The major cation in the blood plasma is sodium (Fig. 21-3). Potassium, calcium, and magnesium constitute the balance of the cation fraction. The primary anion is chloride, with protein, bicarbonate, and some undetermined anions constituting the balance of the anions. The interstitial fluid (i.e., nonplasma ECW) has a solute composition that is similar to plasma except that its protein content is lower. The ICW contains potassium and magnesium as its primary cations, and phosphate, both organic and inorganic, is the major anion, with bicarbonate contributing a smaller fraction.

TABLE 21-1 CHANGES IN BODY WATER AND ELECTROLYTE COMPOSITION DURING INTRAUTERINE AND EARLY POSTNATAL LIFE

Component	Gestational Age (Weeks)					
	24	28	32	36	40	1 to 4 Weeks After Term Birth
Total body water (%)	86	84	82	80	78	74
Extracellular water (%)	59	56	52	48	44	41
Intracellular water (%)	27	28	30	32	34	33
Sodium (mEq/kg)	99	91	85	80	77	73
Potassium (mEq/kg)	40	41	40	41	41	42
Chloride (mEq/kg)	70	67	62	56	51	48

The electrolyte composition of the body fluids of the newborn infant is largely determined by gestational age. Premature infants contain more sodium and chloride per kilogram of body weight than term infants (3,4,5) because of their larger ECW (Table 21-1). Total body potassium content largely reflects ICW and is similar or slightly lower

per kilogram of body weight in premature infants than at term (3,6). These

concepts are important in the management of fluid and electrolyte therapy for newborn infants.

In the fetus, fluid and electrolyte balance depends on maternal homeostasis and placental exchange. Thus, fluid and electrolyte status at birth is influenced by the maternal fluid and electrolyte management in labor (25,26,27,28).

INSENSIBLE WATER LOSS

The loss of water by evaporation from the skin and respiratory tract is known as insensible water loss (IWL). About 30% of IWL normally occurs through the respiratory tract as moisture in expired gas (29,30,31), with the remaining 70% lost through the skin. IWL can be expressed in reference to body surface area (m²) or weight (kg). IWL depends more on surface area than weight, but it is commonly expressed per kilogram because weight is more easily determined than area.

TABLE 21-2 FACTORS AFFECTING INSENSIBLE WATER LOSS IN NEWBORN INFANTS

Factor	Effect on Insensible Water Loss (IWL)
Level of maturity (32,33,35, 36 and 37)	Inversely proportional to birth weight and gestational age (Fig. 21-4)
Respiratory distress (hyperpnea) (38)	Respiratory IWL increases with rising minute ventilation when dry air is being breathed
Environmental temperature above neutral thermal zone (29,39,40)	Increased in proportion to increment in temperature
Elevated body temperature (29,39)	Increased by up to 300%
Skin breakdown or injury	Increased by uncertain magnitude
Congenital skin defect (e.g., gastroschisis, omphalocele, neural tube defect)	Increased by uncertain magnitude until surgically corrected
Radiant warmer (33,41,42,43,44 and 45)	Increased by about 50%
Phototherapy (43,46,47)	Increased by about 50%
Motor activity and crying (29,49,50)	Increased by up to 70%
High ambient or inspired humidity (29,31)	Reduced by 30% when ambient vapor pressure is increased by 200%
Plastic heat shield (32,44,52)	Reduced by 30% to 70%
Plastic blanket (52, 53,54) or chamber (54,55)	Reduced by 30% to 70%
Semipermeable membrane (56, 57 and 58)	Reduced by 50%
Topical agents (59,60)	Reduced by 50%

Figure 21-4 Relation between insensible water loss (IWL) and birth weight of 5-day-old (mean) infants in incubators. (Data from Wu PY, Hodgman JE. Insensible water loss in preterm infants: changes with postnatal development and non-ionizing radiant energy. *Pediatrics* 1974;54:704-712, as redrawn in Shaffer SG, Weismann DN. Fluid requirements in the preterm infant. *Clin Perinatol* 1992;19: 233-250, with permission.)

A number of factors are known to influence IWL in a predictable manner (Table 21-2) (29,30,31,32,33,34,35,36,37,38,39,40,41,42,43,44,45,46,47,48,49,50,51,52,53,54, 55,56,57,58,59,60). When expressed per kilogram of body weight, IWL is inversely proportional to birth weight and gestational age (Figs. 21-4 and 21-5) (32,33,35).

In other words, smaller, more immature infants have larger IWL per kilogram (Table 21-3). The

same is true if IWL is expressed per square meter of body surface (36,37). Therefore, although the greater IWL of smaller premature infants is partly due to the increased ratio of surface area (skin and respiratory tract) to body weight, it also is thought to be related to their thinner skin, greater skin blood flow, larger body water per kilogram of body weight, and higher respiratory rate. Because skin permeability to water varies inversely with gestational age, the degree of immaturity is an important determinant of cutaneous IWL independent of birth weight.

Figure 21-5 Insensible water loss (IWL) as a function of birth weight in premature infants nursed under radiant warmers. (Adapted from Costarino AT, Baumgart. Controversies in fluid and electrolyte therapy for the premature infant. *Clin Perinatol* 1988; 15:863-878, with permission.)

Factors That Increase Insensible Water Loss

An increase in minute ventilation increases the respiratory IWL (38) as long as the water vapor pressure is less in the inspired than in the expired gas. Increased minute ventilation may occur in infants with cardiac disease, pulmonary dysfunction, or metabolic acidosis.

TABLE 21-3 AVERAGE INSENSIBLE WATER LOSS^a OF PREMATURE INFANTS IN INCUBATORS

Age (d)	Birth Weight Range (kg)					
	0.50-0.75	0.75-1.00	1.00-1.25	1.25-1.50	1.50-1.75	1.75-2.00
0-7	100 ^a	65	55	40	20	15
7-14	80	60	50	40	30	20

^a Insensible water loss (mL/kg/day).

Data from Wu PY, Hodgman JE. Insensible water loss in preterm infants: changes with postnatal development and non-ionizing radiant energy. *Pediatrics* 1974;54:704-712; Okken A, Jonxis JH, Rispens P, et al.

Insensible water loss and metabolic rate in low birthweight newborn infants. *Pediatr Res* 1979;13:1072-1075; Hammarlund K, Sedin G. Transepidermal water loss in newborn infants. III. Relation to gestational age. *Acta Paediatr Scand* 1979;68:795-801.

Environmental temperature above the neutral thermal zone increases IWL in proportion to the increment in temperature (29,39,40). This effect can occur even without a rise in body temperature. In contrast, a subneutral environmental temperature is not associated with reduced IWL, although metabolic heat production is increased (40). Increased body temperature, whether caused by fever or environmental overheating, elevates IWL (29,39).

Skin breakdown or injury disrupts the barrier against cutaneous evaporation and raises IWL. Skin trauma from thermal, chemical, or mechanical injury is common among critically ill, small, premature infants. Such injury may result from removal of tape and adherent monitoring devices or from prolonged skin exposure to disinfectant solutions. IWL also is increased in conjunction with the skin manifestations of essential fatty acid deficiency, a potential problem in infants receiving fat-free parenteral nutrition.

Congenital skin defects, such as those seen in gastroschisis, omphalocele, and neural tube defects, are associated with increased IWL until surgically corrected.

Use of nonionizing radiant energy, in the form of either a radiant warmer or phototherapy, has been shown to increase IWL by about 50% (33,41,42,43,44,45,46,47,48). For infants in incubators with controlled air temperature, the increase in IWL with overhead phototherapy is most likely a result of increased body temperature because of the warmer incubator walls (46). For infants in incubators operated to control skin temperature, the rise in IWL with phototherapy can be explained by the lower absolute humidity resulting from the reduced air temperature that accompanies the warming of the incubator walls by the phototherapy. The impact on IWL of phototherapy delivered by fiberoptic blankets or pads is not known but is probably negligible unless the blanket produces a warmer or moister microenvironment around the infant. Investigators using direct measurements of transepidermal and respiratory water loss have obtained P.366

conflicting results regarding the effect of overhead phototherapy on IWL. One group (47) found an increase in transepidermal water loss with phototherapy, but another did not (61,62).

TABLE 21-4 RELATIVE AND ABSOLUTE HUMIDITY AS RELATED TO INSENSIBLE WATER LOSS IN INCUBATORS AND UNDER RADIANT WARMERS

Measurement	Incubator	Radiant Warmer
Air temperature (°C)	35.0	27.6
Saturation pressure (mm Hg)	42.1	27.7
Relative humidity (%)	31.4	39.0
Absolute humidity (mm Hg)	13.2	10.8
Insensible water loss (mL/kg/hour)	2.37	3.40

Data from Bell EF, Weinstein MR, Oh W. Heat balance in premature infants: comparative effects of convectively heated incubator and radiant warmer, with and without plastic heat shield. *J Pediatr* 1980;96: 460-465.

If an infant's IWL is measured at the same skin temperature under a radiant warmer and in an incubator, the IWL is higher (by about 50%) under the radiant warmer. IWL is higher because absolute humidity (water vapor pressure) is lower under the radiant warmer than in the incubator (44). This may be true even if relative humidity is higher under the radiant warmer (43,44) because the lower air temperature with the radiant warmer means that the saturation pressure of water vapor is considerably lower than in the incubator (Table 21-4). This finding has been confirmed using direct measurements of transepidermal water loss (45). It is now understood that

the higher IWL with radiant warmers arises from the lower ambient water vapor pressure and not from higher air velocity or a direct effect of nonionizing radiation on the skin. The same phenomenon explains the effect of phototherapy on IWL of infants in incubators operated by skin temperature servocontrol. The effects on IWL of radiant warmers and phototherapy are additive; the IWL with the combination is approximately twice as large as in an incubator without phototherapy (43,48).

Increased motor activity and crying increase IWL by up to 70% (29,49,50). This effect may be partly due to elevated minute ventilation.

Factors That Reduce Insensible Water Loss

Increasing the humidity or water vapor pressure of inspired gas reduces respiratory IWL. The inspired humidity is raised by humidifying the air-oxygen mixture delivered to a head hood or directly to the infant's upper airway (e.g., via nasal cannula, face mask, or endotracheal tube) if respiratory support is required. If the temperature and water content of the inspired and expired gas are the same, the respiratory IWL will be entirely eliminated (51). Increasing ambient humidity, for example in an incubator, reduces total IWL, but respiratory IWL is decreased more than cutaneous IWL (29); a threefold increase in ambient water vapor pressure, from an average of 7 to 25 mm Hg, resulted in a 30% reduction in total IWL.

Increasing ambient humidity is facilitated by the design of certain recent models of incubators. The use of incubator humidification systems should not be overlooked as a way of reducing IWL.

Plexiglas heat shields are effective in reducing the IWL of small premature infants in incubators (32,44), especially if the ends are at least partially enclosed to decrease air movement near the skin. Plexiglas heat shields are not effective for infants under radiant warmers (44,52) because Plexiglas is opaque to the infrared energy produced by the radiant heaters. Thin barriers of saran and other materials reduce IWL of infants under radiant warmers while allowing the infrared heat to reach the skin (52). These heat shields presumably reduce IWL by limiting air movement and raising water vapor pressure near the infant's body surface.

Thin plastic blankets have been found to reduce IWL by 30% to 70% for infants under radiant warmers and in incubators (52,53,54). Chambers made of thin plastic material also reduce IWL by a similar amount (54,55).

Semipermeable membranes (56,57,58) and waterproof topical agents (59,60) reduce IWL from the covered areas by an average of approximately 50%.

Knowledge of these factors that affect IWL is essential for estimating the water intake required by newborn infants and for making appropriate adjustments in water intake with changes in care. Of all infants, premature and critically ill infants are the ones whose IWL is most significantly influenced by these factors. This is especially true for the extremely premature infant, of whom more are surviving each year. However, these are exactly the infants for whom precise maintenance of fluid and electrolyte balance is most important and for whom the margin of error is smallest.

NEUROENDOCRINE CONTROL OF FLUID AND ELECTROLYTE BALANCE

The pituitary gland, adrenal cortex, parathyroid glands, and heart are the major organs producing hormones involved in the regulation of water and electrolyte balance in the body. The basic mechanisms by which the antidiuretic hormone, arginine vasopressin (AVP), is produced and secreted by the posterior pituitary gland appear to be intact in newborn infants (63,64,65), even in those who are born prematurely (66). It is not clear at what age precise quantitative hypothalamic control of AVP production is established. However, it is known that even in the first week of life, breast-fed term infants release AVP in response to a 10% loss of body weight (65). Aldosterone is the most potent mineralocorticoid produced and secreted by the adrenal cortex. Its synthesis is regulated by the renin-angiotensin system, adrenocorticotrophic hormone, and plasma concentrations of sodium

P.367

and potassium. These mechanisms appear to be intact in newborn infants, even those born prematurely (67,68,69,70,71). Increased sodium loss in the urine of premature infants in the presence of high plasma concentrations of aldosterone and elevated urinary aldosterone excretion suggests that the renal tubule is less responsive in premature than in term infants (69,70). Under conditions of low sodium intake, however, the high

plasma aldosterone concentrations found in sick newborn infants seems to promote increased sodium reabsorption in the distal nephron (71).

Calcium concentration in the blood of newborn infants is regulated by the balance between parathyroid hormone (PTH), which is produced by the parathyroid glands, and calcitonin, which is produced in the thyroid. Serum PTH concentration is low at birth and rises slowly during the first few days, both in term and premature infants (72,73,74). The same pattern has been observed with serum calcitonin concentrations, low at birth and rising thereafter (73,74). Intravenous calcium infusion to large premature and term infants caused elevation of serum calcitonin and a corresponding fall in serum PTH (75). These data together indicate that the hormonal regulation of calcium metabolism is basically intact in newborn infants, even those born prematurely.

Atrial natriuretic factor (ANF) is present in the fetal heart early during development (76). In the human fetus, cardiac atrial levels of ANF increase during gestation and, by the beginning of the third trimester, exceed adult human levels; during the same period, fetal ventricular ANF levels decrease (77). Plasma ANF levels rise after birth, peaking at the time of maximal postnatal diuresis, usually 48 to 72 hours, and then returning to levels below those at birth (78,79,80). ANF secretion is stimulated by volume loading (81), and ANF levels correlate with atrial size (82). ANF in turn stimulates diuresis and natriuresis and seems to play an important role in the regulation of extracellular fluid volume in newborn infants (82,83,84). However, studies of the effects of sodium supplementation on ANF levels and sodium excretion (83) indicate that premature infants are less responsive to ANF than are adults.

RENAL FUNCTION IN RELATION TO FLUID AND ELECTROLYTE THERAPY

Most aspects of renal function are incompletely developed at birth, especially in premature infants

(15,58,59,60,61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80,81,82,83,84,85,86,87,88,89,90). Both glomerular and tubular functions increase with gestational age at birth (15,85,86,87,90) and with postnatal age (15,87,88,89). This development seems to depend most directly on postmenstrual age (gestational age at birth plus postnatal age) and occurs

at approximately the same rate, regardless of whether the infant has been born or is *in utero* (86,87,89).

In spite of the immaturity of some aspects of renal tubular function at birth, the tubules seem to respond to AVP from the first day of life, even in small premature infants (66). However, the maximal urine concentration of premature infants, typically 600 mOsm/L, is less than that of term newborn infants (800 mOsm/L) or adults (1200 mOsm/L) (91,92). Both term and premature infants can excrete urine with osmolarity as low as 50 mOsm/L when challenged with an acute water load (92,93,94,95). Although they can produce dilute urine, newborn infants cannot excrete a water load as rapidly as adults can (93).

The limitations in renal function in premature infants contribute to the problems of fluid and electrolyte regulation in various disease states. The glomerular and tubular functions of premature infants allow them to handle some physiologic variations in water and electrolyte load, but imbalance readily occurs when estimations of the water and electrolyte needs are misjudged, particularly in the case of extremely premature infants.

PRINCIPLES OF FLUID AND ELECTROLYTE THERAPY

As in older children, three steps should be followed in the management of infants with fluid and electrolyte disorders:

- Estimate the deficits of fluid and electrolytes.
- Calculate the amounts of fluid and electrolytes required for replacement of deficits, maintenance, and replacement of ongoing abnormal losses.
- Institute a system of monitoring the response to therapy.

Estimation of Fluid and Electrolyte Deficits

Fluid Deficit

The body water deficit can be estimated by the degree of dehydration. If serial body weight measurements are available, the acute weight loss is considered to represent the water deficit. During the first week of life, however, weight loss of up to 15% occurs normally as a result of

contraction of extracellular water and tissue catabolism. Even those small premature infants who can be enterally fed lose an average of 10% of their body weight during the first 5 days of life (96). Among premature infants who must be nourished intravenously, it is not uncommon to observe weight loss of 15% or more without evidence of circulatory or renal insufficiency resulting from dehydration (97). The precise amount of weight loss desired during the first week of life has not been established because of a lack of reliable physiologic data. In general, smaller infants tend to lose larger fractions of their weight following birth (97). For small premature infants, a weight loss of 2% to 3% per day is a reasonable target in the first week of life. Efforts to completely prevent postnatal weight loss risk overhydration and problems with symptomatic PDA (19). Beyond the first week of life, acute weight loss should be considered to indicate nonphysiologic dehydration, and the calculated deficit of water should be replaced.

P.368

If serial body weight data are not available, urine volume and concentration and physical signs can be used to estimate the degree of dehydration.

Infants with 5% isotonic (i.e., serum sodium concentration of 130 to 150 mEq/L) dehydration have dry mucous membranes, subnormal tear production with crying, flat or slightly sunken anterior fontanel (when quiet in the upright position), and oliguria. Infants with 10% isotonic dehydration have dry mucous membranes, absent tears, sunken eyes and fontanel, cool extremities, poor skin turgor, and oliguria. Infants with 15% isotonic dehydration have the aforementioned signs as well as signs of shock, such as hypotension, tachycardia, weak pulses, mottled skin, and altered sensorium. Infants with hypertonic dehydration (i.e., serum sodium concentration above 150 mEq/L) have less severe symptoms than infants with isotonic dehydration who have lost the same fraction of body water; the intravascular volume is preserved better with hypernatremia than with isotonic dehydration. However, infants with hypotonic dehydration (i.e., serum sodium below 130 mEq/L) may have more severe symptoms with the same degree of dehydration.

The usual clinical signs of dehydration are more difficult to evaluate in small premature infants. Their skin and mucous membranes may appear dry because of thermal or mechanical injury, particularly in infants kept under

radiant warmers. In addition, skin turgor is harder to judge because of the lack of subcutaneous fat.

Electrolyte Deficits

The nature and extent of electrolyte disturbances often can be determined by history and physical examination and by measurement of electrolyte concentrations in serum. Based on serum sodium concentration, electrolyte disturbances are divided into isotonic, hypertonic, and hypotonic abnormalities. The type of electrolyte disorder seen in a clinical situation depends on the cause of fluid and electrolyte abnormality. For example, severe acute diarrhea usually leads to isotonic dehydration. High IWL, such as may occur in small premature infants under radiant warmers, may result in hypernatremic dehydration. Inadequate replacement of salt losses from diarrhea may produce hypotonic dehydration. Although it may be possible to anticipate the type of electrolyte disorder accompanying dehydration in some situations, confirmation must be made by measurement of serum electrolyte concentrations.

TABLE 21-5 CALCULATION OF SODIUM DEFICIT

Type of Dehydration	Serum Sodium Concentration (mEq/L)	Calculation of Total Solute Deficit (mOsm/kg) ^a	Solute Deficit (mOsm/kg)	Sodium Deficit (mEq/kg) ^b
Isotonic (10%)	140	$(0.7 \times 280) - (0.6 \times 280)$	28	14
Hypertonic (10%)	153	$(0.7 \times 280) - (0.6 \times 306)$	12	6

Hypotonic (10%)	127	$(0.7 \times 280) - (0.6 \times 254)$	44	22
--------------------	-----	---------------------------------------	----	----

^a Total solute deficit = $(TBW_e \times \text{solute}_e - (TBW_o \times \text{solute}_o))$, where subscripts e and o indicate expected and observed, respectively. $TBW_e = 0.7 \text{ L/kg}$; $TBW_o = 0.7 - 0.1 = 0.6 \text{ L/kg}$; $\text{solute}_e = 140 \times 2 = 280 \text{ mOsm/L}$, assuming total solute concentration in body water is twice the sodium concentration in serum; $\text{solute}_o = \text{observed serum sodium} \times 2$.

^b Total solute deficit is assumed to be half sodium. Although the serum (and ECW) has lost this amount of sodium, only half this amount has been lost to the environment; the other half has been lost into the cells in exchange for potassium, which in turn has been lost from the body. In practice, therefore, only half the amount listed as "sodium deficit" should be replaced as sodium, and the other half should be given as potassium. TBW, total body water. ECW, extracellular water.

Calculation of Fluid and Electrolyte

Requirements

After replacement of any fluid and electrolyte deficits, the requirements of newborn infants for water and electrolytes are determined by the rates of loss of these substances from the body by various routes and by the net amounts retained by body tissues during changes in body weight and composition. Knowledge of the usual rates of loss and of expected changes in body weight and composition in the first postnatal days and during subsequent growth helps to estimate water and electrolyte requirements. These estimates are then used to guide the management of fluid and electrolyte therapy.

Replacement of Fluid and Electrolyte Deficits

The deficit of fluid is calculated from the estimated degree of dehydration determined from measured body weight loss or by clinical examination. The

rate and composition of initial fluid replacement depend on the severity of dehydration. As a rule, dehydration of acute onset and short duration requires more rapid correction. An exception to this rule is the case of hypertonic dehydration, in which rapid expansion of body water may cause brain swelling and convulsions.

The deficit of electrolytes is calculated as the difference between total body solute expected before dehydration and that observed in the dehydrated state (Table 21-5). It is common to replace half the water deficit over the first 8 hours and the other half over the next 16 hours. The

P.369

sodium deficit is replaced over 24 hours; more rapid replacement is not necessary and may risk overcorrection. If the potassium deficit is large, one should replace it over a longer period (i.e., 48 to 72 hours) to allow ascertainment of adequate renal function and to avoid the possible cardiac effects associated with rapid potassium infusion. Initiation of potassium replacement is best deferred until urine flow is established.

Maintenance Fluid and Electrolytes

IWL, urine, fecal water, and water retained in new tissues during growth are the four components that one must consider in estimating the daily maintenance water requirement. Fecal water loss is approximately 5 to 10 mL/kg/day (98,99). The water retained for growth is about 10 mL/kg/day, assuming a weight gain of 10 to 20 g/kg/day, 60% to 70% of which is water (3). In the first week of life, fecal water loss is small and no water is deposited in new tissues because growth has not yet begun. In fact, water is lost from body tissues during the period of physiologic extracellular dehydration. After growth begins, replacement of fecal and growth water may require up to 20 g/kg/day, but this amount is small compared with the insensible and urine water losses, the two major routes of water loss that must be considered in estimating the water intake required to maintain the desired water balance.

