a positive test reproduces the athlete's symptoms. The axial compression test is performed by applying an axial compressive force on the athlete's head. This maneuver causes narrowing of the intervertebral space and foramina. A positive test reproduces the athlete's pain and is suggestive of foraminal narrowing or disk pathology. The final provocative test of the cervical spine is the distraction test. The examiner applies vertical traction to the athlete's head. If symptoms are relieved by this maneuver, it suggests that the athlete's pain may have been caused by compression of the intervertebral disk or facet joints.

Special tests in an athlete with an upper back injury include springing of the ribs, in which the ribs are compressed toward midline by the examiner's hands. The athlete should be asked to inhale maximally as well as to cough/sneeze and to try to reproduce his or her symptoms.

A thorough neurologic examination is vital in any athlete presenting with a neck or back injury. Muscle strength testing may indicate weakness of specific muscle groups, which can point to the level of spinal injury. Muscle tone may be affected by spinal injuries. Increased muscle tone indicates an upper motor neuron injury or muscle spasm, whereas flaccid muscle tone suggests lower motor neuron injury or spinal shock. Deep tendon reflexes in the arms and legs may be increased or decreased in spinal injuries. Sensation may be decreased. The level of spinal injury can be determined by the distribution of any sensory defect.

Investigations

The four main methods of radiographic imaging include X-ray, computed tomography (CT) scan, magnetic resonance imaging (MRI) scan, and bone scan. Each method has its own strengths in evaluating the spine. It is important to keep in mind that imaging studies may reveal abnormalities that are not associated with the athlete's symptoms. For this reason, the choice of imaging should be specific and localized to the area of possible injury.

X-rays are most appropriately used to evaluate the bony structures of the spine and their spatial relationships to each other. Radiographs can be used as a screening tool to look for congenital malformations of the cervical and thoracic spine. They can also be used to assess injuries such as compression fractures, dislocations, and posterior element injuries. X-rays of the thoracic spine are not routinely indicated, however, as they do not usually add much to the clinical picture.

Radiographs of the cervical spine should begin with the lateral view, particularly in cases of trauma. A proper lateral view of the cervical spine should include all seven cervical vertebrae, C1-C7, and at least the top of T1. Visualization of the C7-T1 junction may be enhanced by arm traction or by a swimmer's view, in which one arm is elevated. If adequate visualization of this area is not possible with plain radiographs, CT may have to be performed.

Several bony relationships of the cervical spine should be assessed on lateral radiographs. There are four lines that need to be evaluated: (1) the anterior vertebral line, (2) the posterior vertebral line, (3) the spinolaminar line, and (4) the tips of the spinous processes. All these lines should have a smooth contour with parallel facets. An interspinous space greater than 10 millimeters (mm) is indicative of instability. In children, there may be a normal pseudosubluxation up to 4 to 5 mm at C2-C3, and sometimes at C3-C4, due to increased ligamentous laxity. The *atlantodens interval* (ADI) should also be evaluated on the lateral view of the cervical spine. The ADI should be less than 3 mm in adults and less than 4 mm in children less than 8 years of age. Another indication of possible spinal injury seen on the lateral view is the presence of retropharyngeal soft tissue swelling. Soft tissue swelling in excess of 6 mm at C2 and 22 mm at C6 in the adult indicates possible injury. In children, swelling in excess of 7 mm in the retropharyngeal space and 14 mm in the retrotracheal space is suggestive of spinal injury.

The anterior-posterior (AP) view of the cervical spine allows for assessment of scoliosis, lytic lesions, and congenital malformations. In the setting of trauma, a displaced spinous process may indicate a facet dislocation.

An open-mouth odontoid view should always be obtained when ruling out a cervical spine injury. This view allows for visualization of an odontoid fracture and signs of C1-C2 instability. Instability is indicated by more than 7 mm of lateral mass overhang or asymmetric dens position between the lateral masses.

Radiograph views of the thoracic spine should include AP and lateral views. The AP view assesses scoliosis and congenital malformations, as well as paravertebral soft tissue swelling. The lateral view of the thoracic spine assesses for kyphosis and changes consistent with Scheuermann disease. Normal thoracic kyphosis is up to 45° to 50°.

CT scan is the best imaging study to assess bony injury in detail. It can be used in trauma situations to assess spinal stability if the patient has mental status changes, if X-rays are inadequate, or there are subtle changes on X-ray. CT can also provide better definition of lytic or sclerotic lesions seen on radiographs.

MRI scan is the best study to assess soft tissues. It also offers good bone resolution without ionizing radiation. Any patient with neurologic symptoms or deficits on exam should have an MRI scan taken to evaluate for spinal cord injury. Disk herniations are also well defined on an MRI scan and can be classified as protruded (contained by the outer annulus), extruded (not contained by the outer annulus), and sequestrated (separated from the disk). However, MRI findings need to be correlated with physical findings and the patient's symptoms as abnormalities can be visualized on an MRI scan that are not necessarily contributing to the patient's pain.

MRI can elucidate subtle spinal cord injuries that are not seen on X-rays or CT. Children, particularly less than 8 years of age, may have significant spinal cord injuries without radiographic abnormality (SCIWORA). Patients who have myelopathy on exam despite normal radiographs or CT should have an MRI done to assess for spinal cord injury.

Bone scan can be used to assess for metabolic activity in bones. It can be used to assess for infection, fractures, stress reactions, tumors, and arthritis. In children, who are still growing, open growth plates will also "light up" on bone scan.

Types of Injury

Table 1 lists the types of neck and upper back injuries.

Table 1 Neck and Upper Back Injuries

Neck	*Upper Back*
Burners	Disk disease
Fractures	Muscle strain/contusion
Disk disease	Scheuermann kyphosis
Muscle strain/contusion	Scoliosis
Facet syndrome	Referred pain
Klippel-Feil syndrome	
Os odontoideum	

Prevention of Injury

Prevention of spinal injuries includes conditioning, proper sports technique, and proper safety equipment. Strengthening of the cervical spine and upper trunk is important to help absorb the forces involved in contact sports, such as hockey and football. Upper back strength helps improve cervical stability. Proper sports technique should be followed to help prevent injuries. Certain techniques have been associated with severe cervical injuries, such as spearhead tackling in football. Abolishing this technique has reduced the incidence of cervical spine injuries in this sport. In hockey, instituting the heads-up policy has reduced spinal injuries. Appropriate equipment can also help reduce injuries. For instance, well-fitted shoulder pads that prevent lateral flexion help reduce "burners" in football.

Table 2 Watkins Neurologic Deficit Rating System for Return to Play

Deficit	*Rating*
Canal narrowing	
>12 mm	1
>10 and <12 mm	2
10 mm	3
8–10 mm	4
<8 mm	5
Neurologic deficit	
Single-arm symptomatic	1
Bilateral upper extremities	2
Hemi-arm and leg symptoms	3
Transient quadriparesis	4
Transient quadriplegia	5
Duration of symptoms	
<5 minutes	1
<1 hour	2
<24 hours	3
<1 week	4
>1 week	5

Return to Sports

In general, an athlete must be painfree, with no neurologic symptoms, and have a full range of motion of the spine and normal strength before returning to sports. However, there are certain structural defects that may preclude athletes from participating in contact sports. Risk categories to determine return to play were developed by Watkins. The classification includes minimal risk, moderate risk, and extreme risk. Minimal-risk injuries imply little more risk than is usually involved in the sport. Examples of minimal-risk injuries include asymptomatic disk herniations, healed undisplaced fractures, healed surgical fusion, and single-level Klippel-Feil syndrome.

Moderate-risk injuries imply a reasonable possibility of recurrent injury. Examples of moderate-risk injuries include disk herniations associated with radiculopathy (radiating pain, weakness, tingling), three or more burners, a healed posterior single-level fusion, and a healed two-level anterior fusion.

Extreme-risk injuries imply a high risk of permanent injury with neurologic deficit. These injuries include Jefferson fractures, unhealed odontoid fractures, unhealed hangman's fractures, partially or fully ruptured transverse ligament of the axis, or any injury with neurologic deficit. Athletes who have sustained extreme-risk spinal injuries should not continue to participate in contact sports.

A unique situation in making return-to-play decisions involves athletes who have suffered a transient neurologic deficit and have spinal stenosis. R. G. Watkins developed a rating system that takes into account the amount of canal narrowing, the extent of neurologic deficit, and the duration of symptoms (Table 2). The total score is determined by adding these three scores. A total score of 6 or less is classified as a mild episode; a score of 6 to 10 is classified as a moderate risk episode; and a score of 10 to 15 would be classified as a severe episode. Regardless of the score, any neurologic deficit should preclude an athlete from returning to sports.

Neck Spasm

The occurrence of neck spasm suggests an injury to the muscles of the neck. Because the muscles of the neck have a low threshold for spasm, the causes of spasm may vary. Because of the importance of the neck in posture, nervous system functions, and activities of daily living, a careful and accurate differential diagnosis is essential.

Neck Strain

Neck strain suggests an injury to the ligaments of the neck, either between the spinous processes as in a whiplash injury or, less commonly, in the ligaments holding the body of the vertebrae in alignment. In all cases, this leads to muscle spasm, which can make diagnosis difficult. The question becomes, "Is this the muscle causing the pain, or is it the muscle protecting an injury that is causing the muscle to spasm?"

Neck Pain in Sports

Neck injury most commonly occurs in contact sports, especially in football, where improper coaching or an ill-timed slip may lead to malpositioning of the neck during a tackle. Athletes in diving and water sports, wrestling, hockey, skiing, gymnastics (especially trampoline), soccer, martial arts, cheerleading, and weight lifting are prone to neck injury.

Anatomy

The neck is formed by seven cervical vertebrae. Vertebrae are bones that create structure, allowing movement in some directions and restricting or limiting movement in others. They are separated by intervertebral disks, which serve as cushioning and help with dissipation of energy when the vertebrae are compressed. The *zygoapophysial joints* in the neck, also called the facet joints, are the joints that connect the vertebrae to each other. They are positioned in pairs, with one on each side of the vertebra connecting with the vertebra below and one on each side connecting to the vertebra above. Both intervertebral disks and facet joints are named by the vertebrae they connect. Because there are seven cervical vertebrae, the disk between the fourth and fifth vertebrae is called the C4-C5 disk, and the facet joint at that location is called the C4-C5 joint.

The vertebrae also create a space for the spinal cord, the *vertebral foramen*, which both the muscles and the bones in the neck work to protect. The peripheral nerves to both the neck and the arms extend from the spinal cord as it passes through the cervical vertebrae, and then these nerves pass through lateral openings in the cervical spine called *intervertebral foramina*. The muscles of the neck are numerous, with a posterior superficial, intermediate, and deep layer of muscles. The anterior muscles of the neck work to protect the neck, much like the abdominal muscles protect the lower back. The important muscles of the shoulder that connect to the neck include the trapezius, the levator scapula, the rhomboid minor, and the serratus posterior superior muscle.

Causes

The most common injuries to the neck muscles or ligaments are caused by motor vehicle accidents. Sports injuries and prolonged poor position of the neck during sleep or at work are also common precipitating factors. When the injury is to the muscle only, the muscle will heal within 2 to 3 weeks. If the muscle is protecting an injury to something else, or an infection, the spasm will tend to persist. In whiplash injuries, the injury is to the ligaments between the vertebrae. When the injury is to the facet joints, the muscles will spasm to keep the joints apart, as this reduces the pain from joint inflammation. If the injury is to the spinal cord, intervertebral disk, vertebrae, or peripheral nerves or is caused by infection, the muscles will spasm to keep the neck in an optimal position to create as much space for the spinal cord as possible. Sometimes the injury is actually to the shoulder, but because of muscle attachments and muscle spasm thresholds, the pain is felt more in the neck.

Symptoms

Neck strain is manifested by muscle spasm or tightness throughout the neck. Most commonly, this is posterior, but it can also be an anterior spasm. When the pain is from the cervical facet joints, the patient reports grinding and cracking through the neck on awakening, then as the muscles begin to fire to pull the joints apart, the pain diminishes. Then as the muscles begin to tire from pulling the joints apart, muscle spasm begins, and the patient reports typical pain in the neck from this spasm. Patients with injury to the spinal cord or peripheral nerves (commonly from bulging of the intervertebral disk into the nerve) will report pain, numbness, and/or weakness in the arms that correspond to the affected nerve when the neck is moved. When the injury is actually in the shoulder, faulty motion of the shoulder blade (scapula) causes irregular tightness or spasm of the muscles trying to control this scapula, and as these muscles attach to the neck, they cause neck pain. This, however, is where neck pain gets complicated. Disk bulges in the neck can lead to weakness in the shoulders, which in turn leads to pain in the neck. Prolonged muscle spasm in the neck from facet joint inflammation can lead to weakness in the shoulder from deconditioning, which can lead to neck pain. In general, prolonged neck pain leads to shoulder pain, and prolonged shoulder pain leads to neck pain. To further this diagnostic dilemma, thoracic outlet symptoms can mimic intervertebral disk bulging. When a patient has neck pain, spasm of the scalene muscles in the neck (which are deep muscles that go from the cervical vertebrae to the first and second ribs) can cause impingement of the nerves to the arms, resulting in pain, numbness, and/or weakness in the arms. When a patient has shoulder pain, he or she often will have tightness of the pectoralis minor muscle anteriorly, as it also attempts to control the motion of the scapula. The nerves to the arms also pass under this muscle, and this can cause radicular symptoms, but they are a type of thoracic outlet. Poor posture from either neck or shoulder pain can cause the clavicle and the first rib to affect the nerves to the arms as they pass between these two bones, again leading to confusing arm symptoms.

Where the muscles in the neck attach to the head is called the nuchal ridge of the skull. At this connection, the muscles intermingle with a muscle called the epicranius. This muscle covers the top of the skull like a cap, and if it starts to spasm, the patient will develop a common tension headache. Also, at the nuchal ridge is a pair of nerves on either side of the head called the greater occipital nerve (GON) and the lesser occipital nerve (LON). Prolonged spasm of the neck muscles can lead to irritation of these nerves. If the GON is irritated, the patient will get pain over the top of the head that feels like it is coming out of the eye. If the LON is irritated, the patient will get pain that goes over the top of the ear to the temple area.

If the patient has redness, swelling, or fever, with bracing of the neck, infection or meningitis must be ruled out. If the patient has recent trauma with persistent bracing of the neck, X-ray and/or computed tomography (CT) scan must be done to rule out vertebral fracture.

Diagnosis

When neck strain is acute and present after trauma, X-rays and CT scans may be indicated. When neck strain is present with symptoms of meningitis or infection, appropriate labs, spinal taps for analysis of cerebrospinal fluid, and magnetic resonance imaging (MRI) scan may be indicated. When radicular symptoms in the neck or arm are present, a physical exam to rule out thoracic outlet syndrome, along with detailed examination of the arm for dermatome, reflexes, and muscle strength abnormalities, must be completed. An MRI may be necessary, but one must keep in mind that in some studies, up to 60% of people with no symptoms at all displayed a disk bulge/herniation on an MRI scan. Examination of the shoulder is imperative, with special attention to motion of the scapula, and palpation of the muscles that pass from the scapula to the neck, along with symptoms of impingement in the shoulder. Palpation of the facet joints in the neck should be attempted, recognizing, however, that if the muscles are spasming, they overlie the facet joints and this palpating has a high false-positive rate. Full range of motion of the neck should be requested, allowing the patients to move themselves, as patients will rarely severely hurt themselves.

Treatment

In acute neck spasm/strain, when infection, fracture, and radicular symptoms have been ruled out, the muscles are treated with rest and ice—two elements of the common RICE or PRICE (*p*rotect, *r*est, *i*ce, *c*ompression, and *e*levation) therapy. Compression of the neck may be unwise, and elevation of the neck may be unnecessary. Protection with a soft or hard collar is the preference of many treating practitioners. Rest of the neck muscles should follow the same protocol as for the lower back, where it is wise to rest for a short while but return to activity after a day or two is better for the patient. Ice should be applied to the muscles of the neck using the accepted 20-minutes-on/2-hours-off protocol. Anti-inflammatories are encouraged if used according to the manufacturer's recommendations. If the physical exam suggests an intervertebral disk bulge/herniation, and MRI confirms it, then an epidural steroid injection and/or surgery to the disk may be warranted. If the cause is facet joint pain, then steroid injections to the facet joints or the nerves that supply these joints may be necessary. Surgical fusion of these joints is also sometimes needed. If the spasm is from the shoulder, physical therapy is often the best option, but again, this is a confusing scenario, and the practitioner must be diligent to unravel this puzzle. If the patients are not taught correctly how to strengthen the motion of the scapula, then they will continue to use their compensatory muscles, and their neck pain will worsen. Thoracic outlet symptoms as described above can also be improved with stretching of the pectoralis minor and scalene muscles and improvement of posture. All this is best achieved with appropriate physical therapy. Once a person has more than a few days of neck pain from either strain or spasm, he or she will develop weakness of the muscles in the anterior neck and tightness in the muscles of the posterior neck. This usually leads to future and further neck problems. Every effort should be made to strengthen the recovered neck's anterior muscles and to stretch the posterior muscles. Injury should also alert the practitioner, coach, parent, and athlete that a careful review of technique, style, and current strength and habits must be undertaken to avoid a repeat of current symptoms and to prevent an even worse injury.

Neurologic Disorders Affecting Sports Participation

Neurologic disorders are conditions that affect the nervous system. Since the nervous system is the part of the body responsible for decision making and coordination, as well as planning and executing movement, disruptions in its function can have significant effects on the ability to perform athletically. Certain neurologic conditions can potentially be made worse through participation in sports. At the same time, the presence of other neurologic conditions can make playing sports unsafe. This entry discusses some of the more common neurological conditions that may affect sports participation. More detailed discussion of these diseases or conditions can be found in other entries in this encyclopedia.

Anatomy

For purposes of discussion, the nervous system can be divided into two components, the *central nervous system* and the *peripheral nervous system*. The central nervous system includes the brain, brainstem, and spinal cord. The peripheral nervous system begins with the *nerve roots* that exit the spinal canal. The nerve roots feed into complex networks that then form the *peripheral nerves*, which carry out the functions of the body. The *cranial nerves* are specialized peripheral nerves that are formed in the brainstem and not only provide much of the functions of the head but also serve certain physiological processes.

Central Nervous System Disorders

Aneurysm

An aneurysm is a deformity of a blood vessel that occurs when that vessel's walls are weakened. The weakened wall causes a balloon-like deformation in the vessel, sometimes compared with a bubble in a garden hose. Aneurysms in the brain are most commonly found in the vascular structure called the *circle of Willis* at the base of the brain. Depending on the size and particular location of the aneurysm, surgical or catheter intervention is warranted. Conversely, some aneurysms do not require treatment. Participation in sports, especially contact sports, may increase the risk of certain aneurysms, bleeding, or rupturing. Consultation with a neurosurgeon is essential to determine the safety of participation.

Arteriovenous Malformation

Arteriovenous malformations (AVMs) occur when the natural organization of how arteries and veins connect to each other is compromised. As with aneurysms, certain AVMs in the brain may represent a bleeding risk that is significant. The size and location of the AVM can help determine the safety of playing sports. Again, neurosurgical consultation is essential.

Concussion

Perhaps the most common neurological condition caused by athletic participation, *concussion* can be defined as a disruption in normal brain physiology as the result of a force applied to the brain. If an athlete experiences a trauma that causes any symptoms of concussion, including headache, disorientation, nausea, memory difficulties, loss of consciousness, unsteadiness, or personality changes, he or she should be removed from competition immediately and evaluated by a physician, a certified athletic trainer, or an emergency medical technician. Continuing to participate after concussion can lead to worsening of symptoms or even death.

Epilepsy

Epilepsy is defined as having more than one unprovoked seizure. A seizure occurs when the normal neuronal activity of the brain is interrupted by excessive or synchronous activity. A single seizure can occur as a result of trauma and does not necessarily mean that the individual in question has epilepsy. The diagnosis of epilepsy should be made by a neurologist. Physical exertion to the point of dehydration or electrolyte imbalance can lead to a seizure in a person with epilepsy. Athletes with epilepsy can participate in the vast majority of sports as long as their epilepsy is under good control with medication. The only sports that may require further consideration involve the same risks that are inherent to that activity outside the sporting arena, such as swimming alone or performing tasks at heights.

Intracranial Hematoma

A *hematoma* is a collection of blood outside the blood vessels, the result of a hemorrhage into the surrounding tissues. An athlete who has experienced an episode of bleeding in or around the brain should have a complete evaluation done by a neurologist or neurosurgeon prior to participating in sports. Depending on the sport in question and the cause of the bleeding, participation may not be ruled out.

Migraine Headache

Extremely common, especially in college-age women, the typical migraine headache produces a pounding, focal head pain with concurrent nausea and sensitivity to light, which lasts from a few hours to a few days. Exertion can be a trigger for migraine headache in athletes. Athletes who experience migraine headache typically have greatly reduced physical performance. Migraines can be treated with acute medications, namely, the triptan class. Neurological consultation may be warranted.

Multiple Sclerosis

Multiple sclerosis (MS) is a disease that affects the brain or spinal cord primarily through the process of *demyelination*. The connections between neurons are interrupted, and a loss of function ensues, typically causing numbness, weakness, or visual disturbance. Increased body temperature can make the symptoms of MS worse, but participation in sports is not generally a problem, as long as the symptoms of the disease do not interfere with the ability to perform adequately.

Spinal Stenosis

A *stenosis* is an abnormal narrowing of a canal or passage. If the spinal canal is narrowed, either as a result of injury or disease, or as a congenital condition, contact sports may be hazardous. Symptoms may include recurrent neck pain, extremity pain, numbness, or weakness. Consultation with a neurologist or neurosurgeon is warranted.

Peripheral Nervous System Disorders

Plexopathy

Each extremity has a corresponding *plexus*, or network, of nerves near where it articulates with the trunk. If the plexus is impinged, stretched, or otherwise damaged, neurological symptoms can occur, including pain, numbness, or weakness in the extremity. Trauma is the most common cause. Athletes with plexopathy should not return to participation until they are completely asymptomatic.

Radiculopathy

Radiculopathy refers to a process that involves the nerve roots. The most common type of injury to the nerve roots involves compression from a vertebral disk. Symptoms included pain in the neck or back that radiates into an extremity. Diagnosis can be made with magnetic resonance imaging (MRI) of the area and/or with an electromyogram (EMG). Repetitive physical trauma can be a risk factor. Depending on the amount of damage, surgical intervention may be warranted. If not, rest is essential to recovery.

"Stingers," Burners

The common term "stinger" or burner refers to a trauma-induced pain, with possible transient loss of neurological function, in the affected arm. They occur, typically, as the result of either a stretch injury to the *brachial plexus* (mentioned above) or a compression injury of a nerve root. In either case, athletes with continued symptoms should not return to participation. Repetitive stingers can have an additive effect, making the next injury easier to incur and with more severe symptoms. Treatment depends on the suspected mechanism, but rest is almost always beneficial.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Sports injuries are often attributed to "inflammation." Consequently, the treatment recommendation regularly includes "anti-inflammatories," or *nonsteroidal anti-inflammatory drugs* (NSAIDs).

However, inflammation is not the primary pathology of injuries in sports. Furthermore, when a person injures a tendon, a ligament, or a bone, inflammation may be necessary for the injury to heal. Since NSAIDs are known to have serious gastrointestinal (GI) toxicity and a variety of other side effects, it is recommended that they be used only after consideration of the pathophysiology of the injury and with the understanding that their main benefit may be due to their analgesic and not their anti-inflammatory properties.

NSAIDs: Mechanism of Action

NSAIDs are used for their analgesic, anti-inflammatory, and antipyretic properties. Their therapeutic actions are believed to result primarily from their ability to block the formation of certain types of prostaglandins through inhibition of the cyclooxygenase (COX) enzymes. COX-1 catalyzes the production of several prostaglandins with protective functions such as coating the stomach lining with mucus and aiding platelet aggregation. COX-2 catalyzes the conversion of arachidonic acid into inflammatory prostaglandins. Inflammatory prostaglandins are involved in three key biological functions: sensitizing skin pain receptors, elevating body temperature through the hypothalamus, and recruiting inflammatory cells to injured body parts.

The Role of Inflammation in the Healing Process

The major rationale given for the specific use of NSAIDs in the treatment of musculoskeletal injuries is their anti-inflammatory qualities. An injured tissue is painful and often swollen; the term *inflammation* implies pain and swelling. Thus, the common treatment for the injured tissue is to administer an anti-inflammatory drug. What is perhaps insufficiently recognized, however, is that inflammation, in addition to being a sign of injury, is a necessary step in the healing process.

The body responds to injury through a sequence of events. Whether the injured tissue is a ligament, tendon, or muscle, the process begins with an influx of inflammatory cells and blood. The inflammatory cells remove debris and recruit cytokines and other growth factors to the site of injury. This "inflammatory phase" is partly mediated by the same prostaglandins that are blocked by the NSAIDs. In a healthy healing process, a "proliferative phase" naturally follows the inflammatory phase. The proliferative phase consists of a mixture of inflammatory cells and fibroblasts. The fibroblasts build a new extracellular matrix and persist into the final phase of repair, the "maturation phase," where functional tissue is laid down. The key point is that each phase of repair is necessary for the subsequent phase. By blocking the inflammatory phase, NSAIDs can, at least theoretically, delay the healing of musculoskeletal injuries.

NSAIDs and Sports Injuries: What Is the Evidence?

NSAIDs are commonly prescribed for the treatment of musculoskeletal complaints such as muscle injuries, ligament sprains, tendon injuries, low back pain, and osteoarthritis. However, an examination of the pathophysiology and healing of such injuries, as well as a remarkable dearth of clinical trials supporting the efficacy of NSAIDs, calls into question their use in many treatment protocols.

Muscle Injuries

Muscle injuries, whether via direct trauma or excessive strain, have been found to be the most common of all sports-related injuries. Although NSAIDs are commonly recommended in treatment protocols, clinical studies documenting their efficacy are notably lacking. Anti-inflammatory treatment for muscle strains, contusions, and delayed-onset muscle soreness generally finds small, if any, benefit when compared with placebo.

Clinical outcome studies of muscle injuries are difficult to conduct as the injuries tend to heal within days without intervention. There is concern that through inhibition of the inflammatory pathway, NSAIDs may delay the rate of muscle fiber regeneration. While some animal studies suggest that this occurs, it is not clear that there is a deleterious effect in humans. Biologic tissue often heals best with mobilization. If the pain relief provided by an NSAID allows more movement, then the benefit of movement may outweigh the downside of interrupting the healing pathway.

Ligament Injuries

A variety of studies have been conducted on the effect of NSAIDs on the strength of rat ligaments after injury. The majority of these have shown no effect on ligament strength. Studies in humans have generally shown NSAIDs to be effective for pain relief and return to activity. However, as with muscle injuries, controlled mobilization is beneficial in ligament healing. The studies in humans have been done comparing NSAIDs with placebo. In this context, if NSAIDs decrease pain and thus encourage activity, they may provide some therapeutic benefit. It is unknown whether a similar effect could be obtained with other analgesics, including simply ice.

Tendon Injuries

When it comes to the treatment of tendon injuries, the argument to use NSAIDs because of their anti-inflammatory agents becomes especially controversial. Contrary to the name historically given to tendon injuries, *tendinitis*, these injuries do not seem to have a strong inflammatory component. (*Note:* The suffix *itis* denotes an inflammatory process.) Several leading researchers in tendon injuries have pointed out this misnomer and emphasized its unfortunate effect of furthering a false perception that an anti-inflammatory medicine should be used in treatment.

Studies with a large number of subjects have looked at tissue biopsies from chronic injuries of the extensor carpi radialis brevis tendon (the site of "tennis elbow"), Achilles tendon, patellar tendon, and rotator cuff tendons. Results show the tendons to be degenerative in quality and lacking in inflammatory cells. Thus, a more proper term would be either *tendinosis*, meaning tendon degeneration, or *tendinopathy*, signifying nonspecific tendon pathology. Some have argued that a poor inflammatory process is the precipitant causing tendon degeneration. Recent research is finding that abnormal tendon vascularity is associated with tendon pain.

Reviews of studies comparing NSAIDs with placebo have found the results to be inconsistent, with some showing a benefit and others showing no difference. A systematic review of studies evaluating NSAID use in lateral epicondylitis of the elbow (or tennis elbow) found that, as compared with placebo, NSAIDs provide a short-term benefit for pain and function. It is unclear if there is any long-term benefit of NSAIDs over placebo. Furthermore, it is unclear if NSAIDs offer a benefit over other pain relievers, physical therapy, or other treatment options. Given the state of current research, when NSAIDs are prescribed, the rationale should be their analgesic and not their anti-inflammatory properties.

Bone

Of all the common structures injured in sports, bone is the one where the use of NSAIDs has been questioned most vigorously. NSAIDs inhibit the prostaglandins that are known to be important for the repair of injured bone. Numerous studies in animals have shown that NSAIDs impair fracture healing, including the healing of stress fractures. NSAIDs are used to decrease the formation of *heterotopic ossification* (i.e., new bone formation in nonbony tissue). Human studies evaluating the effects of NSAIDs on bone healing have primarily been retrospective, looking back on poorly healing fractures. These studies have generally found NSAIDs to be associated with poor fracture repair. Being retrospective, cause and effect cannot be definitively determined. No studies have evaluated the effects of NSAIDs on stress fractures in athletes. The research to date suggests, however, that NSAIDs should be discouraged in patients suffering from fractures that are at risk of delayed healing.

Side Effects of NSAID Use

The decision to use any medication must be made only after considering the potential for side effects. The two most well-described side effects of NSAIDs are those on the GI tract and the cardiovascular system. Although NSAIDs were originally marketed as the safe alternative to aspirin, it quickly became apparent that NSAIDs themselves have serious GI side effects (e.g., GI bleeding). Dyspepsia (upset stomach) is another common side effect. Of importance, the symptom of dyspepsia should not be used as a screening tool for the potential for GI bleeding. Among patients who suffer GI bleeds, less than half will have had dyspepsia prior to the bleed. This might be due to the analgesic effect of NSAIDs. Perhaps as a result of the drugs' inhibition of platelet aggregation, individuals who suffer

GI bleeds while taking NSAIDs have a significantly higher mortality than those with GI bleeds who are not taking NSAIDs.

In the late 1990s, the COX-2 inhibitors were marketed as a safe alternative to NSAIDs. The COX-2 inhibitors preferentially block the COX-2 enzyme (thus blocking the inflammatory prostaglandins) while allowing the homeostatic properties catalyzed by COX-1 to proceed. The intent was to have medications that maintained the benefit of NSAIDs while reducing the side effects in the GI system and the peripheral vascular system. Evidence has shown that COX-2 inhibitors are preferred to nonselective NSAIDs for the purpose of decreasing GI bleeding. However, use of COX-2 inhibitors was severely curtailed once research showed an association between COX-2 inhibitors and myocardial infarctions (perhaps a result of increased platelet aggregation). This resulted in the removal of several COX-2 inhibitors from the market and strict warnings on those that remain. Of note, there is also some concern that nonselective NSAIDs may also increase the risk of myocardial infarctions, and this question continues to be investigated.

For the younger and active sporting community, the major GI and cardiovascular side effects are less of a worry. Still, NSAID use in athletes has been associated with adverse effects. A recent study in Finland found that approximately one in five young athletes reported minor side effects while using NSAIDs. NSAIDs affect the renal and cardiovascular systems, as prostaglandins are necessary for renal blood flow and the secretion of sodium and chloride. Prostaglandin inhibition has been shown to raise mean arterial blood pressure an average of 3 to 5 millimeters of mercury pressure (mmHg). Endurance athletes are often hypohydrated as a consequence of prolonged training. Prostaglandin inhibition can cause further decreases in renal blood flow. Case reports have discussed NSAID use as a potential factor in cases of acute renal failure in endurance events. A side effect that is important when working with competitive athletes is the effect of NSAIDs on the respiratory system. Blocking COX can shunt arachidonic acid toward the formation of the bronchoconstricting leukotrienes. It is estimated that approximately 1 in 10 asthmatics experience a decline in respiratory function as a result of NSAID inhibition of COX.

Conclusion

In recent years, the treatment paradigm for sports injuries has become more complicated. Historically, many injuries were attributed to inflammation, and the recommendation was for rest and an anti-inflammatory medication. However, basic science research regarding the healing of tissue, from muscle to tendon to bone, has called this historical model into question. In most cases, it does not appear that inflammation is a primary component of the injured tissue. Furthermore, when present, inflammation may be a necessary part of the healing process.

These investigations have had a direct bearing on current discussions of how best to treat the athlete with an injured body part and associated pain. In terms of injury healing, there is research supporting controlled mobilization as opposed to rest, as applied to a variety of muscle, ligament, and tendon injuries. Certain fractures may heal faster with gentle compressive forces as compared with complete bone immobilization. For the pain present while the injury is healing, no single recommendation can be made. Acetaminophen has been marketed as a possible pharmaceutical analgesic in the sports medicine community. Although initially believed to have no effect on COX enzymes, evidence is accumulating that COX enzyme inhibition is part of their mechanism of action. Topical NSAIDs are showing promise in treating the pain of sports-related injuries. There appears to be negligible systemic absorption and thus minimal concern for serious side effects. Oral NSAIDs remain excellent pain relievers, and short courses of NSAIDs are likely have no detrimental effect on most injuries.

Nose Injuries

In contact sports, the athlete's nose is at risk in a collision with another player or piece of sporting equipment, and being struck on the bones in one's face can be very painful. A blow to the nose can be frightening, especially because such injuries tend to bleed profusely, even in the absence of more extensive damage to the surrounding tissues. This entry describes common nasal injuries in sports and their treatment.

Epistaxis (Nosebleed)

More than 90% of all nosebleeds are anterior, usually from the Kiesselbach plexus in the Little area of the anterior septum. The first step to stop the bleeding is to sit or lie down with the head and shoulders higher than the waist and legs. Tilting the head forward will help prevent blood from pooling in the posterior pharynx, which can help prevent nausea and airway compromise. Mild epistaxis may resolve spontaneously without any intervention. Persistent cases should be treated with the application of direct pressure to the septum over the area of bleeding. If possible, place an ice pack on the nose and another ice pack on the back of the neck while applying direct pressure. The athlete should breathe through the mouth until the bleeding slows down. Return to play should not be allowed until the bleeding has completely stopped. If the bleeding has not diminished in 15 minutes by the clock, repeat the process for another 15 minutes. If nasal bleeding has not stopped after 30 minutes of appropriate management, further evaluation and referral to a hospital or specialist may be needed.

Cautery may be considered if direct pressure fails and the bleeding can be identified (silver nitrate or electrocautery). A simple pledget treated with petroleum jelly may be inserted or gently screwed into the affected nostril. Nasal packing may be used for compression if bleeding cannot be stopped by simpler means and the bleeding sites cannot be identified easily. Complications of nasal packing may include septal hematoma, nasal abscess, sinusitis, neurogenic syncope during packing, and pressure necrosis. While strenuous activity and return to play should be restricted with nasal packing in place, if no packing is required and the bleeding is controlled with ice and compression, the athlete may return to play. Failure of bleeding to stop with the measures discussed above may be a sign of epistaxis of a posterior origin. Most posterior bleeds require more than on-the-field assessment, and referral to a hospital or specialist for emergent hemostasis may be required.

Nasal Hematomas

Blunt trauma to the nose may rupture the blood vessels and result in the formation of a hematoma, a localized swelling filled with sequestered blood. The clinician must distinguish hematomas from simple swelling and ecchymosis (bruising), both of which tend to hide or obscure underlying injuries to the nasal skeleton. The accumulation of blood between the septal cartilage and the overlying tissue (mucoperichondrium) can produce adjacent tissue necrosis due to destruction of nasal cartilage, which depends on the blood supply from the overlying skin for nourishment. Overlying hematomas interfere with the transport of oxygen and nutrients and are prone to abscess formation. Septal hematomas can lead to pressure necrosis of the underlying bone and cartilage, causing collapse of the nasal dorsum, with resultant "saddle nose deformity" if not properly treated. Decompression with prompt aspiration should be done as soon as possible, with prophylactic antibiotics and nasal packing bilaterally to prevent recurrence. A simple test for septal hematomas is to take a cotton swab and feel any mass noted on the nasal septum for fluctulence. The nasal septum should not be fluctulent, and a nasal septum with a bluish tinge is characteristic of septal hematoma.

Lacerations

Nasal lacerations should undergo primary closure. All foreign material should be cleaned from the wound at the initial evaluation, using a scrub brush if necessary, to prevent scarring. Lacerations of the nose can be closed with 5-0 and 6-0 sutures and/or with steri-strips if appropriate. If any underlying cartilage is involved, antibiotics and referral may be appropriate. If the laceration is minor and can be stabilized well with steri-strips and/or sutures, the athlete may return to competition, provided the wound is not bleeding and is protected with an occlusive dressing. Subsequent participation requires similar nasal protection until healing is complete.

Nasal Fractures

Isolated nasal fractures are the most common sports-related facial fracture. The prominence of the nose and its low impact tolerance and thinness make it especially susceptible to injury. These fractures are less common in children because their nasal bones are less prominent and more flexible.

Clinical diagnosis of a nasal fracture is based on an accurate history and thorough physical examination. The severity may range from a slightly depressed greenstick fracture (commonly seen in adolescents and children) to displacement and/or disruption of the bony and cartilaginous components of the nose. Direct end-on trauma usually results in comminuted fractures of both the bone and the cartilage. Side blows may result in simple fractures with deviation to the opposite side. The most common signs of nasal injury are (in order of frequency) epistaxis, swelling of the nasal dorsum, ecchymosis around the eyes, tenderness of the nasal dorsum, radiographic evidence of fracture, obvious nasal deformity/asymmetry, and nasal bone crepitus. Radiographic evaluation is seldom helpful for immediate treatment decisions but may include an anteroposterior/lateral/oblique film series with a Waters view if necessary. Films are positive only about 40% of the time with a definitive fracture.

Swelling and ecchymosis may preclude an adequate examination. In this case, it is better to wait and reexamine the patient after the ecchymosis and swelling have improved. Nondisplaced fractures do not require reduction. Reduction of a displaced nasal fracture may be attempted immediately before swelling makes an adequate assessment of nasal deformity difficult. Ear, nose, and throat (ENT) follow-up is suggested within a few days for children and within 7 to 10 days for adults. Immediate follow-up is not required for routine fractures. All nasal septums must be adequately visualized during the initial examination to rule out septal hematoma, which requires immediate treatment as previously mentioned. It is always important to rule out other facial injuries, eye injuries, or head trauma that may have occurred in addition to the nasal injury.

Workouts and strenuous exercises are to be restricted if the patient has intranasal packing, which may last 3 to 4 days. Athletes should not return to play the same day unless there are absolutely no other associated injuries and the nose can be protected. Return to play is typically not advised, and the athlete should be restricted to noncontact drills for the first week postreduction, unless the nose can be adequately protected with external protective headgear.

Nutrition and Hydration

Sports participation continues to be increasingly popular, with people of all ages and abilities training and competing in athletic events. Among the factors that contribute to success in sports are nutrition and hydration of the athlete; indeed, proper nutrition forms the basis of training and performance. Furthermore, an athlete's needs change throughout the life cycle, making it important to consider not only the short-term goal of optimal training and performance but also the mid- and long-term goals of optimal growth and development and a healthy adulthood. This entry discusses and offers recommendations for the nutrition and hydration of athletes.

There are a few basic differences between general and sports nutrition. Athletes have essentially the same nutrition needs as nonathletes, but there are four ways in which the nutritional needs of athletes may differ from those of the general sedentary population. First, although the specific needs of the three macronutrients—carbohydrate, fat, and protein—appear to have the same percentages in the diet (approximately 60% carbohydrates, 25% fat, and 15% protein), the total amount of calories required by athletes may be slightly or much greater depending on the sport. Furthermore, micronutrients (including vitamins and minerals) may also be required in greater amounts. Second, athletes benefit from consuming the right forms of nutrition during training and competition. These nutrition and hydration needs differ from pre-event nutrition. Third, athletes have different nutrition and hydration needs for postworkout recovery. Fast and complete postworkout nutrition and rehydration are vital for maximizing the benefits that an athlete gets from a recently completed workout and maximizing performance in the next workout. Finally, there is considerable research regarding the potential benefits of performance-enhancing supplements. Whereas nutritional supplements are not necessary for optimal health, certain supplements may enhance sports performance to a level that foods cannot match. As yet, scientists have not singled out any one supplement for athletes, but various supplements have shown benefits in select studies. All four of these potential differences are considered in the following sections.

Carbohydrates

Good sports nutrition requires a consideration of macronutrients, micronutrients, balance and distribution of the diet, sport-specific concerns, and hydration. Macronutrients include carbohydrates, protein, and fat. Carbohydrates provide a major source of fuel for the body, as well as being the chief storage form of energy. They provide dietary fiber that is important for gastrointestinal health, regulating cholesterol and stabilizing blood glucose. Adequate carbohydrates in the diet, as well as stores in the muscles and liver in the form of blood glucose and glycogen, is of primary importance for optimal sports nutrition.

Carbohydrates should be consumed before, during, and after exercise. Prior to exercise, carbohydrates provide energy to maintain daily activities of living, as well as a pool of calories to spare, or make available protein for muscle growth and repair. In addition, carbohydrates before exercise help maintain optimal stores of muscle and liver glycogen. Glycogen in muscles is the main source of carbohydrates in the body, while liver glycogen helps maintain blood glucose levels both at rest and during exercise. When an athlete is at rest, the brain and central nervous system use most of the blood glucose. During exercise, muscles use more glucose, even up to 30 times more, depending on the intensity and duration of the exercise.

Carbohydrate guidelines for the general public are often expressed as a percentage of the diet. These include 55% to 60% carbohydrates compared with 15% to 20% protein and 30% to 35% fat. These guidelines are appropriate to describe a general distribution of calories, but more specific guidelines are appropriate for athletes. Although research has not definitively described the most optimal macronutrient percentages, one might assume that athletes may need more carbohydrates than sedentary people.

The typical daily diet in the United States provides approximately 4 to 5 grams (g) of carbohydrate per kilogram (kg) of body weight. Carbohydrate recommendations for athletes range from 6 to 10 g kg^{-1} day^{-1}, with an average intake of 5 to 7 g/day for general training, increased to 7 to 10 g/day for those athletes training for endurance events, such as a triathlon or a marathon. Furthermore, a new area of training in the form of the ultramarathon may require as much as 11 g kg^{-1} day^{-1} or higher.

Using an absolute value such as 5 to 7 g kg^{-1} day^{-1} is a better method of determining what is best for an athlete as it takes into account body weight. For example, a more muscular athlete with a higher body weight who has a very intense training schedule may require more total energy with a lower amount of carbohydrates than an athlete with a lower body weight and less intense training regimen. This is often found to be the case in female athletes who may be trying to maintain a low body weight or body fat percentage. The bottom line is that each athlete's carbohydrate prescription is best determined individually, based on body weight, sport-specific considerations, energy balance, and adequacy of macronutrients (protein, carbohydrate, and fat) and micronutrients (vitamins and minerals).

Another important consideration for athletes is to consume enough calories. Research has shown that a low-calorie diet, even if it has adequate carbohydrates, may impair performance by lowering glycogen stores in both muscles and the liver. This applies to athletes who are also interested in weight loss and, thus, consume low-calorie diets. Low-energy diets may decrease muscle mass as well as impair the acid-base balance. However, if energy is increased and adequate carbohydrates are consumed, this damage may be reversed. It is also important for athletes to consider carbohydrate needs not only for the event but for training as well. Often, athletes pay more attention to the event, neglecting the importance of daily carbohydrate consistency. In summary, adequate energy and carbohydrates on a daily basis will help maintain muscle glycogen concentrations. Conversely, inadequate energy and carbohydrates during training may cause a gradual decrease in muscle glycogen content, impairing both training and competitive performance.

Carbohydrates are classified in several ways. Formerly, carbohydrates were referred to as either simple or complex. Simple carbohydrates are basic sugars that are single or one-unit sugars. They include glucose, fructose, and galactose. Disaccharides, or two-unit sugars, are two simple sugars linked together. They include sucrose (broken down into glucose and fructose), lactose (broken down into glucose and galactose), and maltose (broken down into two glucose units). Simple carbohydrates have very few nutrients and must be converted into glucose before the body can use the sugar as fuel. Simple sugars include foods such as honey, raw sugar, syrup, candy, jelly, and table sugar. Complex carbohydrates contain mostly glucose units that are joined together in compounds called *polysaccharides*. Complex carbohydrates include starch, fiber, and glycogen. They include basically any carbohydrate contained in whole foods.

Another classification of carbohydrates is called the *glycemic index* (GI). This is a more comprehensive explanation of the quality of carbohydrates. GI is a relative number that describes the potential of a food to raise the blood glucose level and subsequently the insulin level. Foods are compared with either white bread or pure glucose to obtain a number called the *GI*. In general, the higher the GI, the greater the potential of the food to raise the blood glucose level and thus be rapidly absorbed. Conversely, the lower the GI, the slower the rate of digestion and absorption of the carbohydrate. Foods are often classified into three categories—high, medium, and low GI. Examples of high-GI foods are bread, rice, potatoes, many breakfast cereals, and sports drinks. Moderate-GI foods include foods such as sucrose (as it is broken down into glucose and fructose), bananas, and oats. Low-GI foods include fructose, milk and many milk products, legumes, pasta (as it is made from higher-fiber wheat), and apples.

Not only does the GI reflect the effect of the food on blood glucose and insulin, but it also represents the form of the food, including the size of the carbohydrate grains (e.g., whole or refined grains); the degree of food processing; whether the food contains fructose and lactose (both of which have a low GI); the presence of fat or protein (both of which slow down the absorption of the carbohydrate); and the fiber content.

GI is often a consideration of sports nutrition. Some propose that low-GI foods are best taken before exercise to promote a sustained and slower absorption of carbohydrates, thus promoting more carbohydrate availability. Moderate- to high-GI foods may be recommended during exercise to ensure optimal muscle glycogen stores, as well as to enhance recovery after the exercise. GI may in fact be useful to help guide carbohydrate choices before and during events; however, further studies are warranted. Athletes would be wise not only to consider the GI but also to take into account the nutrient value, taste, cost, preparation, portability, and any gastrointestinal side effects of the food, such as gas, bloating, constipation, or loose stools.

Carbohydrates Before Exercise

Some research has shown that athletes should not consume high-glycemic carbohydrates before exercise. The reason for this is that these carbohydrates may lead to muscle glycogen depletion and even to hypoglycemia. However, other research has shown that this hypoglycemia may resolve in the first 30 minutes of exercise and does not impair performance. Basically, there is as yet no conclusive evidence to recommend that athletes should consume low-GI foods prior to exercise. However, if carbohydrate consumption is not possible during exercise, then a low-GI meal may give more sustained energy. Athletes should experiment with various foods to determine which foods are the most beneficial during training and competition. For athletes who have not eaten prior to aerobic exercise, eating or drinking a low- to moderate-GI food may be beneficial.

Athletes who have more intense training regimens as well as higher body weights may not be able to consume enough solid food to meet their daily caloric needs. In this case, a high-calorie sports beverage may be helpful. Liquid supplements with a high percentage of carbohydrate, as well as glucose polymers, may be helpful if an athlete has trouble meeting caloric needs with solid foods. These supplements are not only convenient but also have low fiber content, thus having less potential to cause gastrointestinal discomfort.

An important aspect of carbohydrates before exercise is the pre-exercise or pre-event meal. The pre-event meal does not provide immediate energy, but it does provide energy for exercise that lasts for 1 hour or longer. Many athletes neglect the pre-exercise meal. As liver glycogen stores may be reduced during sleep, the pre-exercise meal is important to ensure sustained aerobic exercise. It is best to consume carbohydrates 2 to 4 hours before exercise not only to help top off liver glycogen but also to ensure optimal blood glucose for sustained exercise.

There is considerable research on the ideal pre-exercise meal. When preparing this meal, it is important to take into account the total amount of carbohydrate as well as the type and timing of carbohydrate ingestion. Foods consumed right before exercise have the potential to divert blood from the muscles to the gastrointestinal tract. A good way to avoid gastrointestinal distress prior to exercise is to consume less carbohydrate just prior to exercise. Approximately 4 to 5 g/kg of body weight should be consumed 4 hours prior to exercise, whereas 1 g/kg is optimal in the last hour before exercise. This will help avoid any gastrointestinal side effects such as gas or bloating. An easy way to remember the timing of carbohydrate intake prior to exercise is to have 1 g/hour before exercise. Thus, 4 hours prior to exercise, consume 4 g/kg; 3 hours before, consume 3 g/kg; 2 hours, before consume 2 g/kg; and 1 hour before, consume 1 g/kg.

In terms of the type of pre-exercise carbohydrate, the food should be portable, palatable, carbohydrate rich, and easily digested. The GI may be helpful, but the effects of low-, medium-, and high-glycemic foods vary by individual. Thus, it is important for the athlete to experiment with the types of food that foster good performance and are well tolerated.

Carbohydrates During Exercise

Carbohydrates taken during exercise serve to maintain blood glucose stores at higher levels, thus increasing the use of blood glucose during a time when muscle glycogen stores are lower. This is very helpful not only in endurance sports, such as running, but also in sports such as tennis, basketball, soccer, and cycling, which require repeated periods of high-intensity, short-duration effort. During exercise, it is recommended that athletes consume 30 to 60 g of carbohydrates per hour.