A small portion of the water used to replace these normal losses is derived from the oxidation of metabolic fuels (i.e., carbohydrate, protein, and fat). This water of oxidation consists of about 0.60 mL/g of carbohydrate oxidized, 0.43 mL/g protein, and 1.07 mL/g fat (100). A newborn infant

usually produces 5 to 10 mL/kg/day as water of oxidation. This amount is small enough to be neglected in most calculations but, for practical purposes, can be considered to offset the normal fecal water loss of 5 to 10 mL/kg/day.

For a term infant under basal conditions, IWL is approximately 20 mL/kg/day (29). Urine volume depends on the excess of water intake over losses by other routes (i.e., IWL, feces, growth), and urine concentration is determined by the urine volume and renal solute load. The range of urinary water loss within which the infant's immature kidneys can safely excrete the total renal solute load is determined by the limits of urine concentration (volume = solute load/urine concentration) (101). A renal solute load of 15 to 30 mOsm/kg/day would require urine volume of 50 to 100 mL/kg/day to maintain an average urine concentration of 300 mOsm/L. This urine concentration is near the middle of the range of urine osmolarity that can be produced by the neonate's kidneys, and it allows a margin of safety for over- or underestimation of other water requirements.

In the first days of life, a term infant receiving intravenous fluid and electrolytes would need to excrete about 15 mOsm/kg/day, assuming that both endogenous solute production and tissue deposition of solute are negligible. The urine volume of 50 mL/kg/day plus the IWL of 20 mL/kg/day yield a total maintenance water requirement of 70 mL/kg/day; this assumes growth and fecal water to be small enough to be offset by the water of oxidation. If one allows for a negative water balance of 10 mL/kg/day, the true water requirement at birth is about 60 mL/kg/day. With increasing postnatal age and enteral feedings, the renal solute load and fecal water loss increase, and water is deposited in new tissues as growth begins. By the second week of life, a growing term infant needs 120 to 150 mL/kg/day. In premature infants, the maintenance water requirement is larger because of higher IWL (33,35). Therefore, the IWL component of maintenance water should be increased with decreasing birth weight or gestation. During the first days of life, the renal solute load is less because little exogenous solute is provided. If sodium chloride is administered at a rate of 2 mEq/kg/day (4 mOsm/kg/day) and a solute load of 8 mOsm/kg/day resulting from tissue catabolism is assumed to be excreted (102), a urine volume of only 40 mL/kg/day is required to excrete this solute with a urine concentration of 300 mOsm/L. Thus, a small premature infant requires

about 80 mL/kg/day on day 1 (60 IWL + 40 urine -20 for negative balance). The water requirement for this same infant would be about 150 mL/kg/day in the second or third week (55 IWL + 85 urine + 10 feces + 10 growth - 10 oxidation). Very premature (less than 26 weeks of gestation) infants in the first week of life may have considerably higher IWL, raising the total water requirement to 200 or 300 mL/kg/day or even higher, especially if maintained in dry air. The minimum water intake of premature infants is also higher than that of term infants because of premature infant's slightly lower urinary concentrating capacity (91,92). However, the aforementioned urine volumes (40 to 100 mL/kg/day) were selected to avoid taxing this limit of concentration and so are not influenced by this effect of immaturity. The allowance for IWL should be increased by about 50% for infants under radiant warmers (33,41,42,43,44) or receiving overhead phototherapy (33,46). If both are used, the allowance for IWL should be increased by approximately 100% (43). The effect of fiberoptic phototherapy blankets or pads on IWL is not known but is probably less than that of overhead phototherapy. The IWL of infants in incubators also is increased if body or environmental temperature is too high (29,39,40). The IWL can be reduced by increasing the ambient or inspired humidity (29,31) or by using certain types of heat shields (32,44,52), plastic blankets (52,53,54) or chambers (54,55), semipermeable membranes (56,57,58), or waterproof topical agents such as paraffin (59,60) (Table 21-2).

The infant's maintenance requirements of sodium, potassium, and chloride can be estimated by adding the dermal, urinary, and fecal losses to the amounts retained in the body tissues during growth. The estimated requirements for sodium, potassium, and chloride are each between 2 and 4 mEq/kg/day (103,104). Small premature infants may require additional sodium because of increased urinary excretion (105,106,107), especially during the second and third weeks of life. The magnitude of urinary sodium excretion is inversely proportional to gestational age (Fig. 21-6) (85).

Figure 21-6 Urinary sodium excretion in infants from 27 to 40 weeks of gestation. (From Siegel SR, Oh W. Renal function as a marker of human fetal maturation. *Acta Paediatr Scand* 1976;65: 481-485, with permission.)

P.370

Ongoing Abnormal Losses of Fluid and Electrolytes

Ongoing abnormal losses must be replaced along with correction of established deficits and provision of maintenance fluid and electrolytes. Abnormal losses may occur with vomiting or diarrhea, ileostomy output, or removal by aspiration of gastrointestinal, pleural, peritoneal, or cerebrospinal fluid. The amount of extra water required can be determined by carefully measuring the volume lost. The additional amounts of electrolytes required can be estimated by measuring their concentrations in an aliquot of fluid (Table 21-6).

Example of Fluid and Electrolyte Calculation

Consider a 3-kg infant who presents with 10% isotonic dehydration (i.e., serum sodium = 140 mEq/L). In the first 24 hours of therapy, the infant should be given 27 mEq of sodium chloride in 600 mL of water as a dextrose solution (Table 21-7). If the potassium deficit is to be corrected

over 72 hours, 13 mEq of potassium chloride (21/3 + 6) should be given during the first 24 hours. This fluid could then be ordered as dextrose solution with 45 mEq NaCl/L and 20 mEq KCl/L to be infused at 25 mL/hour. If the infant also has significant metabolic acidosis, some or all of the sodium could be given as sodium bicarbonate or sodium acetate.

TABLE 21-6 ELECTROLYTE CONTENT OF BODY FLUIDS

Fluid Source	Sodium (mEq/L)	Potassium (mEq/L)	Chloride (mEq/L)
Stomach	20-80	5-20	100-150
Small intestine	100-140	5-15	90-120
Bile	120-140	5-15	90-120
Ileostomy	45-135	3-15	20-120
Diarrheal stool	10-90	10-80	10-110
Cerebrospinal fluid	130-150	2-5	110-130

The initial glucose concentration is determined by the estimated water requirement and the desired glucose intake, which is usually 5 to 8 mg/kg/minute. Smaller, more premature infants, because they require more water and may tolerate less glucose, are usually begun on solutions containing lower concentrations of glucose (e.g., 5 g/dL); larger term or near-term infants require higher glucose concentrations (e.g., 10 g/dL).

The fluid and electrolyte requirements of very small premature infants vary widely and are difficult to predict. Therefore, close monitoring of the fluid and electrolyte balance of these infants is especially important so that any imbalance can be detected as soon as possible.

Monitoring the Effectiveness of Fluid and Electrolyte Therapy

During the course of parenteral fluid therapy, detailed and organized data collection is necessary for monitoring the adequacy of fluid and electrolyte intake. Data that should be collected and recorded regularly at designated intervals include water and electrolyte intake by all routes, measurable output of water, body weight change, and serum electrolyte concentrations; in addition, clinical assessment should be made for the presence of dehydration, edema, or acute water overload. A calibrated infusion pump should be used to assure accurate administration of prescribed parenteral fluids. Accurate measurement of urine volume is difficult in small infants. It is possible to collect urine from male infants by placing the penis into a collecting vessel that is taped to the abdomen. Urine is then aspirated from the vessel with a catheter and syringe. Urine volume can also be estimated by comparison of the weights of dry and wet diapers, provided the diaper is weighed soon enough to avoid evaporation of the urine.

Inadequate fluid may be administered if the fluid maintenance requirement is underestimated or if a preexisting

P.371

deficit or ongoing loss is neglected or underestimated. Insufficient water intake leads to reduced urine volume and increased urine concentration, and if these compensatory measures are inadequate, water is mobilized from body stores to provide for obligatory insensible loss and to allow solute excretion. This results in weight loss, clinical signs of dehydration, metabolic acidosis, and hemoconcentration. As serum osmolarity rises, neurologic sequelae of hypertonicity may occur. In severe cases, untreated dehydration may lead to decreased circulating blood volume, acute renal failure, and finally to death from cardiovascular collapse.

TABLE 21-7 CALCULATION OF FLUID AND ELECTROLYTE INTAKE FOR A 3-KG INFANT WITH 10% ISOTONIC DEHYDRATION

	Water (mL)	Sodium (mEq)	Potassium (mEq)
Deficit	300 ^a	21 ^b	21 ^{b,c}
Maintenance	300 ^d	6	6
Ongoing losses	0	0	0
Total	600	27	27 ^c
Total/kg	200	9	9 ^c

^a Water deficit: $0.10 \times 3 \text{ kg}$.

^b Electrolyte deficits calculated as in Table 21-5 ($14 \text{ mEq/kg} \times 3 \text{ kg}$ divided between sodium and potassium).

^c Potassium deficit should be replaced slowly over 48 to 72 hours.

^d Maintenance water requirement assumed to be 100 mL/kg/day.

Excessive water intake leads to increased excretion of dilute urine. If these compensatory mechanisms are overtaxed, water will be retained in the body, resulting in edema and weight gain. Rapid overhydration may produce congestive heart failure and pulmonary edema, particularly in ill infants with cardiopulmonary disorders. Even gradual daily administration of excess water (i.e., volumes larger than can be readily eliminated by the kidneys) may increase the risk of heart failure from PDA in premature infants (19).

If appropriate fluid therapy is being provided, body weight should be stable or slowly increasing after the first week of life, and there should be no evidence of dehydration or fluid overload. During the first week of life, loss of as much as 15% of body weight is considered normal, provided urine output is adequate and there is no acidosis or evidence of dehydration. This "physiologic" weight loss is at least partly the result of postnatal contraction of the extracellular water volume. Efforts to prevent this weight loss are ill advised and may lead to fluid overload, edema, and significant PDA. Plotting daily weights on a standard postnatal growth chart (97) may help in detecting excessive weight loss or inappropriate weight gain. Routine measurement of serum electrolyte concentrations is the best way to monitor the body's electrolyte status and the adequacy or excess of electrolyte intake. It is not necessary to add sodium to the parenterally administered fluid during the first 24 hours of life; in fact, starting sodium on the day of birth may delay the physiologic contraction of the extracellular water compartment (108,109). On the other hand, adding some sodium as bicarbonate or acetate facilitates the use of permissive hypercapnia to reduce lung trauma while still maintaining acceptable arterial pH. In any case, it is advisable to determine the serum electrolyte concentrations soon after birth in infants who require parenteral fluids; if the mother received sodium-free fluid during labor, the infant may be hyponatremic (25,26,27,28) and require immediate addition of sodium to the prescribed fluid. If not required earlier, sodium in the form of sodium chloride or sodium acetate should be administered at a dose of 2 to 4 mEq/kg/day beginning on the second day of life. Use of the acetate salt helps to correct the metabolic acidosis sometimes seen in young premature infants as a result of renal immaturity; it also helps the kidneys in buffering the respiratory acidosis resulting from permissive hypercapnia. During the first week of life, infants are usually in negative sodium balance as a result of the mobilization of sodium along with water from the extracellular compartment. This negative balance should be allowed as long as the serum sodium concentration remains normal. In the second and third weeks of life, small premature infants may require more sodium to replace the large amounts that are lost in the urine (105,106,107). It is important to understand that most cases of hyponatremia or hypernatremia result from excessive or inadequate intake of water.

Potassium supplementation (2 mEq/kg/day) may be started after the infant urinates unless the serum potassium concentration is elevated. In most infants, potassium should be added to the infused fluids by the second day. In very small, critically ill premature infants, however, it is wise to wait until the serum potassium concentration falls below 4 mEq/L before administering potassium; these infants are at increased risk of hyperkalemia due to catabolism and release of potassium from cells in combination with decreased renal potassium excretion (110,111,112,113,114). Another mechanism proposed for the hyperkalemia often seen in extremely premature infants is the movement of potassium from cells to the extracellular compartment as a result of decreased sodium-potassium-ATPase activity in erythrocytes (115).

Figure 21-7 Plasma creatinine levels of premature infants during the first 3 months of life. (From Stonestreet BS, Oh W. Plasma creatinine levels in low-birth-weight infants during the first three months of life. *Pediatrics* 1978;61:788-789, with permission.)

Hyperkalemia is the most common life-threatening electrolyte disturbance in newborn infants. If an elevated serum potassium level is reported by the laboratory, it should not be attributed to *in vitro* hemolysis without verification of the result with another blood sample obtained with good technique to minimize hemolysis. If the serum potassium concentration is higher than 6 mEq/L, only potassium-free fluids should be administered. If the serum potassium concentration is above 7 mEq/L, rectal administration of sodium polystyrene sulfonate (Kayexalate) or another potassium-binding resin should be considered. Binding resins, if used, should be given carefully to limit the risk of colonic necrosis and perforation (116,117,118). If a cardiac arrhythmia occurs in the presence of hyperkalemia, calcium, bicarbonate, and insulin with glucose should be given to force potassium into body cells. In small premature infants, hyperkalemic arrhythmias include sinus bradycardia—especially if it occurs without hypoxia—and ventricular tachycardia.

Blood urea nitrogen and serum or plasma creatinine levels (Fig. 21-7) (119) are useful for assessing renal function, although the urea nitrogen may also be elevated with dehydration.

ACID-BASE BALANCE

The physiologic buffer system—primarily bicarbonate and its weak acid counterpart carbonic acid—and the renal and respiratory compensatory systems are the major mechanisms responsible for the maintenance of normal acid-base equilibrium in the body fluids. Changes in the hydrogen ion concentration in body fluids are governed by the Henderson-Hasselbach equation:

$$\text{pH} = 6.1 + \log \left(\frac{[\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]} \right)$$

in which 6.1 is the pK or dissociation constant for carbonic acid (120) and $[\text{H}_2\text{CO}_3]$ is the concentration of carbonic acid. It can be seen from this equation that increase or decrease in the bicarbonate (HCO_3^-) concentration results in *metabolic alkalosis* or *metabolic acidosis*, respectively. Because H_2CO_3 is interchangeably linked to the partial pressure of carbon dioxide (PCO_2) under the influence of carbonic anhydrase, any alteration in PCO_2 in body fluid also alters pH. Thus, hyperventilation, by reducing PCO_2 , produces *respiratory alkalosis*, and hypoventilation, by increasing PCO_2 , causes *respiratory acidosis*.

Metabolic alkalosis occurs with pyloric stenosis because persistent vomiting results in the loss of hydrochloric acid and thus produces a relative excess of bicarbonate. Metabolic acidosis is most commonly seen as a consequence of lactic acid accumulation from anaerobic metabolism in hypoxic infants. Respiratory alkalosis may occur in an infant who is hyperventilated with a mechanical ventilator. Respiratory acidosis occurs as a result of hypercapnia in infants with respiratory distress syndrome or other pulmonary disease.

In all types of acid-base disturbance, compensation by the lungs or kidneys occurs to restore the pH toward 7.4. Metabolic acid-base disorders are corrected by change in ventilation, and respiratory disorders are compensated for by change in renal bicarbonate excretion. If the compensation is adequate to correct the pH to normal, the acid-base disturbance is said to be compensated. For example, if an infant with respiratory distress syndrome has a pH of 7.38, PCO_2 of 32 torr, bicarbonate concentration of 18 mEq/L, and base excess of -5 mEq/L, the acid-base status is called *compensated metabolic acidosis*. If the same infant has a pH of 7.38, PCO_2 of 50 torr, bicarbonate concentration of 29 mEq/L, and base excess of +3 mEq/L, the acid-base status is *compensated respiratory acidosis*.

FLUID AND ELECTROLYTE PROBLEMS ASSOCIATED WITH SPECIFIC CLINICAL CONDITIONS

Extreme Prematurity

Infants born at gestational ages younger than 26 weeks present special problems in fluid and electrolyte management. These infants have large IWL (36,37), in some cases more than 200 mL/kg/day if the infant is nursed under a radiant warmer. The large IWL of extremely premature infants results from their meager skin barrier to evaporation and their large ratio of surface area to body weight. The average water requirement for an infant with birth weight between 500 and 750 grams in the first week of life is estimated to be about 170 mL/kg/day if the infant is in an incubator with low ambient humidity and without phototherapy and perhaps 150 mL/kg/day if moderate humidity is added to the incubator. The requirement would be

210 to 220 mL/kg/day if a radiant warmer or overhead phototherapy is used and 250 to 270 mL/kg/day if both radiant warmer and phototherapy are used (121). In the first week of life, the water requirement may be even higher in infants born after only 22 or 23 weeks of gestation. In these extremely premature infants, the cutaneous IWL and consequently the total water requirement decrease toward the end of the first week

P.373

of life, as the stratum corneum matures and becomes less permeable to water.

Extremely premature infants, unless hyponatremic from maternal hypotonicity (25,26,27,28), should initially be started on electrolyte-free solutions of glucose (5 g/dL) in water or solutions that provide sodium in a dose of 2 to 3 mEq/kg/day as sodium acetate or sodium bicarbonate. The latter bases compensate for respiratory acidosis while allowing hypercapnia with the goal of minimizing lung trauma. Administering some or all of the maintenance sodium as sodium acetate or sodium bicarbonate also serves to mitigate the metabolic acidosis present in many extremely premature infants as a result of renal immaturity and transient renal tubular acidosis. If sodium is not begun initially, it should be added by the second day, provided the serum sodium concentration is below 145 mEq/L.

Hyperkalemia is a very common problem in extremely premature infants during the first week of life. This potentially dangerous condition results from potassium release from catabolized cells in the presence of immature distal renal tubular function (110,112,113). Hyperkalemia is exacerbated if dehydration and oliguria occur as a result of inadequate water intake. No potassium should be given to extremely premature infants until the serum potassium concentration falls below 4 mEq/L. If the serum potassium concentration exceeds 7 mEq/L, rectal administration of a potassium-binding resin should be considered.

Respiratory Distress Syndrome and Bronchopulmonary Dysplasia

The renal function of infants with respiratory distress syndrome (RDS) is similar to that of infants of the same gestational age without respiratory distress, provided their cardiorespiratory status is not significantly

compromised (122,123,124). If infants with RDS become hypoxic and acidotic, however, they may have decreased glomerular filtration, reduced renal blood flow, and lower renal bicarbonate threshold (123,124,125,126). It has been observed that clinical improvement in infants with RDS is accompanied by an increase in urine volume that occurs on the second and third days of life (127) and, at the same time, by a rise in circulating levels of atrial natriuretic peptide (13). It is not clear whether this diuresis causes or is caused by the improving pulmonary function, or whether each enhances the other. These associated events may, in fact, be causally unrelated because this is the time when all infants, especially premature infants, are in negative water balance (128,129) and experience contraction of the extracellular water.

In addition to any changes in renal function that may occur with pulmonary dysfunction resulting from severe RDS, positive-pressure ventilation may also cause water retention through effects on renal function. Positive-pressure ventilation can impair water and sodium excretion by mechanisms that are not well defined but probably include increased aldosterone secretion (130) and increased production of antidiuretic hormone (131,132). It is also possible for impaired filtration and solute excretion to result from decreased aortic pressure and renal perfusion if excessive mean airway pressure is used during ventilatory support. Infants with RDS and other pulmonary disorders may have increased secretion of antidiuretic hormone, especially if they develop pneumothorax (64,133,134). When carefully used, positive-pressure ventilation, either conventional or high-frequency ventilation, does not impair diuresis or cause water retention (135).

PDA is a problem that affects premature infants; those with RDS are more likely to develop cardiorespiratory signs related to PDA than those without RDS. Infants receiving carefully limited intake of water are less likely to develop significant PDA (19,21,22).

RDS is commonly associated with a combined respiratory and metabolic acidosis resulting from hypercapnia and lactic acidemia. In severe RDS, when the acidosis is primarily respiratory, assisted ventilation should be instituted. If the acidosis is primarily metabolic, the underlying cause should be identified and corrected; if this cannot be done, sodium bicarbonate may be given to correct the acidosis. There is little evidence to

support the routine use of bicarbonate in infants with RDS (21,136,137,138). Therefore, the current approach is to treat only significant metabolic acidosis, generally if the pH is below 7.25. When bicarbonate is used, the dose should be calculated from the following equation:

$$\text{NaHCO}_3 \text{ dose} = (\text{base deficit})(\text{body weight})(0.5 \text{ L/kg})$$

The 0.5 value in the equation is the volume of distribution (i.e., bicarbonate space), which is confined mostly to the extracellular fluid compartment (Fig. 21-3). There is some disagreement regarding the true bicarbonate space; the reported values range from 0.3 to 0.6 L/kg. The 0.5 value in the preceding equation applies to term infants; 0.6 L/kg is a more appropriate value for premature infants because of their larger volume of extracellular water (1).

The calculated bicarbonate dose should be diluted to a concentration of 0.5 mEq/mL and given intravenously at a rate no faster than 1 mEq/kg/minute. A slow infusion over 30 to 60 minutes is preferable, especially for premature infants, because it may reduce the risk of rapid osmolar changes in the intravascular and interstitial fluid compartments (139), which have been associated with intracranial hemorrhage in infants receiving bicarbonate infusions (140).

Infants with RDS or BPD are sometimes treated with dexamethasone or other corticosteroid hormones in an attempt to ameliorate the severity of their lung disease. During dexamethasone therapy, infants may have impaired glucose tolerance, growth failure, and elevated blood urea nitrogen resulting from the catabolic effects of dexamethasone (141,142,143). Dexamethasone also perturbs the balance of phosphorus and potassium by increasing urinary excretion of these elements (144).

Perinatal Asphyxia

Infants with hypoxia or ischemia of the brain and kidneys during the perinatal period may suffer brain or kidney

P.374

injury. Increased secretion of AVP often accompanies hypoxic encephalopathy (64,145,146). Moreover, acute renal failure may result from

renal ischemia in these infants (147,148). Both conditions cause oliguria and therefore decrease the need for exogenous water. After birth asphyxia, it is advisable to restrict water intake in anticipation of possible increased AVP secretion (also known as inappropriate antidiuretic hormone secretion) or acute renal failure. During the first 24 hours of life, the water intake for asphyxiated infants should be limited to IWL plus urine output minus about 20 mL/kg/day to allow for some physiologic contraction of the extracellular water volume. If urine production is normal by the third postnatal day, water intake can be restored to a normal level.

During the oliguric phase of acute renal failure, potassium should not be administered unless the serum potassium concentration is less than 3.5 mEq/L. With acute renal failure resulting from hypoxia or ischemia, the initial period of oliguria may be followed by a diuretic phase with polyuria. If urine output increases and body weight falls below the expected level (i.e., the weight before fluid retention began), the intake of water must be increased to prevent dehydration. This diuretic phase may be accompanied by large losses of sodium and other electrolytes, which must be replaced. Replacement of the urinary sodium losses is facilitated by measuring the volume and sodium concentration in an aliquot of urine from a timed collection.

Central Nervous System Injury

Infants with brain injury from other causes, such as intracranial hemorrhage or central nervous system infection, may also have oliguria and water retention because of inappropriately increased secretion of AVP (64,145).