This translates to 120 to 240 calories (cal; 1 cal = 4.18 joules) of carbohydrates per hour. This can be obtained from either solid or liquid foods, depending on the athlete's preference. The GI may make a difference, but research has not yet supported intake of any one type of carbohydrate during exercise. Again, it is up to the individual to determine what works best. Most athletes prefer medium- to high-glycemic foods, such as sports bars, cookies, or fruits such as bananas.

Energy bars are one of the most popular options for snacks during exercise. The best type of exercise bar is one that has more than 80% carbohydrate and less than 10% fat. Some protein in the bar is also helpful, as research shows that during exercise as much as 10% of the energy may come from protein stores in the body. Some athletes choose cookies or candy bars. However, the higher fat content of these foods may not be optimal for performance, as fat may slow down the absorption of the carbohydrates. The primary fuel used during exercise is carbohydrates, so it is best to choose a food that is mostly rich in carbohydrates. One other consideration is to consume fluid with the energy bar. A carbohydrate-rich diet and adequate hydration are the greatest ergogenic aids.

Some athletes prefer to consume liquid supplements during exercise. The typical liquid supplement contains between 4% and 8% carbohydrate. Therefore, if an athlete consumes a sports beverage that is 8% carbohydrate, 24 fluid ounces (oz; 1 fl oz 29.57 milliliters [ml]) consumed per hour will supply 57 g of carbohydrates. By comparison, sports gels provide an average of 25 g/hour, one banana provides 30 g, and an average sports bar provides 66 g. Thus, both liquid and solid foods rich in carbohydrates will supply adequate carbohydrates during exercise.

Fructose is another sugar that is used by some athletes during exercise. Fructose has a low GI as it is converted to glycogen primarily in the liver. However, most likely, it is not converted rapidly enough to blood glucose to support optimal performance during exercise. There also are potential gastrointestinal side effects with fructose, as it may have an osmotic effect in the gastrointestinal tract, where it draws in excess water, and may lead to cramping, bloating, and diarrhea. Some sports beverages contain more than one source of carbohydrate, such as glucose, sucrose, maltodextrins, and fructose. These types of sports beverages may actually enhance performance owing to the extra absorption of water.

Carbohydrates After Exercise

Carbohydrates should also be consumed after exercise. This is particularly important in restoring muscle glycogen stores to ensure optimal performance for consecutive exercise sessions. Athletes who train hard over a period of days or several times in 1 day, as well as those who compete in events that last more than 1 day, especially need to ensure that they have a recovery snack after each exercise session. This will help avoid the discouraging feeling of "hitting the wall" and not performing at one's best.

Research shows that consuming carbohydrates within 15 minutes of completing the event or practice will provide optimal muscle glycogen restoration. Exercise lasting more than 60 to 90 minutes requires 1.5 g of carbohydrates per kilogram of body weight immediately after exercise and another 1.5 to 2 g/kg 2 hours later. Research has shown that delaying the ingestion of carbohydrate by 1 to 2 hours may reduce muscle glycogen stores by more than 50%. In terms of the types of carbohydrate that promote optimal restoration of muscle glycogen, glucose and sucrose seem to be better than fructose.

Athletes need to experiment with foods to determine the best foods to consume after exercise. Many athletes prefer foods with a high GI. These foods include bread, potatoes, cereals, and sports drinks. Other athletes prefer a moderate-glycemic food, such as chocolate milk, a banana, or a tropical fruit such as dried mangoes. For those athletes who complain that they are not hungry after exercise and have trouble consuming food, liquids that are high in carbohydrates, such as a high-carbohydrate sports beverage, may be helpful. Another consideration after exercise is to restore hydration. This will be covered in a later section.

There is also research supporting that some protein consumed along with carbohydrates after exercise facilitates recovery. No conclusive data have been found that suggest that the addition of protein aids in restoring muscle glycogen. However, the addition of protein may enhance muscle growth and repair. When combined with proteins, carbohydrates may have a sparing effect on the protein, thus further enhancing muscle synthesis.

One final consideration about carbohydrates is their fiber content. Studies of populations suggest that adequate dietary fiber helps protect against heart disease, certain kinds of cancers, and diabetes. Fiber is often classified according to its solubility in water. Soluble fiber, or fiber that is soluble in water, creates a viscous material that helps promote satiety or the feeling of fullness after a meal, lowers blood cholesterol, and also slows down the absorption of blood glucose, providing longer-lasting energy. Examples of soluble fiber include citrus fruits, oats, barley, and legumes. Insoluble fiber does not dissolve in water and is found in high concentration in vegetables, cereals, and wheat. Insoluble fiber plays an important role in gastrointestinal health as it helps increase the bulk of the stools and thus promotes a faster transit time. As with all food, athletes are encouraged to experiment with amounts of dietary fiber that enhance their training and performance. In general, the amount of fiber recommended for adults is between 25 and 30 g/day.

Protein

Protein builds and repairs body tissue and forms the major component of enzymes, hormones, and antibodies. The dietary reference intake (DRI) for protein is 0.8 g kg^{-1} day^{-1}, which translates to 0.36 g $pound^{-1}$ (lb) day^{-1} (1 lb = 0.45 kg). This amount is established for individuals above 18 years of age and does not take into account the amount of physical activity. As with carbohydrates, protein supplies 4 cal/g. Fat provides more than twice the energy of carbohydrates or protein, providing 9 cal/g.

Research suggests that active individuals may require more than the DRI of protein to sustain their activity and to support optimal performance. Recently, the American College of Sports Medicine (ACSM), the American Dietetic Association (ADA), and the Dietitians of Canada (DC), all have agreed that active individuals have higher protein requirements. Their position statement recommends that protein consumed by endurance athletes should be 1.2 to 1.4 g kg^{-1} day^{-1} and that strength or resistance-trained athletes may need to consume up to 1.6 to 1.7 g kg^{-1} day^{-1}. Athletes may determine their daily protein needs by multiplying these figures by their weight in either kilograms or pounds.

To determine the amount of protein needed to meet daily requirements, the average amounts in foods are totaled. For example, in each cup of milk or yogurt, as well as in 1 oz of cheese, the average amount of protein is 8 g. Each ounce of meat, poultry, or fish has an average of 7 g of protein. Carbohydrates such as bread, rice, and pasta also contain protein. Each slice of bread, one half cup of pasta, or one third cup of rice has an average of 3 g of protein. Of note is that the average American diet contains about 100 g of protein per day, thus insufficient protein is rarely a problem.

One of the reasons why athletes may require more protein than sedentary individuals is that it contributes 5% to 15% of the fuel required for exercise. The amount of protein used for fuel increases as the amount of muscle glycogen decreases. Thus, endurance athletes may use greater amounts of protein. Second, exercise may cause muscle breakdown, which increases the amount of protein needed, as protein is the only macronutrient used to build and repair muscles. Finally, endurance athletes seem to lose a small amount of protein in the urine, whereas protein is typically not lost in the urine of a healthy person who engages in little to no exercise.

Protein requirements remain somewhat controversial among athletes. Many falsely believe that they need more protein than they actually do. This is a common misconception and may lead to an athlete consuming more protein than is necessary. The key concept is that an athlete needs adequate protein and, most important, enough protein to spare or make available for growth and muscle repair. This ensures that the protein is not pulled into the pool of total calories and is used just to keep the athlete functioning, instead of functioning optimally.

Excess protein may actually be detrimental to optimal performance. When there is excess protein and it is burned as fuel, the nitrogen must be removed from the protein and excreted. When the excretion of nitrogen is increased, the amount of water lost in the urine also increases. Thus, the use of protein as fuel not only diverts protein from its main functions of cell growth and repair but also increases the risk of dehydration. High-protein diets have also been shown to increase the amount of calcium in the urine. This is a particular problem for athletes and for bone health. Finally, a high-protein diet may also indicate a high-fat diet. This could increase the risk of certain diseases, such as cardiovascular disease. In summary, adequate protein, and not excessive protein, should be a guiding nutrition principle for athletes.

Some athletes may actually require more protein. These include athletes who are still growing, especially those who have not had their pubertal growth spurt. Other athletes who may require more protein are those who are restricting food intake to achieve a desirable weight. Furthermore, athletes who restrict protein for religious or cultural purposes or those who practice some form of vegetarianism may need to monitor food choices carefully to ensure that they consume enough protein to support optimal training and performance.

Protein is found in both animal and plant sources. Animal protein includes meat, poultry, fish, dairy products, and eggs. Plant sources of protein include legumes, nuts, seeds, grains, and vegetables. Formerly, it was thought that vegetarians needed to combine proteins at each meal and snack to ensure an optimal balance of amino acids. These regulations have been relaxed, and the guidelines are to consume enough total protein in a day to meet the basic needs, as well as any additional protein needed for growth and optimal training and performance.

Athletes often consider using protein supplements to enhance their performance. Not only are protein supplements costly, but for the most part, they are unnecessary. As stated above, although athletes may need slightly more protein than nonathletes, these additional requirements can be easily met through increased calorie intake in food. It is important to remember that muscle strength, shape, and size come from genetics and athletic training and not from protein supplements.

Fat

Fat is a major energy source that not only helps meet daily energy needs but also supplies energy when other sources of readily available energy, such as glucose, are depleted. The extent to which fat supplies energy depends on the duration and intensity of the exercise. Fatty acid oxidation during endurance exercise provides more energy than when carbohydrates are oxidized. However, fatty acid oxidation also requires more oxygen and, thus, puts more stress on an athlete's cardiovascular system.

Fat also helps maintain body temperature and provides insulation for body organs. It lines brain and nerve cells and, thus, is an important part of nervous system and brain functioning. Fat is involved in the regulation and action of insulin, a food-related hormone or control substance that regulates the formation and storage of glucose as fat. Fat is also the vehicle for the absorption of fat-soluble vitamins such as vitamin D (for bone health), vitamin A (for optimal eye function), vitamin E (for antioxidant function), and vitamin K (for normal blood clotting). Dietary fat contributes to the taste of foods, as well as helps promote satiety, or the feeling of fullness after eating.

The total amount of fat necessary in a diet has not been precisely described. Rather, based on the role that excess dietary fat may have in chronic diseases such as heart disease, a value called the acceptable macronutrient distribution range (AMDR) has been established instead. There is a range for all macronutrients (protein, carbohydrates, and fat) that not only considers reducing the risk of chronic diseases but also ensures adequate intake of the nutrients contained within each macronutrient group. The AMDR for total dietary fat is set at 20% to 35% of the total calories consumed per day.

The amount of fat in an athlete's diet will vary depending on the amount of total calories consumed, the type of sport, and the level of training. The overall guideline is that, as with all macronutrients, dietary fat should be individualized, taking into account an athlete's growth stage, nutrition needs, taste preference, physical activity level, energy expenditure, and sport-specific considerations. Runners, cyclists, and other endurance athletes may require more fat so that they have enough energy when stores of glycogen are low. Athletes in appearance sports such as gymnastics and figure skating can have much lower intakes of fat and may even consume well below the recommended range, particularly if they are trying to achieve lower body fat levels.

Low-fat diets, especially those with fat content less than 20% of the total calories, are not necessarily optimal. Athletes who are trying to lower body weight or body fat often tend to increase the intake of carbohydrate at the expense of both fat and protein. For some athletes, especially those who are still growing, a low-fat diet may not provide sufficient energy to meet the needs of both growth and training. Athletes are wise to consider not only the short-term goal of optimal training and performance but also the midterm goal of growth and development and finally the long-term goal of a healthy adulthood.

Another unhealthy consequence of a low-fat diet is that deficiencies of both fat-soluble vitamins and essential fatty acids (e.g., the omega-3 fatty acids) may develop. Furthermore, athletes following low-fat diets may also avoid dairy products, meat, fish, poultry, and eggs, leading to deficiencies of calcium, iron, and zinc. Female athletes may compromise estrogen production with accompanying menstrual dysfunction. Male levels of testosterone may also be compromised with low-fat diets. Thus, low-fat diets in both sexes may compromise not only reproductive function but also training and performance.

The type of fat consumed is an important consideration in a healthful diet. Athletes should watch their consumption of saturated fat by consuming both low-fat dairy products and lean meats. Trans fats (hydrogenated or partially hydrogenated oils) should be eliminated. The emphasis should be on heart-healthful monounsaturated fats, found in foods such as nuts, seeds, avocados, and oils such as olive oil. Polyunsaturated fats are also important as they supply essential fats that are not made in the body and hence must be consumed in the diet instead. These fats include the omega-3 fatty acids.

The omega-3 fatty acids are one type of polyunsaturated fat that have many positive benefits for athletes. These benefits include improved delivery of oxygen and nutrients, increased aerobic metabolism, reduced inflammation of fatigued muscles, and possible prevention of tissue inflammation. Athletes would be wise to consider adding omega-3 fats to their diets. A good dietary practice is to include two, 4- to 5-ounce (oz; 1 oz = 28.35 grams) servings of a cold-water fish each week. Examples of cold-water fish include salmon, albacore tuna, Atlantic herring, and sardine.

One type of fat called medium-chain triglycerides (MCT) is hypothesized to have beneficial attributes for athletes. MCT oil is more directly absorbed than other fats and is rapidly converted into the component parts of fats—fatty acids and glycerol. There is also some evidence to suggest that MCT oil may help mobilize fats from storage and increase the rate at which these fats are burned. MCT oil may also offer benefits for athletes who are trying to maintain lower body fat levels, as the metabolism of these fats may increase overall metabolism in the short term. It should be noted that MCT oil consumed in amounts greater than 30 g (270 calories) may cause gastrointestinal distress such as cramping and diarrhea.

Vitamins and Minerals

Along with the three large nutrients or macronutrients, the micronutrients (including vitamins and minerals) also play an important role in sports nutrition. Vitamins and minerals are necessary for the proper functioning of all body tissues. They are essential for the release of energy from macronutrients by serving as enzymes and cofactors for metabolism. They are called micro- or small nutrients, as although each vitamin and mineral has an important role in maintaining normal cell and body function, they are needed in only small amounts. This is an important consideration for athletes as many think that they need to take vitamins and minerals in mega doses to achieve optimal performance.

The government agency called the Food and Nutrition Board publishes the Recommended Daily Intake (RDI), which includes the recommended daily allowance (RDA) for vitamins and minerals. The RDA is the amount of a vitamin or mineral that will protect a person from certain chronic illnesses or diseases associated with deficiency states of vitamins or minerals. As the RDA is set using sedentary adults as the base, it is often hypothesized that athletes may need more as they are active.

Thiamin, riboflavin, and niacin are B vitamins that are needed to produce energy from food. Carbohydrate and protein foods are excellent sources of these vitamins. Adequate amounts of these vitamins will be obtained from a diet with adequate calories. However, one exception is that some women athletes may lack riboflavin as they do not consume milk and milk products. Milk products not only increase the riboflavin level but also provide protein and calcium. In terms of fat-soluble vitamins, including vitamins A, D, E, and K, the body stores excess of these vitamins. Thus, excessive amounts of these vitamins, especially vitamin D, may have toxic effects.

Minerals play an important role in athletic performance. Endurance or heavy exercise may affect the body's supply of sodium, potassium, iron, and calcium. Sodium lost through sweating may be replenished by eating normally following a competition. Consuming potassium-rich foods, such as oranges, bananas, and potatoes, will supply the necessary potassium. Iron carries oxygen and is another important mineral for athletes. Some athletes, especially women athletes, may have inadequate supplies of iron. Iron supplements may be prescribed by a physician if laboratory tests indicate an iron deficiency. Calcium is another important nutrient, not just for athletes but for bone health in everyone. Women athletes who avoid consuming dairy products may need supplementation to avoid calcium loss from bones. Dairy products, especially low-fat choices, are considered good sources of calcium.

Many athletes take a low-dose multivitamin and mineral supplement to give them the mental satisfaction that they are getting enough of each vitamin and mineral. Research shows that in low doses, vitamin and mineral supplements pose no risk. Conversely, there may be individuals who require more of certain vitamins or minerals. These individuals include those with monotonous diets, those who follow some type of a vegetarian diet, or those with conditions such as food allergies, lactose intolerance, inflammatory bowel disease, celiac disease, or diabetes. In these cases, it is best to consult with a registered dietitian to determine the best supplementation regimen. The bottom line on supplementation is that athletes who consume enough total calories, in a varied diet, to support regular daily activities of living, as well as sport-specific increased caloric needs, will most likely have sufficient vitamins and minerals for optimal performance.

Hydration

Proper hydration is essential to sports nutrition. Athletes should make a conscious effort to drink fluids throughout the day. Fluids include not only the free water in foods (e.g., fruits and vegetables that have a high water content) but also plain water, juice, sports beverages, decaffeinated beverages, and soups. Many athletes prefer the taste of sports drinks to water. However, a sports drink is really no better than water, unless exercise lasts for more than 90 minutes or occurs in hot weather. The additional carbohydrates and electrolytes may improve performance in these conditions, but otherwise the body will do just as well with water. Drinking carbonated drinks or juice is not recommended as they may cause cramping, bloating, or diarrhea during training or competition.

A simple way to gauge fluid needs is to weigh before and after a workout. A minimal weight loss usually means that there is adequate fluid and fluid replacement. A weight loss of more than 2 pounds probably indicates inadequate fluid intake and possibly dehydration. Conversely, gaining weight during exercise may be a sign of excessive drinking or overhydration, indicating the need to reduce the amount of fluid during exercise.

There is individual variation in how much an athlete should drink. Fluid needs depend on the individual's age, size, and level of physical activity, and the environmental temperature. Athletes should drink before, during, and after exercise. In general, most athletes need one to two cups prior to exercise and half to one cup every 15 to 20 minutes during exercise. Thirst is not a reliable indication of the need for hydration and may actually indicate dehydration. Therefore, it is important for an athlete to drink before thirst occurs to maintain proper hydration.

Finally, if dehydration does occur during a period of strenuous exercise, it may take 1 to 2 days to fully recover and replace sweat losses. If this does happen, the athlete should drink often during this time and monitor hydration by checking the urine for its color. If the urine is straw colored, then the athlete is most likely properly hydrated. However, if it is dark, the urine may still be concentrated with metabolic waste. One exception to this is if a multivitamin is consumed, as it may cause urine to be yellow. In this case, hydration should be monitored by the volume of urine produced.

In summary, proper nutrition and hydration not only influence growth but also lead to optimal training and performance. Athletes are urged to consider constructing their diets carefully. Professional help from a registered dietitian is advised for all serious athletes.

O

Obesity

Obesity is a condition that can have wide-ranging effects on the physical, mental, and economic health of an individual. Contributors to obesity include an individual's environment and behavior (e.g., consumption of energy-dense foods and decreased physical activity), genetics, and sociocultural networks. Obesity can cause social stigma and create strong emotional reactions, such as anger, fear, and depression. It also can affect the economic health of societies.

The Epidemic of Obesity

After a gradual but sustained increase, the prevalence of obesity in adults in the United States has reached a plateau, with about one third of adults currently meeting the body mass index (BMI) criteria for obesity, according to data from the November 2007 National Health and Nutrition Examination Surveys. The prevalence of obesity in U.S. children, although it has tripled over the past 30 years, has also shown signs of reaching a plateau. Unfortunately, the global prevalence of obesity is steadily increasing, multiplying threefold in the past 20 years. Ten percent of children worldwide are considered obese. An additional review of the epidemiology of obesity demonstrates an overall increased incidence in those affected by poverty.

What Is Obesity?

The current definition of obesity, for adults and children, centers on a person's BMI, the ratio of one's weight (in kilograms [kg]) to the square of one's height (in meters [m]). The metric formula for BMI is as follows: BMI = kg/m^2. Although it is not a direct measure of adiposity, BMI has been shown to correlate with body fat. In adults, a person is overweight when his or her BMI reaches the range of 25 to 29.9 kg/m^2; he or she is obese when his or her BMI is ≥30 kg/m^2. As natural fluctuations of the appropriate ratio of weight to height occur in growing children, the use of BMI for children greater than 2 years of age is based on the percentile of BMI for gender and age from the 2000 Centers for Disease Control growth charts. Obesity in children under the age of 2 is determined by simple weight-for-height values. BMI weight categories in children are defined as follows:

- Obesity: ≥95th percentile or BMI ≥30kg/m^2 (whichever number is lower)
- Overweight: 85th to 94th percentile
- Healthy weight: 5th to 84th percentile
- Underweight: <5th percentile

The 85th and 95th percentiles were chosen to avoid the overdiagnosis of obesity in muscular teens and the underdiagnosis in lower-BMI teens with higher percentages of body fat. With the increasing prevalence of severely obese children, new recommendations are being proposed to add an additional percentile category of ≥99th percentile, as those children will have significantly increased risk of the associated medical complications of obesity.

The Etiologies of Obesity

At its simplest, weight gain relates to an alteration of the balance between energy intake and energy expenditure in favor of intake. Today, increased intake can take many forms, including increased consumption of sugary drinks, increased portion sizes for meals and snacks, and increased restaurant eating. Energy expenditure has also fallen due to decreased physical activity in schools, decreased routine daily physical activity (e.g., walking to school/work from home), and a greater prevalence of automatic gadgets (e.g., escalators, elevators).

Other related causes of obesity include psychosocial cues, genetics, and the gastrointestinal system. Socially, people are more likely to be obese if a close friend or family member is also obese. In the realm of genetics, twin studies of the past have demonstrated a genetic basis for obesity. In addition, recent research suggests that specific genes may play at least a small role in the tendency toward obesity—for example, genes affecting appetite, satiety, or fat absorption. However, the combination of multiple "obesity genes" and/or environment can augment or lessen the effects of one gene. New research has also found a different composition of intestinal flora (bacteria) in lean versus obese mice and humans, the exact effect of which is currently unknown. Other surveys have demonstrated that sports can lead to obesity as well. The extreme sports fan has a higher BMI than the average spectator. He or she tends to be more sedentary, and while sitting and watching the event, he or she will eat more, have higher-fat foods, and drink more alcohol.

The Effects of Obesity

Obesity affects the physical, mental, and psychosocial health of an individual. People diagnosed with obesity have a shorter life span and are at increased risk for diabetes, coronary heart disease, hypertension, arthritis, certain cancers, and obstructive sleep apnea. They are more likely to experience depression and anxiety than the nonobese. People who are diagnosed as obese have also been subjected to social stigmatization. Obese children can develop general musculoskeletal disorders, such as shin splints and stress fractures, and painful joint conditions, such as *Blount disease,* an abnormal and painful bowing of the leg, or *slipped capital femoral epiphysis,* a shift of the growing part of the femur, resulting in hip pain and decreased motion. They are also at higher risk for heat illness than their same-age, normal-weight counterparts. They also can develop many of the adverse physiologic consequences of obesity listed above.

Unfortunately, obesity has socioeconomic effects as well. Obesity can lead to increased levels of disability, decreased ability to perform activities of daily living, and decreased functional capacity. Obese individuals also experience increased health care utilization and increased overall health care costs.

Prevention and Management of Obesity

It is often said that difficult things become more difficult when they are performed alone. For children, particularly, obesity prevention and management should involve the entire family. The school and the community should also play a role in overcoming obesity (e.g., adequate physical education and recess time, healthy nutrition programs, safe parks and recreation centers, mandates for healthy food grocery stores).

As with any medical condition, preventing the disease from occurring should be the primary goal. This is especially true of obesity, as managing obesity can be costly in time, energy, and money. Prevention includes frequent risk assessments (medical and behavioral) at routine doctor's visits and frequent praise of current healthy behaviors. It is important to identify less healthy behaviors and other barriers to achieving a healthy weight, such as an individual's cultural beliefs and community infrastructure and safety.

Once a person is diagnosed with obesity, the next step is an assessment of his or her stage of readiness to change, his or her strengths to make the change, any barriers preventing the change, and the individual's goals to direct change.

Depending on the obese individual's readiness to change, the management of his or her obesity can follow four general courses, listed in increasing levels of treatment risk and effectiveness:

(1) acceptance of the current weight, (2) losing weight with behavior modification (i.e., diet and exercise), (3) losing weight with medications, and (4) losing weight with surgery. Increased consideration is being given to a combination of these therapies.

The simplest description of a diet for weight loss is one of reduced caloric consumption. Although the method of attaining this reduced consumption can vary from low fat to low carbohydrate to high protein, important considerations when determining an appropriate weight loss diet include long-term maintenance and the direct health benefits of the diet itself (e.g., a low-fat diet to help lower one's cholesterol).

When it comes to adding exercise to an individual's weight loss routine, in general, a little is good, more is better. Exercise has been shown to decrease weight as well as all-cause mortality (even when still obese but fit). The way in which an individual increases his or her activity can vary; however, a successful approach to increase physical activity in adults is by walking and using a pedometer. Recent studies support the use of team sports in treating obesity in children. Not only do obese children benefit from the added physical activity, but they also experience a boost in self-esteem, sports interest, and athletic capabilities.