Sepsis and Necrotizing Enterocolitis

Systematic reviews of randomized clinical trials of varying fluid intake in premature infants have identified overhydration as a risk factor in the pathogenesis of NEC (20,21,22). Infants with septicemia who also have meningitis may develop inappropriate AVP secretion, reducing their water requirement. Infants with septicemia or NEC may also develop shock from endotoxin production or from hypovolemia due to loss of intravascular water and protein to the interstitial and peritoneal spaces or to the intestinal

lumen, or from frank hemorrhage resulting from thrombocytopenia, disseminated intravascular coagulopathy, or intestinal injury. In infants with shock, it is essential to replace lost water and solutes in the form of blood products or other solute-containing fluids. Even if properly treated, septic shock may cause renal injury, which then further complicates fluid and electrolyte management.

Pyloric Stenosis

With pyloric stenosis, water, electrolytes, and hydrogen ions are lost from the stomach as a result of repeated vomiting of gastric contents. Infants with severe vomiting caused by pyloric stenosis have elevated intracellular concentrations of sodium and decreased concentrations of potassium. Infants with pyloric stenosis are likely to be dehydrated and may have hypochloremic metabolic alkalosis and hypokalemia. The alkalosis may cause lethargy, hypoventilation, and, in severe cases, tetany.

Parenteral fluid therapy consists of replacing the deficits of water, potassium, and chloride. The chloride should initially be given as sodium chloride. Potassium chloride should be added after adequate urination has been established. Specific treatment of the metabolic alkalosis with acidic agents is not necessary. In most cases, control of vomiting, correction of dehydration, and replacement of chloride and potassium deficits will restore the blood acid-base status to normal.

Abdominal Wall Defects

Infants born with abdominal wall defects (gastroschisis or omphalocele) have increased IWL from the exposed viscera and require extra water prior to surgical repair. This is especially true of infants with gastroschisis because there is no membrane covering the extruding organs. Once the abdominal wall has been closed, evaporative water loss is no longer increased, although there may still be abnormal loss of water into the peritoneal cavity or interstitial fluid compartment.

Diarrhea

The principles of parenteral fluid therapy of diarrheal dehydration in the newborn infant are similar to those applied to older infants and children. Because of their limited renal concentrating ability, newborn infants are

quicker to develop severe dehydration, hypovolemia, and cardiovascular collapse. Therefore, rapid establishment of intravenous access for vascular expansion is of the utmost importance in newborn infants with moderate to severe dehydration from diarrhea. After stabilization, fluid and electrolyte deficits should be estimated as described earlier in this chapter. Water and electrolytes should be given to correct established deficits, meet maintenance requirements, and counteract ongoing losses.

Metabolic acidosis is a frequent finding in diarrheal dehydration. During initial volume reexpansion, preexisting acidosis may worsen as the body bicarbonate is further diluted with bicarbonate-free replacement fluids. Prerenal azotemia is common with diarrheal dehydration. It usually corrects spontaneously within several days as the infant is rehydrated.

Oral fluids and feeding should be withheld during recovery from diarrheal dehydration. Oral rehydration has been used successfully in older children with diarrhea, but there has been less experience with this technique in newborn infants (149). For this reason, oral rehydration is not recommended for newborn infants in areas where adequate personnel and supplies are available

P.375

to maintain parenteral infusions. However, oral rehydration provides an important alternate therapy when intravenous therapy is not feasible for economic or technical reasons. The appropriate period of fasting for diarrhea depends on the severity and duration of the diarrheal episode. As a rule, a more severe, protracted bout requires a longer period of fasting. How long diarrheal stools persist following the onset of fasting also helps to determine the duration of fasting. Reintroduction of oral fluids should be carried out with extreme care. Aggressive refeeding may precipitate a recurrence of diarrhea or even protracted chronic diarrhea and malabsorption with consequent growth failure.

Fluid and Electrolyte Management of Neonatal Surgical Patients

If a condition that requires surgery (e.g., pyloric stenosis) results in dehydration and electrolyte or acid-base disturbance, the infant should be

restored as close as possible to normal fluid, electrolyte, and acid-base status before surgery. Otherwise, the risks of anesthesia and surgery might be increased by dehydration, acidosis, alkalosis, or abnormal serum potassium concentration.

During surgery, the prescribed fluid and electrolyte therapy should be continued with the same fluid composition and rate of infusion unless additional intraoperative losses require replacement. The anesthesiologist and surgeons should be apprised of the plan for parenteral fluid therapy to avoid errors resulting from lack of communication. The operative losses of fluid and blood should be recorded and replaced either during surgery or shortly thereafter.

During the initial postoperative period, some infants have reduced urine output as a result of fluid loss from the vascular compartment or increased secretion of AVP. Therefore, the fluid provided for maintenance may need to be reduced during the immediate postoperative period. However, this reduction may be offset by the extra fluid required to replace abnormal operative and postoperative losses. A system of careful monitoring of fluid and electrolyte balance is essential in the surgical patient, as in other ill newborn infants.

TECHNICAL ASPECTS OF PARENTERAL FLUID THERAPY

Blood Sampling

Sampling of capillary blood by heel puncture is a safe and commonly used technique in newborn infants. Automated, spring-loaded lancets provide a safe and simple way to create an incision of standardized length and depth. Capillary blood is adequate for determination of serum electrolyte and blood urea nitrogen concentrations because most of these values agree closely with venous samples. Serum potassium concentration is slightly higher when obtained by heel puncture, but the difference is minimized if the blood flows freely from the puncture wound so that little squeezing is required. Blood flow can be enhanced by prior warming of the foot. Because the amount of blood that can be obtained by heel puncture is limited, the neonatology service should be supported by a laboratory in close proximity

to the nurseries that is capable of performing the required analyses on blood samples of small volume. Such laboratory support is also crucial to minimize blood transfusions, which are necessitated in part by phlebotomy blood losses (150).

Blood samples for blood gas and acid-base determination can also be obtained by heel puncture. Their reliability is enhanced by warming the skin to 44°C, which reduces the arterial-capillary differences in blood gases and pH; however, oxygen pressure (PO_2) measurements on samples obtained by heel puncture tend to underestimate true arterial PO_2 , especially in the hyperoxic range. Sufficient information for clinical management can usually be obtained by using capillary acid-base and PCO_2 values in conjunction with oxygen saturation values determined by continuous pulse oximetry. However, indwelling umbilical or radial artery catheters often are used in infants who are extremely ill and require continuous blood pressure monitoring or high levels of oxygen and ventilatory support. Because indwelling arterial catheters are associated with serious thromboembolic complications, they should be removed as soon as possible. For occasional sampling of arterial blood, direct puncture and aspiration from a peripheral artery can be used. This procedure is fairly safe in skilled hands but can cause serious complications, such as arterial obstruction or nerve injury.

Intravenous Fluid Infusion

Short catheters inserted into peripheral veins in a limb or the scalp can be used for infusion of water, electrolytes, and nutrient solutions. Hypertonic and vasoconstrictive solutions should be infused with caution into peripheral veins. Peripheral infusion of solutions containing dextrose in concentrations higher than 12.5 g/dL is generally contraindicated. Central venous access, if available, is preferred for such infusions. Shaving scalp hair to expose veins is distressing to many parents; the scalp should be used only if extremity sites have been exhausted and only after the procedure has been discussed with the parents. Intravenous sites must be carefully inspected on each nursing shift for evidence of infection at the insertion site or for extravasation of infusate that might injure subcutaneous tissues. Long catheters of silicone elastomer or other materials can be inserted percutaneously so that the tip lies centrally in a large vein within the

abdomen or chest. These catheters can be used for long-term intravenous access with lower risks of infection and thrombosis than occur with surgically inserted central vein catheters. Serious complications are rare with percutaneous central vein catheters. However, infectious complications are an ever-present threat. In addition, life-threatening complications, such as

P.376

pleural effusion and cardiac tamponade, are possible (151).

Venous cutdown for vascular access is seldom necessary if skilled personnel are available to insert and maintain standard intravenous catheters.

Surgical cutdown for venous access risks local infection or septicemia and permanent venous obstruction. Moreover, catheters inserted by cutdown usually do not last as long in newborn infants as they do in older children and adults. For these reasons, venous cutdown should be avoided in newborns whenever possible.

A catheter in the umbilical vein with its tip in the inferior vena cava may be used for infusion of fluid, electrolytes, and nutrients during the first few days, until potential infection can be treated and percutaneous central vein access can be established if needed. Umbilical vein catheters ordinarily should be removed within a few days of birth because of the risks of infection, portal phlebitis, and liver damage. Umbilical vein catheters can also be used for central venous pressure monitoring and exchange transfusions. Except in unusual circumstances, an umbilical vein catheter should be removed by the end of the first week of life, when the risks of infection and thrombosis probably surpass the advantages of continued catheter use.

With any route of parenteral fluid administration to newborn infants, it is essential to use infusion pumps that can be precisely regulated and can deliver fluids at an absolutely steady rate, even when very low flow rates are used. A fluctuating infusion rate may cause erratic delivery of water, glucose and other nutrients, or drugs.

Chapter 22

Nutrition

Michael K. Georgieff

The provision of nutrition to term and preterm newborn infants remains one of the most important aspects of neonatal care. With increasing survival rates among sick newborns, the nourishment of full-term and preterm infants has assumed an increasingly greater role in the neonatal intensive care unit in the past 25 years. Great strides have been made in understanding neonatal nutritional physiology and pathophysiology in these years, allowing physicians to more precisely estimate the nutritional needs of the infants in their care. Knowledge of newborn infants' nutritional requirements and of their neurological, gastrointestinal, and metabolic capabilities is a prerequisite to informed decision making about nutritional therapy in the nursery. It is also important to understand the tools available for assessment of neonatal nutritional status to judge the success or failure of nutritional therapies.

The goal of nutritional therapy in the term neonate is to ensure a successful growth transition from the fetal to the postnatal period. In the preterm infant, the goal has been to continue the process of intrauterine growth in what is now an extrauterine environment until 40 weeks postconception and to foster catch-up growth and nutrient accretion in the postdischarge period. Until lately, the goal for the growing preterm infant has been to match the third trimester intrauterine rates of weight gain, linear growth, and brain growth. Even if these rates are successfully attained, the body composition of the preterm infant raised in an extrauterine environment nevertheless remains remarkably different than that of the same postconceptional-age infant who has remained in utero (1,2). Current efforts are aimed at understanding the metabolic processes that determine the body composition of the preterm infant. Additionally, the preterm infant is still likely to be well below the standard gestational growth curves at discharge (3) because of nutrient deficits that have accrued during the prolonged period of neonatal illness (4). The effect of illness on neonatal metabolism and nutritional requirements is being recognized (5). Conditions such as bronchopulmonary dysplasia (BPD), congestive heart failure (CHF), acute respiratory distress, intrauterine growth retardation, and sepsis (and their treatments) have negative effects on neonatal energy, protein, and mineral and vitamin requirements. These conditions may also affect the digestive and absorptive capacities of the neonate.

This chapter reviews the nutritional requirements, digestive capabilities, and expected growth of term and preterm infants. These factors will be addressed in the context of the three time phases of neonatal nutritional development:

transition, premie growth, and postdischarge. The chapter also provides an overview of various nutrient delivery systems, both enteral and parenteral. Finally, the chapter covers techniques of nutritional assessment and offers suggestions for appropriate monitoring of neonatal nutritional status.

NUTRITIONAL CAPABILITIES OF THE NEWBORN INFANT

The ability to suck and swallow a meal in a coordinated fashion and then process those nutrients for utilization by the body may be one of the most complex developmental tasks facing the newborn infant (6). Success depends on a certain amount of neurological, digestive, absorptive and metabolic maturity. The term infant is quite mature in these respects. However, the preterm infant's physiology is progressively more immature as a function of decreased gestational age.

Neurological Maturity

The neurologically intact term infant is able to suck and swallow in a coordinated fashion within minutes of birth (7). In the preterm infant, the sucking reflex is strong at the limit of viability (23 weeks) and likely prior to that age (8). However, the ability to coordinate the suck reflex with swallowing to ensure that food is propelled into the gastrointestinal tract rather than the airway matures at approximately 34 weeks gestation (9). To a great extent, this coordinated suck and swallow reflex appears to be postconceptional-age mediated; that is, it does not appear that "practice" can stimulate the infant to become more mature at an earlier postconceptional age. Nevertheless,

P.381

the age at which the infant matures varies widely, and some preterm infants are able to suck and swallow in a coordinated manner by 32 weeks postconception.

Motility in the gastrointestinal tract is also dependent on neurological maturation (10). For example, the esophagus shows a very discoordinated pattern of peristalsis at 24 weeks gestation, with weak peristaltic waves beginning sporadically and propagating either rostrally or caudally (11). By term, the pattern has matured into a coordinated pattern that propels food downward to the stomach (12). The lower esophageal sphincter of the very preterm infant is tenuous and provides little barrier to gastroesophageal reflux (GER). GER disease in the preterm infant can be associated with apnea and bradycardia, aspiration syndromes, and feeding intolerance. At term, although GER remains demonstrable in most infants, it is generally not the potentially life-threatening problem seen at earlier gestational ages.

The stomach also undergoes maturation during the third trimester. The preterm infant's stomach does not coordinately "wring" the stomach from antrum to

pylorus, frequently being subject to periods of antiperistalsis, which in turn promotes GER disease (13). Additionally, pyloric function is different in the preterm compared to the term infant. Gastric emptying is longer in the preterm infant, although stomach volume is smaller (14). The small stomach capacity frequently results in the need to feed small volumes to preterm infants on a more frequent schedule. The prolonged gastric emptying time, however, causes retention of the food in the stomach and subsequent obtainment of “preaspirates” prior to the next feeding. Since the presence of preaspirates may also signify an ileus associated with more severe diseases such as necrotizing enterocolitis (NEC), feedings are often discontinued with this sign.

The maturation of small intestinal motility has been extensively studied by Berseth and her colleagues (15,16,17,18). They have demonstrated an orderly progression of peristaltic frequency, amplitude, and duration with increasing gestational age. They have also demonstrated a two-hour periodicity to peristalsis in very preterm infants (18). This finding may influence decisions about feeding schedules. The lack of a coordinated motility pattern in the very preterm infant makes it more likely that they will present with signs of feeding intolerance, usually marked by abdominal distention. When compared to adults, neonates retain food in their small intestine for proportionately longer periods and in their colon for shorter periods. The newborn's ability to modulate stool water and electrolyte content is immature compared to adults.

In summary, multiple neuromaturational factors work against the preterm infant's ability to enterally feed as successfully as the term infant (9). These immaturities have an impact on feeding management, as will be discussed in a later section.

Digestive and Absorptive Capabilities

The newborn infant does not have the capability to digest and absorb nutrients from a complex diet (9). Fortunately, the term human infant has a ready source of nutrition in the form of human milk (7). Human milk is remarkably adapted to fit the digestive capacities of the term newborn and to meet the infant's nutritional needs for at least the first 6 months of life (7). Recent studies have also shown the nutritional value of feeding human milk to preterm infants; however, for infants weighing more than 1,500 g, human milk needs to be fortified (19).

The functional immaturities of the gastrointestinal, hepatic, and renal systems in the newborn have an impact on the delivery of all classes of nutrients: macronutrients, minerals, trace elements, and vitamins.

Protein

Protein digestion begins in the stomach with the action of pepsin on the intact protein (20). Pepsin is activated by acid hydrolysis of its precursor molecule,

pepsinogen. The newborn is capable of creating an acidic stomach environment by 1 week of age (21); thus, pepsin activation is thought to be intact. Dietary protein is then acted upon by pancreatic peptidases released into the duodenum. These enzymes include trypsin, chymotrypsin, carboxypeptidases A and B, and elastase, and are amino acid selective with respect to cleavage sites, resulting in peptides of relatively small length. The peptides are subsequently cleaved once more by peptidases located in the intestinal mucosal cells, absorbed as amino acids or dipeptides, and transported to the liver. Protein digestion and absorption in adults is very efficient; up to 95% of a protein load can be fully digested. Although term and preterm infants have relatively low concentrations of chymotrypsin, the carboxypeptidases, and elastase (22), they nevertheless achieve more than 80% protein digestion.

Fat

The efficiency of fat digestion in the neonate has been a controversial topic. Data from the 1970s and 1980s suggested that fat is the most poorly digested macronutrient in the neonate (23). Whereas adults will absorb close to 95% of a fat meal and term infants absorb 85% to 90%, early studies indicated that preterm infants absorb as little as 50%, depending on the type of fat presented to them (24). The perceived functional immaturity of fat digestion in the preterm infant led to modification of fat blends in the formulas used in preterm infants.

Fat digestion in the neonate begins in the stomach with the action of a lipase secreted in the mouth (lingual lipase) or by the gastric mucosa (gastric lipase) (25). The two lipases are identical, function ideally at acid pH, work primarily on medium-chain triglycerides (MCT), and do not require bile salts. Hamosh has estimated that this enzyme may be responsible for up to 50% of fat digestion in the newborn (26). Infants fed human milk have the additional benefit of a lipase secreted into the milk by the mother (27). This lipase is found in all carnivores (but not herbivores) and functions more like pancreatic or intestinal

P.382

lipases found in adults. It works primarily on long-chain triglycerides at a neutral pH, as is found in the intestine, and requires bile salts. This lipase may be responsible for the digestion of up to 20% of dietary fat (28). These two lipases are referred to as the "compensatory lipases" of the newborn and function in place of pancreatic and intestinal lipases seen in more mature humans (29).

Long-chain fatty acids are dependent on bile salts for proper micellization and uptake into the intestinal lymphatics. From there, the micelles are carried to the venous system via the thoracic duct, ultimately destined for the liver. Medium-chain fatty acids do not require micellization and can be directly absorbed into the blood stream. The bile acid, and hence bile salt, pools of the preterm newborn are low, thus restricting the fat-absorption capacity of the infant. Prenatal

administration of glucocorticoids to the mother can mature the fetal bile salt pool in the preterm infant less than 34 weeks gestation to the level of the term infant (30). Without such priming, however, the preterm infant has significant impairment of fat absorption (including fat-soluble vitamins) prior to 34 weeks gestation. The fat blend in preterm infant formulas designed for infants less than 34 weeks gestation has been significantly modified to optimize fat absorption. These formulas contain a higher percentage of MCT and higher vitamin A, D, and E levels than formulas manufactured for term infants.

Carbohydrate

Like fats, carbohydrates can present a significant digestive challenge. The neonate has a limited ability to digest complex carbohydrates because of relatively small amounts of pancreatic amylase (31). Thus, beikost in the form of cereal rarely makes up a significant portion of the infant's diet until after 4 months of age. The term and preterm newborn readily uses glucose, which can be delivered either parenterally or enterally. Intestinal glucose uptake is seen as early as ten weeks gestation, long before the fetus is viable (32). However, provision of all carbohydrate calories as glucose would result in the neonatal gut being exposed to a hyperosmolar solution with a high potential for mucosal damage.

The primary carbohydrate found in mammalian milk is the disaccharide lactose. Like other disaccharides (sucrose, maltose, isomaltose), enzymatic cleavage by a disaccharidase must occur before the monosaccharides can be absorbed. In the case of lactose, glucose and galactose are produced by the action of lactase. The disaccharidases sucrase and maltase appear very early in gestation and appear to be inducible enzymes (33). In contrast, lactase begins to appear at 24 weeks gestation and rises in concentration very slowly until term. It does not appear to be a particularly inducible enzyme (34). The preterm infant is thus functionally somewhat lactose intolerant and will have typical symptoms of gas formation, diarrhea, and acidic stools characteristic of lactose malabsorption when fed high doses of lactose. Positive hydrogen breath tests have been documented in preterm infants following lactose challenges (35).

Preterm infant formulas have lower lactose contents than term formulas for this reason. Up to 60% of carbohydrate calories in preterm infant formulas are derived from linear glucose polymers, which produce a lower osmolar load than the equivalent number of individual glucose molecules. The enzyme required to digest glucose polymers (glucoamylase) is present from 24 weeks gestation (36). The lower lactose content is also present in the premature discharge formulas, although it is likely that the preterm infant is fully mature with respect to lactose absorption at the time of discharge (37).

NUTRIENT REQUIREMENTS FOR TERM AND

PRETERM INFANTS

Estimation of nutrient requirements is an inexact process, particularly when the goal is unclear. To date, the goal has been to achieve the same growth rates and body composition as the "reference" infant; the healthy breastfed infant serves as the "gold standard" for the term infant. Nevertheless, it is clear that breastfed babies have different growth rates and body compositions than formula-fed infants (38). Human milk composition varies greatly among mothers, and the length of time that it remains sufficient for all the nutrient needs of the infant is not uniform. Breastfed infants may have lower iron stores (39) and be at greater risk for vitamin D deficiency than formula-fed infants (40).

Determining the ideal growth for the infant born before term is far more problematic. Indeed, the ideal growth rate and body composition of the "healthy" preterm infant remain unknown and are likely to be different from his or her gestationally age-matched fetal counterpart. Until recently, the daily and weekly accretion rates of various nutrients in the preterm infant have been modeled on in utero accretion rates of these nutrients in gestationally age-matched fetuses. The "reference fetus" described by Widdowson and again by Ziegler has served as the benchmark by which neonatal nutritionists judge fetal growth and body composition (2,41). Nevertheless, energy requirements are likely to be different in a 28-week-gestational-age newborn exposed to the thermal stresses of extrauterine life than in a 28-week fetus comfortably surrounded by amniotic fluid.

The rates of weight gain, linear growth, and head growth between the ages of 24 and 36 weeks gestation can be calculated from the standard growth curves generated from infants born prematurely (42,43). It must be recognized that the data used to generate these plots are necessarily cross-sectional and thus need smoothing to create the resemblance of a curve. Additionally, since premature birth is an abnormal event and up to 30% of very-low-birth-weight (VLBW) infants are small for dates (most likely as a result of the pregnancy failing over time), the reliability of newborn data to assess the growth velocity of healthy fetuses

P.383

is suspect. Nevertheless, these curves are used extensively as guideposts for neonatal growth of the preterm infant. On average, these curves predict that the preterm infant should gain 10 to 15 g/kg body weight each day, grow 0.75 to 1.0 cm per week linearly, and demonstrate 0.75 cm per week of head growth. These values had been utilized to calculate the energy and protein needs of the preterm infant until recently. More accurate ultrasonographic techniques have been used to measure fetal growth in healthy pregnancies. These studies suggest that the rate of weight gain is closer to 18 to 20 g/kg body weight per day (44).

The nutrient requirements of term and preterm infants can be calculated based on fetal reference figures, balance studies, serum nutrient values, or a combination of these.

Energy Requirements

Energy requirements must take into account the amount and caloric density of the solution ingested, the route of administration (enteral versus parenteral), the amount lost in stool or urine, and the energy requirements in the body (e.g., basal metabolic rate, cost of growth, energy cost of food processing by the body) (45). Many of these are now measurable, and reasonable estimates of energy requirements to maintain optimal growth velocities can be made for both term and preterm infants.