Slow progress has been made in using medications to aid weight loss, due to difficulty translating successful animal research to humans. Two approved drugs operate at different points in the obesity cascade. Orlistat, approved by the Food and Drug Administration (FDA) for ages 12 and older, works by causing malabsorption of fat in the intestines. Sibutramine, which affects brain chemistry, is an FDA-approved drug for weight loss in individuals 16 years of age or older when combined with diet and exercise.

For those who have been unsuccessful in losing weight with behavior modification and medication, surgery presents an additional option. Various successful surgical methods are currently performed, the selection of which is patient specific. Weight loss, or bariatric, surgery has been shown to decrease all-cause mortality, as well as mortality from diabetes, heart disease, and cancer, related to obesity. With the benefits of surgery come risks as well. One study noted a slightly higher rate of accidents and suicide in the surgery versus nonsurgery group. Additionally, some general complications may occur with any surgical procedure and may include anesthetic complications, infection, and bleeding. Bariatric surgery in children is restricted and must meet certain criteria related to BMI (≥40 kg/m^2 with medical concerns or ≥50 kg/m^2), their complete physical maturity, their cognitive and emotional maturity levels, and their previous weight loss efforts.

Olecranon Stress Injury

Stress fractures of the olecranon are relatively uncommon sources of posterior elbow pain. They have been reported primarily in baseball players, particularly pitchers, and also in gymnasts, weight lifters, and javelin throwers. They must be considered in the differential diagnosis of posterior elbow pain with activity.

Anatomy

The olecranon is the most proximal portion of the ulna bone. It helps the elbow to flex and extend, and when the olecranon articulates with the olecranon fossa, it helps keep the elbow locked in extension. The lower portion of the triceps attaches to the olecranon, allowing for elbow extension.

The injury is considered to be due to either repetitive stressful trauma to the olecranon as it strikes into the olecranon fossa or tension from the triceps tendon on the olecranon. In the skeletally immature athlete, the repeated stress may cause widening of the olecranon epiphysis, resulting in a nonunion or delayed closure of the physis.

Signs and Symptoms

The athlete will present with pain in the posterior elbow, typically posterior lateral. Pain will be most frequent with activity but may occur with rest or direct pressure on the posterior elbow. In throwers, pain is often reported during the late acceleration and deceleration phases of throwing. Often, periods of rest may have been attempted, with return of symptoms soon after resumption of activity.

Physical Examination

On examination, pain will usually be felt on palpation of the olecranon around the posterior, and often posterior, lateral elbow. Soft tissue swelling may be present. Forced extension of the elbow may reproduce the pain. Pain may also be present with active resistance of the triceps. Limited extension of the elbow may be present but is not a unique finding of this condition.

Imaging Studies

Plain-film X-rays are the first-line imaging choice in evaluating for olecranon stress fractures. In adolescent athletes, a comparison with the lateral radiograph of the unaffected elbow may be helpful to see if the olecranon physis has fused. If the physis has fused on the unaffected side, then the likelihood of a delayed fusion or an olecranon stress fracture is higher than if a fracture or persistent physis is visualized on the affected side.

Further imaging with a bone scan, a computerized tomography (CT) scan, or a magnetic resonance imaging (MRI) scan may be helpful in confirming the diagnosis. An MRI scan may also identify other conditions contributing to the problem, such as insufficiency of the ulnar collateral ligament.

Treatment

Both surgical and nonsurgical options have been reported to help treat this condition. Nonsurgical treatment includes complete rest from all activities that produce pain. Generally, the time taken to heal may be 6 months or longer. To help facilitate healing, electrical bone stimulation may be considered. But with this stimulation, there is a potential risk of this stress fracture becoming a painful nonunion. Because of this risk and the uncertainty of nonsurgical treatment, many high-level athletes are encouraged to undergo surgical fixation with open reduction and internal fixation of the stress fracture. Arthroscopy of the elbow is often undertaken at the time of surgery to address any coexisting conditions in the elbow.

Operating Room Equipment and Environment

Sports injuries are frequently minor and heal without much intervention. Unfortunately, many other types of sports injuries cannot heal without surgery. For this reason, it is useful to understand the surgical environment and the equipment used in the operating room.

The concept of the ideal operating room environment and equipment means different things to different people. The patient's concept of the ideal operating room equipment and environment is different from the surgeon's concept. In fact, the patient, the surgeon, the anesthesiologist, the nursing staff, the hospital administration, and the insurance company all have different concepts about what constitutes the ideal operating room and the equipment in that room.

Shared Goals

Despite having different needs and desires at many levels, all groups share three basic goals. First and foremost is patient safety. Many, if not most, of the rules regarding operating rooms involve patient safety. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) and the Accreditation Association for Ambulatory Health Care (AAAHC) mandate many rules in and around the operating room to ensure patient safety. If the hospital or surgery center does not meet JCAHO or AAAHC guidelines, it loses its accreditation and is unable to perform operations until the shortcomings are corrected. Hospitals spend months getting ready for these inspections, ensuring that everyone knows and follows the rules. If, during such an inspection, someone does not know where to find a fire extinguisher, for example, the hospital is cited.

The second shared goal is optimal surgical results. This means minimizing complications such as infection and maximizing outcomes. While the nursing and anesthesia staff cannot do much to improve surgical techniques, they can continuously help decrease infections and pain and can help create an environment in which the surgeon can better concentrate on the operation. Administration tries to attract the most qualified doctors, and insurance companies help by rewarding excellence with incentives called "Best Practices."

The third shared goal is making the surgical environment and experience pleasant. When everyone works in a pleasant atmosphere, the outcomes will be better. Less anxious patients require lesser anesthesia and have fewer complications. No one can work at his or her best in a hostile environment.

If these three are the only variables to be considered, all operating rooms would have a perfect environment with perfect equipment. Unfortunately, other variables interfere with the ability to achieve perfection.

Patient's Perspective

For the patient, the environment starts with easy and free parking at the center. If the hospital provides hassle-free check-in and soothing music and décor in all patient areas, the patient's pain and anxiety are minimized. The patient expects state-of-the-art anesthesia and surgical equipment that is perfectly maintained. The patient wants a perfect operation, a nausea-free wake-up, no pain, and an easy transition back home with full directions regarding postoperative concerns. The patient also desires to have little or no out-of-pocket expenses associated with the operation.

Nurses and Staff Members' Perspective

Nurses and other staff members expect the patient to be well-informed about the operation, relaxed, and cooperative. They hope the doctors are on schedule and pleasant to work with. All paperwork needs to be perfect, and the patient should be protected from harm. After surgery, the nursing staff want the patient to be comfortable, to awaken safely, and to get full information before leaving the center. When nursing staff are efficient and get things done quickly, they do not want to be taken advantage of by being given additional work to do.

Surgeon's Perspective

The surgeon wants a relaxed, happy patient prior to surgery. He or she wants the operating room ready for surgery, with well-maintained, state-of-the-art equipment. All associated personnel should be focused on the operation and not get distracted by any other activities around. The surgeon wants perfect results, no complications, to stay on schedule, and to maximize efficiency.

Anesthesiologist's Perspective

Patient safety comes first, and the schedule may have to be modified if anesthesia takes longer than anticipated. First-rate anesthesia gear is desired, and it must be perfectly maintained. Anxious patients are more difficult to anesthetize, and so a happy, relaxed patient is desired. During the operation, the anesthesiologist wants a surgeon who is calm and efficient. In the recovery area, the anesthesiologist wants the nurses to be first-rate and to be able to respond to any patient's need.

Hospital Administrator's Perspective

Hospital administrators want safe, happy, well-prepared patients, and at the same time the administration needs to be financially prudent. Some patient amenities, such as parking, may not be good. The amenities in the hospital might not be ideal. Surgical equipment and anesthesia gear will be on a budget as well. The administrators have to walk a fine line trying to optimize outcomes while minimizing expenses.

Insurance Company's Perspective

Insurance companies want maximum care for minimal expense. Toward that end, they have forced patients to consult surgeons who have agreed to operate for lower fees. Likewise they have insisted that their members get their surgeries done at centers that have negotiated lower fees. When medical professionals and surgery centers accept low fees from insurance companies, they must work extra hard to keep their expenses down. The lower the fees, the more difficult it is to maintain the highest quality in the surgery center and hence the operating room equipment.

A Typical Knee Operation

The following example of a common sports medicine operation can demonstrate how equipment is used for surgery. A patient has a torn meniscus (spacer cartilage in the knee) and is scheduled for arthroscopic partial removal

Typical arthroscopic equipment for sports medicine surgery. Gear includes high-definition video camera, telescope, light source and fiberoptic cable, recording device, suction shaver to remove tissue, sterile fluid supply, suction drainage, and several hand tools.

Source: Peter G. Gerbino, M.D.

The hand tools include a probe to "feel" tissues and several instruments with tips that grasp, cut, punch, and otherwise handle various tissues. Another instrument frequently used is an electrocautery. This device uses radiofrequency current to heat tissues for removing, sealing, or shrinking those tissues. Special devices for sewing tissue, placing anchors in bone, creating waterproof gateways into the joint, and other unique functions are used as necessary.

Source: Peter G. Gerbino, M.D.

of the damaged tissue. Arthroscopy is a modern technique of doing most or all of an operation through tiny holes. Many, if not most, sports medicine operations are performed arthroscopically. These operations are done on the shoulder, elbow, wrist, hip, knee, ankle, and foot. Equipment includes a tiny, high-definition video camera, a telescope, a light source, a monitor, recording devices, and several hand tools. A typical equipment setup for arthroscopic surgery is shown at the top of page 1000.

The history and physical examination were done several days earlier at the surgeon's office. All paperwork (digital preferred) has been done, and the surgery center awaits the patient's arrival.

The patient arrives 1 hour prior to surgery, and the administrative and nursing paperwork is evaluated and processed. Nursing staff get the patient out of street clothes and record the information needed for administering medicines and ensuring a safe operation. The anesthesiologist meets the patient and discusses anesthesia options.

The surgeon arrives, signs his or her initials on the correct knee, and discusses any of the patient's or family's last-minute concerns. The surgeon ensures that all equipment is ready and functional.

In the operation room, the nurse transfers the patient to the operating table, and the anesthesiologist gets the patient off to sleep or uses other types of anesthesia to ensure a painfree operation. At this time, the anesthesiologist will typically give the patient an intravenous antibiotic to help decrease the risk of infection.

The surgeon positions the patient for knee arthroscopy and "scrubs in" (washes hands and puts on a sterile gown and gloves).

A ballet of sorts begins, with the anesthesiologist, surgeon, scrub nurse or tech, and circulating nurse doing their jobs and assisting one another. For meniscectomy, the arthroscope is inserted into the joint, and tiny instruments are passed through a 0.25-inch hole to repair or remove the damaged tissue. The surgeon's skill comes into play here, since identifying the problem, choosing the right tools for the job, and performing the actual meniscus repair or resection all depend on training and ability.

When the operation is done, dressings are applied, and the patient is awakened and taken to the postanesthesia recovery unit (PARU). This is frequently referred to as the recovery room. Here, the patient is supported until fully awake and ready to leave. Instructions on wound care and pain management are given prior to discharge.

Conclusion

The operating room is not simply a place where a surgeon fixes an injured athlete. There are many personnel and needs that must be considered. Everyone wants a safe, happy patient with an excellent result, but costs and incentives must be factored into the equation. The ideal operating room equipment and environment maximize safety, comfort, and excellent results while being mindful of fiscal and personnel costs.

Organ Injuries

Traumatic injuries, including organ injuries, occur mainly in contact sports where the players often suffer from blunt trauma, ranging from minor contusions to surgical emergencies. Most organ injuries, defined as "harm" or "damage" done or sustained to an organ, occur in sports that involve repeated collision with players or objects, such as football and rugby. Commonly encountered organ injuries are superficial and can be effectively treated, but some are more serious and can result in lifelong disability and even death.

Incidence

Statistics show that of all abdominal injuries being reported in the United States, 10% are sports related. Liver and spleen are the most commonly injured organs, making up one third of all abdominal injuries. Twenty-one percent of traumatic brain injuries (TBIs) are attributed to sports. Lung trauma is one of the major manifestations of thoracic injury. In the genitourinary system, kidneys are the most commonly affected viscera, mainly in children, and account for 2% to 28% of the cases of sports injury. Genital injuries are more common in males.

Following is a brief account of the most commonly injured organs.

Spleen

The spleen is a soft, highly vascular, lymphatic organ that lies along the axis of the 10th rib, under the diaphragm, lateral to the stomach in the left upper quadrant (LUQ) of the abdomen. It is enclosed by a tough, fibrous capsule.

Although it is protected by the rib cage, the spleen is the most frequently injured organ in all age-groups. Increase in size (splenomegaly) is a major risk factor, which occurs in cases of infectious mononucleosis, sickle cell anemia, and immune system disorders such as lymphomas. Any blunt trauma that affects the LUQ directly or a rib fracture can result, secondarily, in spleen injury.

Types of Injuries

Mild Splenic Subcapsular Hematoma. Hematomas are a collection of blood due to internal bleeding as in blunt trauma. They occur in small patches on and around the spleen. The bleeding is limited as the capsule is not ruptured.

Splenic Contusions. Also known as bruising, contusions are tissue injuries in which capillaries are ruptured and result in blood accumulation. Bleeding is on a larger area.

Splenic Lacerations (Tears). Laceration is the most common splenic injury. Profuse bleeding occurs due to its rich blood supply.

Diagnosis

A computerized axial tomography (CAT) scan is performed to help in diagnosis.

Treatment

Patient monitoring is required with maintenance of an intravenous (IV) fluid line. Splenectomy is often done if the noninvasive treatment fails. However, it is not preferred in children as it leads to greater risk of bacterial infections.

Liver

The liver is the largest solid organ of the body, lying in the right upper quadrant (RUQ) of the abdomen, extending up to the midregion. It is one of the intraperitoneal organs (the peritoneum is a membrane lining the abdominal cavity and covers most of the organs). Being a massive organ with a thin tissue capsule and a relatively fixed position in relation to the spine makes the liver the most frequently injured organ. Biliary tract injury is uncommon.

Blunt trauma injuries to the liver can occur by direct impact on the RUQ or upper midabdomen, a high-velocity impact on the right side of the body, crush injuries against the spine or ribs, or bursting of the liver capsule at its attachments.

Types of Injuries

Liver Contusion. Contusions occur as a result of direct impact on the abdomen during sports such as motorbike racing, skiing, soccer, and rugby.

Liver Laceration. Lacerations are cuts to the liver. As it is a highly vascularized organ, athletes with a lacerated liver can develop symptoms of shock rapidly due to profuse bleeding. Javelin throw, rugby, and football account mostly for this injury.

Clinical Findings

Extreme Tenderness Over the RUQ. Due to impact collision, fractures of the seventh to ninth ribs can also cause liver lacerations. Peritoneal irritation, which is characterized by pain on pressing the site and releasing it (rebound tenderness), is seen after 2 hours of injury due to accumulation of blood.

Diagnosis

Diagnosis is based on palpation for a stable player. Ultrasound and CAT scan are the most reliable methods for accuracy of diagnosis. Peritoneal lavage can be done to assess if there is any blood in the cavity. The extent of damage can be evaluated through liver enzyme tests.

Treatment

Contusions are cleared by the body's own healing mechanism. Rest is vital, along with maintenance of an IV fluid line. Lacerations also heal with time unless they are large, in which case laparotomy (a surgical procedure involving incision on the abdominal wall to gain entry into the cavity) is done.

Return to Sports

It depends on the clearance of hepatic injury, as shown by various imaging techniques.

Kidney

The kidneys are located behind the peritoneal cavity (retroperitoneal) bilaterally on the back of the body and are protected by the lower ribs and musculature.

Renal injuries account for 65% of the genitourinary injuries. They occur mostly in American football, hockey, and the martial arts. In children, cycling accounts for 24% of the renal injuries, whereas team sports account for only 5%.

Types of Injury

The different types of renal injury are renal contusion, small parenchyma renal hematomas, renal parenchyma laceration, and injury to the vascular pedicle.

Clinical Findings

There is flank pain with gross or microscopic hematuria (blood in the urine).

Diagnosis

Excretory urogram is advised. Patient can also be evaluated through a computed tomography (CT) scan.

Treatment

Minor injuries require bed rest. Immediate surgical intervention is done for hemodynamically unstable athletes.

Brain

The human brain is situated inside the skull, within the cranial cavity. The protective layers of the brain from outside inward are the scalp, skull, meninges (three membranes: dura mater, arachnoid mater, and pia mater) and ventricles (expansion of the central canal of the spinal cord). The cavity is filled with cerebrospinal fluid.

Cycling, boxing, baseball, horseback riding, soccer, basketball, wrestling, rugby, water sports, and winter sports are among the 20 most causative agents of brain injury treated in U.S. hospital emergency rooms.

The common forms of injuries are as follows.

Concussion (Mild Traumatic Brain Injury, MTBI). These are head injuries with a transient loss of brain function, resulting in physical, emotional, or cognitive symptoms. They occur due to either impact or impulsive forces. These are diffuse brain injuries and occur in both contact and noncontact sports. They are graded based on severity as follows:

> *Grade 1:* No loss of consciousness occurs. Posttraumatic amnesia is absent or occurs for less than 30 minutes.
>
> *Grade 2:* Loss of consciousness occurs for less than 5 minutes. Posttraumatic amnesia remains for more than 30 minutes and up to 24 hours.
>
> *Grade 3:* Loss of consciousness occurs for more than 5 minutes and posttraumatic amnesia for more than 24 hours.

Players who suffer from Grade 1 or 2 concussions can return to play if they are asymptomatic for a week. Athletes with Grade 3 concussion have to be sidelined for a month.

Second-Impact Syndrome. When a second concussion is suffered during the course of recovery from the previous episode, it results in acute, usually fatal, brain swelling known as *second-impact syndrome*. Boxing, football, ice or roller hockey, soccer, baseball, basketball, and snow skiing have a higher incidence of this condition.

Coma. Coma is defined as lack of consciousness. Athletes with severe head injuries may become comatose, which may result in permanent brain damage.

Intracranial Hematoma. Sports injuries may result in epidural or subdural (above or below the dura mater) hematomas. These are severe injuries; unconsciousness occurs, and the injury is sometimes fatal.

Treatment

Airway, breathing, and circulation (ABCs) must be maintained. CT scan and magnetic resonance imaging (MRI) scan provide the most important information about the type of injury and its treatment.

Prevention

Headgear must be worn in contact sports to prevent such injuries.

Lung

The lungs are situated bilaterally in the thoracic cavity, covered by a serous membrane known as *pleura*. It is divided into different lobes and is protected by the rib cage.

Types of Injuries

Pulmonary Contusion. It occurs in injuries from blunt trauma involving high velocity. It results in severe lack of oxygen in blood.

Pulmonary Barotraumas. Heavy exertion and rapid ascent during diving are the common causes. Overpressure of 95 to 110 centimeters (cm) of water can result in lung damage.

Pneumothorax. This is caused by the presence of air or blood (hemothorax) in the pleural space due to penetrating injuries of the chest or rib fractures and compromised breathing.

Diagnosis

The extent of contusions is diagnosed by CT scans. Absence of breathing sounds and wheezing on chest auscultation and chest X-rays can help detect pneumothorax.

Treatment

Resolution of the contusion occurs in a few days, so oxygen support is needed only for severe cases. Pneumothorax of 15% to 20% or less can be treated with rest and oxygen therapy. A 20% or greater injury requires hospitalization.

Testicular Injury

This type of injury occurs as a result of a direct blow to the scrotum, causing compression of the testicles against the pubic bones.

Orthopedist in Sports Medicine, Role of

The field of orthopedics is concerned with the diagnosis and treatment of derangements of the bones, joints, ligaments, and muscles. The first reference to the term was in 1741, in *Orthopaedia: Or the Art of Correcting and Preventing Deformities in Children.* The author, Nicholas Andry, derived the term from the Greek words *ortho* (straight) and *paedia* (rearing a child). The origins of orthopedics are intimately related to the treatment of skeletal deformity in children.

The first orthopedic hospital was established in 1780 by Jean-Andre Venel for the treatment of children. Since its early beginnings, orthopedics has expanded to many subspecialties. Areas of specialty training include pediatrics, spine, trauma, joint replacement, tumor, and sports. Today, only a few orthopedic surgeons focus on correcting deformity in children. The general orthopedic surgeon sees a disproportionate number of adults in the treatment of fractures, sports injuries, and joint replacement.

History of the Orthopedist and Sports Medicine

Conceptually, the field of sports medicine is thousands of years old. The ancient cultures used exercise in some form to promote health and healing. In ancient China, the use of exercise and breathing to improve congested organs was known as kung fu. Herodikos of Selymbria, in ancient Greece, is often considered the father of sports medicine. Prior to studying medicine, he was a sports teacher. At the medical school of Cnidus, he described the imbalance between diet and exercise, resulting in bad health. Later in his text "On Diet," Hippocrates noted that "in order to remain healthy, the entire day should be devoted exclusively to ways and means of increasing one's strength and staying healthy, and the best way to do so is through physical exercise."

Modern sports medicine focuses on the benefits of exercise and promotes the health of athletes. There are a number of organizations that have been integral in the growing field of sports medicine. The International Federation of Sports Medicine (FIMS) was established in 1928 to assist the athletes of the Winter Games in St. Moritz. In 1950, the National Athletic Trainers Association was founded for the education of athletic trainers. In 1951, the American Medical Association established a committee on Injuries in Sports, which is now a standing committee. The American College of Sports Medicine was created in 1954 and is now the largest sports medicine organization in the world. More recently, the American Orthopedic Society for Sports Medicine was founded in 1971.

In the infancy of sports medicine, the orthopedist was synonymous with the treatment of musculoskeletal complaints. When an athlete was injured, he or she saw an orthopedist. There were fewer operative options, and the majority of injuries were treated with some type of rest and bracing. As the field of sports medicine expanded, the role of the orthopedist evolved. There are now numerous examples of orthopedic surgeons facilitating athletes' return to sports, even at the highest level. In the 1970s, Frank Jobe enabled Tommy John to return as a professional pitcher for the Dodgers by reconstructing the inner ligament of his elbow. In 2009, Tiger Woods was able to return to professional golf after the reconstruction of the anterior cruciate ligament of his knee.

Currently, the field of sports medicine encompasses a wide range of practitioners. The orthopedist is now often considered the technician of the sports medicine world. He or she is a surgeon by trade. The physician has to complete a minimum of 10 years of postsecondary education. The training to become an orthopedist focuses on the diagnosis of musculoskeletal problems and their treatment. In the office, injections of the joints can be given to help diagnose or treat a problem. The ultimate decision for surgery lies in the hands of the orthopedist. He or she incorporates diagnostic information from imaging with clinical information from the history and physical exam to make this decision. Whereas the orthopedist reviews the findings of the radiologist, it is often necessary to have the radiographs and magnetic resonance imaging (MRI) scan present in the office for decisions regarding surgery.

Sports Medicine Fellowship in Orthopedics

Some orthopedists undergo additional training in sports medicine. This year of training focuses on athletic injuries and their treatment. Many of these injuries can be treated with minimally invasive techniques. A common tool of the sports medicine orthopedist is the arthroscope. The use of diagnostic arthroscopy was first described in the 1920s by Eugen Bircher. The technique has been expanded to perform many procedures of the joints. From 1999 to 2003, the most common orthopedic procedure performed was knee arthroscopy with partial meniscectomy, followed by shoulder arthroscopy with decompression. A small incision is made at the knee, shoulder, ankle, elbow, or hip for the insertion of an underwater camera. Clear sterile fluid, normal saline, flows into the joint as the sports surgeon is able to directly visualize the bones, ligaments, and tendons. Another small incision is made at the skin for the insertion of instruments to help treat the problem. This is often referred to as a "scope." Arthroscopy has allowed patients to return to sports within days after procedures that formerly had required a recovery period of weeks to months.

Orthopedic Scientist

As with most fields of medicine, there is constant progress. There is a steady influx of nutritional supplements that claim to give the athlete an advantage. New techniques are developed to return players to the field more efficiently and effectively. The media often sensationalize new products. The orthopedist has a role interpreting the literature and educating the community. This can be accomplished by talks to the community or by spending time with the patient in the office to reach an informed decision regarding treatment.

Patient's Advocate

The orthopedic physician is first and foremost an advocate for the athlete. This can at times conflict with the patient's relationship with other members of the team, including the coach. The orthopedist has a responsibility to protect the player by limiting exposure to environments and conditions that could injure the athlete and only allowing the player to return when fully recovered from injury. This role of patient's advocate is exemplified by recommendations for the adolescent athlete. In baseball pitchers, restricting the number of pitches that can be thrown in a period of time reduces overuse injuries to the shoulder and elbow. The orthopedic surgeon has an obligation to inform the athlete of the conditions and treatments that could pose future risks. In elite female athletes, the rigors of training can lead to a dangerous condition resulting in amenorrhea, the absence or suppression of menstrual flow, and osteopenia, or low bone density. Disordered eating is also often a component of the condition known as the *female athlete triad.*

Relationship With Other Specialists

Typically, there is a close interaction between the orthopedist and the physical therapist. Many conditions that require treatment can be overcome with proper physical therapy modalities. The decision for surgery is a major one but is only part of the solution. For the athlete to progress through the rehabilitation process, it is necessary for communication between the surgeon and the physical therapist. Not every procedure is the same, of course, and the orthopedist should participate in the design of a rehabilitation program tailored to what was found and accomplished in the operating room.

In large practices, there are often multiple specialists to diagnose and treat sports-related problems. The sports medicine orthopedist works closely with many other sports medicine specialists and clinicians, including family physicians, emergency physicians, pediatricians, athletic trainers, and physical therapists, to improve the identification, prevention, treatment, and rehabilitation of sports injuries. In some situations, the athlete is first seen by a primary care sports medicine specialist and then referred to the orthopedic surgeon when there is an indication for surgery or a question as to the diagnosis. In smaller practice settings, the orthopedist is often the first to see the athlete with a musculoskeletal complaint. The majority of these injuries can be treated without surgery, necessitating an understanding of the nonoperative management of these conditions with physical therapy and bracing.

Athletic Events

In the setting of athletic events, there is often an orthopedist present. As a physician, he or she is trained in emergency medical management of injuries. These include head injuries, spine injuries, and cardiac emergencies. On the athletic field, the orthopedist is the coordinator of care for the injured patient. While there is a myth that has been perpetuated by the media industry that the orthopedist will simply give the player a "shot" and send him or her back into the game, this is rarely the case. Typically, there is an on-field assessment of the player. Emergent conditions are ruled out, and the player is assisted to the sideline. On the sideline, further evaluation of the player is conducted. The patient's orientation is assessed to rule out concussion (see the entry Concussion). If there is any question of an injury that could lead to further impairment with return to play, the athlete is held on the sideline until further workup can be performed. Once again, there are many components of the sports medicine team. The orthopedist typically relies on the trainers and the physical therapist for treatment of minor injuries with taping, massaging, and stretching.

Conclusion

In conclusion, orthopedic surgeons are intimately involved in all levels of sports. These include protecting the young athlete from overuse injuries, assessing injured players on the field, diagnosing injuries sustained in athletic events, providing operative management for those injuries that do not respond to physical therapy, educating the community, and playing a leadership role in expanding the field of sports medicine through research.

Orthotics

Orthotics is the medical field concerned with the design, development, and fitting of orthoses, which are devices that support or correct imbalances in the musculoskeletal system. Those who fit and apply orthoses are known as orthotists.

In sports, the term *orthotics* refers to any type of formed or prefabricated device that corrects musculoskeletal abnormalities that limit or affect participation in sports.

Orthoses have a wide array of medical uses. These range from simple orthoses that support a single injured limb to complex structures used in the rehabilitation of patients with serious medical problems such as stroke and spina bifida.

The development of orthotics began in ancient times with splint and brace making. Especially over the past 40 to 50 years, the field has developed and grown, particularly with the development of thermoplastics—plastics that can be warmed and molded to an area of the body and retain their shape after cooling.

Different Types of Orthoses

There are two major types of orthoses: custom and prefabricated.

In general, prefabricated orthoses are formed based on a "normal" anatomic model and are usually obtained over the counter. This type of orthosis is typically mass manufactured and is therefore cheaper than custom orthotics.

Custom orthoses are typically fit to a specific patient by an allied health professional, such as an orthotist. These are typically formed using a mold and then are made specifically for the patient. In general, these are more expensive and are often favored by athletes.

Orthoses for the feet are the most common class of orthotics. Because of the weight bearing associated with most forms of work and sports, foot orthotics are extremely popular. These range from over-the-counter "shoe inserts" to custom orthotics molded to the foot. Some orthotics are made simply to provide comfort, while others are formed to help with correction of structural abnormalities.

Orthotics are generally either "soft" or "rigid." Rigid orthotics are formed to maintain the body part (typically the foot) in proper position. An example of this type of orthotic is an ankle-foot orthotic (AFO), which is prescribed for patients who suffer from foot drop as a result of a stroke or other injury to the peroneal nerve. Soft orthotics are used for cushioning and can be used in a variety of medical conditions, such as plantar fasciitis or diabetes; these are also sometimes called "accommodative" orthotics.

Developments in Orthotics

Over the past two decades, there has been a movement in sports toward helping keep the foot in what is thought to be the most anatomically correct position. Particular attention is paid to maintenance of the arch of the foot, as well as maintaining the foot in a subtalar neutral position (the normal position of the foot when walking) as much as possible. This development has resulted in the formation of semirigid and calibrated orthotic devices. Semirigid orthotics are made of a mixture of soft and rigid materials and are used to correct abnormalities such as flat feet (pes planus) and inward rolling of the foot (overpronation), and these are very popular among athletes. Calibrated orthotics also take into account other factors such as body weight and flexibility to provide greater levels of support.

Os Odontoideum

The structures of the neck include the cervical portion of the spine, consisting of seven cervical vertebrae. The top two vertebrae, C1 (atlas) and C2 (axis), have an anatomy different from that of the lower cervical vertebrae to provide for much of neck rotation and nodding. In the lower cervical vertebrae, C3 through C7, each vertebra has an anterior cylindrical structure called the vertebral body, with a posterior bony canal housing the spinal cord. Each vertebral body is separated above and below by a cervical disk. At the axis, however, there is a superior projection of the vertebral body called the odontoid process (also called the dens), which goes up into the anterior ring of the atlas (Figure 1a). The dens takes the

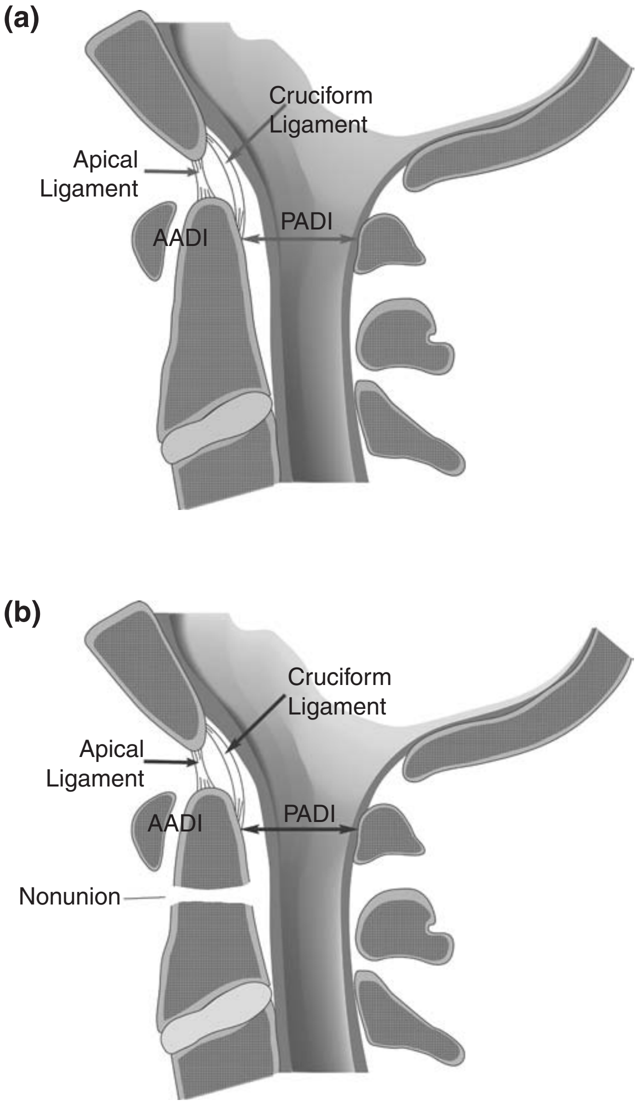

Figure 1 (a) Normal Upper Cervical Spine, Lateral View, and (b) Os Odontoideum, Showing Separation (Nonunion) of the Dens From the C2 Vertebral Body

Source: Illustration by Michael d'Hemecourt.

Note: AADI = anterior atlanto-dens interval; PADI = posterior atlanto-dens interval.

place of the disk and acts as a pivot point for rotation of the atlas on the axis. In early life, this dens is separated from the main body of C2 by a cartilaginous layer called the synchondrosis. During young age, this layer fills in with bone, becoming almost indistinct.

An important ligament, the *transverse atlantal ligament,* holds the dens to the anterior aspect of the axis, away from the posterior placed spinal cord. Maintaining this relationship away from the posterior spinal canal is very important for the integrity of the spinal cord. When this relationship of the dens in the anterior aspect of the atlas is compromised, it is referred to as *instability*. Certain traumatic events can compromise this integrity, such as fracturing the dens or disrupting the ligament. Certain chronic conditions can also cause some compromise. One of these chronic conditions is an *os odontoideum*. This refers to a separation of the top of the dens from the C2 vertebral body (Figure 1b). Other odontoid abnormalities include rare complete or incomplete dens formation. Another chronic condition in this category of instability of C1 and C2 is ligamentous laxity of the transverse atlantoaxial ligament, seen in Down syndrome. Any of these entities has severe implications for sports that involve contact and collision.

The etiology of os odontoideum is controversial with respect to its being traumatic versus congenital in origin. Supporting a theory of a trauma in the distant past are multiple case reports of patients with an os odontoideum and a history of previous unrecognized traumatic events in early childhood. Since older fractures often have a well-rounded appearance, the rounded os odontoideum lends credence to its having been a previous fracture through the synchondrosis before it filled in with bone. Conversely, other case reports indicate a congenital abnormality as there are often other associated spinal formation deformities, such as incomplete arch closure, as well as other nonspinal congenital malformations. Nonetheless, the etiology is not as important as detecting this and determining its stability.

When the dens loses stability with the axis, there is the potential for spinal cord injury, especially in the motion of flexion. In this case of instability, flexion will widen the gap of the dens and the axis. This increased atlanto-dens interval (ADI) may substantially compromise the posterior spinal canal. The normal ADI is less than 3 millimeters (mm) in the adult and 4 to 5 mm in the young child. Intervals above this are abnormal and referred to as unstable. Another problem with instability at this level is compromise to the small vertebral arteries (the vertebrobasilar arteries) that travel along the outer parts of the vertebrae to supply blood to the posterior parts of the brain. As such, these patients may present intracranial symptoms due to vertebrobasilar artery insufficiency, such as dizziness and double vision.

Natural History

This entity is a critical issue for athletes who participate in collision sports. The strong concern is that even minor contact may cause permanent catastrophic spinal cord injury. Understanding the natural history of the entity may help the athlete understand why he or she should withdraw from collision sports.

Usually, these structural abnormalities are incidentally detected on radiographs for other reasons. However, some are symptomatic. The symptoms can be placed in three categories: pain syndromes, myelopathy, and intracranial symptoms. Pain is the most common accompanying symptom, but myelopathy is more catastrophic. *Myelopathy* refers to spinal cord injury patterns that can present with weakness and spasticity of the extremities as well as clumsiness and the inability to hold urine or stool. Myelopathy may be transient with a minor traumatic event or progressive.

Once one detects an os odontoideum, one must classify the type of symptoms experienced by the patient as well as the amount of instability and posterior spinal cord impingement. There are no long-term studies that look at the true incidence of an os odontoideum. However, numerous studies have looked at the outcomes of patients with varying degrees of instability and myelopathy treated both conservatively and surgically. Patients with instability or myelopathy do well with surgical fusion of C1-C2. However, some small case reviews show patients with mild myelopathy and instability doing well with conservative management over a short follow-up time of 3 years. Patients without instability or myelopathy seem to do well if treated conservatively. Nonetheless, there have been some reported cases demonstrating progression to instability and myelopathic changes with minor traumatic episodes. This latter experience is one reason why collision sports are contraindicated.

Imaging

Plain radiographs are usually sufficient to detect the presence of an os odontoideum. This would include an anteroposterior (AP), lateral, and open-mouth odontoid view. As mentioned previously, instability at this level is a problem for the spinal cord. This is typically measured on the lateral radiograph by the ADI. However, a more sensitive measurement of spinal canal compromise is the posterior atlanto-axial interval (PAAI). This latter issue appears to be the most significant with respect to development of myelopathy. Dynamic radiographic evaluation should include lateral flexion and extension views, with attention to instability. A posterior atlanto-dens interval (PADI) less than 13 mm indicates instability with cord impingement and neurologic decline. An ADI interval of greater than 5 mm is also a sign of instability. Any of these findings may indicate the need for surgical stabilization.

Computed tomography (CT) scanning may be helpful in presurgical evaluation of associated anomalies at the cervico-occipital juncture. Magnetic resonance imaging (MRI) is very useful to determine cord compression as well as myelopathic changes in the cord not apparent on the CT scan.

Treatment

Patients who have an os odontoideum found incidentally should be evaluated for instability with dynamic radiographs. If this is found, an MRI scan is useful in determining myelopathy. For those patients without symptoms of instability, nonoperative management is a reasonable approach. However, because delayed instability has been reported, follow-up of the patients should be done to reconfirm stability. Most authors have recommended surgical stabilization for those patients with instability and/or myelopathic changes. Surgical stabilization usually involves using a bone graft to fuse the C1 and C2 vertebral bodies. This is often reinforced with posterior wires or screw fixation. Overall, patients treated with these fusions do well, with nonunion being a small but possible complication. Some reports have shown that some patients treated conservatively even with mild instability have done well at follow-up. However, most investigators still recommend stabilization in these patients because of the possibility of catastrophic instability with mild trauma.

Return-to-Sports Considerations

Unfortunately, there is no allowance for these athletes to return to collision sports. Even in the athlete with no instability documented on flexion and extension views, catastrophic injury is still a possibility. There are documented cases of delayed instability in those who were initially stable. Furthermore, acute traumatic instability at this level could cause disastrous neurologic injury and be life threatening. Even if the athlete has a solid C1-C2 fusion with resultant stability as seen on dynamic radiographs, collision sports are contraindicated. Although a single-level fusion is not an absolute contraindication below this level, a C1-C2 fusion is considered unstable. These athletes may participate in noncollision and noncontact sports. Those without surgical stabilization should be monitored indefinitely with dynamic radiographs for development of instability.

Osgood-Schlatter Disease

Osgood-Schlatter disease, or syndrome, is a rupture of the growth plate at the tibial tuberosity, a form of apophysitis first described by the physicians Robert Bayley Osgood and Carl Schlatter separately in 1903. It is one of the more common sources of anterior knee pain in the preteen athlete and the teenage athlete. This condition most commonly occurs from ages 8 through 13 in females and ages 10 through 15 in males, although certainly those with earlier or delayed growth may present at other ages. Males seem to be affected at a slightly higher rate than females. Both knees can be painful in up to 30% of athletes.

Anatomy

Osgood-Schlatter syndrome is a disorder of the *apophysis*. An apophysis is an area of bone growth, although growth at the apophysis does not result in a person becoming taller. The apophysis serves as an attachment site for a tendon. In Osgood-Schlatter syndrome, the tibial tubercle apophysis is the affected area, which is located on the upper end of the tibia, which is the larger of the two shinbones. The patellar tendon originates from the lower portion of the patella (or kneecap) and attaches to the tibial tuberosity.

Pathogenesis

Osgood-Schlatter syndrome is considered a traction apophysitis, meaning that the traction of the patellar tendon on the growth area at the tibial tubercle produces the signs and symptoms of this condition. With physical activity, particularly running and jumping, the stresses of the patellar tendon on the apophysis put traction on the apophysis. This can lead to mild separation or fragmenting of the apophysis. As the athlete continues to grow, the fragmented area may continue to add an additional bone, and a prominent bony bump may occur at the tibial tubercle, giving the typical appearance of the lump below the patella that many patients present with. Decreased flexibility in the quadriceps or hamstring muscles may develop as the athlete goes through a rapid growth spurt, which will put additional traction on the affected area and contribute to the problem (Figure 1).

Presenting Signs and Symptoms

Affected athletes will present with pain with activity, most frequently due to running or jumping. Many will describe pain with kneeling or any direct pressure put on the knee. Pain is localized over the tibial tuberosity. Swelling or a prominence of the tibial tuberosity is often reported and noted on exam. Occasionally, a limp will occur.

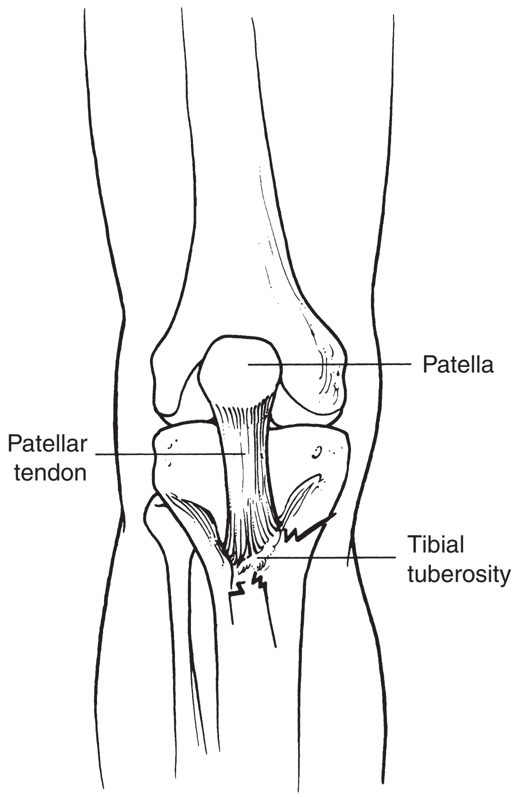

Figure 1 Tibial Tuberosity

Notes: In children, repetitive knee-bending activities may cause irritation at the tibial tuberosity, where the patellar tendon attaches. Athletes 9 to 14 years old are at most risk.

A less common injury, although it should not be considered a complication of Osgood-Schlatter syndrome, is an avulsion fracture of the tibial tuberosity, in which the athlete loses the ability to extend his or her knee. A deformity is noted below the patella when this occurs. The athlete will not be able to walk on the affected leg and will lose the ability to extend his or her knee, similar to a patellar or quadriceps tendon rupture in an adult.

Physical Exam Findings

On physical examination, the athlete may have a prominent bump over the upper end of the tibia. There may be overlying soft tissue swelling over the tibial tuberosity. Often, there will be pain when the athlete is asked to straighten his or her knee from a bent position against the resistance of someone holding on to the front of his or her shin. By definition, there must be tenderness with pushing directly over the tibial tuberosity. Swelling in the knee joint is not present. In more severely affected patients, there may be a noticeable limp while walking.

Radiologic Findings

X-ray studies are not necessary to make the diagnosis of Osgood-Schlatter syndrome. Patients with pain in one knee only, progressively worsening pain, limping, or nighttime pain may benefit from radiographs to evaluate for other problems such as tumors, infections, or stress fractures. Common findings on X-ray include widening of the apophysis compared with the nonpainful side or development of ossicles, which are small fragmented bones or calcifications in the patellar tendon.

Treatment

The mainstay of treatment of Osgood-Schlatter syndrome is nonsurgical. In those with milder symptoms, treatment may include decreasing activity, such as the duration or frequency of the painful activities. The use of ice after activity may be helpful and is encouraged. Bracing with a patellar tendon strap, which wraps around the patellar tendon, situated just below the lower end of the kneecap but above the painful area, may help. This reduces some of the traction on the tibial tuberosity. For athletes who have to kneel and put direct pressure on the painful area, a knee pad may be helpful. Anti-inflammatory medications, such as ibuprofen or naproxen, may be helpful after activity for pain relief but should not be encouraged prior to activity to avoid masking the increasing pain that may help cue the athletes that they should stop their activity.

Physical therapy may be helpful in focusing primarily on stretching of the quadriceps, hamstrings, and calf muscles. Strengthening of the quadriceps muscles, especially while the athlete is still experiencing pain, may aggravate this. Rarely, an athlete may benefit from immobilization if he or she is in significant pain with daily activities.

Surgery is considered for patients who have finished their growth and have persistent pain despite attempts at nonsurgical treatment.

OSTEITIS PUBIS

Osteitis pubis is characterized by inflammation of the pubic symphysis and the adjacent bones. This inflammation leads to bony changes of the pubis symphysis, causing both acute and chronic groin pain. The condition is one of the most common causes of chronic groin pain in athletes, but it may affect nonathletes as well. Osteitis pubis is a self-limited condition that resolves with time, but a variety of treatment modalities may be used to treat the symptoms.

Anatomy

The pelvis is a bony structure that connects the lower spine and trunk to each of the lower extremities. The pelvis is composed of two bony structures known as the os coxae (hipbone). There is a left and a right os coxa. Each os coxa consists of three bones (the ilium, ischium, and pubis) that are fused together. The muscles of the abdomen, groin, and thigh attach to the bones of the pelvis. The two hipbones are joined anteriorly (in the front) at the pubic symphysis and posteriorly (in the back) to the base of the spinal column. The pubic symphysis is the midline cartilaginous joint uniting the left and right pubic bones. It includes a cartilaginous disk that is approximately 3 to 5 millimeters (mm) wide.

Causes

Osteitis pubis is an inflammatory lesion of the pubic symphysis. It is commonly seen in athletes, but it may also be seen during or after pregnancy and after prostate or bladder surgery. Although its exact cause is undetermined, in athletes it is associated with mechanical strain from trauma and repetitive twisting and cutting movement. These actions cause the abdominal and groin muscles to exercise a pulling or traction force on the pubic bone, which in some cases can result in excessive stress and inflammation. Osteitis pubis most commonly affects long-distance runners, weight lifters, ice hockey players, swimmers, fencers, soccer players, football players, and Australian-rules football players.

Symptoms

Increased stresses across the pubic symphysis lead to inflammation and groin pain. Patients report a gradual onset of groin pain, which may be felt on one or both hips. The pain may radiate into the inner aspect of the thigh, groin area, scrotum, or testicles or into the abdomen. This pain worsens with kicking, running, jumping, abdominal straining (e.g., coughing or doing sit-ups), or pivoting on one leg. In addition to pain, osteitis pubis may also be associated with instability of the pubic symphysis and/or loss of hip range of motion.

Diagnosis

The diagnosis of osteitis pubis is made by correlating the patient's history of symptoms with characteristic physical examination and radiographic findings.

Physical Examination

Tenderness along the upper border of the pubic bone and pubic symphysis directly beneath the skin are the characteristic findings on physical examination; lack of tenderness in this area rules out the diagnosis of osteitis pubis. Pain is often present when the examiner outwardly moves the patient's leg away from the body (hip abduction). In addition, having the patient attempt to bring the leg back toward the body (hip adduction) while

X-ray of a normal pelvis, including the two pubic bones (white arrows) and the pubic symphysis (gray arrow)

Source: Adam J. Farber, M.D.

X-ray showing the pelvis in a patient with osteitis pubis. Note the widened pubic symphysis and irregular edges of the left and right pubic bones (circle).

Source: Adam J. Farber, M.D.

the examiner resists this motion will also typically elicit pain. Limitations in hip rotation also may be seen on physical examination.

Radiographic Findings

Plain radiographs (X-rays) are a critical part of the work-up of suspected osteitis pubis. On X-ray, the pubic symphysis normally appears as a dark space between the two ends of the pubic bones, which normally have smooth, regular edges. Occasionally, in cases of osteitis pubis, the X-rays will be normal and show no abnormalities because findings may not be apparent for 2 to 4 weeks after the onset of symptoms. The typical radiographic findings of osteitis pubis include bone resorption of the ends of both the left and the right pubic bones; this leads to irregular margins at the ends of the pubic bones. The other classic radiographic finding seen with osteitis pubis is widening of the pubic symphysis; this appears as a widened (>5 mm) dark space between the two ends of the pubic bones. Gradual reossification (reformation of bone) with complete restoration of the pubic symphysis joint is seen with healing, but this may take several months.

X-rays taken with the patient standing on one leg (known as "flamingo" views) are beneficial if instability of the pubic symphysis joint is suspected. Instability is defined as >2 mm of height difference between the ends of the pubic bones at the pubic symphysis.

Bone scans are also diagnostic but are not typically needed to make the diagnosis. Early in the course of the disease, bone scans show diffuse increased uptake unilaterally or bilaterally in the pubic bones.

Magnetic resonance imaging (MRI) findings are also diagnostic for osteitis pubis, but an MRI scan is not typically required to make the diagnosis. MRI findings include increased fluid in the pubic bones (often in both the left and the right pubic bones) early in the course of the condition, followed by decreased fluid and thickening of the bones as the disease progresses.