Energy is predominantly derived from carbohydrates and fat in the diet, which provide 4 and 9 kcal/g, respectively. The infant fed human milk receives calories predominantly from fat (46), whereas the formula-fed infant receives calories more evenly distributed between fat and carbohydrate (47). The calories derived from these sources are used first to maintain the total energy need of the infant, which consists of the basal metabolic rate, the thermic effect of feeding, and physical activity. Energy intake beyond this baseline is stored and recorded as weight gain. Protein is not normally utilized as an energy source, unless the total energy intake is less than the total energy expenditure of the infant. In those cases, certain amino acids can be deaminated and shunted into the gluconeogenic pathways to provide approximately 4 kcal/g of protein (48).

Energy requirements can be affected by numerous factors, including the route of delivery and the disease state. Energy requirements are lower when infants are fed parenterally as opposed to enterally because no energy is excreted in the stool. Thus, the term infant who normally requires 100 kcal/kg/day enterally may be fed 90 kcal/kg/day parenterally. Diseases that increase energy needs include CHF (49), BPD (50), acute respiratory disease (51), and overwhelming sepsis (52). Diseases that decrease energy needs include hypoxic-ischemic encephalopathy and degenerative neurological conditions in which there is paucity of physical movement.

Term Infants

Healthy breastfed term infants show adequate growth on as little as 85 to 100 kcal/kg body weight per day during the first four months of life (53). Formula-fed infants have higher energy requirements (100-110 kcal/kg), most likely as a result of a lower efficiency of digestion and absorption of fat (54). The presence of a lipase in human milk increases the digestibility of its fats.

Preterm Infants

Preterm infants have higher energy requirements than term infants because of a higher resting energy expenditure and greater stool losses as a result of immature

absorptive capacities (55,56) (Appendix J-1). Whereas the resting energy expenditure of the term infant is 45 to 50 kcal/kg/day, the preterm infant less than 34 weeks gestation consumes 50 to 60 kcal/kg/day (55,56). Stool losses vary between 10% and 40% of intake, depending on the diet. For example, a diet in which the carbohydrate is 100% lactose and the fats are predominantly long-chain triglycerides will promote more stool losses because of the low levels of lactase and the small bile salt pools in the premature infant. Replacement of up to 50% of the lactose with glucose polymers and between 10% and 40% of the fat with medium-chain triglycerides (MCT) appears to reduce malabsorption to approximately 10% (57). The preterm infant will need an additional 50 to 60 kcal/kg/day beyond the daily energy expenditure and the loss of energy in the stool to maintain growth along the intrauterine growth curve (10 to 15 g/kg/day). Thus, barring any excess needs from diseases that increase oxygen consumption or from malabsorption, the preterm infant will gain weight adequately on approximately 120 kcal/kg/day. Assuming that 2.5 kcal are needed to achieve 1 gram of weight gain, this upward adjustment of expected weight gain would require feeding an additional 10 to 15 kcal/kg body weight per day to the preterm infant. Thus, it is likely that energy intake on the order of 130 to 135 kcal/kg/day is a more reasonable target for the premature infant than the previous recommended intake of 120 kcal/kg/day (57).

Energy Sources

Carbohydrates

Newborn infants are highly dependent on a source of glucose for normal brain metabolism (58). The primary source of glucose in the term infant is lactose in human milk and cow-milk formulas. Soy-based formulas provide glucose from the metabolism of dietary sucrose or glucose polymers. Preterm infants also receive glucose, initially as dextrose in parenteral solutions, but subsequently enterally from lactose or glucose polymers. Galactose is also important to the newborn, as it is needed for glycogen storage (59). The newborn infant typically utilizes between 4 and 8 mg/kg/minute of glucose (60). This figure is commonly used as the glucose infusion rate for parenteral nutrition. Because of their low glycogen stores and poorer gluconeogenic capacities, preterm infants are more prone to hypoglycemia than term infants (61). Higher rates of

P.384

glucose delivery (up to 15 mg/kg/minute) may be required in growth-retarded infants and in infants of diabetic mothers to maintain normal glucose concentrations.

Intravenous dextrose infusion rates up to 12.5 mg/kg/ minute are commonly used in preterm infants to promote catch-up weight gain. Beyond this rate, a cost/

benefit analysis must be made. Although faster rates of weight gain can be achieved on higher glucose infusion rates (especially if the serum glucose is controlled with exogenous insulin infusion) (62), a higher metabolic rate and a shift in the respiratory quotient will also occur. Thus, a higher oxygen consumption rate coupled with proportionately more carbon dioxide generated by the cells may significantly affect serum carbon dioxide and ventilatory requirements. In one study, infants who received glucose and insulin remained on the respirator an average of 13 days longer than their counterparts given lower glucose infusion rates (63). Moreover, the increased "growth rates" demonstrated with high glucose infusion rates are as a result of fatty weight gain, without any increase in linear or brain growth (62). The overall metabolic cost of glucose infusion rates > 12.5 mg/kg/minute must be weighed against the benefit of increased rates of nonlean weight gain.

Fats

Lipids constitute the other major energy source for neonates. Certain fatty acids, such as linoleic (omega-6, 18:2) and linolenic (omega-3, 18:3), are essential in the diet, and their absence will produce deficiency syndromes characterized by growth failure and skin rash (64). Although the full syndrome is rare, lower essential fatty acid concentrations are seen within one week of discontinuing lipid intake. Infants receiving parenteral nutrition or on a fat-restricted enteral diet require 0.5 mg/kg/day of an intravenous fat blend containing these fatty acids at least three times per week to prevent deficiency. The American Academy of Pediatrics (AAP) has recommended that 3% of total energy intake in infants should be in the form of linoleic acid (65).

Daily fat intake varies greatly based on the method of delivery (enteral vs. parenteral) and the dietary source (human milk vs. formula). Enterally fed term infants consume approximately 5 to 6 g/kg/day of fat, whereas parenterally fed infants rarely receive greater than 4 g/kg/day, largely because of concerns about toxicity. Infants receiving human milk (especially human milk expressed by mothers who have delivered preterm) may receive up to 7 g/kg/day.

Infants fed human milk receive a unique blend of fats that has not been precisely replicated in infant formulas. Cow-milk fat is generally not well tolerated by newborn infants, forcing formula manufacturers to use vegetable oils as substitutes. The spectrum of fatty acids found in palm, palm-olein, corn, and coconut oils are distinctly different from human-milk fats.

The role of omega fatty acids such as docosahexaenoic acid (DHA) and arachidonic acid (ARA) in the infant diet continues to be a subject of intense research (57,66). These fatty acids are products of an elongation pathway from linoleic acid and are important in cell membrane structure, in cell-signaling cascades and in myelination (67). The synthetic pathways may be immature in

preterm infants, and for some undetermined period of time after birth in term infants (68). Sources of these fatty acids include the placenta and human milk. In contrast, cow-milk fat and vegetable oil do not contain these compounds. A number of studies addressed whether these particular fatty acids are essential in the preterm and term infant (69,70,71,72). Because the preterm infant may be less capable of synthesizing the compounds and would have received them in utero, the European Society for Pediatric Gastroenterology and Nutrition has recommended that a source of these fatty acids be added to preterm infant formula (73). Evidence of their efficacy includes studies that demonstrate better visual acuity, more mature electroretinograms, and short-term gains in general neurodevelopment (74,75,76). Studies of the longer-term growth and developmental outcomes of infants who have been supplemented with these fatty acids are in their early stages but suggest continued positive effects on the visual system at one year of age (77). It remains unclear whether potential early neurodevelopmental gains are sustained beyond the first year (78). A review assessing the role of long-chain polyunsaturated fatty acid (LC-PUFA) supplementation on neurodevelopment concluded that the studies remain too underpowered to support a positive long-term effect (79). The lack of a consistent effect may be as a result of suboptimal dosing of the compounds. Additionally, any time a single component of human milk can be isolated and added to cow-milk-based infant formula, an important consideration is whether the component exerts its nutritional effect individually or in consort with other compounds (80).

The Food and Drug Administration (FDA) in the United States has recently approved a fungal source of DHA and ARA and its incorporation into infant formula under a provision termed "Generally Recognized as Safe" (GRAS). This designation confirms that the FDA has no questions of the manufacturers regarding the safety of the source and stability of these compounds when used in the intended matrix (e.g., infant formula). The GRAS designation is used to indicate that the ingredient in question has been in the food chain of humans and, based on prior usage or experimental evidence reviewed by an expert scientific panel, poses no safety concern. The GRAS determination does not assess efficacy claims; indeed, claims of efficacy for a new ingredient added to infant formula would be subjected to a more thorough examination process by the FDA, not unlike that required of new drugs. The major formula manufacturers in the United States have now added DHA and ARA to their term, preterm hospital, and preterm discharge formulas without making efficacy claims. The formulas appear to be as safe as formulas without added DHA and ARA. It is likely that formulas without the added fats will be phased out over time.

Carnitine is another compound involved in fat metabolism in the neonate. Although carnitine deficiency is rare in

the enterally fed infant because of high levels in human milk and supplementation

of formulas, it remains a concern in infants receiving long-term exclusive parenteral nutrition in which carnitine has not been supplemented (81). Carnitine supplements can be added to total parenteral nutrition (TPN), and this is recommended in infants who receive TPN for greater than 3 weeks (82).

Protein Requirements

Protein requirements in humans are determined by a number of factors including protein quality and quantity, the amount of energy delivered, and the protein nutritional status of the subject (20). The latter is influenced by the degree of previous malnutrition, by the rate of catch-up growth, and potentially by inflammatory processes. The sick newborn infant is exposed to many of these influences. Additionally, they have a high basal requirement for protein accretion based on in utero nitrogen accretion rates (2,41). Adequate energy intake is important to promote optimal protein utilization, with a nonprotein calorie-to-gram nitrogen ratio of 200:1 considered ideal. Overall protein intake in the neonate is ultimately limited to about 4 to 4.5 g/kg/day because of the inability of the immature kidney to excrete titratable acid, blood urea nitrogen (BUN), and ammonium ion (83). The renal excretion limitations are proportional to the degree of prematurity.

Protein requirements, in general, and branched-chain amino acid needs, in particular, are increased in adults with physiological instability as a result of septic or surgical illness (84). Recently, the possibility that similar changes might occur in sick neonates has been preliminarily investigated (51,52,85). Neither acute respiratory disease nor sepsis nor surgical ligation of the patent ductus arteriosus (PDA) results in increased protein requirements (51,52,85). At this time, increasing protein delivery routinely on the basis of illness or physiological instability is not recommended. Conversely, practitioners frequently limit nutrient delivery during illness out of concern that high loads may be metabolically taxing. Recent studies demonstrate that up to 3 g of protein/kg body weight can be administered daily to sick preterm infants beginning in the first 24 hours after birth (86).

Term Infants

The full-term breastfed infant grows adequately and maintains normal serum and somatic i.e., muscle protein status on as little as 1.5 g/kg/day of protein. Although the protein content is low (1.1%), the quality of human milk protein is excellent because the spectrum of amino acids provides a unique "match" for the amino acid needs of the newborn. The protein content is predominantly lactalbumin, as opposed to casein, which makes for smaller curds and easier digestibility. Additionally, human milk is replete with nondietary nitrogen sources including nucleotides, which may enhance the immune system (87); immunoglobulins and

other antimicrobial factors, which help protect the gut epithelium (88,89); growth factors, which stimulate intestinal growth (90); and enzymes (e.g., lipases), which aid digestion.

The term infant fed a cow-milk or soy-based infant formula requires a greater protein delivery rate, most likely to compensate for the less-than-ideal protein quality. Thus, the infant on cow-milk formula typically requires 2.14 g/ kg/day and the infant on soy formula up to 2.7 g/kg/day of protein (47). Cow-milk protein is predominantly casein, although a number of cow-milk-based formulas are modified to be whey predominant. The soy formulas also promote adequate growth of lean body mass. However, these formulas contain a smaller percentage of available nitrogen as essential or semi-essential amino acids (91).

Protein can also be delivered to the term infant by way of protein hydrolysate or individual amino acid formulas. These formulas are specifically designed to decrease the exposure of the infant to potentially antigenic cow- or soy-milk proteins. By hydrolyzing the cow-milk-based protein such that greater than 90% of the proteins have a molecular weight of 1,250 Daltons or less, allergic disease as a result of cow-milk allergy can be treated or potentially prophylaxed. These formulas provide approximately 2.8 g/kg/day of protein at an energy delivery of 100 kcal/kg/day.

Preterm infants

Recommendations for protein intake in preterm infants follow many of the same parameters as in term infants. However, the needs of the preterm infant appear to be greater than the term infant. Early studies suggested that the most rapid weight gain and most efficient energy utilization was achieved with protein intakes of 3 to 5 g/kg/day (92,93). Kashyap and associates refined these goals when they demonstrated that weight gain and nitrogen retention were greatest in healthy 32-week-gestational-age infants fed 3.9 g/kg/day of protein (94). They also attempted to define the optimal energy-to-protein ratio which promoted growth, finding that approximately 30 kcal were necessary for each gram of protein delivered. In a later study by the same group, Schulze and associates proposed that preterm infants tolerate 3.6 g/kg/day of protein with an energy intake of at least 120 kcal/kg/day (95). Heird has emphasized that increasing protein delivery requires increased energy delivery, and vice versa (96). His conclusions include:

- The low-birth-weight (LBW) infant who can take feeds soon after birth requires a protein intake of at least 2.8 g/kg/day.
- Infants who do not receive protein in the first few days of life lose at least 1% of their endogenous protein stores daily. (These findings are consistent

with research stating that preterm neonates were in better nutritional status if amino acids were added to dextrose solutions in the first days of life [97].)

- Infants with delayed protein intake subsequently require higher protein intakes to correct for early losses.

P.386

Denne has used stable isotopes of nitrogen to study the protein requirements and distribution (synthesis versus breakdown) in extremely-low-birth-weight (ELBW) infants (98). His calculations indicate that an average daily intake of 3.2 g/kg of protein is necessary to counter the negative nitrogen balance of neonatal illness and to match the expected in utero protein accretion rate. Ziegler's data in stable, growing premature infants also confirms that enteral protein delivery less than 3.5 g/kg/day results in suboptimal growth (99).

Besides total protein delivery, recent studies have considered which amino acids may limit protein accretion in the preterm infant. The terms "essential" and "nonessential" amino acids have been replaced in the neonatal lexicon by "indispensable" or "limiting" and "dispensable" (100) because they are more descriptive of the effects of amino acids on protein metabolism. Threonine and lysine are clearly indispensable because they cannot be synthesized de novo from products of carbon intermediary metabolism. Heird suggests that these two amino acids may currently be the limiting amino acids in TPN solutions.

Finally, illnesses or medications that increase protein turnover or muscle breakdown will have an influence on protein delivery. Van Goudoever and associates demonstrated that the steroids used for the treatment of BPD cause negative nitrogen balance by increasing the rate of protein breakdown but have little effect on protein synthesis (101).

Many preterm infants receive protein initially as part of a regimen of parenteral nutrition. Intravenous amino acid solutions have advanced to the point of being specifically formulated for preterm infants. These amino acid solutions are designed to normalize the plasma amino acid profile of the healthy infant, promoting levels similar to those of a one-month-old breastfed infant (102). Anderson and associates demonstrated that dextrose solutions with amino acids given early in life promote better nutritional status than dextrose solutions without protein (97). Denne et al. have shown that newborn preterm infants respond to parenteral nutrition with an acute increase in protein synthesis and a decrease in proteolysis (103). Thus, it appears that amino acid delivery in the first days of life is critical.

Element ^a	Days 3–7	Day 21	Days 29–42	Days 57–98

Calcium, phosphorus and magnesium contents of human milk during early lactation. *J Pediatr Gastroenterol Nutr* 1983;2:262–267, with permission.

The recommended amount of amino acids to be delivered and the rate of advancement remain to be determined, and are influenced by the infant's condition. Based on the estimates of protein loss by Heird and associates (96), it is prudent to begin amino acids on day one. The BUN and acid-base status of the infant must be followed. Older studies in sick neonates suggest that 1.5 g/kg/day of amino acids on day two would achieve neutral nitrogen balance (51). However, more recent data from Thureen and associates indicate that preterm infants can be safely started on 3.0 g/kg/day on day one (86). Ultimately, the goal is to deliver between 3.0 and 4.0 g/kg/day of parenteral amino acids. Some newborn intensive care units carry stock solutions of dextrose with added protein to be started upon admission to the nursery before parenteral nutrition from the pharmacy can be ordered and obtained. The amount of protein is designed to deliver 2 g/kg/day when the fluid solution is prescribed at 75 cc/kg/day.

Preterm infants who begin enteral feeds in the first days after birth will be relatively protein restricted because they are typically given human milk or low amounts of preterm infant formula. Although human milk from mothers delivering preterm is initially higher in protein (Table 22-1) compared to term human milk (104,105,106), the content is still relatively low and the infant will likely receive low volumes. Fortification with a human milk fortifier addresses this low protein issue. Preterm infant formula has a high concentration of protein (3.1 to 3.6 g/120 kcal), but it is unlikely that the infant will achieve that type of delivery in

the first week. With the trend toward increased protein delivery to the preterm infant, Ziegler and others have stressed the importance of supplying adequate energy intake (99,107).

Mineral And Element Requirements

Mineral requirements in newborns are influenced by the immature status of the kidney, prematurity, and medications that affect mineral metabolism (108). In general, preterm infants require higher amounts of minerals than term infants. The daily needs of some minerals (e.g., sodium, potassium chloride) are determined by measuring serum levels, although others (e.g., calcium, phosphorus) are estimated from in utero accretion rates (2,41). A more comprehensive discussion of these needs can be found in other chapters in this volume (e.g., Fluid/Electrolyte, Bone Mineralization) and in other sources (109). The following discussion focuses on selected minerals, comparing requirements in the preterm infant to the term infant and emphasizing the effects of diseases and their treatments on mineral status.

Sodium, Potassium, and Chloride

The typical term infant requires 1 to 3 mEq/kg/day of sodium (108). Breastfed infants have a lower sodium intake than formula-fed infants, although formula manufacturers have reduced the sodium content of cow-milk formula to levels comparable to human milk. Preterm infants have higher sodium requirements and may become hyponatremic on human milk (19,110). Baseline sodium requirements range from 2 to 4 mEq/kg/day in the preterm infant. The higher sodium requirement with lower gestational age is due predominantly to the immaturity of the proximal renal tubule in the small preterm infant. Treatment of these infants with salt-wasting diuretics, e.g., furosemide, hydrochlorothiazide may increase the needs to 10 to 13 mEq/kg/day.

Potassium requirements in the term infant generally range between 1 and 2 mEq/kg/day. Because potassium is also reabsorbed at the proximal tubule, the preterm infant needs 2 to 4 mEq/kg/day (110). Diuretics such as furosemide, metolazone, and hydrochlorothiazide can increase requirements to 8 mEq/kg/day.

Sodium and potassium are provided in human milk and infant formulas to satisfy the daily requirement for the normal infant. However, excessive demands from prior or ongoing losses may require supplementation. Supplements are typically in the form of chloride salts (NaCl or KCl) and are dosed based on calculations of maintenance requirements plus deficits. Depending on the acid-base status of the infant receiving parenteral nutrition, sodium and potassium can be added as chloride or as acetate.

Calcium, Magnesium, and Phosphorus

The term infant who has not experienced intrauterine growth retardation has well-mineralized bones. Analysis of the reference fetus demonstrated that the average fetus accretes 80% to 90% of its calcium during the last trimester (2). If there has been no interruption of the process, the average term infant will grow well and remain well mineralized on a diet that provides approximately 40 to 60 mg/kg/day of calcium and 20 to 30 mg/kg/day of phosphorus. Human milk is an excellent source for this rate of delivery. Infant formulas have higher concentrations of calcium than human milk, but there is little evidence that term infants who are formula fed are better mineralized.

LBW infants (intrauterine growth retarded or preterm) have significantly lower calcium and phosphorus content than term, appropriate-for-dates infants. Daily enteral calcium and phosphorus requirements in the preterm infant are estimated at 120 to 230 and 60 to 140 mg/kg/day, respectively (111). This rate of daily accretion can only be achieved enterally. The two minerals become insoluble in typical TPN solutions when added at concentrations that would provide more than 60 mg/kg/day of calcium and 30 mg/kg/day of phosphorus (at typical fluid delivery of 150 cc/kg/day). Human milk is relatively low in calcium and phosphorus and thus must be supplemented with a fortifier to achieve adequate mineralization in the less than 1,500 g infant (112). Preterm infant formula contains enough calcium and phosphorus to deliver the recommended daily amount and some excess to begin to replace previously acquired deficits. This is important because most preterm infants do not tolerate full enteral feedings immediately after birth. Preterm infants will invariably need intakes greater than the projected daily in utero requirement to avoid becoming osteopenic since parenteral nutrition results in negative calcium and phosphorus balance (4). Because serum calcium levels will always be maintained at the expense of the bone, following calcium levels as a way of monitoring status is not useful. Instead, indicators of bone activity (serum alkaline phosphatase) or urinary phosphorus excretion are used to monitor long-term calcium status.

As with calcium, the rates of magnesium accretion *in utero* are high during the third trimester. Thus, the magnesium requirement for infants born preterm are greater than those for term infants. Human milk and preterm infant formula appear to support normal magnesium levels. Magnesium delivery in parenteral nutrition is titrated based on serum magnesium levels, which should be monitored. The daily enteral magnesium intake should be 10 to 26 mg/kg/day (57) although the advisable parenteral intake should be 4.3 to 7.2 mg/kg/day (111).

Iron

The majority of total body iron found in the term infant is accreted during the third trimester. The fetus maintains a constant total body iron content of 75 mg/kg during the last trimester, increasing from 35 to 40 mg at 24 weeks gestation to 225 mg at term (113). Preterm delivery results in disruption of this process, and premature infants are therefore born with lower iron stores than term infants. Small-for-dates infants are frequently born with low iron stores, presumably because of decreased placental iron transport (114). Infants of diabetic mothers are born with low stores

P.388

because much of the fetal iron is in the expanded red cell mass (114). These infants also appear to be low in total body iron, most likely as a result of altered transport of iron by the diabetic placenta, such that the increased iron need of the infants of diabetic mothers exceeds the placental transport capacity (116,117).

Term Infants

The appropriate-for-dates newborn infant has sufficient iron stores to last four to six months; the small-for-dates infant has closer to a 2-month supply (118,119). In the absence of adequate dietary iron, these stores are mobilized for hemoglobin synthesis in the rapidly expanding blood volume of the growing infant. An adequate source of iron generally maintains iron stores until the infant begins to obtain iron from other dietary sources in the second 6 months of life. The estimated daily iron requirement for the term infant is 1 mg/kg/day (118,119).