Treatment

Osteitis pubis is a self-limiting condition that requires no treatment other than time. However, despite its self-limited nature, osteitis pubis tends to have a protracted course, and 6 to 9 months or more may elapse before the athlete can return to the pre-injury level of functioning. During this time, a variety of nonoperative treatment modalities may be used to treat the symptoms, but this will not affect the ultimate course of the condition. Treatment options include activity modification (especially avoiding vigorous sports activities that involve running, jumping, kicking, and twisting motions), ice, nonsteroidal anti-inflammatory drugs (NSAIDs), stretching, strengthening, hip range-of-motion exercises, and physical therapy modalities. If symptoms persist despite these treatment measures, corticosteroid injections may be considered in an attempt to hasten the recovery process. The steroid injection is most effective if given within 2 weeks of the onset of symptoms.

Rarely, in chronic cases that are unresponsive to nonoperative therapy and injections, surgical treatment options may be considered. One procedure entails fusing the two pubic bones together (also known as arthrodesis) at the pubic symphysis if symphyseal instability is present. Another surgical option involves surgically removing the ends of the pubic bones adjacent to the pubic symphysis. These options are rarely pursued and are associated with unpredictable results.

Osteoporosis Prevention Through Exercise

Osteoporosis is a disease that affects the density of bones. Bones gradually become weak due to loss of calcium, making them more susceptible to breaking. More than half of Americans have some loss of bone density, also called *osteopenia,* or low bone mass, and are at risk for osteoporosis. The majority of people with osteoporosis are women, but osteoporosis also affects men. Osteoporosis can occur at any age but is more common in people 50 years of age or older. Certain strategies exist that can help decrease the risk of developing osteoporosis.

Bone Health

Bone mass develops early in life. The majority of a person's bone mass is established by 20 years of age, and bone density peaks by the late 20s or early 30s. After this peak occurs, bones slowly lose mass through the rest of the life span. The speed of bone loss depends on a number of factors. Women tend to lose bone mass more quickly than men, and the rate of loss for women increases after menopause.

Maximizing Bone Density

A number of methods exist for maximizing bone density during the early decades of life and minimizing bone loss throughout life.

Nutrition

Adequate intake of calcium and vitamin D is essential to optimize bone density during bone formation. The amount of calcium and vitamin D needed varies depending on one's age, sex, and activity level. Preteens and teenagers should consume at least 1,300 milligrams (mg) of calcium per day along with at least 400 international units (IU) of vitamin D. It is better to obtain calcium and vitamin D from natural sources, but supplementation is recommended if the intake is not enough. Continuing to obtain appropriate amounts of these minerals throughout life will also help decrease the rate of bone loss.

Lifestyle Choices

Smoking increases the risk of developing osteoporosis. Patients who avoid smoking or quit smoking decrease this risk. Excessive alcohol intake also increases the risk. Consuming alcohol in moderation can be helpful to limit the negative effect of alcohol on bone density.

Exercise

Exercise helps build bone density. Specifically, exercise that is considered high impact is the best. These types of exercise involve weight bearing, being on one's feet, and movement so that the feet repetitively strike the ground. Examples of high-impact exercise are aerobics, running, and basketball. Resistance exercises, such as lifting weights or using exercise bands, can also help keep the bones strong.

If a patient cannot participate in high-impact exercise, any exercise will still be better than none. Using an elliptical machine or walking can be beneficial for bone health as well. Exercises that can increase balance can help prevent falls and decrease the risk of breaking bones, even in patients with osteoporosis.

While it is best for bone health to take in plenty of calcium, avoid smoking, and exercise early in life to build the maximum bone density possible, it is never too late to start an exercise program. Elderly patients with osteoporosis still benefit from starting an impact exercise program. Nursing homes have started to include interactive video games for senior citizens to increase participation in activities. It is too early to determine to what extent these programs will help with increasing bone density and decreasing fracture risk, but increasing the activity level of this group of people is a positive step.

Diagnosis of Osteoporosis

Physicians look for clues of decreasing bone mass during physical examinations. Loss of height or increasing curvature of the spine as patients age can be signs of weakening bones. If a decrease in bone density is suspected, a bone density test, or a dual-energy X-ray absorptiometry (DEXA) scan, should be obtained. This test will compare the density of the patient's bones with that of a young adult of the same sex with peak bone mass, giving a degree of how thin the bones have become. Some guidelines exist that recommend routine screening for osteoporosis at a certain age depending on what other risk factors are present.

Treatment of Osteoporosis

Good nutritional intake, adequate amounts of calcium and vitamin D, and exercise all play a role in helping maintain bone density. Medications also exist that can decrease the rate of bone loss and help limit the risk of fractures. Unfortunately, these medications also have potential side effects, and the benefits of the medications must be weighed against the risks. Discussion with a physician can determine which treatments are appropriate for an individual.

Outdoor Athlete

The *outdoor athlete* is a term applied to any athlete, recreational or professional, who enjoys exercising outside. The term encompasses a range of athletes from those who simply run outdoors to those who brave the elements in extreme outdoor sports. Though a wide range of talents exist among outdoor athletes, they all share one key thing in common: the love of the outdoors.

The outdoor athlete has some special considerations to think about before his or her workout. Since these athletes are not working out in a gym or other controlled environment, they must pay careful attention to their surroundings to ensure a safe, effective workout session.

Climate

Outdoor sports, from kayaking and whitewater rafting to ice climbing and cross-country skiing, cover a wide range of climates. An important consideration for all outdoor athletes is the climate in which they will be active. For those working out in hot, sunny conditions, careful attention must be paid to proper hydration, finding shade when needed, and sun protection. Recent studies have demonstrated that outdoor athletes are at an increased risk of developing skin cancer from excessive exposure to sunlight and thus must be careful and thoughtful about wearing sunscreen during their outdoor activities. At the other end of the spectrum, those choosing sports that are played in cold conditions must also ensure that they have proper hydration in addition to warmth.

The outdoor climate can also exacerbate underlying chronic medical conditions, such as allergies and asthma, in athletes, which may not be an issue during indoor exercise. Outdoor athletes who suffer such symptoms should discuss them with their doctor before continuing outdoor activities.

Severe allergies to plants and insect bites are other special considerations for outdoor athletes. Those who have a known possible anaphylactic reaction should always carry an epinephrine autoinjector with them while outdoors.

Gear

The market for outdoor sports gear has grown tremendously in the past few decades as outdoor and adventure sports become increasingly popular. Each particular outdoor sport has a unique niche for gear. The specifics of equipment for each individual outdoor sport are beyond the scope of this entry, but each outdoor athlete should be familiar with the proper safety and technical equipment for his or her sport.

As mentioned above, outdoor gear for all athletes includes protection from the sun as well as protection from insects and any other environmental factors. All water sport participants should wear life jackets.

Conditioning

Outdoor sports tend to involve uneven surfaces and often recruit the use of muscles that might not be used as much in indoor activities. For these reasons, specific strengthening and conditioning regimens will often help outdoor athletes prepare for and improve their performance in outdoor athletic activities. In addition, many outdoor sports, including climbing, skiing, snowboarding, and mountain biking, take place at higher altitudes. Each athlete will have to acclimate to these higher altitudes before reaching peak performance potential.

Specific conditioning regimens for each outdoor activity are also beyond the scope of this entry. Many outdoor magazines, websites, and personal trainers can offer tips for training and conditioning for specific outdoor activities.

Ovary, Absence of One

The ovaries are part of the female reproductive system. There are normally two, one on each side of a woman's lower pelvis. The ovaries are responsible for producing the eggs that are released during a female's menstrual cycle as well as the production of the female sex hormones, estrogen and progesterone. Fertilization of the egg by a sperm will result in pregnancy.

Congenital absence of one ovary is rare and is usually associated with other abnormalities of the genitourinary tract. The genitourinary system includes organs involved in reproduction as well as urination. This system includes the kidneys, ureter, bladder, fallopian tube, uterus, and vagina. More commonly, women suffer the loss of an ovary due to a medical or surgical condition. An *oophorectomy* is the surgical removal of one or both of the ovaries. This may be necessary because of, but not limited to, the following conditions: symptomatic ovarian cysts unresponsive to conservative treatment, ovarian cancer, endometriosis (endometrial tissue occurring outside its normal location), ovarian abscess or infection, ovarian torsion (where the ovary gets twisted, loses blood supply, and dies), or known increased risk of ovarian caner due to a genetic mutation. Concern has been raised that participation in sports may pose a risk to those with one ovary, the concern being that if they lose the second ovary, it will render them infertile as well as menopausal.

In terms of sports participation, the absence of one ovary does not represent any contraindication. The ovaries are well protected within the lower pelvic region, and the risk of injury to the remaining ovary is minimal. The ovaries lie on the lateral wall of the pelvis on either side of a woman's uterus and are held in place by several different ligaments. This position places them deep within the pelvis, where they are relatively immobile and safe from outside forces or trauma. Therefore, athletes are able to participate in any type of sport and do not require any special protective measures or equipment even with the absence of one ovary.

Overpronating Foot

The biomechanics of gait are important in many conditions related to the foot, ankle, lower leg, knee, hip, and lower back. The most common abnormality involves the pronating foot. Overpronation is the overrotation of the foot toward the midline of the body that results in the relative flattening of the medial arch.

A small degree of pronation is normal—it helps absorb the shock while walking and running. Pronation is more commonly found than supination in the general population. An overpronating foot describes an abnormality where the foot spends a majority of the gait cycle in pronation and with weight bearing in general.

Gait Cycle

A review of the gait cycle is helpful in understanding this concept of overpronation and its contribution to injury. The gait cycle consists of four phases: (1) heel strike, (2) midstance, (3) toe-off, and (4) swing.

During the first two phases, the heel strikes the ground with the foot inverted or supinated (landing on the outside of the heel), and the ankle is dorsiflexed (the foot pointed up). This is followed by the foot pronating (rolling toward the inside) as the body weight is loaded onto the foot in midstance. During the last two phases, the foot supinates again as the weight shifts onto the toes, allowing the foot to propel and swing forward. During the cycle, the weight starts at the outer side of the heel and ends on the inside part of the front of the foot as one pushes off. Thus, pronation is a normal part of the gait cycle.

It is a simplification to refer to the pronating motion of the foot as "rolling inward," because it is a three-dimensional movement involving the foot turning away and the leg, knee, and hips rotating inward. Because of this kinetic chain, a small degree of overpronation can contribute to pain not just in the foot or ankle but also up the leg (medial tibial stress syndrome, or "shin splint"; posterior tibialis tendinitis, which causes pain along the inside of the ankle and leg), the knee (patellofemoral pain syndrome, or "kneecap maltracking"; pes anserine bursitis, which causes pain on the inside of the knee), and hip (iliotibial band syndrome, causing pain on the outside of the knee; trochanteric bursitis, causing pain on the outside of the hip).

Foot Anatomy

The arch of the foot is supported by three arches: (1) medial longitudinal, (2) lateral longitudinal, and (3) transverse midfoot arches. Of the three, pronation is the most closely associated with lowering of the medial longitudinal arch. You can either be born with a low medial longitudinal arch or acquire it with age or weight gain.

The posterior tibialis tendon provides additional support for the medial arch as it comes around the posteroinferior medial malleolus and makes its multiple attachments on the navicular, cuneiforms, and bases of the second, third, and fourth metatarsals. Because it helps control pronation, tendinitis is a common result of an overpronating foot.

Another important structure in the arch is the navicular bone, which interfaces with the talus bone, which sits at the base of the ankle, and the first, second, and third metatarsals or "foot bones." Situated at the "roof" of the arch, the navicular plays an important role, accepting and transmitting much of the foot's stress.

A common contributor to overpronation is pes planus, or "flat feet." Pes planus can be rigid or flexible, with the latter being more common. With a flexible pes planus, a flattening of the arch is noted only when standing or weight bearing. It is thus important to remember to always examine a patient's arch while the patient is standing. Pes planus, like overpronation, is not always pathological, as it is the normal foot shape in infants and in up to 20% of adults.

The persistence of pes planus in non–weight-bearing positions suggests a rigid pes planus. If this is found in a patient with pain, then an investigation into the causes, such as tarsal coalition or fusion of ankle bones, is done.

Physical Examination

The pronating foot in and of itself does not cause symptoms. Many people have pes planus and mild to moderate pronation but are completely without complaints or pain.

However, various structures, starting from the foot and moving up the kinetic chain, are subject to abnormal stresses with excessive pronation during the gait cycle. The symptoms vary depending on the condition associated with the pronating foot.

Common pronation diagnoses are listed below.

Foot and Ankle

- Plantar fasciitis
- Achilles tendinitis
- Posterior tibial tendinitis
- Tarsal tunnel syndrome
- Sinus tarsi syndrome
- Neuroma
- Metatarsalgia
- Hallux valgus
- Hammertoes

Lower Leg and Knee

- Medial tibial stress syndrome
- Patellofemoral syndrome
- Iliotibial band syndrome

As a result, physical examination of any patient presenting with pain in the lower back, hip, knee, leg, and foot or ankle should include an examination of the foot.

The foot examination consists of inspection, palpation, range of motion, and provocative tests. Inspection of the foot requires observing the foot from multiple views, including anterior (front), medial (inside), lateral (outside), and posterior (behind). The arch is best evaluated from the medial side and by comparing non–weight bearing with weight bearing to determine whether the flat foot is flexible or rigid. Looking from behind while the patient is standing also provides information about the biomechanics of the foot. In a patient with an acquired flat foot from posterior tibial tendon dysfunction, the calcaneus will be noted to have increased valgus. Another finding is the "too many toes sign," where more than two visible toes are seen lateral to the calcaneus when looking from behind the patient.

The patient should also be observed standing on his or her toes to see if the heels move into a normal varus position. Those with pes planus may have difficulty rising up on their toes on the affected side.

Because the conditions associated with the pronating foot are related to the repetitive stresses during walking or running, observing gait should also be included in the exam, analyzing the foot during the heel strike, midstance, toe-off, and swing phases.

Some specialty centers use video analysis or pressure pad recording to further evaluate and quantify excessive pronation and its consequences.

Treatment

As mentioned earlier, the presence of pes planus or a pronating foot does not require treatment if there are no problems (asymptomatic). If the pronating foot appears to be related to the patient's symptoms, correction of this can be useful, especially with chronic or recurrent conditions.

Mechanical support with a motion control shoe or over-the-counter orthotics are the first line of treatments for most mechanical foot problems involving overpronation. Most major shoe manufacturers offer motion control shoes to correct overpronation. The major feature of these shoes is a large and firm medial bar to prevent this excessive movement. Each shoe manufacturer may have a different name for this feature, but the key is that the patient understands its importance. Motion control shoes typically do not feel initially as comfortable as a cushioning shoe, so the novice athlete may gravitate toward a shoe that can actually aggravate his or her injury. This motion control feature, as with any component of the shoe, will break down with age and use, so the athlete needs to regularly replace shoes even if they appear in good condition superficially.

Over-the-counter orthotics may help up to 90% of patients. For those patients with unique anatomic needs, such as significant differences in pronation in one foot versus the other, custom orthotics should be considered.

Specific stretching and strengthening exercises can be helpful as well. A tight Achilles tendon is often associated with higher rates of symptomatic pes planus conditions. Therefore, a vigorous program of heel cord stretches is often helpful. Strengthening of the posterior tibialis muscle and tendon may be helpful since dysfunction or weakness of this muscle reduces support for the arch.

The rehabilitation program must also address other conditions associated with the pronating foot. A formal physical therapy program should be considered in those with persistent symptoms after attempting a trial of home exercises. Most conditions can be managed by a primary care physician, with orthopedic or podiatry referrals reserved for those who fail conservative management. Depending on the condition, surgery may be considered, as with hallux valgus that has failed conservative management.

Surgical management of an overpronating foot is almost never needed. The rare cases usually involve a rigid pes planus from a tarsal coalition that contributes to pain and limited motion.

Oversupinating Foot

During walking and running, foot and ankle motion involves both pronation and supination. Understanding these foot biomechanics allows more precise prevention of injuries. This entry will describe the supination part of walking and running and how inappropriate supination can be assessed and managed.

Pronation Versus Supination

Pronation is a complex combination of movements that can be roughly described as a "rolling in" of the foot and ankle as the foot first touches the ground in a step. It is important for shock absorption and adapting to terrain changes. After the initial pronation, as a person's body continues to move forward over the foot during a stride, that foot and ankle need to "roll out," or supinate, for the foot to change from energy absorption of the foot strike to energy transfer of the push-off phase. During supination, the bones of the foot become more tightly compacted, so that when the leg muscles provide force, it is transferred efficiently to the ground for a fast, powerful stride. Without supination, the foot bones remain loose, and the ligaments trying to hold them together are susceptible to injury as the forces are transmitted not through the bones that are made for this task but through the ligaments, which may stretch and tear.

These actions can be seen by observing your own foot motions. While standing in stockings or on bare feet, roll your feet inward so that much of your weight is on the inner half of both feet. Then roll your feet out, so that most of the weight is on the outer half of your feet. Notice how much hip and knee movements are connected with these actions. If you find that you stand naturally with much of your weight on the inner half of your foot, you may be an overpronator. If you tend to stand with much of your weight on the outer half of your foot, and/or you find you are unable to roll inward, you are probably an oversupinator. It is the inability to pronate that is of most concern. Oversupinators are less common than either overpronators or persons with neutral foot mechanics.

Arch Height

There is a correlation between pronation/supination and the height of the arches. When a person with a low arch walks with wet bare feet at the swimming pool, he or she will leave a wide, almost oval footprint. A person with a high arch will usually leave a narrow footprint, because very little of the inner half of the footever touches the ground.

Many persons who overpronate have low or fallen arches. Virtually all persons who oversupinate have high rigid arches. However, the converse, that most persons with high arches are oversupinators, is not true. Some persons with high arches are able to pronate during the initial phase of a stride and would therefore not be considered oversupinators.

Foot Biomechanics

Ideal foot biomechanics would involve not only being able to stand with equal weight on the big and little toes but also having the ability to roll the foot inward so that the weight is more on the inner part. With ideal foot mechanics, the forces of running are transmitted efficiently to and from the pelvis. Many excellent athletes have less than perfect foot mechanics, and while they may be very successful, they are predisposed to certain injuries.

Lack of Shock Absorption

Oversupinators are unable to pronate and have more pressure on the outer half of the foot throughout the gait cycle. Thus, they are prone to skin and toe joint problems on the outer half of the foot. They also miss the shock absorption features of a more balanced foot mechanics, and this is where most problems arise. The lower leg forces of walking or running are not transmitted up to the hip and pelvis. Knee pain, especially lateral knee pain, may occur. The risk of stress fractures is higher. Oversupinators must pay attention to shin or foot pain that develops when running mileage is increased. Stress fractures that are not allowed to heal through activity modification can be very problematic.

Injury Prevention

To offset this lack of natural shock absorption, it is important to use other mechanisms for shock absorption. Oversupinators should run on soft surfaces as much as possible and work on a smooth technique. Attention to maintaining balanced strength and flexibility of hip and core muscle is critical. Cushioned orthotics, which will shift some of the pressure to the inner part of the feet, are often helpful.

Wearing proper shoes is important. Oversupinators should not wear motion control shoes that limit pronation but, on the contrary, should have flexible, yet cushioned shoes that allow as much pronation as possible. The good news is that these shoes are often light and lively and fun to run in. The shoes should be replaced after a few hundred miles, as shock absorption wears out.

Cyclists may need canting of shoes or pedals, again to distribute the pressures across the foot.

Knowing which athletes are oversupinators will allow adjustments to reduce the injuries most common with this type of foot mechanics. Some of the measures are opposite to what is recommended for overpronators.

Overtraining

Commonly called *staleness* or *burnout,* overtraining syndrome is a potentially serious medical illness experienced by endurance athletes. It is characterized by a decline in athletic performance, fatigue, and emotional changes despite intense physical training. The physiological changes most often seen are reduced exercise time before exhaustion, reduced maximum performance (decreased lactate production and increased anaerobic threshold), and decrease in the maximum heart rate. In females, menstrual changes can be seen. Psychologically, athletes have complaints similar to those seen in depression, including severe fatigue, disturbed sleep, soreness and heaviness of muscles, concentration problems, decreased appetite, generalized depressed mood, and, in males, decreased sexual drive. The etiology is related to an imbalance between training and recovery and is likely multifactorial. The overall prevalence is not known, but it is more commonly seen in males and in athletes trained in endurance sports, such as running, cycling, and multisport events.

Causes

A significant amount of effort and resources have been invested in determining the etiology of overtraining syndrome. Unfortunately, the definitive cause has not been elucidated. We know that repeated intense physical training sessions stress the body and lead to tissue damage. The stress and tissue damage can be reversed with adequate periods of recovery and are often purposely incorporated into training programs because of their beneficial effects. The body has an impressive ability to adapt and regenerate after these episodes of intense exercise, and on recovery, the body has the ability to physiologically adapt to endure higher stress during future training. Unfortunately, for intensely trained individuals, there is a fine line that can be crossed from hard training with adequate recovery to training with inadequate recovery. If this line is crossed, it is called overreaching and is characterized by fatigue and decreased performance. Overreaching can be reversed by a short period of rest for up to 1 to 2 weeks.

Overtraining syndrome is at the extreme end of the continuum, including overreaching. The best evidence suggests that overtraining syndrome arises when there is a prolonged or significant imbalance in this training and recovery interaction. Despite continuing the same level of exercise, or often increased levels of exercise, performance measures decrease. Experts believe that during overtraining syndrome, there is an alteration of the normal chemical messages sent by the brain and glands to the body that signals tissue breakdown rather than the normal tissue regeneration and repair. Therefore, no matter how intense the training is, the body cannot recover and perform at its optimal level. Many athletes misinterpret these early signals, and rather than back off and rest, they further intensify their training. The structures believed to be the most involved are the hypothalamus (brain), pituitary gland (brain), and endocrine glands (which secrete chemicals and hormones). The chemical messengers that have been implicated in this syndrome most often include serotonin, tryptophan, cortisol, adrenaline, growth hormone, and testosterone.

Diagnosis

Diagnosis of overtraining syndrome is often difficult and can be delayed due to the lack of specific criteria and testing currently available. This diagnosis is made clinically and relies on excluding the many other overlapping diagnoses. Evaluation should start with a complete medical history and physical examination by a trained and qualified sports medicine provider. These exams are vital for the physician when making the diagnosis and excluding other causes for the athlete's physical and psychological complaints. Although nonspecific, laboratory evaluations including a complete blood count (for infection and anemia), chemical evaluation (which includes sodium, potassium, kidney function), thyroid studies, iron studies including ferritin (low ferritin represents low body stores of iron and may lead to decreased performance), and tests for infection (mononucleosis, human immunodeficiency virus [HIV] infection, hepatitis) may be performed. Other, more specialized laboratory testing can be ordered based on the individual situation and physician preferences.

Although the hallmark of this diagnosis is decreased performance, with the wide variability in course conditions, competition, and weather, increasing race times are not specific enough for diagnosis of overtraining syndrome. Therefore, currently the best measurement is decreased time to exhaustion and decreased $\dot{V}O_2max$ (measure of the maximum amount of oxygen consumed during activity) during sport-specific exercise, such as time trials or graded exercise testing. Physicians may also order other physiological testing, such as lactate testing (blood tests with exercise) and respiratory testing. A simple, yet nonspecific, physiological test can also be performed at home. Morning pulse readings, taken before arising in the morning, that show 3 to 5 beats elevated beyond an individual normal can be a signal of inadequate recovery, overreaching, or overtraining syndrome.

Treatment and Prevention

Once other causes have been excluded and the diagnosis of overtraining syndrome has been made, the cornerstone of treatment is rest. This treatment plan is often difficult for highly driven athletes to accept, and a great amount of empathy is required when discussing the treatment and return to participation. The length of time required before a structured training program is restarted is variable and ranges from 6 weeks to many months. Athletes will often be more compliant with the prolonged treatment program if light cross-training activities are prescribed. It should be noted that these physical activities should be in a different activity from the athlete's main sport, and all efforts should be focused on maintaining these activities at a nonintense level.

Before the athlete returns to a training program, evaluation of his or her previous level of activity, recovery time, diet, and psychological well-being should be done. Dietary consultation is beneficial for athletes to review their specific individual needs. Consultation with a sports psychologist, both during recovery and during return to sport, can often be useful for the athlete to develop coping skills, reduce stress, and improve mental training skills such as visualization. Furthermore, some athletes will require and respond to the use of antidepressant medications to treat their mood disturbances. Use of these medications is not universally necessary and should be based on a case-by-case evaluation of need.