The major source of iron for the healthy, term infant is dietary, either through human milk or infant formula fortified with iron (119). Although human milk has a low iron content (0.3 mg/L) compared to either iron-fortified infant formula (10-12 mg/L) or "low-iron" formula (4.5 mg/L), the iron is much more bioavailable as a result of proteins such as lactoferrin (120). Greater than 50% of the iron in human milk is absorbed, compared to only 4% to 12% of formula iron (121). The rate of iron deficiency in breastfed infants before six months is relatively low, although few methodologically sound studies have been performed (122). After 6 months, iron deficiency rates of 20% to 30% have been recorded in breastfed infants (123), although it has been unclear whether the infants in these studies were exclusively breastfed. Innis and associates showed an iron-deficiency anemia rate of 15% in 8-month-old breastfed infants (124). Given this, it may be wise to screen the breastfed infant's iron status at 6 months.

The FDA defines "low-iron formulas" as those containing less than 6.7 mg/L. Prior to changes in the iron content of "low-iron formula" at the end of the millennium, the rate of iron deficiency in infants fed exclusively a low-iron formula containing less than 2 mg/L was unacceptably high, with rates between 28% and 38% (123). This compares with a rate of less than 5% in infants fed iron-fortified formula (12 mg/L) during the first 6 months of life. Indeed, the introduction of iron fortification

of formulas in the early 1970s represents one of the most effective public health campaigns in this country. Recent studies indicate that infants fed formulas containing either 4 or 7 mg/L remain iron sufficient (125). No advantage in iron status is conferred to infants consuming formulas containing 8 as compared to 12 mg/L (126). Low-iron formulas have been reconstituted during the last 4 years such that they all contain at least 4 mg of iron/L, thus meeting the AAP recommendations (119). They continue to carry the designation "low iron" because of the FDA standard.

Low-iron formula continues to account for 9% to 30% of elective, e.g., non WIC formula sales. The reasons appear to involve the unfounded perception that iron in formula causes gastrointestinal symptoms such as colic, diarrhea, constipation, and GER. Double-blind studies have failed to support these claims (127,128).

Preterm Infants

The preterm infant that is not growth retarded begins extra-uterine life with the same iron stores per kilogram body weight as the term infant (approximately 12 mg/kg). However, the preterm infant is exposed to several stressors that perturb iron balance, with the result that by the time of hospital discharge, the infant may be iron deficient (129,130) or iron overloaded (131,132). The range of iron status of the preterm infant at 40 weeks postconception appears to be far wider than the term infant, although systematic studies are lacking.

The preterm infant frequently goes into negative iron balance because of blood lost during phlebotomy although sick, coupled with a rapid growth rate (and expansion of the red cell mass) during the convalescent period. In the past, phlebotomy losses were replaced by red cell transfusions, but criteria for transfusion have become more stringent because of concerns of exposure to infectious agents (133). Recombinant human erythropoietin has been used to stimulate endogenous red cell production in place of red cell transfusion, and produces additional negative stress on neonatal iron balance (134). Since 3.4 mg of iron are necessary to synthesize 1 g of hemoglobin, the therapeutic use of recombinant erythropoietin significantly taxes the already low iron stores of the preterm infant. Because of these factors, the daily enteral iron requirement for the preterm infant who does not receive recombinant erythropoietin is 2 to 4 mg/kg/day, with the greater requirement for the more preterm infant (108). Infants who receive recombinant erythropoietin require at least 6 mg/kg/day of iron (108).

The issue of when to begin iron supplementation in the preterm infant is controversial. Iron is necessary for normal growth and development of all tissues, including the brain. A rich literature supports the hypothesis that early iron deficiency results in neurodevelopmental sequelae at the time of the deficiency and persists well after iron has been repleted (135). Iron deficiency in infants as young as 6 months of age slows nerve conduction (136), a finding that persists

even after repletion of iron (137). Nevertheless, iron is also a very potent oxidant stressor since it catalyzes the Fenton reaction to produce reactive oxygen species. Since preterm infants have immature antioxidant systems, there is concern that free iron (i.e., in excess of the total iron-binding capacity) can exacerbate diseases that may be related etiologically to oxidative stress, including BPD, necrotizing enterocolitis, neuronal injury, and retinopathy of prematurity (ROP) (137,138,139,140,141). Although definitive studies on the role of iron in these diseases of prematurity have not been performed, it is clear that infants who are multiply transfused with packed red blood cells and those who receive parenteral iron are at risk for having free circulating iron and increased markers of oxidative stress

P.389

(131,132,142). Because of these concerns, parenteral iron should be used very sparingly. Since infants are born with adequate iron stores, there is no need to begin iron supplementation in a sick, nongrowing preterm infant. Therefore, enteral iron supplementation should not be started before two weeks postnatal age (108,138). Conversely, delaying iron supplementation until after two months confers a very high risk of iron deficiency in the postdischarge period (129).

TABLE 22-2 RECOMMENDED MICROMINERAL INTAKES FOR PRETERM INFANTS^d

	Transitional Period (0–14 days)		Stable/Postdischarge Periods	
	Enteral(μg/kg/day)	Parenteral(μg/kg/day)	Enteral(μg/kg/day)	Parenteral(μg/kg/day)

^d From Reifen RM, Zlotkin SH. Microminerals. In: Tsang RC, Lucas A, Vauy R, et al., eds. Nutritional needs of the preterm infant. Baltimore: Williams & Wilkins, 1993:195–207; Greene H, Hambridge K, Schanler R, et al. Guidelines for the use of vitamins, trace elements, calcium, magnesium, and phosphorus in infants and children receiving total parenteral nutrition: report of the Subcommittee on Pediatric Parenteral Nutrient Requirements

from the Committee on Clinical Practice Issues of the American Society for Clinical Nutrition. *Am J Clin Nutr* 1988;48: 1324-1342, with permission.

Generally, human milk should be used whenever possible in preterm infants. However, because of the low iron content of human milk and the rapid growth rate of these infants, iron supplementation is highly recommended. Additionally, those who receive recombinant human erythropoietin should be supplemented earlier with iron sulfate to have an adequate erythropoietic response. It is clear that iron must be available to see a sustained erythropoietic response with recombinant erythropoietin treatment (143). Preterm infant formulas are iron fortified and should provide adequate amounts to the larger preterm infant. However, preterm infants less than 30 weeks gestation may well need enteral iron supplementation in addition to their preterm formula to bring their total dose closer to 4 mg/kg/day.

Trace Elements

Ten trace elements are nutritionally essential for the human: zinc, copper, selenium, chromium, manganese, molybdenum, cobalt, fluoride, iodine, and iron (144). Zlotkin and associates have written an excellent review of trace element requirements in newborns (144). Most trace elements are accreted during the last trimester. Thus, the term infant is fully replete and needs modest dietary intake of these elements. Both human milk and infant formula ensure adequate intakes. The preterm infant or the term infant on prolonged TPN would rapidly go into negative balance of any of these elements if not provided with an exogenous source. While on TPN, infants should receive neonatal trace elements (Table 22-2). Preterm infant formulas and preterm human milk appear to supply adequate amounts of trace elements to the enterally fed premature infant (145).

Selenium is a potent antioxidant. Preterm infants have lower selenium stores than term infants (146), and this has been proposed as an etiology for diseases such as BPD and ROP (147). Studies linking selenium insufficiency with these diseases have not been persuasive (148), but the general consensus is that selenium status should be supported in the preterm infant (149). Selenium is not found in commercially available products and must be added separately to TPN at the rate of 2 µg/kg/day (149). Iodine is not added to TPN, but adequate amounts of iodine are absorbed through the infant's skin from iodine solutions applied topically (144). Nevertheless, a dose of 1 µg/kg/day has been recommended for infants who are on TPN for more than 6 weeks (149).

Vitamins

Vitamin requirements in newborn infants can be most easily conceptualized by considering water- and fat-soluble vitamins separately. An extensive review of all of the vitamins and their deficiencies is beyond the scope of this chapter and the

reader is referred to sources dedicated to this subject (150). This section will deal primarily with vitamins that are of particular relevance to neonates and to those with a specific risk for deficiency.

Water-Soluble Vitamins

Term newborns are rarely deficient of water-soluble vitamins in the B group (150). As with all humans, neonates need a daily source of vitamin C and folate. These are provided in adequate concentrations in human milk, infant formulas and multivitamin preparations added to parenteral nutrition. The AAP has stated that term breastfed infants do not need supplemental water-soluble vitamins during the first six months unless there are extenuating circumstances (7). Preterm infants also do not appear to need supplemental water-soluble vitamins once they are taking an adequate amount of formula or fortified human milk. The minimum amount of enteral feeds needed to maintain vitamin sufficiency varies among the formulas and the human milk fortifiers available. Infants receiving Enfamil Premature Formula or human milk fortified with Enfamil Human Milk Fortifier need no vitamin supplementation if their intake exceeds 150 mL/day. Those receiving Similac Special Care Formula or human milk fortified with Natural Care must exceed 300 mL/day to remain vitamin sufficient (151).

Fat-Soluble Vitamins

Fat-soluble vitamin deficiencies are also rarely a problem for term, healthy newborns fed human milk or infant formula. Nevertheless, certain groups of infants are at risk for vitamin D deficiency (150). These include breastfed infants whose mothers are vitamin D deficient as a result of their diet (vegan) or whose mothers completely protect their own skin from sunlight. Their infants must also be exposed to less than 30 minutes of sunlight per day to be at greatest risk. Most reports of rickets in breastfed infants in these circumstances have been in far-northern climates, although in the United States the problem has been seen as far south as San Diego and North Carolina (152,153). The AAP has recently recommended that all infants receive 200 IU of vitamin D daily. For infants consuming less than 500 mL of infant formula per day (including all breastfed infants), the least expensive and easiest way to achieve this goal is through a tri-vitamin preparation.

Virtually all infants receive vitamin K in the delivery room to prevent hemorrhagic disease of the newborn. The prevalence of this condition is very low, but the neurological consequences are so disastrous and preventable that the current recommendation is to continue to give vitamin K at birth. Once a gut flora has been established in the first 2 postnatal days, vitamin K deficiency is exceedingly rare (154). However, infants who receive broad-spectrum antibiotics, which

markedly reduce the intestinal flora, should be supplemented with vitamin K at least twice per week (154).

Whereas infants are not wholly dependent on dietary sources for vitamin D (it can be synthesized *de novo* from sterol precursors by 1 week of age) and vitamin K (supplied by gut bacteria), vitamins E and A must be provided in the diet. The term infant who consumes human milk or infant formula receives an adequate amount of each, assuming that there are no impediments to fat absorption, such as cystic fibrosis or short bowel syndrome. In infants with those conditions, a water-soluble A and E preparation should be utilized and serum levels monitored.

There are significant issues with fat-soluble vitamins, particularly vitamins A and E, in preterm infants less than 34 weeks gestation because of their relatively poor digestion of fats. As with term infants, vitamin K and, most likely, vitamin D are not a major problem, although preterm infant formulas are supplemented with more vitamin D than are term formulas. Even the most premature infants are capable of synthesizing the active vitamin D metabolite by one week of age (155).

Vitamin A deficiency in growing mammals results in significant tissue fibrosis, particularly of the lung and liver. In 1925, Wolbach and Howe noted that lambs born to vitamin A-deficient mothers had significant lung disease that, in retrospect, bears remarkable similarity to BPD (156). These animals had squamous metaplasia, loss of cilia, and loss of ciliary motility. Several investigators have noted that preterm infants have low vitamin A levels and hepatic stores (157). Moreover, preterm infants with respiratory distress syndrome who had low cord-blood vitamin A concentrations are more likely to develop BPD (158). Additionally, both prenatal and postnatal steroid administration increased serum vitamin A levels in preterm infants although preventing and treating BPD, respectively (159, 160). Two small but well-controlled studies assessed whether prophylactically administering 2,000 IU of vitamin A intramuscularly every other day from birth in <1500 g infants prevented BPD. Shenai and associates found a significant reduction of BPD in their treated infants, from 85% to 45%, with a concomitant rise in serum vitamin A levels (161). The serum retinol levels of placebo-treated infants remained abnormally low (<20 µg/dL). In contrast, Pearson et al., utilizing the same protocol, found no difference in BPD between the vitamin A- and placebo-treated groups (46% vs. 44%) despite a significant rise in serum retinol concentrations in the treated group (162). Of note was that retinol levels remained above 20 µg/dL in the placebo group. The unifying conclusion of these two studies is that vitamin A deficiency, as seen in the control group of Shenai and associates is indeed a risk factor for BPD, but not all infants less than 1,500 g are vitamin A deficient in the first month of life. Further supplementation of infants with adequate vitamin A status does not appear to further reduce the risk of BPD according to Pearson's data (162). More recently, the National Institute of Child Health and Human Development network addressed this issue in a multi-center, randomized trial

(163). There was a small but statistically significant reduction in the rate of BPD in the vitamin A-treated group. The data were not analyzed as a function of initial serum retinol concentration. At this time, treatment with vitamin A for all infants at risk for BPD is not unreasonable. The risks are relatively small, but include three-time-weekly intramuscular injections for 4 weeks in infants with little muscle mass and the relatively remote possibility of vitamin A toxicity. Vitamin A levels should be followed

P.391

weekly to monitor for toxicity and efficacy since the early studies suggest the greatest benefit occurs in infants with low initial vitamin A levels. Another approach is to check vitamin A levels in preterm infants at risk for BPD at birth and treat only those with low serum concentrations, realizing that serum concentrations are not the most reliable measure of tissue vitamin A status.

Ever since Oski and associates reported on hemolytic anemia caused by vitamin E deficiency, studies have assessed vitamin E sufficiency in the context of oxidative stress (164). Clearly, phospholipid membranes are at high risk for oxidative stresses; and if not adequately protected by circulating antioxidants such as vitamin E, selenium and superoxide dismutase will be damaged, with subsequent cell death. Thus, it was hoped that vitamin E supplementation of the preterm infant who has an immature antioxidant system might prevent or ameliorate established BPD or ROP. Studies along those lines have been a disappointment; after initial reports that vitamin E supplementation at birth prevented BPD (165,166,167,168), subsequent studies have not been able to duplicate the effect (168). Similarly, a meta-analysis of trials of vitamin E supplementation to prevent the occurrence or progression of ROP has not shown a significant effect (169). Moreover, high vitamin E levels following supplementation appear to increase the risk of sepsis and NEC (170).

Preterm infant formulas are supplemented with vitamins E and A. For most infants fed the preterm infant formula with higher vitamin E and A concentrations, serum levels remain in the normal range. However, routine assessment of these levels in the high-risk infant less than 1,500 g may be prudent, since it is likely that the deficiency state is not advantageous to the growing infant. The consensus panel recommendations for daily vitamin intake via parenteral nutrition were published in 1993 (171) and were adapted from a special report of the subcommittee on pediatric parenteral nutrient requirements (149).

The Effect Of Neonatal Illness on Nutritional Requirements

Most studies of neonatal nutritional requirements have dealt with defining the needs of the healthy growing term or preterm infant. Nevertheless, adults and older children who are ill undergo profound changes in metabolism based on the

type and degree of illness (172,173). Cerra and associates have investigated the independent effects of surgery, trauma, and sepsis on adult metabolism and have found consistent changes in protein-energy requirements (173). Each incident increases cellular oxygen consumption and promotes more negative nitrogen balance; sepsis has the most profound effects. Cytokines such as tumor necrosis factor (TNF-alpha), interleukin-6 (IL-6) and interleukin-1 (IL-1) appear to be important mediators of the response (174). These are elevated in preterm and term infants with sepsis (175). The adult studies suggest that energy and amino acid delivery must be significantly modified in sick patients. In particular, these patients appear to require higher energy delivery and more protein to remain in neutral or positive nitrogen balance. Special amino acid solutions that are rich in branched-chain amino acids are utilized to support nitrogen balance (176). Fewer studies have assessed these issues in preterm and term newborns. Nevertheless, some of the metabolic effects of acute lung disease, chronic lung disease, CHF, and sepsis have been studied (5). The conclusions of these studies support the concept that simply supplying the nutrients normally required by the healthy newborn will not be sufficient for infants with these illnesses.

Overall Approach Based on Stage of Illness in Preterm Infants

In 1995, the Canadian Pediatric Society proposed a novel approach to neonatal nutrition, primarily designed for premature infants but adaptable for term infants (177). This approach acknowledged that nutritional needs of premature infants change based on the phase of their illnesses. The initial "transition" phase is characterized as the time of neonatal illness and physiological instability. Although defined as the first ten postnatal days, the timing is flexible based on the duration of neonatal illness. The sick premature infant is likely to be relatively insulin resistant and to have increased circulating counter-regulatory (gluconeogenic) hormones, including cortisol and glucagon. Vasopressor therapy with dopamine, dobutamine, or epinephrine may have effects similar to the endogenous hormones. These factors, combined with the release of cytokines during illness (177), place the infant in a catabolic rather than anabolic state. Under such circumstances, growth factors are down-regulated (178) and growth is unlikely. Premature infants typically show weight loss and lack of head growth during their period of illness. The nutritional strategy for this first phase is incompletely defined. Principles gleaned from the adult critical care literature would suggest that energy delivery should at least meet resting energy expenditure to prevent further glycogen, muscle, and fat breakdown for gluconeogenesis. Once resting energy expenditure has been met in the stable, growing infant (approximately 60 kcal/kg/d), excess calories are channeled for growth, with a cost of about 2.5 calories per gram of weight gain. However, in the insulin-resistant sick infant with down-regulated growth factors, these extra calories are likely to increase the

cellular metabolic rate, generating more carbon dioxide but not resulting in growth. Carbohydrates, with their respiratory quotient of 1.0, are more likely than fat to create more carbon dioxide. The source of nutrition is usually parenteral with minimal enteral or trophic feedings. Administration of protein appears to be beneficial during this period to reduce the degree of negative nitrogen balance. Recent data of Thureen and associates demonstrating the safety and efficacy of 3 grams of protein/kg body weight on day one supports this concept (86). The use of specialized protein blends to replace particular amino acids lost during illness has not yet been studied extensively.

P.392

The in-hospital growth period is characterized by physiological stability and an anabolic state. The goal during this period is to match intrauterine growth rates and mineral accretion. For the preterm infants less than 34 weeks postconception, nutrient delivery should be adjusted to take into account digestive and absorptive immaturities. Fortification of preterm human milk and the use of premature infant formulas typically address these issues.

Preterm infants in the postdischarge phase are also anabolic and growing. Compared to the term infant, their physiology is characterized by a mature absorptive and digestive system. Unlike the term infant, however, these infants have accrued large energy, protein, and mineral deficits (3,4), and their growth is frequently below the 5th percentile for their age adjusted for prematurity. Premature infant discharge formula and fortification/supplementation of human milk after hospital discharge are indicated. The premature infant discharge formulas have increased energy, protein, calcium, phosphorus, iron, vitamin A, and vitamin D compared to term infant formulas. Infants on these formulas have more rapid catch-up growth and mineralization than premature infants-fed term formula (179).

In summary, a tri-phasic system seeks to customize nutritional delivery for the preterm infant based on physiology and nutrient needs. Future directions may include better definition of specific nutrient needs (e.g., amino acids, growth factors) for each phase and the development of noninflammatory formulas to be delivered enterally during transition or periods of medical instability.

Specific Disease Effects on Nutrient Needs

Whether acute lung disease, such as hyaline membrane disease, increases the oxygen consumption of the infant in direct proportion to the degree of respiratory illness remains debated (51,86,98). Unlike in adults, however, nitrogen balance in newborns appears to be unaffected by respiratory illness. The mean protein requirement to maintain neutral nitrogen balance during respiratory disease is 1.5 to 2.0 g/kg/day. Severe respiratory illness is associated with a higher incidence of hypocalcemia and hypoglycemia. There appears to be no indication to increase

protein delivery beyond what would normally be given.

BPD increases the resting energy expenditure by up to 30% (50), and infants with BPD will require energy intakes up to 150 kcal/kg/day to grow adequately. Much of the growth failure in BPD occurs in the first month, after which the rate of weight gain can be quite similar (although at a lower percentile) to infants without BPD (180). Protein requirements have not been extensively studied in infants with BPD, but those who are treated with steroids have increased muscle breakdown and a more negative nitrogen balance (101). Clearly, malnutrition plays an important role in the genesis of the disease and the rate of recovery (181). Sodium and potassium requirements are increased in infants with BPD treated with salt-wasting diuretics, occasionally requiring supplementation. Calcium balance is more tenuous as a result of more prolonged periods of parenteral nutrition, renal calcium wasting as a result of calciuric diuretics (furosemide), and bone demineralization as a result of corticosteroid therapy. A relationship between vitamin A deficiency and BPD has been documented (161,163); thus, it is important to monitor and support vitamin A status in infants with BPD.

CHF has a profound effect on resting energy expenditure equal to that of BPD. Infants with CHF as a result of structural heart disease may require up to 150 kcal/kg/day on the basis of both an increased metabolic rate and malabsorption as a result of intestinal edema. The protein requirement of infants with CHF has not been studied, although it is clear many fail to thrive and have reduced muscle mass. It is prudent to increase the protein delivery commensurate with the increase in energy delivery, maintaining a 25 to 30 kcal:g protein ratio. Diuretics used to treat CHF cause the same sodium, potassium, and calcium deficiencies seen in infants with chronic lung disease. Furthermore, the use of citrated blood products to replace losses perioperatively can cause profound hypocalcemia. Persistent cyanosis (See color plate) causes an additional nutritional stress by increasing the infant's need for iron. Since many of these infants have secondary polycythemia, there must be enough iron in the diet to support augmented erythropoiesis. Failure of a cyanotic infant to maintain an elevated hemoglobin may be as a result of iron deficiency, which can be screened for with a ferritin concentration and by assessing the red cell indices for microcytosis.

The effect of sepsis on neonatal nutritional status has not been well evaluated. Infants rarely present with the overwhelming multi-system organ failure that adults routinely have with sepsis. This may be as a result of an incomplete cytokine response. Septic infants have increased TNF and IL-6 levels, but their levels are not nearly as high as in adults (52). Furthermore, neonatal sepsis does not result in a profoundly negative nitrogen balance. Sepsis does increase oxygen consumption—although this appears to be a nonspecific response to illness, as it is seen in other nonseptic states. It appears that sepsis increases energy but not protein needs in the neonate.

NUTRIENT DELIVERY

Almost all term infants and many preterm infants more than 33 weeks gestation will feed orally on demand immediately after birth. Breastfed infants should be offered the breast within 30 minutes of delivery. However, ill term infants and preterm infants who are not physiologically mature or who are unstable will require alternate forms of nutrient delivery. The first decision revolves around whether the infant is stable enough to be fed enterally or if parenteral nutrition is indicated. If long-term parenteral nutrition is anticipated, decisions will need to be made whether a central catheter should be placed or whether the nutrients should be given through a peripheral vein. If the infant is to be enterally gavage fed, the practitioner has multiple options with respect to where the gavage tube is

P.393

placed, whether it remains indwelling or is replaced after each feed, and whether the feedings are by continuous drip or bolus.