The best treatment for overreaching and overtraining syndrome is certainly prevention. It is important for athletes and coaches to individualize training programs for all athletes, since all members of the same team or club will invariably have different genetic abilities, base volume of training, and motivation. One of the best keys to prevention is for the athletes to keep a training log. This should include not only daily volume and intensity but also dietary information, major life stressors, and, of significant importance, perceived exertion for each workout. The perceived exertion for each workout may clue the athlete in to a subtle change in training and recovery that may be necessary to prevent injury or overtraining. In the event of a problem, this training log can be beneficial for the sports medicine physician in making a diagnosis and prescribing appropriate treatment.

Pain Management in Sports Medicine

For many athletes, pain is an inherent pitfall associated with sports participation. While exertion-related, generalized soreness is a common, self-resolving, and expected result, persistent and localized pain can be an indicator of a more serious underlying injury. Ignoring or masking such signs, which potentially can occur when self-medicating with over-the-counter analgesics, can delay proper diagnosis, lead to worsening of the underlying condition, and ultimately postpone an athlete's return to play. Sports medicine physicians and team members can play a vital role in assessing an athlete's pain and assist in guiding the athlete through a multitude of pharmacologic and nonpharmacologic treatment options, with the ultimate goal of facilitating early functional mobilization and expediting injury rehabilitation.

Pharmacologic Considerations

Acetaminophen

Acetaminophen is frequently suggested as the drug of choice for musculoskeletal pain. Its mechanism of action is not clearly understood. In healthy adults with limb pain, the recommended dosing schedule of 1,000 milligrams (mg) four times a day has been shown in a prospective, double-blind, randomized controlled trial to provide an analgesic effect similar to that of nonsteroidal anti-inflammatory drugs (NSAIDs), with, however, a low adverse effect profile.

Athletes who consume alcohol, have liver conditions, or take additional medications that potentially could cause liver injury should exercise caution when taking acetaminophen. Overdoses can lead to irreversible liver injury and/or death.

Suboptimal pain control with acetaminophen is typically due to medication underdosing. Evidence-based working groups on pain management recommend using acetaminophen as first-line therapy for acute and chronic musculoskeletal pain.

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs are commonly used for the treatment of a wide variety of sports medicine conditions, including pain, soft tissue injuries, fever, and sprains/strains. While the role of NSAIDs in treating pain and inflammation related to rheumatoid arthritis (RA) and osteoarthritis (OA) is better established, the beneficial effects of NSAIDs for common musculoskeletal injuries remain debatable and somewhat inconclusive. Deciding whether or not to use this class of medications should take into consideration underlying medical conditions due to their higher risk profile. Side effects such as exacerbation of asthma and gastrointestinal, kidney, and cardiovascular conditions may be attributed to NSAID use.

The mechanism of action is categorized based on selective versus nonselective blockade of cyclooxygenase. Traditional NSAIDs (e.g., ibuprofen, naproxen, diclofenac, meloxicam, piroxicam) nonselectively block cyclooxygenase-1 and -2

(COX-1 and COX-2, respectively), which typically catalyze the transformation of arachidonic acid to prostaglandin. Blockade of this cyclooxygenase pathway leads to a decreased inflammatory response and ultimately decreased pain. Newer COX-2–specific inhibitors (e.g., celecoxib, valdecoxib) were developed with the goal of sparing gastrointestinal bleeding largely due to the antiplatelet effect of COX-1 inhibition of thromboxane A2. However, thromboxane A2 when unopposed by prostacyclin causes vasoconstriction and platelet aggregation in vascular endothelial cells. This theoretically can lead to clot formation and an increase in cardiovascular adverse events. Several COX-2–specific inhibitors have been removed from the market in recent years due to these cardiovascular concerns; those remaining carry black box warnings regarding their increased cardiovascular risk—potentially fatal ischemic heart disease and stroke.

NSAIDs in sports medicine can be delivered as topical, oral, intramuscular, or intravenous preparations. While the route of delivery is often dictated by the underlying injury or medical condition, in most circumstances a trial of oral NSAIDs prior to more aggressive pain management interventions is considered acceptable practice. Conditions where NSAID use is not generally indicated because they may complicate healing include complete fractures and chronic tendinopathies associated with impingement.

Opioids

Tramadol possesses unique analgesic qualities by acting as a weak, atypical central opioid agonist. Analgesia is produced by binding to mu opioid receptors and weakly inhibiting norepinephrine/serotonin reuptake. Tramadol is proposed to be a preferred choice among opioids due to its superior safety profile and decreased abuse potential when compared with other, stronger opioids. Neurotoxicity, however, is a concern with overdosing. A fixed-dose combination of acetaminophen (325 mg) plus tramadol (37.5 mg) has been shown to deliver better efficacy when compared with either agent alone. Additionally, this combination is better tolerated than tramadol alone or a fixed-dose combination of acetaminophen plus codeine.

Codeine is a prodrug which relies on cytochrome P450 metabolism to morphine for analgesic effect. Ten percent of Caucasian patients are cytochrome P450 deficient, which may explain why it has poor efficacy in certain patients. Codeine is typically available in fixed-dose combination with acetaminophen.

Propoxyphene, like codeine, is typically used in fixed-dose combination with acetaminophen. Like codeine, it has been found to have poor efficacy as an analgesic and to have significant adverse effects.

Hydrocodone is generally considered the most potent oral narcotic used in the treatment of acute musculoskeletal pain. Oxycodone, with or without acetaminophen, appears to have an analgesic effect comparable with that of intramuscular morphine and NSAIDs. Side effects of narcotics include constipation, cardiorespiratory depression, sedation, nausea, and pruritus. Tolerance and physical dependence can occur with chronic use; however, this is generally not a concern in the treatment of acute pain.

Antidepressants

Tricyclic antidepressants (TCAs), in particular amitryptiline, are useful in the treatment of neuropathic pain, low back pain (LBP), and other chronic musculoskeletal pain conditions. *Serotonin and noradrenaline reuptake inhibitors* (e.g., venlafaxine) have similar efficacy to TCAs in providing relief from chronic musculoskeletal pain. *Serotonin selective reuptake inhibitors,* however, have not been promising with regard to pain reduction in musculoskeletal conditions.

Injection Therapy

Injections can play an important role in reducing pain associated with a variety of musculoskeletal injuries. Often, such injections allow an athlete to restore functional range of motion, complete physical therapy, and ultimately regain the strength necessary to escape the cycle of inflammation, pain, and muscular atrophy characteristic of many overuse injuries.

Corticosteroid injections have been used since the 1950s for palliative treatment of inflamed joints, tendon sheaths, and bursae. Common sites of injection include (but aren't limited to) the acromioclavicular joint, intraarticular shoulder, subacromial space, lateral epicondyle of the elbow, greater trochanter of the femur, and intraarticular knee. Care must be taken to limit injections into a weight-bearing joint to no more than three per year. Also, with the understanding that certain tendon injuries have a degenerative (tendinosis/tendinopathy) origin rather than an inflammatory one, the utility of corticosteroid injections for classic tendinitis conditions such as Achilles tendinitis and lateral epicondylitis (tennis elbow) must be reconsidered as corticosteroids may have a deleterious effect in tendinopathies by masking pain that typically results from stimulation of pain receptors by chemicals released from the degrading tissue.

Viscosupplementation, a treatment that involves the injection of high–molecular weight hyaluronic acid into an osteoarthritic joint, has become an option for older athletes who have failed to benefit from conservative pain treatment. Hyaluronic acid is a substance naturally found in synovial fluid and cartilage matrix. It serves as a lubricant, shock absorber, and anti-inflammatory in joints, where it is synthesized by chondrocytes and synovial cells. Treatment cycles typically involve three injections, and cycles can be repeated after 6 months—typically the minimal period for clinical benefit. Although FDA (Food and Drug Administration) approval of hyaluronans is currently limited to the knee, it holds promise as a treatment option for OA of the shoulder, the hip, and several hand/foot joints.

Nonpharmacologic Considerations

Physical activity and exercise have been shown to reduce pain and improve function, particularly in patients with OA, disseminated pain, and chronic LBP. Strategies to encourage adherence are essential to the success of a physical exercise program.

Physical therapy, including manipulation, range of motion, modalities, and massage, can play a significant role in reducing pain and facilitating functional mobilization. Ultrasound is often used as an adjuvant therapy to reduce pain and inflammation in various musculoskeletal conditions. Thermotherapy (e.g., heat wrap therapy for subacute LBP, cold packs for decreasing swelling in knee OA) is an effective, nonpharmacologic alternative for various musculoskeletal injuries. Massage has been effective for LBP relief, particularly when combined with exercise and education.

Transcutaneous electrical nerve stimulation (TENS) is a physical therapy modality that reduces pain by stimulating the peripheral nerves electrically through electrodes placed on the skin surface. TENS has an adjuvant role in the treatment of localized musculoskeletal pain encountered in knee OA, chronic LBP, and RA.

Accupuncture is an effective adjuvant therapy for improving pain and function in the following musculoskeletal conditions: knee OA, chronic LBP and neck pain, shoulder pain, lateral epicondylitis, and RA.

Conclusion

Athletes encounter pain as a result of training, overuse, and traumatic injuries. Many of these injuries can be self-resolving. Athletes commonly use over-the-counter analgesics such as acetaminophen or NSAIDs as the initial treatment of pain and injury. When self-medicating, accurate knowledge regarding effective dosing ranges, intervals, and duration can lead to optimal pain control and avoidance of medication side effects. In some instances, more potent analgesics such as opioids will be necessary; however, the expectation prior to prescribing these agents is that an initial short-course trial of nonnarcotic medication has been attempted. More aggressive therapies such as joint injections depend on the injury's location, the pain severity, and the athlete's level of competition.

The inclusion of nonpharmacologic therapies as part of a multimodal treatment plan is essential to restoring functional mobilization, expediting rehabilitation, and returning athletes as quickly as possible to their sport. The importance of early physical activity in injury rehabilitation cannot be emphasized enough; it remains the cornerstone of a musculoskeletal treatment plan. Involving a sports medicine team comprising physicians, therapists, and additional health professionals can provide an athlete with the tools and resources necessary to return to sports with minimal pain and functional limitation.

Pancreatic Injury

Athletic injuries to the pancreas are relatively rare and most often occur due to trauma to the upper abdomen. The pancreas can also become inflamed (pancreatitis) due to atraumatic causes, which are also worthy of consideration.

Anatomy and Function

The pancreas is an internal organ located in the upper left side of the abdomen. It has a relatively protected position due to the rib cage and spine surrounding it. Pancreatic functions include the production of hormones such as insulin and glucagon (involved in glucose homeostasis) and of pancreatic enzymes to help digest food. It is directly connected to the duodenum (small bowel) and the gall bladder and liver via the bile duct.

Pathology

Pancreatitis that is not due to trauma results from direct digestive enzyme release from injured cells. These pancreatic digestive enzymes cause inflammation in the pancreas and the surrounding region. Involvement of the pancreas can progress with lack of oxygen and obstruction of the pancreatic cells.

Epidemiology

Traumatic injury to the pancreas is unusual and seldom reported. Inflammation of the pancreas, or pancreatitis, has many causes other than traumatic injury. Atraumatic etiologies of acute pancreatitis (predominantly in adults) include

- Gallstones
- Insect or scorpion bites
- Alcohol use
- Procedures such as endoscopic retrograde cholangio-pancreatogram (ERCP)
- Hypercalcemia
- Viral infections
- Hyperlipidemia
- Various drugs
- Hereditary factors

The pancreas is injured in 1% to 2% of abdominal trauma cases, with 10% of abdominal traumas occurring in sports in one historical series in Scandinavia (reported in D. Bergqvist, H. Hedelin, G. Karlsson, B. Lindblad, and T. Mätzsch's 1981 article "Abdominal Trauma During Thirty Years"). It has been suggested that the jarring motions of repetitive activity such as running might result in pancreatic injury, and a low oxygen supply–induced pancreatic pathology has been proposed in the setting of strenuous exercise. Case reports of running-induced diarrhea and other gastrointestinal problems suggest that these disorders result from exercise-related low blood supply to the abdominal organs. Three cases of distance runners who developed an acute abdominal crisis requiring removal of the bowel have been reported. Evidence exists of pancreatitis occurring in surgery patients who underwent periods of low oxygen and blood supply. This supports the conclusion that low oxygen may play a role in the initiation of acute pancreatitis.

Contact/collision sports (e.g., soccer, football, rugby, hockey, karate) seem to have a higher incidence of traumatic pancreatic injury, as do higher-velocity sports (e.g., skiing and snowboarding, cycling) or sports that can result in a fall (e.g., equestrian sports or rock climbing) or being struck by an object (e.g., baseball, lacrosse, track-and-field events).

Biomechanics

Impact mechanics are important in determining the likelihood of injury. An object or body part (e.g., a foot or knee) striking a localized abdominal segment, such as the upper left quadrant, with a large deceleration or acceleration is the most common mechanism of injury. For instance, a bicycle fall where the handlebar twists and "spears" a child may be the presenting history. In this scenario, the handlebar compresses the pancreas against the spine, resulting in a pancreatic laceration. Body type may influence the risk of injury, as leaner individuals have greater susceptibility because of less fatty abdominal tissue to protect their internal organs from trauma. Acute pancreatitis in the pediatric population primarily results from direct traumatic injury, perhaps in part because most children have such a body type.

The duodenum (small bowel) is very close to the pancreas and is also commonly injured through localized trauma such as the impact from a bicycle handlebar. Bowel perforation (a hole in the bowel) is an important potential coexisting event and also should be included in the initial differential diagnosis as duodenal perforation can mimic acute pancreatitis in many ways.

Clinical Presentation

As with other internal organs, there is often a subtle presentation and minimal physical signs. A high index of suspicion is warranted as catastrophic outcomes (i.e., death) are possible if the symptoms go unrecognized. Patients can develop nausea, vomiting, and abdominal pain up to 48 hours after injury. Typically, the abdominal pain radiates to the back and is central in original localization.

The physical exam technique should follow the traditional medical model of inspection, palpation, percussion, and auscultation. There may be bruising evident in the area of injury on inspection. Lower rib fractures may also be present, hence tenderness to palpation in this location should alert one to potential underlying injury. Serial examination (repeating the exam periodically) of individuals suspected to be at risk for a traumatic event involving the pancreas is necessary. Abdominal tenderness localized centrally, in the left upper quadrant, or more diffuse, increases the suspicion. Rebound tenderness, where pain is provoked by releasing pressure from palpation of the abdomen, is less common. Tapping the abdomen's surface (percussion) can help determine the presence of peritonitis, with an increased note of resonance when intra-abdominal air is present. Auscultation with a stethoscope can elicit bowel sounds unless the bowel has stopped working.

It should be remembered that severe pancreatic contusions and lacerations from a direct injury may confound attempts at clinical diagnosis, as patients often demonstrate minimal blood loss and only subtle signs and symptoms are elucidated. The most common presenting symptoms and signs of trauma to the pancreas are abdominal pain (78.9%; either diffuse or upper abdomen), bowel sounds at initial contact (45.5%), abdominal tenderness (79.5%; most often diffuse), rebound tenderness (9%), and abdominal wall bruising (34.6%).

Investigation

Laboratory blood tests showing elevated levels of the pancreatic enzymes amylase and lipase can alert one to an underlying pancreatic injury; however, the lack of elevation in these blood enzyme levels *does not* rule out pancreatic injury. Serial monitoring may be most appropriate, as elevations in amylase may not occur for hours after injury. Serial monitoring of amylase levels has been suggested in several studies as a means of increasing sensitivity to pancreatic injury. The presence of elevated amylase levels after blunt pancreatic trauma is time dependent, and the elevated serum amylase level may be found in the majority of patients when a specimen is drawn more than 3 hours after injury.

Diagnostic peritoneal lavage (DPL) can improve the ability to diagnose intra-abdominal trauma, and if the criterion of >100,000 erythrocytes (red blood corpuscles) per cubic millimeter is used, then sensitivity is high (96%–100%). DPL is now performed less frequently, perhaps due to the emergence and availability of imaging. It is often perceived as invasive, however, and has a <1% complication rate.

Imaging

Computed tomography (CT) is the most useful imaging modality, though ultrasound is also useful in some circumstances. An ERCP or magnetic resonance retrograde choleopancreatogram (MRCP) may be better for visualizing the pancreatic duct. Contrast-enhanced multislice CT has been regarded as an efficient screening modality for pancreatic trauma.

Focused sonography for abdominal trauma (FAST) is an accepted method for abdominal bleeding screening in athletes with blunt abdominal trauma. Many trauma centers do not have the trained personnel or equipment necessary to use diagnostic abdominal sonography. It has been suggested that the combined DPL and CT screening modalities are a more cost-effective and sensitive pancreatic injury detection method than FAST.

Management

Management decisions have little evidence base due to the rarity of injury to this organ. There are several isolated case reports in the literature. High morbidity (42%) and mortality (16.6%) rates have been reported sometimes when the pancreas is injured in a sports setting. This mortality risk may be related to acute pancreatic duct injury; however, morbidity is associated more with complications.

A common method of describing the severity of pancreatic injury is the Pancreatic Organ Injury Scale (POIS), designed by the American Association for the Surgery of Trauma. Pancreatic injury–related morbidity and mortality are most closely associated with POIS Classes III through V, which involve pancreatic ductal injury.

Treatment is principally supportive, including intravenous hydration, management of electrolyte and metabolic consequences, and pain control. Resting the digestive system and providing nutrition by methods that don't use the gut are accepted.

Complications

Pseudocyst formation is the most frequent complication of acute atraumatic and traumatic pancreatitis. A pseudocyst is a large collection of fluid without a true lining. The clinical course of a traumatic pseudocyst is often lengthy and frequently complicated. Resting the gut, pseudocyst drainage, and procedures to correct the complications of a pseudocyst or pancreatic fistula are required in many cases. Management options include observation to see if the pseudocyst resolves with time, drainage by interventional radiology, and general surgical drainage.

Return to Sports

There are currently no established return-to-play guidelines published in the literature. The physician should rely on the principles of abdominal organ and soft tissue healing to allow anatomic and functional healing. The resolution of all active processes should occur before the athlete is allowed to return to sports in a stepwise fashion. The progress toward return to sports activity typically involves aerobic conditioning, then strengthening, skills practice, contact practice, and scrimmage, followed by competitive return to play if the previous steps have been successfully completed without a recurrence of symptoms.

Panner Disease

Panner disease was initially described in 1927 by Dr. Hans Jessen Panner, a radiologist, to explain lateral elbow pain in young patients. This diagnosis is unique to the skeletally immature athlete. *Skeletally immature* refers to those who still have the potential for growth of their bones. Panner disease is similar to Legg-Calvé-Perthes disease (often referred to as Perthes disease), which can occur in children's hips and is a necrosis or breakdown of the femoral head, the end of the thighbone that fits into a person's hip socket.

Anatomy

Panner disease is an osteochondrosis of the capitellum involving the entire ossific nucleus (the growth center). *Osteochondrosis* refers to the necrosis or breakdown of growth centers in the pediatric or skeletally immature patient followed by regeneration or healing. The growth centers are important because they are responsible for growth of the bones, in this case the growth of the humerus, or long bone of the upper arm. The growth centers at the end of the humerus are responsible for 20% of the final limb length of the upper arm. Thus, injury can result in abnormal growth and decreased length of the arm. The capitellum is the lateral humeral condyle, which is the rounded portion at the end of the humerus. The capitellum articulates with the radial head (one of the forearm bones). The articulation of the capitellum and the radius contributes to movement at the elbow. Simply stated, Panner disease involves the breakdown and then healing of the growth center at the end of the humerus on the lateral (outside) portion. It is the most common cause of chronic lateral elbow pain in athletes under age 10.

Panner disease should be differentiated from osteochondritis dissecans (OCD) of the capitellum, which occurs in an older pediatric population, usually ages 11 to 16, and only involves a portion of the growth center. It is also not characterized by the classic regeneration and recalcification seen in Panner disease. It has the potential for more long-term complications, unlike Panner disease, which is generally a self-limiting condition.

Causes

With increasing participation and an emphasis on excellence at a young age, injuries are becoming more prevalent in the younger population. Often, kids are now participating year-round in only one sport. This does not allow for any rest time and results in an increased incidence of injuries, especially the overuse-type injuries. As described above, the presence of open growth plates represents a unique situation and opportunity for different injuries to occur compared with those seen in the adult or skeletally mature population.

Panner disease is one example of an overuse-type injury. It occurs due to repetitive axial loading or lateral compression of the elbow during activities such as gymnastics and baseball throwing, respectively. During pitching, especially the early- and late-cocking as well as early-acceleration phases, the lateral portion of the elbow experiences large compressive forces. With repetition, these forces can lead to abnormalities in the radiocapitellar articulation, such as Panner disease, in the young athlete. Gymnasts spend a lot of time using their upper extremities as weight-bearing joints. It is thought that this repetitive axial loading is responsible for injury to the lateral elbow growth center in these athletes.

Signs and Symptoms

Panner disease is typically seen in the younger athlete, ages 5 to 10, and more commonly in boys.

Children usually present with dull, achy lateral elbow pain and subjective stiffness, most always involving the dominant upper extremity. Throwing athletes will complain of pain with throwing or a decrease in their throwing speed. The pain usually resolves with rest. It can be due to an acute traumatic event; however, as mentioned above, it is more commonly due to overuse. On physical exam, patients may have decreased ability to fully extend their arm. This is due to a flexion contracture from an abnormal amount of joint fluid in the elbow, known as an effusion, or from stiffness at the elbow from not moving it due to the pain. They may also have tenderness to palpation on the lateral portion of their elbow.

In differentiating Panner disease from an OCD lesion of the capitellum, clues in the history and physical exam involve the age of the patient and a history of catching or locking of the elbow joint. As stated, Panner disease typically occurs in those younger than age 10, whereas OCD is found in the older pediatric patient. OCD is also associated with loose bodies in the elbow joint that can cause catching or locking, while Panner disease is not. A loose body represents a piece of the end of the bone or the articular cartilage that has broken loose and is free to move around within the joint.

Diagnosis and Treatment

X-rays are used to diagnose this condition. Elbow X-rays will show fragmentation of the capitellar growth center. Comparison views of the contralateral elbow are needed to help make the diagnosis. The natural history of Panner disease involves a self-limited, benign condition. Therefore, treatment is focused on conservative, nonsurgical measures. It involves activity modification (i.e., avoiding activities that produce discomfort), anti-inflammatory medications (such as ibuprofen), and ice. If there is decreased range of motion of the elbow, the patient may be referred to a physical therapist, or a home exercise program that focuses on regaining motion may be prescribed. If the pain is severe, an arm sling or posterior splint may be temporarily recommended. Most symptoms will improve over 3 to 4 weeks, but complete recovery can take up to 3 years. X-rays should be taken intermittently to assess healing. To date, there is no consistent evidence to suggest any long-term sequelae, but some studies do show permanent deformity within the joint.

Patellar Dislocation

Patellar dislocation is an acute injury where the patella (kneecap) fully dislocates or slides out of its groove on the femur. Patellar dislocation can occur with minor trauma in those with certain anatomical variations that predispose them to this condition. Patellar dislocation can also occur with direct trauma or a sudden change in direction. Patients will sometimes report hearing a pop and will often have rapid swelling and difficulty with any knee flexion.

Anatomy

The patella, or kneecap, is a thick triangular piece of bone that covers and protects the knee joint. It lies within a vertical groove on the femur (thighbone). This vertical groove is called the trochlear groove and is located between the medial and lateral femoral condyles. The condyles are two bulbous ends of the femur through which our weight passes. The patella is covered by a fibrous capsule and is attached above to the tendon of the quadriceps femoris (the main extensor muscle on the front of the thigh). It is attached below to the patellar tendon, which then connects to the tibial tuberosity (an oblong elevation of the tibia).

The quadriceps muscle group consists of the vastus lateralis (outer portion of the thigh muscle), vastus medialis (inner portion of the thigh muscle), and vastus intermedius (middle portion of the thigh muscle), which originate on the femoral shaft and have muscle tendons that insert on the superior (upper) pole of the patella.

The medial patellofemoral ligament (MPFL) originates at the medial femoral condyle on the inner aspect of the knee and attaches to the medial (inside) border of the patella. The MPFL has been found to be the major soft tissue restraint to lateral patellar dislocation (kneecap dislocating to the outside of the knee). The MPFL and two other ligaments comprise the medial patellar retinaculum.

The lateral aspect of the patella is stabilized by the lateral patellar retinaculum. The lateral patellar retinaculum is the confluence of several fibrous structures, including the lateral patellofemoral ligament (LPFL), which connects from the lateral femoral condyle to the outer portion of the patella.