Parenteral Nutrition

Indications

Parenteral nutrition is indicated in all infants in which enteral nutrition is contraindicated or delivers less than 75% of total protein and energy requirements. Although parenteral nutrition has become a more refined nutritional tool with fewer complications over the past decade, the enteral route remains the preferred way to nourish babies. For all practical purposes, infants on ventilators in the acute stage of their diseases are rarely enterally fed nutritionally meaningful amounts. It is also not appropriate to simply provide these infants with a dextrose and electrolyte solution. Anderson et al. demonstrated that the addition of amino acids to dextrose solutions shortly after birth improves the nutritional status of infants (97). Earlier initiation of parenteral nutrition was one factor associated with higher weight, length, and OFC percentiles at discharge and better long-term developmental outcome (182). Therefore, it is appropriate to begin parenteral nutrition for infants within 24 hours of birth. The trend in the past five years has been to begin feedings earlier in preterm infants to promote ongoing maturity of the intestinal tract, to avoid villous atrophy as a result of disuse, and to kindle gut hormone activity (183). Thus, infants who still require moderate respiratory support will receive "trophic" feeds, but these feedings are hypocaloric, and parenteral nutrition is indicated in these infants.

Absolute indications for parenteral nutrition include surgical lesions such as omphalocele, gastroschisis, intestinal tract atresias (e.g., tracheoesophageal atresia, duodenal atresia, ileal atresia), meconium peritonitis, diaphragmatic hernia, short bowel syndrome, and Hirschsprung's disease. Medical indications

include NEC (or feeding intolerance), meconium ileus, ileus as a result of generalized illness, infants on extracorporeal membrane oxygen (ECMO) therapy, and preterm infants on slowly advancing feedings.

Routes of Delivery

The decision whether to supply parenteral nutrition centrally or peripherally requires weighing the benefits versus the risks. Parenteral nutrition administered through a central line allows for greater energy delivery because solutions with dextrose concentrations more than 12.5% can be administered. Dextrose concentrations of that magnitude and calcium infusions are poorly tolerated by peripheral veins and carry a high rate of venous sclerosis (184). Skin sloughs are likely to occur if the solution extravasates from the vein. For the same reasons, many intensive care nurseries will not allow or will limit the amount of calcium to be run through a peripheral venous line. This practice is sound, but effectively limits the amount of calcium and phosphorus that can be delivered to an infant who is already at great risk for osteopenia.

The risks of central TPN relate primarily to the risk of central venous line placement and maintenance. Umbilical venous catheters placed at birth have traditionally been used as the primary central catheter, but the incidence of venous thromboses is high (185). Clots can be detected as early as 24 hours after catheter placement. The clots are frequently infected with *Staphylococcus epidermidis*, which has become the most common pathogen isolated in the ELBW infant after seven days of age (186). Equally concerning is the high rate of *Candida* septicemia seen with high dextrose delivery and high serum concentrations (187).

One risk of peripheral TPN is undernutrition. The infant receiving maximal concentrations of dextrose (D12.5%), amino acids (3.0 g/kg/day), and intravenous fat (3.5 g/kg/day) at an average fluid rate of 150 cc/kg/day will receive approximately 95 nonprotein kcal/kg/day. Although this amount of intake meets the daily resting energy expenditure of the premature infant (65 kcal/kg/day), there are insufficient "extra" calories to sustain weight gain at 15 to 18 g/kg/day. Thus, long-term peripheral TPN will result in preterm infants slowly falling away from the growth curve. Calcium delivery will also be constrained, either because of an absolute contraindication (in some nurseries) or because of osmolarity issues. Each day on peripheral TPN results in a larger deficit calcium balance and a higher risk of osteopenia of prematurity.

Infants who are not expected to tolerate oral feedings within a week of starting parenteral nutrition should have a central line placed and be maintained on central parenteral nutrition. The choice of venous access also involves weighing the risks and benefits. Surgical placement of an anchored catheter (e.g., Broviak) is a riskier procedure than placement of a peripherally inserted central catheter (PICC). However, it is likely that the Broviak, placed under sterile operating room

conditions, will last longer. Additionally, the choice of lines (single lumen vs. double lumen, differences in gauges) is greater with surgically placed lines, and frequently blood can be drawn from one of the ports for laboratory monitoring. Conversely, the PICC lines are easily placed in the unit, can be as small as 27 gauge, and are silastic (which are less prone to clotting and infection). Their disadvantage is that they generally cannot be used for blood drawing. In our unit we try to remove all umbilical venous catheters after the infant has been stabilized following delivery room resuscitation and attempt to place a percutaneously inserted central catheters (PICC) line within the first 24 to 48 hours if the infant is expected to be on parenteral nutrition. Because of the low incidence of infection with these lines, we typically do not use peripheral parenteral nutrition.

Maintaining patency of the lines is important for the success of parenteral nutrition. Most centers use heparin in TPN solutions to keep central lines patent and reduce the formation of a fibrin sheath around the catheters. These

P.394

fibrin sheaths are most likely to be the site of infectious agents. In order to maintain patency, our unit utilizes the following protocol for PICC lines: for flow rates more than 7 cc/hour, no heparin is used; for flow between 2 and 7 cc/hr, 0.25 U of heparin/cc is added; for flow rates more than 2 cc/hour, 0.5 U of heparin/cc is added. We do not "heparin-lock" our PICC lines and run them with a minimum rate of 0.5 cc/hour with 1 U heparin/cc of solution. We do heparin-lock surgically placed lines, administering 10 Units of heparin in 1 cc of solution, given every 12 hours.

Catheter occlusions are usually treated with removal of the line because so many of the clots are infected. Nevertheless, catheter occlusions that occur without signs of sepsis (e.g., if the line was inadvertently shut off) can be treated with urokinase (5000 U/mL). The amount of urokinase solution should approximate the internal volume of the catheter (0.2 to 0.5 mL). After instillation, the solution should be allowed to dwell in the catheter for 30 minutes. If two attempts at clearing the line fail or if a positive blood culture has been obtained from the clotted line, the catheter should be removed (188).

Nutritional Management

Parenteral nutrition should be started within 24 hours of delivery, since dextrose solutions alone cannot meet the resting energy requirements or the protein requirements of the neonate.

Dextrose delivery should typically begin between 4 and 6 mg/kg/minute and be advanced as tolerated. Extremely preterm infants are frequently glucose intolerant because of relative insulin hypoactivity and poor peripheral glucose utilization. Although their energy needs are higher because of higher basal

metabolic rates and higher brain-liver weight ratios, they frequently develop hyperglycemia and glycosuria. These are serious complications that must be treated immediately. Persistent glycosuria will result in a large free-water diuresis, intravascular dehydration, hyponatremia, and azotemia. Persistent hyperglycemia is a significant risk factor for fungal infection. Dextrose delivery can be slowly advanced based on how well the infant tolerates this. Typically we do not administer more than 12.5 g/kg/day because of the significant effect on the respiratory quotient. However, others have advocated rates up to 20 g/kg/day, aided by the administration of insulin to maintain normoglycemia (62). As stated earlier, I do not advocate this approach because the weight gain is predominantly fat rather than lean body mass, and the metabolic cost of fat synthesis from glucose is high in terms of both oxygen consumption and carbon dioxide production. On the other hand, insulin is very useful in treating the hyperglycemia seen in ELBW infants in the first week of life, in which glucose intolerance may necessitate decreasing dextrose delivery to unacceptably low rates (<4 mg/kg/minute).

Protein in the form of amino acid solutions designed for newborns should be administered within the first 24 hours. There are few contraindications to early protein delivery, and there is evidence that amino acid solutions improve nitrogen balance (52,86,97,98,189). At energy intakes above resting energy expenditure (65 kcal/kg/day), the main determinant of positive nitrogen balance is the nitrogen intake (190). The goal is to achieve in utero nitrogen accretion rates although compensating for nitrogen losses as a result of illness. This appears to be possible with amino acid delivery rates of 2.7 to 4.0 g/kg/day (86,98,191). Although protein requirements may be higher as a result of prior malnutrition, to diseases that increase nitrogen turnover, or to catch-up growth, it is rarely practical to give more than 4.0 g/kg/day of parenteral amino acids because of increasing BUN concentrations. Recent studies demonstrate that administration of amino acids is safe for all infants on day one to two. Most infants can be safely started on at least 2 g/kg/day and advanced by 1 g/kg/day to a maximum of 4.0 g/kg/day, thus ensuring that they will be on full protein delivery within 48 hours. Very unstable preterm infants and those with renal insufficiency as a result of indomethacin administration, surgery, a patent ductus arteriosus, or shock may need to be advanced more slowly. Monitoring the BUN allows the practitioner to decide on a daily basis whether the protein delivery can increase. A rising BUN is an indication that the infant is not clearing nitrogen waste and that the rate of amino acid infusion should not be increased. Initially, when amino acid solutions intended for adults were given to infants, significant complications occurred because these solutions did not meet their metabolic needs. In the mid-1980s, improved solutions were introduced that added the semi-essential amino acids taurine, water-soluble tyrosine, and L-cysteine. Potentially toxic amino acids such as phenylalanine and glycine were reduced. These newer solutions promote a more normal serum amino acid profile (103), better nitrogen retention and weight

gain (190,191,192,193), and lower rates of cholestasis (194). The lower rates of cholestasis may be as a result of the addition of taurine, which may also be important in neuronal development (194,195,196). Nevertheless, the neonatal parenteral amino acid solutions are not perfectly formulated, and investigations continue to determine whether threonine, lysine, and glutamine are limiting amino acids (100). There is no evidence that specialized solutions such as HepatAmine, BranchAmine or NephroAmine are indicated in newborns and the spectrum of amino acids found in them may dangerously imbalance an infant's serum amino acid profile.

Intravenous fats provide a low-volume source of calories and shift cellular metabolism toward less carbon dioxide production, perhaps improving the respiratory load of the infant. They can be utilized within the first three days of life and are important in preventing essential fatty acid deficiency (197). Close monitoring of serum triglyceride levels is important during intravenous fat therapy. Intravenous fat solutions can be started at a delivery rate of 1 g/kg/day and advanced to a maximum of 4 g/kg/day. Total fat calories should be less than 60% of the diet and typically are in the 30% to 40% range. Like amino acids, intravenous fats can be advanced by 1 g/kg/day if tolerated. Since fat incorporation into cells is dependent on insulin, fat intolerance in

P.395

VLBW infants is more likely to be manifested by hypertriglyceridemia or, interestingly, hyperglycemia, requiring a slower rate of advancement (0.5 g/kg/day) or interruption of fat delivery. Infants with birth weights less than 1,250 g and gestational ages less than 30 weeks may need to have their fat dose held at 1 g/kg/day until their hyperbilirubinemia begins to resolve. This group of infants seems to be at greatest risk for intravenous lipids exacerbating hyperbilirubinemia (see TPN complications). Fat emulsions are predominantly 20% solutions and are generally infused over no fewer than 16 hours to allow for metabolic clearing. It is important both to run them separately from other solutions, so as not to disturb the stability of the emulsion, and to cover the solution from light, to decrease breakdown. The solutions can be joined with the amino-acid-containing solution with a Y-connector near the infusion point on the infant.

Since infants initially undergo a free-water diuresis before a salt diuresis, sodium needs remain low until after day three of life (198). Thereafter, sodium and potassium requirements increase rapidly and serum concentrations should be monitored at least daily although infants are on intravenous solutions. Table 22-3 lists the approximate electrolyte requirements for premature infants in the face of no extraneous losses, such as those incurred by renal failure or diuretic therapy. However, requirements may approach 10 mEq/kg/day for each if there are excessive urinary losses. Chloride is the usual anion for both sodium and potassium; however, these cations also can be given as acetates, allowing for fine tuning of acid-base balance. Amino acid solutions have an inherent chloride and acetate load (e.g., TrophAmine contains 1 mEq of acetate for every gram of amino

acid).

Calcium and phosphorus are the most difficult minerals to maintain in positive balance in the preterm infant because of the large requirements for adequate mineralization, excessive losses as a result of calciuric diuretics and steroids, and the limited solubility of these nutrients in TPN (199). A calcium-to-phosphorus ratio of 1.7:2.0 appears to be optimal for mineralization (200). Because of solubility issues, calcium concentrations more than 16.6 mEq/L with a concomitant phosphorus concentration of 8.3 mM are rarely obtained. In an infant receiving 150 cc/kg/day, these values are equivalent to a calcium delivery of 50 mg/kg/day and a phosphorus delivery of 25 mg/kg/day—far less than the *in utero* accretion rate. Strategies to increase calcium retention and bone mineralization have been largely unsuccessful, but have included infusing calcium in one line and phosphorus in another and alternate infusions of higher doses of the two minerals (201,202). Monitoring of serum phosphorus and calcium levels is important. Infants are prone to hypocalcemia in the first 72 hours as a result of transient hypoparathyroidism and to hypophosphatemia. Both calcium and phosphorus should be added early during TPN therapy. Calcium delivery without phosphorus delivery should be avoided because of the likelihood of hypophosphatemia. This complication tends to occur in the first 72 to 96 hours because of the focus on the diagnosis and treatment of neonatal hypocalcemia. More acidic TPN solutions appear less likely to cause calcium-phosphorous precipitation (203,204).

TABLE 22-3 DAILY REQUIREMENTS OF TOTAL PARENTERAL NUTRITION

Nutrient	Requirement
Protein	2.5–3.5 g/kg
Fat emulsion	2–4 g/kg (max 3.5 g/kg in infants <2.5 kg)
Calories	90–110 kcal/kg or as needed
H ₂ O	125–150 mL/kg or as needed
Na	3–4 mEq/kg
K	2–3 mEq/kg
Ca	50–100 mg/kg, depending on size of infant
P	1–1.5 mM/kg
Mg	0.5–1 mEq/kg
Multivitamins (<i>e.g.</i> , MVI Pediatric)	10 mL (40%/kg/d)

Infants on TPN receive 0.2 mL/kg body weight of a neonatal trace element solution that supplies 0.02 mg/kg of copper, 0.3 mg/kg of zinc, 5 µg/kg of manganese, and 0.17 µg/kg of chromium. This supplement should be added with initiation of TPN and given daily. Selenium should be added after 2 weeks of TPN (149). Although we do not routinely measure zinc, copper, chromium, manganese, or selenium levels in infants on TPN, the practitioner should be aware

that preterm infants in particular have low stores of these trace elements and that deficiencies have been described (205,206,207). Water- and fat-soluble vitamins are added as a pediatric multi-vitamin solution to match the recommended parenteral dosing guidelines (149,171). This supplement should be added at initiation of TPN and given daily.

Complications of TPN

Administration of parenteral nutrition remains an inexact science. Because it is not the normal mode of nutritional delivery, it is not surprising that complications occur. For the most part, complications can be divided into those associated with catheters and those related to the nutrients themselves. As discussed above, centrally placed catheters are prone to thrombosis and infection. Thrombi can occur in the right atrium or in the veins. Clotting in the superior vena cava is of particular concern. Superior vena cava syndrome with or without hydrocephalus can result. Occasionally, back pressure from the clot on the thoracic duct will cause a chylothorax. Additionally, nonseptic complications such as skin sloughs can occur. Erosion of catheters through vessels or cardiac walls has caused pleural effusions, pericardial effusions, and endothelial damage. Improper technique of catheter insertion can result in pneumothorax or nerve injuries, although improper handling of fluids can result in air or fat embolisms. It is important for all personnel involved in parenteral nutrition

P.396

therapy, including nurses, pharmacists, and physicians, to be aware of the complications and the techniques to avoid them.

Intravenous lipids have been associated with hypoxia, pulmonary hypertension, hyperbilirubinemia, and infection (208). Infants with respiratory disease have minimally lower PaO₂ values when given intravenous lipids, most likely because lipids can uncouple hypoxic vasoconstriction (209). Normally, to optimize ventilation/perfusion matching, the pulmonary vasculature supplying a poorly oxygenated alveolar area will constrict. This effect is reduced by the infusion of lipids, most likely moderated by serotonin. Similarly, higher pulmonary arterial pressures are seen in neonatal lambs infused with pharmacological doses of lipids (6 mg/kg over 1-4 hours) (210). Finally, trials that have assessed whether early administration of intravenous lipids causes chronic lung disease (211,212) have had mixed results. Overall, given the profound and early onset of growth failure in infants with severe lung disease, it seems prudent to start small amounts of lipids early in life.

Free fatty acids can displace bilirubin from albumin-binding sites, prompting some practitioners to limit the dose of lipids to very small preterm infants. A study of infants weighing 670 to 3360 g demonstrated adequate albumin binding of bilirubin and no effect on serum bilirubin levels (213,214). There are no reports of

fat emulsions increasing the incidence of kernicterus. Theoretically, chylomicrons can be taken up by the reticuloendothelial system and interfere with fighting infection. Fat emulsions are also good media for fungi, including *Candida albicans* and *Malassezia furfur* (215). Whether these risks clinically outweigh the benefits of higher energy intake for small preterm infants has not been studied. At this time it is likely that intravenous lipids improve the survival of infants through better growth.

Parenteral amino acids also are associated with toxicity. Excessive amino acid delivery will lead to increased serum BUN and ammonia levels as a result of the newborn infant's relatively immature renal and hepatic status. Parenteral amino acids also have been associated with cholestasis, although the mechanism remains unknown (216). Infants at greatest risk are those who receive TPN for more than 3 weeks, those with intestinal disease, particularly NEC, those with sepsis, and those who remain NPO. Small amounts of trophic feeds reduce the prevalence of cholestasis, most likely by stimulating bile flow via cholecystokinin. Reduced bile flow from prolonged TPN is frequently associated with gallstones. In rare cases, prolonged TPN with no enteral intake will lead to cirrhosis.

Aluminum toxicity is worth considering in infants who have been on TPN for more than 3 weeks. The largest contamination comes from the calcium and phosphorus salts that are added (217). The risk to the neonate is two-fold. Aluminum accumulates in the bones of infants on TPN in which it is avidly taken up because of underlying osteopenia of prematurity (218). Of greater concern is the possibility that aluminum will cross the blood-brain barrier and induce an acute or chronic encephalopathy, as has been described in adult patients (219). Reduced renal capacity for excreting aluminum appears to be a necessary setting for this to occur, but it is not unusual for preterm infants to have a significant measure of renal insufficiency after treatment with indomethacin (220). Some have proposed that aluminum toxicity may be a factor in the poorer neurodevelopment of preterm infants. Since the body has no need for aluminum, manufacturers are being pressured to reduce the aluminum content of their solutions (221).

Monitoring TPN Efficacy and Toxicity

Administering TPN is an inexact science still in the process of evolution. Matching nutrient delivery to the infant's needs presupposes knowledge of how a particular disease or its treatment affects the infant's metabolism and, therefore, nutritional requirements. Careful monitoring of growth is indicated for any infant on TPN or partial parenteral nutrition. Weight should be measured daily and length and head circumference weekly. Standards have been published for arm muscle area and arm fat area for preterm and term infants, and these areas can be measured using a tape measure and skin caliper (180,222). Protein status can be assessed in two ways: somatic protein deposition (arm muscle area) and serum protein synthesis (serum albumin and prealbumin). The former provides a longitudinal

view of protein accretion, although the latter reflects a more rapidly turned-over pool of protein. Assessment of serum concentrations of proteins with short half-lives such as prealbumin has been shown to reflect recent protein intake and to predict future weight gain (223). Prealbumin, also known as transthyretin, has a half-life of 1.9 days and can be measured once or twice per week to yield useful nutritional information. If the serum concentration remains stable or increases, one can expect that the infant is in reasonable nitrogen balance and will gain weight subsequently (224). A decrease of more than 10% from the previous measurement suggests relative protein-energy malnutrition and the need for a higher intake. Like most rapidly turned-over proteins, prealbumin acts as an acute-phase reactant and will rise rapidly with stress, infection, and glucocorticosteroid administration, rendering it useless as a nutritional marker. Serum albumin, which has a half-life of 21 days, can be monitored every two to four weeks.

It is important to monitor infants on parenteral nutrition because of the toxicities associated with its administration. Table 22-4 provides guidelines for nutritional monitoring of infants on TPN. At the least, infants on TPN should have a set of electrolytes and a serum glucose checked daily. Serum glucose concentrations more than 110 mg/dL are an indication not to increase the glucose infusion rate; concentrations more than 150 mg/dL are an indication to reduce the rate. Serum triglyceride concentrations should be checked at least twice per week, or more frequently if the infant is showing signs of lipid intolerance. ELBW infants and infants with sepsis are especially

P.397

prone to hypertriglyceridemia, even if they have tolerated intravenous fat previously. Methylxanthines and glucocorticosteroids increase the likelihood of both glucose and fat intolerance in preterm infants. A triglyceride level more than 150 mg/dL measured with the infant off lipid infusion is an indicator of impending intolerance and lipid doses should not be increased. A triglyceride concentration more than 200 mg/dL is considered a sign of intolerance and the lipid dose should be decreased. Since persistent hypertriglyceridemia represents a risk to the pulmonary system, daily serum triglyceride levels should be monitored in the infant who exhibits intolerance.

TABLE 22-4 SUGGESTED MONITORING FOR TOTAL PARENTERAL NUTRITION

TABLE 22-4 SUGGESTED MONITORING FOR TOTAL PARENTERAL NUTRITION	

Variable	First Week	Later
Growth		
Weight	Daily	Daily
Length and head circumference	Weekly	Weekly
Chemistry		
Na, K, Cl, CO ₂	Daily until stable	Daily
Glucose (Chemstrip bG)	Daily	Daily
Triglycerides	With each increase in IL	Twice weekly when stable
Ca (ionized Ca is most accurate)	Daily until stable	Weekly
P	Initially	Twice weekly for first week, then weekly
Albumin	Initially	Monthly
Prealbumin	Initially	Weekly (biweekly) in infants <1000 g
Alkaline phosphatase	Initially	Weekly
Bilirubin	Initially	Every 4 wk or PRN
Mg	Initially	Weekly
Ammonia	As needed	As needed
Gamma GT	Initially	Weekly
Alanine aminotransferase	As needed	Monthly
Amino acids	As needed	Monthly
Zinc		Monthly
Serum osmolarity	Initially	Weekly
Vitamin A (if infant is < 1,300 g)	Weekly	Weekly while supplemented
Hematology		
Complete blood count	Initially	At least weekly
Type and screen	Initially	
Urinalysis		
Sugar	Each void	Each shift
Protein	Each void	Each shift
Specific gravity	Each void	Each shift

Calcium status must be monitored carefully in the first days of postnatal life because hypocalcemia is commonly seen in ill newborns. Preterm infants, growth-retarded infants, and infants of diabetic mothers appear particularly prone to hypocalcemia. Infants receiving large amounts of citrated blood products, such as those who are postoperative, who are on ECMO or who have disseminated

intravascular coagulopathy, will require large amounts of calcium. Similarly, maintenance of normophosphatemia is important for normal metabolism. Therefore, serum calcium, phosphorus, and magnesium should be monitored daily in the first week of life, or until stable, and then weekly thereafter (Table 22-4).