Causes

Patellar dislocation can result from minor trauma in those with risk factors or can result from a high-impact force in a patient with normal anatomy. A common mechanism is dislocation of the right patella when the torso rotates left and the right foot is planted on the ground. The patella then dislocates laterally (to the outside of the knee). Lateral instability is much more common than medial instability. Risk factors for patellar dislocation include the following:

- Any abnormality that increases the lateral (outside) force on the patella
- Weakness of the vastus medialis muscle
- Hypertrophy of the vastus lateralis muscle, thus pulling the patella laterally
- Patella alta—an abnormally high-riding patella with a long patellar tendon
- Shallow trochlear groove, which makes it easier for the patella to slide out of this groove
- Foot pronation, where the foot turns outward at the ankle, causing walking to be done on the inner side of the foot
- Pes planus, or flat feet
- Genu valgum, also called “knock-knees,” where the knees angle inward and the lower legs angle outward
- Femoral anteversion, where the femoral neck (the top of the femur near the hip joint) leans forward with respect to the rest of the femur, causing the knees to rotate inward
- External tibial torsion, where the tibia is rotated outward

Symptoms

An acute patellar dislocation often occurs after direct contact or a sudden change in direction. Symptoms include rapid swelling of the knee joint, intense knee pain, and inability to extend the knee joint. Sometimes patients will report having heard a pop when the injury occurred. The knee is usually maintained in a flexed position. Patients who have had one episode of dislocation are more likely to have another because the tissues have been stretched out by the initial episode. Such patients usually have some of the anatomic predisposing factors listed above.

Symptoms may also manifest as a slow progression of pain located at the front of the knee (anterior). This type of pain is exacerbated with physical activity including using the stairs, squatting, or prolonged sitting. These activities can cause lateral tracking of the patella on the trochlear groove.

Diagnosis

Diagnosis begins with taking a complete history, including asking questions about the mechanism of injury. A physical exam is the next step. The examiner begins with inspection of the knee. With acute patellar dislocation, a knee effusion is often noted. If the patella is still dislocated at the time of inspection, the normal anatomy of the knee joint will be disturbed, and one can palpate the patella off to the side of the knee. The knee may be kept in flexion. Range of motion may be limited in both flexion and extension. There may be tenderness along the medial (inner) edge of the patella if the medial retinaculum has been torn. If the MPFL has been torn, there will be tenderness near the medial femoral epicondyle. Patients may demonstrate apprehension or anxiety at any attempts to manipulate or maneuver the patella. This is called the "apprehension sign." The examiner should also check for signs of malalignment, including genu valgum, pronation, and femoral anteversion. One can also assess for abnormal lateral tracking of the patella during extension (called a *positive J sign*).

Plain radiography is the most common diagnostic test used for patellar dislocation. Anteroposterior, lateral, and sunrise or axial views are used to demonstrate the location of the patella. The axial or sunrise view shows the relationship of the patella to the trochlear groove of the femur. This view can demonstrate the presence of a dislocation. A lateral radiograph can be used to demonstrate patella alta or patellar tilt. Plain radiography can also reveal patellar, femoral, or tibial fractures. Computed tomography (CT) scanning may be more sensitive in depicting the relationship between the patella and the trochlear groove. Magnetic resonance imaging (MRI) can be used to identify soft tissue anomalies if no bony anomalies are found with plain radiography or CT. MRI can be very helpful in evaluating the patellar cartilage and other soft tissue structures surrounding the patella.

Treatment

Nonsurgical

In some patients, the patella may spontaneously reduce with leg extension. In others, manual reduction may be required. This involves applying gentle medial force to the patella while extending the knee. Immediately after the injury, management includes the PRICE principle: *p*rotection of the injured joint, *r*est, *i*ce, *c*ompression, and *e*levation to control swelling. It has been shown that a period of immobility may be helpful during the acute phase. Many patients use a posterior splint with the knee in extension to approximate and heal the disrupted medial structures. During the acute phase, most physicians will limit weight bearing or recommend partial weight bearing. The athlete is then started on a program of static exercises to strengthen the quadriceps muscles, initially with the splint on. The duration of immobilization varies but usually does not exceed 6 weeks. This will prevent atrophy of the muscles surrounding the knee joint. Physical therapy involves strengthening the quadriceps muscle group and stretching the hamstrings. An elastic brace with lateral reinforcement can be used when the athlete returns to physical activity to prevent lateral tracking of the patella. This brace is called a *lateral buttress brace.*

Surgical

Surgical intervention is usually reserved for those in whom the dislocation was traumatic with associated fractures or in those who experience recurrent dislocation and instability. After an acute dislocation, cartilaginous injuries can occur to the patella or lateral femoral condyle. Knee arthroscopy can repair or remove the fracture fragments. Arthroscopy is an operation that involves inserting a small fiberoptic TV camera into the knee joint to visualize the structures inside the joint. Arthroscopy may also be indicated when conservative management is not effective and the athlete experiences symptoms that indicate the presence of a loose body—such as locking or catching or persistent knee pain.

Procedures can be classified into soft tissue and bony procedures. Soft tissue procedures include medial repair and lateral release. Reconstructing the medial (those inside the knee) structures may provide a restraint to lateral dislocation. Often the medial retinaculum and/or the MPFL is repaired. Lateral release involves making an incision in the lateral retinaculum to reduce the pull of this fibrous cartilage on the patella. Dislocation of the patella medially is almost always due to a lateral release that has been extended too far. The most common bony procedure is a tibial tuberosity transfer. This involves moving the tibial tuberosity more medially to maintain better alignment of the patella in the trochlear groove. Often, surgery involves a combination of these procedures.

Patellar Tendinitis

Patellar tendinitis is an overuse injury involving the tendon between the patella and the tibia (the patellar tendon). The patellar tendon is the attachment of the quadriceps muscle to the tibia. The role of the quadriceps, and therefore the role of the tendon, is to extend the knee. Aggravation of the patellar tendon is a common source of pain. This is caused by repetitive trauma to the tendon, frequently associated with jumping, kicking, or running. The process of injury is usually a repetitive microtrauma with acceleration and deceleration (as occurs with jumping and landing) and extrinsic loading of the tendon. The individual forces cause only slight injury, but there are not adequate periods of rest for the tendon to heal. The process of repeated microtrauma leading to the development of tendinitis is similar to the process leading to stress fractures. Because it occurs frequently under the repetitive loading of jumping, patellar tendinitis is frequently referred to as jumper's knee.

The name *tendinitis* suggests that it is the result of an inflammatory process; however, pathologically there is usually little or no evidence of acute inflammation. Pathologic evaluation reveals a mucoid substance separating the collagen bundles. There may also be evidence of microscopic or partial tearing of the tendon. These findings are consistent with degenerative change. Regenerative changes may also be seen, including increased cellularity and neovascularization—the growth of small blood vessels throughout the tendon. Because of this, other terms commonly used for this condition are patellar *tendinosis* and *tendinopathy*, which suggest a degenerative change or any abnormality of the tendon instead of only inflammation (Figure 1).

Clinically affected individuals complain of pain over the tendon. This usually is noticed as a progression of symptoms over days or weeks. Occasionally, there may be a more rapid onset of pain with one step or jump. The most common location of pain is the proximal portion of the tendon just beneath the patella.

In the early stages, the pain is present only after a hard activity or workout. It may be noticed at the beginning of the activity and may diminish after a warm-up. The pain will then progress to last longer. It will last through the entire workout and then occur during other periods of activity throughout the day. Again, activities that load the tendon will tend to be the most painful. This includes going up or down the stairs, squatting, kneeling, and lifting or carrying weight. If left untreated, the condition will progress to a painful state even at rest. The following table classifies patellar tendinopathy according to four grades:

Grade I	Pain after activity
Grade II	Pain before and after activity
Grade III	Pain causing restriction of activity
Grade IV	Pain during activities of daily living

There are multiple intrinsic and extrinsic factors that may predispose one to patellar tendinosis. Intrinsic factors include knee alignment, hamstring, and quadriceps tightness, core hip and girdle strength, and motion of the ankle and knee. Any restriction of complete ankle or knee motion may increase the force across the patellar tendon at impact. Excessive pronation or excessive fast pronation (with a neutral foot) will create excessive force on the patellar tendon. Finally, a rigid cavus foot may also predispose to patellar tendinosis. Extrinsic factors include the magnitude of the force, the duration of the force, and the angle of the knee when maximal stress is applied. Harder playing surfaces, such as concrete, transmit a greater force than softer surfaces, such as grass. A longer workout will increase the total duration of the impact. Impact with the knee in a flexed position, as occurs when running uphill or lunging, creates greater stress along the patellar tendon.

Examination

Evaluation for patellar tendinosis should include evaluation for intrinsic factors that may predispose the development or prolongation of the tendinosis. This should include assessment of alignment of the foot and knee, flexibility, and strength. Evaluation of the patellar tendon should be done with the individual in a supine position with the knee straight. The patellar tendon will most frequently be tender to palpation at the inferior pole of the patella. Then with the knee flexed, pulling the patellar tendon tight, the tenderness will be decreased. There may be notable atrophy of the quadriceps. The affected and unaffected sides should be compared for flexibility of the hamstring and quadriceps. The iliotibial band (ITB) should be checked for flexibility, again comparing with the unaffected side. Knee effusion is rarely present with an isolated patellar tendinosis and indicates that there is likely a coexisting injury.

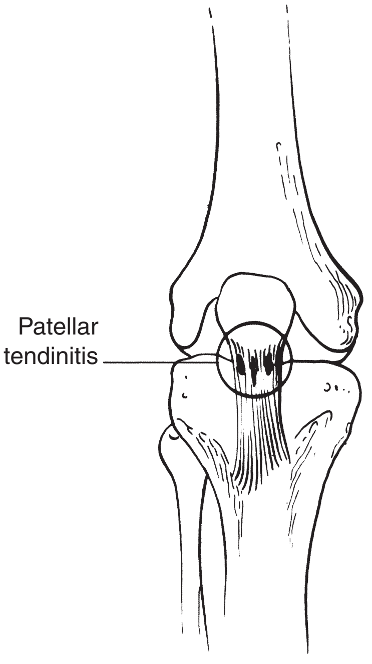

Figure 1 Patellar Tendinitis

Patellar tendinitis should involve only the patellar tendon. If there is bony tenderness over the tibial tuberosity or the inferior pole of the patella in a skeletally immature individual, it may indicate either Sinding-Larsen-Johansson syndrome or Osgood-Schlatter syndrome.

Radiographic Findings

The diagnosis is generally made clinically, so X-rays are not usually necessary but can be useful to rule out other diagnoses. In the case of Sinding-Larsen-Johansson syndrome, the inferior pole of the patella may have decalcification or fragmentation, which will be noted on the radiograph. The patellar tendon is not visualized on plain radiographs; however, the diagnosis can be confirmed with magnetic resonance imaging (MRI) or ultrasound. On an MRI scan, there is typically evidence of inflammation or swelling within the tendon. Ultrasound may show thickening of the tendon, a focal tear, or the presence of neovascularization (new blood vessel formation within the tendon).

Treatment

Conservative treatment consisting of rest, ice, and anti-inflammatory medications is the standard of care. Initial treatment should begin with rest. Complete rest should be considered if possible with higher-grade (III or IV) injuries. Relative rest may be an option with lower-grade injuries. Relative rest will include a decrease in the activity that is triggering the injury. Therefore, sprinting and jumping activities as well as weight lifting involving knee extension should all be eliminated or severely limited. Ice application after activity will help reduce pain and acute inflammation. Use of nonsteroidal anti-inflammatory medications (NSAIDs) is somewhat controversial since the disease process is not inflammatory; however, NSAIDs are useful to control pain. Physical therapy modalities including ultrasound and iontophoresis may also help with pain modulation. Ultrasound has been shown to increase collagen synthesis in surgically severed animal tendons and may play a role in stimulating tendon repair in tendinosis.

The use of a counterforce patellar tendon strap will decrease pain with activity. This is a simple strap that is worn around the lower leg so that it places force on the mid portion of the patellar tendon. This distributes the force away from the injured portion of the tendon. This strap only needs to be worn during activity.

Biomechanical correction is required to allow for healing and to prevent reinjury. This includes increasing the flexibility of the calf, hamstrings, quadriceps, and ITB; correction of excessive pronation with the use of orthotics; as well as core strengthening. These corrections will decrease future stress on the tendon.

Finally, emphasis should be placed on progressive strengthening of the patellar tendon and quadriceps.

In cases of severe tendinosis, more invasive therapies may be considered. Although steroid injection of the tendon is not recommended, recently the use of prolotherapy injections to the tendon to promote a healing response has been considered. In extreme cases, or cases not responsive to the above measures, surgery may be considered. Surgical treatment consists of debridement of the diseased portion of the tendon. Surgical outcomes are not perfect, and only about 50% of surgical patients are able to return to their previous level of competition.

Patellofemoral Pain Syndrome

Anterior knee pain is one of the most common clinical complaints in all age-groups. It may affect as many as 25% of all athletes. Patellofemoral pain is more common in women than in men. The symptoms are pain, instability, or a combination of the two. Instability ranges from mild maltracking to gross patellofemoral dislocation. It may present as an acute or chronic condition.

Anatomy

Soft Tissue Elements

Active Restraints of the Kneecap

The *quadriceps muscle* holds the kneecap in the intercondylar notch. The four components of the quadriceps muscle are the rectus femoris, the vastus lateralis, the vastus intermedius, and the vastus medialis. The most medial one is the vastus medialis obliquus (VMO).

The VMO has distinct fibers in the distal third of the vastus medialis. The VMO is located medial to and is innervated separately from the group. It inserts at an angle of 55° to 65° and counteracts the normal laterally directed pull on the patella. The outside aspect of the quadriceps is the vastus lateralis obliquus (VLO). It is a component of the vastus lateralis. The fibers of the VLO insert at an angle of 38° to 48°, while the vastus lateralis inserts at an angle of 12° to 15°. The VLO provides a direct lateral pull.

Passive Restraints of the Kneecap

The *patellar tendon* limits patellar movement away from the tibia. It articulates with the trochlea in deep flexion to increase the contact area of the kneecap.

The *lateral retinaculum* tethers the patella to the iliotibial band, the lateral femur, and the tibia. It is stronger than its medial counterpart. The fibers of the lateral retinaculum can be divided into the superficial oblique lateral retinaculum, the deep lateral retinaculum (which is the primary restraint), the proximal epicondylo-patellar band, the distal patello-tibial band (which extends below the lateral joint line), and the deep transverse retinaculum.

The medial soft tissue restraints contain the *medial patellofemoral ligament.* This is a capsular thickening arising from the adductor tubercle and inserts into the posterior, superior two thirds of the medial border of the patella. It has its maximal tension at 30° of knee flexion and serves as the major medial soft tissue restraint to lateral displacement (53%). Other parts of the medial restraint are the *patello-tibial ligament* (22% restraint), the *patello-meniscal ligament,* and the *medial retinaculum.*

Bony Elements

The Kneecap/Patella

The patella is the largest sesamoid bone in the body. The kneecap has seven facets—three lateral (concave) and three medial (flat or convex) facets separated by a median ridge. A medial odd facet articulates only in extremes of knee flexion. The retropatellar articular cartilage is up to 7 millimeters thick, the thickest in the body. It is free of nerve endings, more permeable, and more pliable than other articular cartilage. The cartilage has a different contour from the underlying bone.

The Femoral Trochlea

The femoral trochlea can be divided into medial and lateral facets and the supratrochlear fossa. It is shallow at its proximal extent and deeper distally. The lateral facet predominates, is stronger and taller, and has a greater radius. In comparison, the cartilage of the femoral trochlea is significantly thinner than that of the patella.

Motion

The patella serves as a fulcrum and increases the moment arm of the quadriceps by transmitting force at a greater distance from the axis of rotation. The efficiency of the extensor mechanism is increased 1.5 times. This increases the moment arm of the quadriceps by 30% near extension and 15% at 30° of flexion. This raises the efficiency of the extensor mechanism by 1.5 times.

Contact between the patella and the femur is initiated at 10° degrees of flexion. From 0° to 90°, the contact area of the patella shifts from distally to proximally.

Patellofemoral Compressive Forces

The compression forces that work on the patella depend on the activity. Walking leads to compression forces of half the body weight, while climbing stairs leads to forces 3.3 times the body weight. The contact area between the patella and the femur increases from 0° to 60° of flexion. At 60° and higher, there are variable contact area changes. The contact area increases with increasing quadriceps force as a result of articular surface changes.

As the knee flexes from full extension, contact between the patella and the femur progresses from distal to proximal along the patella as forces within the patellar tendon diminish relative to forces in the quad tendon. In full extension, the patella lies at the upper end of the trochlea, and the median patellar ridge lies lateral to the center of the trochlea.

At 10° to 15° flexion, the patella is centered in the trochlea with distal patellar articulation in early flexion.

The quadriceps forces increase dramatically at 90° of flexion, which also increases the articular contact forces.

Beyond 90°, the trochlea articulates with the proximal patella, and the medial facet articulates with the medial femoral condyle.

Patellofemoral Trauma

Patellar Fractures

Transverse fractures are the predominant presentation (50%–80%), secondary to an indirect force. A longitudinal, stellate, or comminuted fracture is usually the result of a direct blow.

The usual treatment for these is open reduction and internal fixation (ORIF), nonoperative treatment, or patellectomy.

Patellar Stress Fractures

Patellar stress fractures are a rare overuse injury. The literature reports occurrence of this injury in endurance runners, volleyball players, basketball players, fencers, and high jumpers. Two types, a longitudinal and a transverse pattern, have been described. If the diagnosis is delayed, a surgical solution is indicated.

Quadriceps Tendon Rupture

The quadriceps tendon rupture is an injury that occurs in patients older than 40 years. X-rays show a low patella position. In case of a complete tear, early operative intervention is necessary.

Patellar Tendon Rupture

The patellar tendon can also rupture. This is also an injury that usually occurs in athletes age 40 years and older. The most common site is the inferior pole of the kneecap. It may be associated with a history of patellar tendinitis. Early surgical repair is the preferred treatment.

Nontraumatic Patellofemoral Pain

Patellar Tendinosis or "Jumper's Knee"

As a result of repetitive microtrauma, as occurs in running, jumping, and kicking sports, an athlete can develop tenderness, usually on the inferior pole of the patella. This tendinosis is classified into grades:

In Grade I tendinosis, pain is perceived only after activity. In Grade II tendinosis, pain is experienced with activity, but it does not interfere with participation. In Grade III tendinosis, pain occurs during and after participation. This time it interferes with competition.

Treatment

Treatment for Grades I and II includes activity modification, stretching, ice, and anti-inflammatory medication. Grade III requires the same treatment as Grades I and II. In addition, cessation of sports is required. If symptoms persist, surgical debridement may be indicated.

Plica Syndrome

The medial synovial plica is the most common location. If this syndrome is present, the lateral and suprapatellar plica can also cause symptoms. Plicas can become symptomatic after repetitive trauma. Inflammation and impingement on the medial femoral condyle can be found. The plica can often be palpated over the medial femoral condyle with passive flexion and extension.

Treatment

A symptomatic plica syndrome is first treated conservatively (with anti-inflammatory medication, quads exercises, and steroid injection). Should symptoms persist, arthroscopic excision may be indicated.

Chondromalacia

Chondromalacia refers to structural damage of the articular cartilage. It is classified into four groups. Group I shows softening of the articular cartilage. Group II has chondral fibrillation or fissuring. In Group III, the chondral fibrillation has fissuring that extends to the subchondral bone. Group IV is characterized by exposed subchondral bone. Chondromalacia may be idiopathic but is usually secondary to malalignment or instability.

Treatment

Treatment options are complex and depend on alignment issues and lesion location.

Osteochondritis dissecans (OCD)

Osteochondritis dissecans (OCD) lesions have been reported in both the patella and the femoral trochlea. They are characterized by cartilage and adjacent subchondral bone detaching from the bony bed. The most common complaints are pain and swelling. OCD is typically found in teenage athletes. Healing may occur in the skeletally immature with 6 to 12 weeks of immobilization. Computed tomography (CT) or magnetic resonance imaging (MRI) can help with the diagnosis. Unfortunately, the healing rate of patellar or trochlear OCD is lower than that of OCD in its more typical location on the medial femoral condyle.

Treatment

An OCD lesion can be found incidentally. In this case, and when the patient is asymptomatic, observation is indicated. If the loose segment is small, surgical removal may be indicated. If the fragment is large, fixation with screws or bioabsorbable pins is the treatment of choice.

Dorsal Defect of the Patella

In general, this is a benign lesion containing nonspecific fibrous tissue. It is located along the superolateral aspect of the articular surface of the patella. Radiographically, a radiolucency with sclerotic margins and intact overlying articular cartilage can be found. This frequently heals spontaneously by sclerosis.

Bipartite Patella

A bipartite patella describes an ununited ossification center and usually involves the superolateral corner of the patella. The symptomatic area can be excised if symptoms persist.

Chronic Regional Pain Syndrome (CRPS)

Chronic regional pain syndrome (CRPS) is characterized by severe pain out of proportion to the physical findings, delayed recovery after the injury, vasomotor disturbances, and trophic changes. Up to 30% of CRPS patients have had an arthroscopy in the past.

Treatment

If diagnosed within 6 weeks, conservative treatments are indicated. These include anti-inflammatory medication, physical therapy, weight bearing, and contrast baths. If symptoms persist beyond 6 weeks, a sympathetic blockade or new, stronger medications may be indicated. This can be a very difficult problem to treat.

Intraosseous Hypertension of the Patella

This is a controversial diagnosis. If the intraoperative intraosseus pressure is higher than 90 mmHg (millimeters of mercury pressure), a core decompression to lower the pressure is indicated.

Patellofemoral Malalignment

Normal Patellofemoral Position

Almost always, an underlying malalignment problem and/or a tight lateral retinaculum are the cause for patellofemoral pain in this variant. Ligamentous laxity of the knee, particularly anterior cruciate ligament laxity, can be the culprit. If the patella is normally positioned (no alta/baja), a realignment procedure itself will usually correct the problem. If chondrosis/arthrosis is also present, an anterior transfer of anterior tibial tuberosity to decompress forces may be required.

Abnormal Patellofemoral Position

An existing problem such as patella alta/baja associated with lateral subluxation needs to be assessed. This may require a three-dimensional tuberosity shift.

Medial Patellar Subluxation/Dislocation

This condition is usually iatrogenic, secondary to realignment procedures. It can be associated with internal tibial torsion or paralysis (polio). Surgical correction is difficult. Ancillary information including MRI, CT, and femoral nerve stimulation for dynamic tracking should be maximized.

Nonoperative Treatment

This is historically the cornerstone of treatment for patellofemoral disorders. Rehabilitative goals are symptom reduction and improvement in strength and endurance. Each program needs to be individualized to meet the patients' needs. Patients need to understand that symptoms may wax and wane regardless of the mode of treatment (i.e., operative or nonoperative).

Strengthening

Short Arc Quad Exercises

Short arc quad exercises are intended to help use low contact pressures at 0° to 30° flexion. They claim to better isolate the VMO. Whether the exercises are better in open chain or in closed chain is being debated. Some reports indicate that closed-chain exercises are superior.

Isokinetic Exercises

Isokinetic exercises are less appropriate due to the significant risk of overloading the cartilage, especially in eccentric contractions.

Pelvic Position

An anterior pelvic position and internal femoral rotation are detrimental for the knee. Therefore, strengthening of the hip extensors and hip abductors, in addition to reducing postural habits that cause anterior pelvic tilt, may help reduce patellofemoral pain.

The advent of dynamic MRI introduced a new component to the diagnosis and treatment. For the first time, it was possible to show the femur internally rotating under the patella. This led to reconsideration of many traditional rehabilitation protocols. In this case, the focus is now more on hip external rotation and abduction strengthening, in combination with core strengthening.

Bracing and Taping

The use of a brace or athletic taping may reduce instability symptoms. As a specific type of taping, McConnell taping serves as an adjunct to the rehabilitative strengthening program. These measures may provide immediate relief, thereby increasing effective training.

Correcting Foot Deformities

If a concurrent foot deformity is found, the use of corrective orthotics may be beneficial to the knee as well.

Operative Treatment

Procedures intended to correct malalignment can be divided into five categories:

1. Release of tight lateral retinaculum
2. Proximal realignment of the extensor mechanism
3. Distal realignment of the extensor mechanism
4. Combined proximal and distal realignment
5. Articular cartilage procedures

Lateral Retinaculum Release

This is done alone or with other realignment procedures. Current indications are based on the medical literature. They include patellofemoral pain with lateral tilt, lateral retinacular pain with lateral tilt or lateral patellar position, and tight lateral retinaculum leading to an excessive lateral pressure syndrome.

Contraindications for this procedure include advanced patellofemoral arthritis, normal patellar tracking, and significant subluxation or dislocation. In the case of dislocation, a medial soft tissue procedure or distal realignment procedure is often needed in addition to the lateral release.

Proximal Realignment Procedures