Bone mineralization is problematic for the preterm infant on long-term parenteral nutrition; therefore, close monitoring is indicated. Unfortunately, this can be quite difficult. Although osteopenia of prematurity is predominantly as a result of deficient intakes of calcium and phosphorus, the serum levels of these minerals will be maintained at the expense of the bones. Thus, serial measurements of calcium and phosphorus are not useful in monitoring this complication. Serum alkaline phosphatase is an indirect measure of osteopenia because its level will increase with the bone remodeling that takes place to supply the serum calcium pool. The level should be monitored weekly, particularly in preterm and growth-retarded infants. The level may be difficult to interpret, since the alkaline phosphatase will rise with cholestatic liver disease (a complication of parenteral nutrition itself) and with intestinal injury (such as NEC). Fractionating the alkaline phosphatase level into its bone and nonbone components can be done, but may take weeks depending on whether the laboratory has the capability to perform the fractionation. As with monitoring of the prealbumin concentration, the most important aspect of the alkaline phosphatase to follow is the trend. Rising alkaline phosphatase levels generally mean aggressive bone remodeling and an increased risk of osteopenia.

P.398

Strategies to increase calcium and phosphorus delivery should be considered.

The incidence and severity of hepatic toxicity from parenteral nutrition has been on the decline with the introduction of more specialized neonatal amino acid solutions. The toxicity is typically cholestatic in nature, with an initial rise in serum bile acids followed by an increase in the direct bilirubin, alkaline phosphatase, and gamma glutamyl transferase. Transaminase elevations are seen only in very severe cases. The liver toxicity was initially thought to be as a result of intravenous lipids (fatty liver), but has now quite conclusively been associated with amino acid solutions. Although these solutions have been refined (192,193), the problem persists and its cause is unknown. Total and direct bilirubin concentrations will typically be monitored in all newborns in the first week of life. Infants on prolonged TPN should have direct bilirubin measured weekly. If it is elevated, the remaining liver function tests should be assayed and followed weekly.

Trace minerals are rarely deficient in infants on TPN because of supplementation. Nevertheless, the importance of maintaining normal zinc status for growth and protein utilization (225) makes it wise to monitor the serum zinc concentration monthly, particularly if the infant is not growing adequately or has physical signs of zinc deficiency.

With the exception of vitamins E and A, vitamin status generally need not be checked in infants on TPN. Most vitamin assays are cumbersome and are a poor reflection of total body load. Serum vitamin E and A levels also do not necessarily reflect total body stores. Nevertheless, the association of low serum retinol (circulating vitamin A) levels with an increased risk for BPD in the VLBW infant suggests that monitoring may be appropriate (161,163). An initial measurement in all infants less than 1500 g with respiratory disease should indicate the degree of risk. Infants with levels less than 20 µg/dL should be supplemented and their levels followed weekly. The methodologies for assaying vitamin A (high performance liquid chromatography or fluorometry) are the same as for vitamin E and the values for both can be done simultaneously. As with vitamin A, it is important to keep vitamin E concentrations in the normal range, as an insufficient concentration has been associated with anemia (164) and perhaps ROP (165), although toxic levels increase the risk of sepsis and NEC (170).

Enteral Nutrition

Oral Feeding

The goal for virtually all infants prior to discharge from the hospital is full oral feedings, preferably by breast. Oral feedings come naturally to infants born at term, but can be a significant task for those born at less than 34 weeks gestation, those with significant central nervous system disease, and those with anatomical abnormalities that prevent oral feedings.

Oral feedings should be initiated within half an hour of birth by placing the infant to the mother's breast. Infants who are breastfed will have a different sucking motion than those who are bottle fed. Thus, it is important that artificial nipples (and probably pacifiers) not be introduced as the infant is establishing breastfeeding (7). The oral pattern associated with breastfeeding is typically well established within two weeks, although a substantial number of infants who are then supplemented with bottles will demonstrate nipple confusion and may give up on breastfeeding. The healthy breastfed infant has no need for supplemental water, juice, or formula (7). Breastfeeding can be supported in the delivery hospital by training all of the staff to encourage mothers to breast-feed and to provide the necessary environment to promote breastfeeding. This includes allowing the mother to nurse within half an hour of delivery, having the infant room with the mother, and having the mother learn the cues of her infant's hunger. Hospitals can contribute by eliminating policies about supplementing breastfed babies and by supplying charts that assess the infant's feeding and hydration status (7).

Oral feedings can be more problematic for the healthy premature infant. These infants rarely show any interest in oral feeding until approximately 32 weeks

gestation and rarely have a mature, safe feeding pattern until 34 weeks gestation (9). Coordination of sucking, swallowing, and breathing is most difficult; the issue is predominantly one of inappropriate swallow-respiration interface rather than suck-swallow interaction (226). There is little evidence that "practice" helps the gestationally immature infant to feed orally sooner. Nevertheless, Meier has reported that breastfed premature infants have longer periods of sucking with fewer obstructive apnea and desaturation spells than comparably sized bottle-fed infants (227). This may relate to the more metered rate of milk flow. It is important to note that preterm infants are frequently exposed to pacifiers to stimulate nonnutritive sucking, which improves gastric motility and likely increases the flow of important gastrointestinal hormones (228,229,230). It is unclear whether this nonnutritive sucking at an earlier postconceptional age affects the success of breastfeeding at 34 weeks gestation.

A strong case can be made for feeding breast milk to the preterm infant, either by gavage tube or by breastfeeding, because of its superior performance with respect to immune status and neurodevelopment, among other advantages (19,227,231). In order to successfully breast-feed the premature infant, the mother needs to be available to begin the process as the infant nears 33 weeks gestation. Before that point, it is important that she maintain her milk supply. The intensive care nursery can help by providing a place to nurse, an electric breast pump, storage containers, and a freezer for storing the milk. An organized program with an informed leader is quite useful in timing the introduction of actual breastfeeding and in overseeing the progress made by the individual infant. With such a program, more than 60% of preterm infants whose mothers desire to nurse can successfully breast-feed at the time of discharge.

Preterm infants who are bottle fed also require close observation as they transition from gavage to nipple feeds. There is an energy cost to bottle feeding. Gavage feedings

P.399

require between 4% and 17% less energy to process, and excessive oral feedings may tire an infant and reduce weight gain velocity (232,233). Typically, attempts at bottling should begin around 33 weeks' gestation with one feeding per day. If the infant shows no interest or has significant obstructive apnea, it may be prudent to wait several days before attempting again. The frequency of feedings can be increased as the infant shows more aptitude. Once the infant has advanced to full oral feedings, it is important to see whether weight gain can be maintained on an ad libitum on-demand schedule prior to discharge. Consistency in feeding personnel can improve the infant's performance, and in the best of all worlds, having the mother give most of the feedings is ideal. Adopting a cue-based feeding program, in which personnel pay attention to the feeding cues exhibited by the infant, may reduce the number of episodes in which the infant refuses to feed because of fatigue and aversion.

Oral aversion is a significant problem in infants who have been NPO or on ventilators for long periods of time. Symptoms include aversive behaviors such as tongue-thrusting, head-turning, pooling of milk in the mouth, and occasionally breath-holding apneic spells. A barium swallowing study with fluoroscopy can help identify whether the problem is anatomical, or is as a result of discoordination, immaturity, or neurological pathology. For infants with severe cases, the worst course is to force oral feedings. The involvement of an occupational or speech therapist can be invaluable in desensitizing the oral area.

Gavage Feeding

Gavage feedings are indicated for infants who can be fed enterally but not orally. For the most part, this approach is used in premature infants who are neurologically immature and the full expectation is that they will feed orally. Infants who will not be candidates for oral feeds either because of anatomical or neurological conditions can have gastrostomy tubes placed. Gavage feedings are most frequently accomplished by placing a naso- or orogastric tube and bolusing feedings intermittently. Some practitioners prefer to place an indwelling transpyloric tube to reduce aspirates and to ensure nutrient delivery. Infants can receive feeds by continuous drip and by bolus.

Oro- or nasogastric tube feedings can be initiated using a soft silastic 5-French or 8-French catheter. The tube is most commonly placed into the stomach prior to a feeding and the contents of the stomach aspirated to ensure there are no residuals from the previous feeding. The feeding is allowed to run in by gravity, although in some infants with very slow gastric emptying the feeding can be titrated in over one hour. The tube is typically withdrawn rapidly after the feeding, although there is some increased risk of the infant vomiting in response to this stimulus. A long-term indwelling catheter can be placed, but this type of catheter may lose flexibility over time and increase the risk of stomach perforation.

Gastric gavage feedings can be given on a schedule between every one and four hours. Typically, smaller infants do not tolerate excessive stomach distention with large-volume feedings and may exhibit respiratory compromise. They may need to be fed small amounts on a more frequent schedule. Infants less than 1,000 g can be fed on a bolus schedule of every one to two hours or with continuous-drip feedings. This approach may reduce oxygen consumption and total energy expenditure, and potentially contribute to faster rates of weight gain. Infants may be fed on this schedule until 1,250 to 1,500 g, after which every-3-hour feeds are more appropriate. Nevertheless, larger infants who are not tolerating bolus feedings, those who remain on ventilators, or those with severe apnea and bradycardia may require drip feedings. Term infants who require gavage feedings may do best on an every-four-hour schedule.

Tube placement and maintenance may cause significant problems in the infant.

Tubes can be malpositioned in the airway instead of in the stomach. With the placement of any new tube it is important to document its position by auscultation and by checking the pH of aspirated stomach contents. Placement of the tube can cause significant vagal stimulation that results in apnea or bradycardia. The presence of an indwelling tube can cause apnea and bradycardia either by excessive vagal stimulation or, more commonly, by upper airway obstruction. Although nasogastric tubes are more stable, they appear to cause more problems with airway obstruction. Gastric and esophageal perforations are rare but must be considered if there is a significant change in the infant's behavior or physical exam.

Gavage feedings can also be given through a transpyloric tube. The advantages of this type of feeding include ensured nutrient delivery and a smaller chance of GER and aspiration pneumonia. There are significant mechanical and nutritional disadvantages to this approach. The mechanical problems include the difficulty of placing the tube, although this becomes easier with practice. In order to place the tube, the infant is turned with his or her right side down and the tube is inserted into the stomach with small amounts of injected air. As the infant remains in the right-side-down position, the tube has a reasonable chance of advancing through the pylorus into the duodenum. The tube has reached the duodenum when bile-stained fluid is returned or when the pH of the aspirated fluid changes from acidic (pH 3) to alkaline (pH 5-7). Infants on histamine-2 blocking agents cannot be assessed in this way. The procedure can also be done in the radiology suite under fluoroscopy with a weighted tube. The position of the tube is confirmed on x-ray. Frequently, the tip of the tube will curl back on itself or simply move back into the stomach, and the process will need to be repeated. Although rare, the most devastating complication of transpyloric feedings is intestinal perforation and peritonitis.

Transpyloric feedings also pose significant nutritional risks (233,234,235). Bypassing the stomach decreases fat digestion and absorption, since up to 50% of fat processing takes place in the stomach by the lingual and gastric lipase enzymes. Additionally, secretion of gut hormones such as cholecystokinin and gastrin are dependent in part on stomach distention by a meal. Potassium accretion may

P.400

be impaired. Bacterial colonization of the normally sterile intestine may be a significant risk since the normal mechanism by which the stomach acid kills bacteria has been bypassed.

TABLE 22-5 ORAL FEEDING SCHEDULE FOR THE LOW-BIRTH-WEIGHT INFANT

Time	Substance ^a	≤ 1,000 g		1,001–1,500 g		1,501–2,000 g		> 2000 g	
		Amount	Frequency	Amount	Frequency	Amount	Frequency	Amount	Frequency
First feeding	Full-strength human milk or 1/4 strength formula	1–2 mL/kg	1–2 h or continuous drip	1–3 mL/kg	2 h	3–4 mL/kg	2–3 h	10 mL/kg (full strength)	3 h
Subsequent feedings, 12–72 h	Formula or full-strength human milk	Increase 1 mL every other feeding to maximum of 5 mL	2 h	Increase 1 mL every other feeding to maximum of 20 mL 20–28 mL	2 h	Increase 2 mL every other feeding to maximum of 15 mL 28–37 mL	2–3 h	Increase 5 mL every other feeding to maximum of 20 mL	3 h
Final feeding schedule, 150 mL/kg	Full-strength formula or human milk	10–15 mL	2 h		2–3 h		3 h	37–50 mL, then ad libitum	3–4 h
Total time to full feeds			10–14 d or more for infants <705 g		7–10 d		5–7 d		3–5 d

^a Supplemental intravenous fluids should be given to fulfill requirements of 140–160 mL/kg and caloric requirements of 90–130 cal/kg

Initiation of gavage feedings through any of the tubes mentioned above requires a careful assessment of the infant. The stable infant more than 1500 g birth weight can typically be fed within hours of birth, although if the infant is less than 35 weeks gestation it is prudent to advance the strength and volume of feedings in a proscribed manner. Table 22-5 provides a sample of feeding schedules in stable infants based on birth weight. Advancement at a rate of 20 cc/kg body weight per day appears to be safe as long as the infant shows no signs of feeding intolerance. Interestingly, a meta-analysis of randomized or quasi-randomized trials of rapid versus slow rates of advancement revealed that more rapid rates were associated with a shorter time to regain birth weight and to achieve full enteral feedings without an increase in morbidity (236). Infants with birth weights more than 1,500 g can be started on every-3-hour feedings; infants between 1,000 and 1,500 g on every-two-hour feedings; and infants less than 1,000 g on every-one-hour, two-hour, or continuous-drip feedings. It must be remembered that although low-volume feedings are better tolerated from a respiratory standpoint, the gastric emptying time of the preterm infant is often between 60 and 90 minutes. Therefore, it is likely that gastric aspirates will be present in an infant fed every hour or by continuous drip. In the infant fed every two hours or less frequently, gastric aspirates should be less than 2 cc/kg body weight. Aspirates greater than that amount may be indicative of an ileus as a result of feeding intolerance or impending NEC. A thorough evaluation including an abdominal examination is indicated before resuming feedings. The availability and ease of administration of parenteral nutrition makes a strong argument for being conservative with feeding advancement in preterm infants.

Trophic Feeds

Slow advancement of feedings is recommended in an infant who has been ill and likely had an ileus. The trend in the last ten years has been to start with trophic feeds in infants who in the past would otherwise have remained NPO. Trophic feedings are defined as continuous-drip feedings at 1 cc/hour or less. Studies of VLBW infants begun on trophic feedings in the first week of life have shown a lower incidence of feeding intolerance and NEC, a more mature gastrointestinal tract, and a shorter duration of time to regain birth weight (237,238,239,240,241). Animal studies demonstrate that early feedings prevent involution of the gut villi and loss of intestinal enzymes normally seen as few as three days after beginning intravenous feedings (242). Trophic feedings can be considered more as "oral medication" than as true feedings because little is gained nutritionally from them. Trophic feedings have not been studied in infants less than 800 g birth weight, and it is unclear whether the benefits, if any, of early feedings in these infants would outweigh the risks. Most practitioners agree that these infants should not receive feedings although they are unstable. However, mechanical ventilation or the presence of an umbilical arterial catheter per se is

not absolute contraindication to initiating feedings.

WHAT TO FEED NEWBORN INFANTS

What one decides to feed infants is dependent on understanding the developmental physiology of the newborn

P.401

gastrointestinal tract, the requirements of the infant for normal growth and body composition, and the available mechanisms of nutrient delivery. It is not surprising that term infants will thrive on different amounts and types of foods than will preterm infants, and that allowances in both groups must be made for the effect of illness on nutrient requirements.

Term Infants

Human Milk

Human milk is species-specific food for human beings (7). As such, it represents the best choice of food for the newborn infant. Substitute feedings, usually made from an animal-milk base, have been available for hundreds of years and have been highly refined in the past century. Nevertheless, no manufactured food can match the content of human milk for several reasons. Human milk is delivered fresh and has no "shelf life." This simple property allows live cells, growth factors, enzymes, and immune factors to remain intact and active. Formulas, which are designed to have a shelf life of one to two years (depending on the type of formulation), do not incorporate most of these factors because they would be unstable and would degrade over time. The factors found in human milk are thought to be responsible for many of its immunological and developmental advantages. Human milk is always at the correct temperature and requires no sterilization.

Approximately 69% of women in the United States elect to breast-feed their infants (243). This figure has remained relatively stable during the past five years and represents a rise from the nadir of 40% in the 1950s. It falls short of the goal of 75% set by the Healthy People 2000 initiative sponsored by the National Institutes of Health and endorsed by the AAP (7). The obstacles to improving the rate of initiation of breastfeeding include physician apathy or misinformation (244), insufficient prenatal breastfeeding education (245), and the lack of a perception of breastfeeding as culturally normal (246). By 6 months of age, only 33% of infants are breastfed even though human milk is nutritionally sufficient for infants through the first six months (243). This figure falls far short of the Healthy People 2000 goal of 50%. The decrement is due primarily to failure to maintain a milk supply in the first days after birth and discontinuation of breastfeeding upon the mother's return to work, typically at 6 or 12 weeks postpartum. The former

relates to hospital and office practices that encourage formula feeding or are, at best, ambivalent to breastfeeding. For example, early hospital discharges combined with lack of timely routine follow-up care and postpartum health visits contribute to this early loss (247,248). The late dropout relates to the fact that many mothers work and many workplaces are not equipped to support the mother to maintain her milk supply (249,250,251). The AAP reaffirmed its support of breastfeeding and provided recommendations to improve the initiation and retention rates (7).

There are few absolute contraindications to breastfeeding. Infants with galactosemia should not be breastfed (252), nor should infants whose mothers are using illegal drugs (253). Mothers with active tuberculosis and mothers in first world countries who have human immunodeficiency virus (HIV) should also not breast-feed (254,255). Mothers who are taking certain medications (e.g., amethopterin, bromocriptine, cimetidine, clemastine, cyclophosphamide, ergotamine, gold salts, methimazole, phenindione, thiouracil) should not breast-feed. Complete lists of maternal medications that contraindicate breastfeeding are available (256,257). Temporary disorders, such as maternal mastitis or engorgement, are not contraindications to breastfeeding.

Human milk is nutritionally complete for most term infants for the first 6 months of life. Its primary carbohydrate is lactose. The protein content is low (1.1%) but the amino acid spectrum is well matched for the human infants' needs, and the predominance of lactalbumin ensures a low curd tension. The fat content of human milk is high and may approach 55% of total calories. The fat blend is unique and has been difficult to imitate in formula. In particular, the presence of certain omega fatty acids (DHA and ARA) may be important for optimal retinal and neurological development (258). Human milk is relatively low in sodium and osmolality. Not surprisingly, gastric emptying is rapid with human milk, making it ideal for infants with slow gastrointestinal motility as a result of illness. Human milk is relatively low in iron content but high in iron bioavailability. The vast majority of term infants exclusively fed human milk will remain iron sufficient, although their stores at 6 months may be lower than infants fed iron-supplemented formula (124). Human milk may have a low-vitamin D content, particularly in women consuming a diet low in vitamin D and having low exposure to sunshine. Their infants are at risk of developing rickets if they too are not exposed to sunshine or given a vitamin D supplement. The AAP now recommends that all breastfed infants receive 200 IU of vitamin D daily.

Epidemiological studies provide evidence for the advantages of human milk over formulas, including better immune status, fewer infections (259,260,261,262), greater psychological benefits, more rapid neurodevelopment (263), protection from chronic childhood diseases (264,265,266), protection for the mother from certain diseases (267,268), and a lower rate of allergic disease (269,270). The reader is referred to the AAP statement on breastfeeding for a more complete

review of these benefits (7).

Infant Formula

Many women choose formula feeding instead of breastfeeding for their infants. Infant formulas promote excellent growth and development when used as an alternative to breastfeeding. They should be given for the first year (271). Formula manufacturers are continuously attempting to improve their products, with the goal of matching human milk composition or performance. Most infant formulas

P.402

are cow-milk based and are formulated at 20 calories per ounce. Alternatives include soy-based formula and elemental formulas.

Carbohydrates provide approximately 40% to 45% of the calories in formula. The most commonly used cow-milk-based formulas contain lactose as the primary carbohydrate, whereas the soy formulas contain either sucrose or glucose polymers.

The protein in formula provides approximately 10% of the total calories. Cow-milk protein is casein predominant, which is reported to have a higher curd tension than whey. Formula manufacturers have increasingly processed the cow-milk protein to make the formulas whey predominant with the whey-to-casein ratio approaching 60:40. The ratio in human milk is 70:30 (19). One formula in the United States has hydrolyzed the whey. Soy formulas contain soy proteins, which also support normal linear growth and muscle accretion. The protein content of soy formulas is higher than that of cow-milk formula. Soy formulas contain phytic acid, which may bind divalent cations (Ca, Mg) in the formula. For this reason, the calcium content of soy formulas is greater than that of cow-milk formulas. Both bone mineralization and linear bone growth in term infants fed soy formulas appear to be adequate.

Fat constitutes 40% to 55% of calories in infant formula and is usually a blend of vegetable oils, such as corn, coconut, soy, or palm-olein. Vegetable oils are added to cow-milk-based formulas because babies do not tolerate butterfat well. The fat blends are generally well tolerated, although infants will malabsorb up to 1 g/kg/day of ingested fat in the first 10 days of life (272). This malabsorption is lower than what is observed with whole milk (2 g/kg/day) or evaporated milk (1 to 2 g/kg/day). Recent research has focused on whether LC-PUFAs, such as DHA and ARA, are essential in the diets of newborns. Human milk contains these fatty acids whereas cow milk does not. Newborn infants have a relatively limited ability to synthesize these fats at birth, although the rates of maturation of the enzymatic pathways (elongation and desaturation) in the postnatal period are only now being elucidated. The content of DHA in human milk decreases rapidly after 44 weeks postconception, yet infants maintain adequate DHA levels, suggesting that

the synthetic process is intact near that age (273). Addition of DHA to term infant formula has yielded mixed results with respect to growth and neurodevelopment (69,70,72,77). Those studies that have shown a positive effect on early retinal development or neurodevelopment have failed to demonstrate long-term or permanent benefits. From a safety standpoint, the FDA has determined that it has no questions whether the addition of LC-PUFAs derived from fungal sources are GRAS (generally recognized as safe), as claimed by the manufacturer. Based on this safety designation, major formula manufacturers in the United States have added DHA and ARA to their term infant formulas, although formula without the added PUFAs remain available.

Substantial alterations need to be made to whole cow milk to create a formula that a newborn infant will tolerate and thrive on. Whole cow milk is highly osmolar, low in calcium, high in phosphorus, low in vitamins A and D, and very low in bioavailable iron. Significant adjusting of all of these nutrients, in addition to the protein and fat manipulations, is necessary before an infant formula is safe for newborns.

Soy formulas are indicated for infants with galactosemia or lactase deficiency, infants whose mothers choose a vegetarian diet for their family, and infants with documented IgE-mediated allergy to cow-milk protein (274). On the other hand, there is no evidence that soy formula prevents atopic disease. Soy formulas do not relieve colic and are not indicated for premature infants (see below).

Elemental and casein hydrolysate formulas continue to make up a larger part of the infant formula market despite their very high cost and poor taste. Their main use has been in the treatment and prevention of allergy because 90% of the protein fragments are less than 1250 Daltons molecular weight. These low molecular weight fragments are less antigenic than cow-milk protein. In spite of this, anaphylaxis to these formulas has been reported (275,276). Additionally, the rate of true cow-milk protein allergy in newborns is less than 3%. Whey hydrolysate formulas are similar in cost to standard term infant formulas but are not as finely hydrolyzed as the casein hydrolysates and thus may present more of an antigenic challenge. Their ability to prevent and treat cow-milk allergy is debatable. All hydrolysate formulas promote adequate growth and nitrogen retention. Hydrolysates are not indicated for refeeding infants after gastroenteritis or for treating colic. They are more osmolar than standard cow-milk or soy formulas and thus possess a potential risk to the intestinal epithelium, particularly in the preterm infant.

Preterm Infants

Human Milk

Extensive research has assessed the adequacy and desirability of human milk

feedings in the preterm infant. The reader is referred to a recent review of the subject (19). This research is predicated on the argument that human milk is the ideal food for the term neonate and that the immunological, gastrointestinal trophic, and psychological aspects are even more relevant to the preterm infant. When beginning human milk feedings in the preterm neonate, one must ask whether human milk is a good match for the preterm infant's nutritional requirements.

Mothers who deliver preterm produce a milk that has a higher protein content, higher caloric density, higher calcium content, and higher sodium content than milk from mothers who deliver at term (103,104,105,106). To a certain extent these higher concentrations match the increased needs for these nutrients in preterm infants. The composition of preterm human milk changes during the first month postnatally and becomes more like term human milk thereafter. Table 22-1 demonstrates the change in content of preterm human milk in the first months of life.

P.403

Human milk provides multiple nutritional advantages for the LBW infant (19). The carbohydrate composition is predominantly lactose, but also includes oligosaccharides that are important for intestinal host defenses (277). These oligosaccharides may play a role in protecting the human-milk-fed premature infant from NEC (19).

The fat blend of preterm human milk is unique and allows up to 95% absorption of dietary fat. This is due in part to the presence of lipases in human milk, but also apparently as a result of the fat blend. Preterm human milk also has detectable concentrations of omega-3 and omega-6 fatty acids. These fatty acids, particularly DHA, are important constituents of phospholipid membranes in the brain (278) and are normally delivered transplacentally. They are not found in cow milk, but are currently added to preterm infant formula in the United States. They do not appear to be readily synthesized by the preterm infant from linoleic and linolenic acid precursors and are thus considered by some to be semi-essential. Studies of infants who receive a source of these fatty acids either from human milk or in preterm infant formula suggest better visual acuity (71,74,279). Studies of long-term developmental outcome continue to determine whether any early advantages fade over time.

The protein content of human milk is predominantly whey, as opposed to the casein predominance of whole cow milk. Although preterm infant formulas are whey predominant, there are important differences in the proteins that make up the whey. The main human milk whey protein is alpha-lactalbumin, as opposed to β -lactalbumin in cow milk. Additionally, only human milk has significant concentrations of important proteins involved in host defense, such as lactoferrin and secretory IgA, in the whey fraction. These proteins may contribute to the

observed protective effect that human milk has on the occurrence of NEC. There is evidence that these proteins act at a local (280) and systemic (281) level. Their effects may be in combination with a more benign fecal flora (282). Human milk contains multiple growth factors (19), including erythropoietin (283) and epidermal growth factor (284).

In spite of these advantages, feeding human milk to preterm infants poses several nutritional problems, particularly for the infant less than 1500 g. Preterm infants fed unsupplemented human milk have slow growth rates and higher rates of hyponatremia and osteopenia (285,286,287,288,289). These findings suggest that despite the altered content of preterm human milk, there is still not enough energy, protein, calcium, phosphorus and sodium to sustain adequate growth and bone mineralization. There is concern that some of the energy loss occurs when fat separates from human milk (290) and adheres to delivery tubing and storage containers.

Rather than abandon human-milk feedings, the solutions to these nutritional inadequacies include preventing losses by using short tubing lengths and employing a syringe and pump, maintaining the syringe upright (19).

Most importantly, human milk delivered to all infants less than 1,500 g should be fortified with commercial products that increase the caloric, protein, sodium, and calcium density of the milk (19). Two preformulated powder products are currently available. Each promotes better growth and bone mineralization than unsupplemented preterm human milk when fortified to a presumed caloric density of 24 kcal/ounce.

There is great variability in the milk expressed by mothers delivering preterm. Therefore, monitoring of nutritional status is critically important in preterm infants fed fortified human milk. In particular, growth rates, serum sodium concentrations, and bone mineralization status (serum alkaline phosphatase concentration, urinary excretion of phosphorus) must be assessed with regularity in these infants. Inadequate weight gain (<15 g/kg/day consistently over one week) can be treated by giving the infant more hind milk in the diet (19). Persistent increases in serum alkaline phosphatase concentrations despite fortification may necessitate adding some feedings of preterm infant formula.

Care must be taken in handling human milk to protect its important nutritional and immunological advantages. Fresh human milk is best, but is often impractical, particularly if the mother lives out of town. Fresh milk can be kept refrigerated up to 24 hours, but must then be frozen. Although live cells are destroyed by deep freezing (291), proteins remain largely intact. Suboptimal freezing results in fat breakdown. Rewarming frozen human milk can be dangerous as microwaving heats milk unevenly and can cause esophageal or gastric burns (292). It is more prudent to thaw an aliquot of milk for the entire shift or day and dispense it once it has been warmed in a water bath.

Initiating, advancing, and maintaining human milk feedings in the preterm infant who cannot take oral feeds can be accomplished in many ways. Unlike preterm infant formula, human milk does not need to be diluted since gastric aspirates are less of a problem with human milk because of better gastric emptying.

Preterm Infant Formulas

The development of formulas specifically designed for the preterm infant represented an important advancement in the nutrition of these infants. Prior to the introduction of these formulas in the late 1970s through mid-1980s, preterm infants were fed various formulations intended for infants with very different intestinal maturity, nutrient assimilation capability, and nutritional requirements. The science that went into developing preterm infant formulas carefully measured the nutrient needs of the preterm infant (described above) and the digestive and absorptive capabilities. When these two factors were considered together, a unique formulation for preterm infants evolved. For the most part, the preterm infant formulas are designed with the physiology of the less than 34 week gestational age infant in mind. Infants more than or equal to 34 weeks whose mothers choose not to breast-feed can be started on term infant formulas. If they show signs of intolerance (usually diarrhea, excessive gas, abdominal distention),

P.404

relative lactase insufficiency as a result of immature intestinal development should be suspected, and a preterm formula can be used.

Two preterm infant formulas are available in the United States, and their nutritional constituents are remarkably similar. The carbohydrate source for both is a combination of lactose and glucose polymers. The lactose content is reduced compared to term infant formulas because of the relatively lower lactase concentration found in the preterm intestine. Glucose polymers are easily digested and are low-osmolar.

The protein source is cow milk that has been made whey predominant. The concentration of protein is quite high, delivering up to 3.6 g/kg/day when the formula is fed at a typical volume of 150 cc/kg/day. This high rate of delivery is designed to match the intrauterine accretion of nitrogen and follows the guidelines established by Heird and associates (96). Protein intakes at this rate maintain reasonable muscle mass accretion and support normal serum albumin and prealbumin concentrations.

As in term formulas, the fat blend is derived from vegetable oils. However, preterm infant formulas contain between 10% and 50% of the fat content as MCT. The necessity of MCT remains controversial (57). Addition of MCT was stimulated by the finding that lingual and gastric lipases are particularly effective at hydrolyzing fatty acids of this length and because long-chain fatty acids require an adequate bile salt pool for absorption. As discussed previously, preterm infants

have low bile salt pools, which contributes to their higher fat malabsorption rate. Excessive MCT are not indicated, as they are poorly utilized for fat storage. They are an excellent source of energy, with the excess being excreted in the form of dicarboxylic acids (293). As a result of the GRAS determination of LC-PUFAs in infant formula, manufacturers of preterm infant formula are now adding DHA and ARA to their products.

The sodium and potassium contents of preterm infant formulas are higher than term formulas to compensate for renal tubular immaturity. Levels of trace elements are likewise higher. The preterm infant formulas contain the most calcium and phosphorus of any formula available. The current formulations, when fed at a volume of 150 cc/kg/day, will provide approximately 225 mg/kg/day of calcium and 110 mg/kg/day of phosphorus. This is well in excess of intrauterine accretion rates, allowing these formulas to be utilized to provide catch-up bone mineralization for those infants who have been on prolonged parenteral nutrition or dilute formulas. In spite of this high content, most premature infants less than 1,500 g have evidence of osteopenia of prematurity at the time of discharge. The bones of VLBW infants are frequently demineralized at discharge (294). Preterm infant formulas have recently been supplemented with iron in recognition of the fact that preterm infants are born with low iron stores compared to term infants, and that a rapid expansion of the red cell mass when catch-up growth ensues places a large stress on maintaining iron balance.

The preterm infant formulas are replete with water- and fat-soluble vitamins. Both formulations have higher vitamin D, E, and A concentrations compared to term formulas because of the poor fat absorption in preterm infants and the concern about the consequences of deficiency states in the infants. Studies assessing vitamin A and E levels in preterm infants fed the preterm infant formula with higher vitamin A and E concentrations demonstrated that additional supplementation with vitamins is not necessary once the infant is consuming at least 150 cc. Infants on the product that has a lower concentration may need additional supplementation. In either case, serum vitamin A and E levels should be followed weekly in preterm infants less than 1,500 g birth weight.

Techniques for the initiation, advancement, and maintenance of preterm infant formula feedings vary widely. The formula manufacturers have recommended initiating feedings with dilute (12 kcal/ounce) formula. Most infants will be on parenteral nutrition although their feedings are advanced. Although opinions vary greatly regarding whether formula volume or strength should be increased first, one should keep in mind that 1 cc of fully advanced peripheral parenteral nutrition (D12.5%, 3.0 g/kg/day of amino acids, 3.5 g/kg/day of lipids) is equivalent to approximately three-quarter-strength formula. Thus, volume-for-volume substitution of TPN with half-strength formula will dilute the caloric delivery to the infant, although substitution with full-strength formula will advance caloric intake.

Other Formulas

Although a large number of other formulas have been used for preterm infants, none are specifically designed to meet the nutritional needs of these infants. Any potential advantage of these formulas must be weighed against some fairly serious side effects. For example, soy formulas were used extensively in the late 1970s and early 1980s for preterm infants because they do not contain lactose and because of the concern that the preterm infant's intestine was particularly permeable to translocation of antigenic milk proteins (295). However, calcium absorption from soy formulas is very poor because the phytates in soy bind divalent cations. The incidence of osteopenia and rickets in preterm infants who are fed soy formulas is too high to justify recommending these products for this population (296).

Similarly, the possibility of using elemental or casein hydrolysate formulas for preterm infants has been suggested. The attractiveness of these formulas stems from their more elemental nature, thus presenting less of a digestive challenge to the immature preterm intestine. Unfortunately, these formulas are a poor nutritional match for the preterm infant from a fat-soluble vitamin and mineral standpoint. The vitamin E and A contents of the hydrolysates are one-quarter to one-half that of premature infant formula. The significantly lower vitamin D levels, lower calcium levels, and poor calcium-to-phosphorus ratio (1.4:1) place the preterm infant at high risk for

P.405

osteopenia of prematurity. Finally, the osmolarity of these formulas ranges from 290 to 330 mOsm/L at 20 kcal/ounce, 25% higher than the preterm infant formulas, which have osmolarities of 210 to 220 mOsm/L at 20 kcal/ounce and 250 to 270 mOsm/L at 24 kcal/ounce. Hyperosmolarity is associated with a higher risk of NEC in preterm infants. As currently formulated, elemental or casein hydrolysate formulas are not recommended for routine use in preterm infants.

Preterm Discharge Formulas

Follow-up formulas for preterm infants have recently been introduced. Prior to their introduction, the preterm infant was usually switched to a formula designed for term infants prior to discharge from the hospital. This made sense from a digestive standpoint because most intestinal capacities are similar to term by 34 weeks postconception and preterm infants rarely leave the hospital prior to that age. Nevertheless, this practice did not take into account the large deficits in muscle stores, fat stores, and bone mineralization that occur in many of these infants (3,4), nor did they take into account the high rates of growth in preterm infants in the first year. Follow-up formulas represent a hybrid between preterm and term infant formulas. The ones marketed in the United States are powders designed to be diluted to 22 cal/ounce, but able to be prepared at various

concentrations. At the 22-kcal/ounce concentration, they have a 50% higher calcium and vitamin D content than cow-milk-based formula for term infants (297). The carbohydrate content is a blend of lactose and glucose polymers, and the fat blends contain MCT oil in a manner similar to preterm infant formulas. There is less vitamin A and less sodium than in preterm infant formulas, but more vitamin A and D than in term formulas. The recommendation has been to give these formulas for at least the first six months postdischarge, although the manufacturers state that the formulas are safe for the entire first postnatal year. These formulas promote better growth rates and mineral status than does term formula in the preterm infant at follow-up (179). This is an important concept because of the large nutritional deficits that are accrued by the preterm infant in the neonatal intensive care unit (NICU) and the association between poor in-hospital growth and neurodevelopmental disability (182,298). The protein-energy deficit at hospital discharge at 25 grams of protein and 1000 kcal per kg of body weight (e.g., 50 grams of protein and 2000 kcal of energy for the average 2 kg premature infant at discharge) (4).

An alternative approach has been to continue to feed the discharged patient premature infant formula (299). Two problems arise with this solution: the formulas are not available commercially, and the improved fat digestive capacity of the infant after 34 weeks postconception raises the possibility of excessive vitamin A absorption. Moreover, the preterm infant formulas were designed for the special physiology of the less than 1,500 g, less than 34 week-postconceptional age infant.

NUTRITIONAL MONITORING

Any plan to nourish newborn infants should include plans for monitoring the nutritional status. For the healthy term infant, periodic plotting of the infant's weight, length, and head circumference on a standard growth curve is sufficient (Appendix I). The assessment of these parameters at birth provides a metric of the quality of fetal growth and also provides a starting point for postnatal monitoring. Small-for-dates infants should be assessed for signs and symptoms of intrauterine growth retardation. Signs of intrauterine wasting include small weight-for-length and mid-arm circumference:head circumference ratio (300,301), and may be seen in many small-for-dates infants and some appropriate-for-dates infants. It is important to plot newborns on a population-appropriate growth curve. For example, the growth curves published by Lubchenco in the 1960s are widely used, but were generated from a predominantly inner-city population born at high altitude (43) (Appendix D and I). Both factors tend to be associated with less intrauterine growth. It would not be appropriate to plot an infant of Scandinavian heritage (in which birth weights are on average 11 oz higher than in the United States [302,303]) born at sea level on the Lubchenco curves as it would overestimate the rate of macrosomia. The current debate is whether

breastfed infants should be plotted on their own unique curve rather than on one generated from a mixed or formula-fed population (53).

Similarly, appropriate curves must be used to judge the growth and nutritional health of preterm infants. The IHDP growth curves (Infant Health and Development Program, Ross Laboratories) have separate charts for VLBW and LBW infants and for boys and girls (304) (Appendix I). These curves can be used for the first two postnatal years. The weight gain velocity of the VLBW infant is not as rapid as the LBW infant or the term infant, and little catch-up growth occurs in the first year after discharge (305). Catch-up growth has been reported to occur during late childhood (306).

The importance of monitoring protein-energy status in the hospitalized newborn cannot be overemphasized. It is state of the art for NICUs with substantial numbers of nutritionally at-risk infants to have nutrition support services that review the infants' status at least weekly and provide nutritional recommendations. Ideally, these nutrition support teams should include a registered dietician, a doctor of pharmacy, and a physician. All should have a background or additional training in neonatal nutritional principles. Studies support the positive effect of such teams on nutritional status of the infants at discharge (182).

Daily weights and weekly length and head circumference measurements should be routinely performed and charted. The effect of manipulating protein-energy delivery should be reflected with delays in the rate of weight gain. Interpretation of protein-energy status from weight measurements can be complicated by fluid retention or dehydration. Length measurements are the least reliable because of the difficulty in obtaining reproducible numbers. Assessments of energy requirements can also be made

P.406

by indirect calorimetry to estimate resting energy expenditure. These measurements require special equipment and provide only a brief (usually 20 min) glimpse into energy utilization. The daily energy expenditure is extrapolated from the short-term measurement with the potential errors introduced by the extrapolation. Stable isotope techniques such as double-labeled water are the province of research institutions and are not used for clinical monitoring. Similarly, dual photon absorptiometry x-ray (DEXA) has been used in research studies to assess fat and lean body mass. A more practical assessment of the infant's relative fat status can be achieved with skinfold measurements and calculation of the arm fat area (180).

Protein status can be assessed by measurements of somatic or serum proteins or the serum BUN and creatinine concentrations in the absence of renal disease. The BUN will reflect recent nitrogen intake although the creatinine will index muscle mass. Low values are valid screening markers of poor protein status. Somatic protein status is best reflected in measurements of peripheral muscles, usually in

the arm. The arm muscle area is calculated from the arm circumference and the skinfold thickness (307). The somatic muscle pool turns over relatively slowly and serial measurements, like those of length, do not provide acute information with respect to recent nutritional manipulations. Serum proteins have various half-lives and thus give differential time information. Serum prealbumin (transthyretin) concentrations reflect recent protein intake and predict subsequent weight gain velocity (224). The half-life of the protein is 1.9 days; therefore, a weekly assessment of the serum prealbumin is useful. Serum albumin has a half-life of 10 to 21 days, can be used as a marker of chronic protein status, and can be assessed monthly if needed. It is not very responsive to recent manipulations in protein delivery. Serum transferrin concentrations, used extensively in older children and adults because of its half-life of 10 days, is not useful in premature infants either for assessing recent intake or for predicting weight gain (308). It likely reflects a combination of iron and protein status and thus can be difficult to interpret. Nitrogen balance, urinary excretion of 3-methyl histidine, and stable isotope assessments using N-15 glycine or H-3 leucine are research tools that assess protein status.

Rapidly changing glucose, mineral, and electrolyte status is best monitored with serum levels. Sodium and potassium levels should be followed in infants on who are on TPN or are receiving diuretics. Similarly, infants on TPN should have their serum glucose concentrations monitored. In the first days after birth, sick infants should have serum calcium, magnesium, and phosphorus levels assessed.

Chronic calcium and bone mineralization status should not be monitored solely with serum calcium and phosphorus levels because they will usually be in the normal to low-normal range. The serum alkaline phosphatase concentration is an indirect measurement of bone mineralization since it is closely tied to rapid bone turnover. An infant who is becoming osteopenic will have more rapid bone turnover and will have a higher alkaline phosphatase level. It should be expected that any growing premature infant will have relatively higher levels than a term infant, but a rapidly rising weekly alkaline phosphatase level is often indicative of active osteopenia. X-ray changes demonstrating demineralization are late findings and indicate that the bones are at least 33% demineralized. An elevated urinary excretion of phosphorus is also found during osteopenia of prematurity (309). DEXA can also be used to assess bone mineralization, but is used primarily in the research setting (310).

In general, it is unnecessary to routinely monitor trace element or vitamin status in the healthy, growing premature infant (See Appendix J-2 for nutrients in commercially available foods). However, higher risk infants should be monitored periodically, depending on the micronutrient in question and the disease state of the infant. Infants less than 1,500 g who are at high risk for BPD should have a vitamin A level measured at birth and should be treated with supplemental vitamin A if the level is less than 20 µg/dL (161,162). Concomitant vitamin E

measurements can also be obtained. Weekly vitamin A and E levels should be followed in infants treated for deficiency.

The recent introduction of recombinant human erythropoietin has made monitoring of iron status an important consideration in the preterm infant. The iron status of the premature infant can fluctuate widely; infants who are multiply transfused have extremely high ferritin concentrations (311). Conversely, the meager iron stores of those who receive few or no transfusions will be rapidly consumed by erythropoiesis. Those treated with recombinant erythropoietin experience a decrease in their ferritin levels (134). They are likely to need iron supplementation earlier than premature infants who have been transfused. Currently, reference values for ferritin, serum iron, and transferrin concentrations in newborn infants have not been generated. Since iron has a narrow therapeutic-to-toxic ratio, better norms for assessing iron status in preterm infants are needed. At this time, it may be prudent to assay the serum ferritin concentration at one month of age to assess iron stores.

Chapter 23

Breastfeeding and the Use of Human Milk in the Neonatal Intensive Care Unit

Kathleen A. Marinelli

Kathy Hamelin

OVERVIEW

Over the past two decades, as advances in technology have markedly improved our success in neonatal medicine, we have concomitantly recognized that nutrition is the cornerstone of the care we provide to sick and preterm neonates. The introduction and refinement of total parenteral nutrition, and the development of specialty premature enteral formulas have paralleled these improved outcomes. Over this same time period, there has also been an increasing awareness by both the general public and the medical community of the short- and long-term advantages of both human milk and breastfeeding. Based on a rapidly increasing body of research, there is no question that human milk is uniquely superior to other forms of nutrition for infants. The most recent American Academy of Pediatrics (AAP) policy statement on the use of human milk reminds us that the breastfed infant is the reference or normative model against which all alternative feeding methods must be measured regarding growth, health, development, and other short- and long-term outcomes (1). This position is endorsed and echoed by the American College of Obstetrics and Gynecology (2), the American Academy of Family Physicians (3), the American Dietetic Association (4), and the Canadian Pediatric Society (5). The evidence for the advantages of human milk to not only babies, but mothers, families and society in such diverse areas as health, nutrition, development, and immunology, with psychological, social, economic, and environmental impact (1,2,3,4) is so compelling that the U. S. government has made the support and promotion of breastfeeding a national public health priority. With the release of the Surgeon General's HHS *Blueprint for Action on Breastfeeding* (6) and the United States Breastfeeding Committee's *Breastfeeding in the United States: A National Agenda* (7) the federal government has embraced the Healthy People 2010 breastfeeding goals of 75% initiation, 50% breastfeeding at 6 months, and 25% breastfeeding at 1 year (8). The June 2004 launching of a 3 year, \$40 million National Breastfeeding Awareness Campaign by the U.S. Department of Health and Human Services, Office of Women's Health, with the tag line "Babies were born to be breastfed" exclusively for 6 months, is clear indication of the commitment to breastfeeding promotion and support (9). Produced in conjunction with the Ad Council, whose previous credits include "Only you can prevent forest fires," "A mind is a terrible thing to waste," and "Friends don't let friends drive drunk," these Public Service Announcements will target the general market, particularly first time parents, and the African American community, as rates of breastfeeding are lowest among this population (10).

In the ideal scenario, a discussion of breastfeeding generally conjures up a Madonna-like picture of a robust, healthy term newborn, eagerly latched and nursing well with a mother who has had an uncomplicated delivery and is supported and empowered by her ability to continue to nourish her baby. However, the reality of the neonatal intensive care unit (NICU) is often in stark contrast to this. Are the uncertainty, the stress, the technology, the constantly changing and critical nature of our patients and our

P.414

environment incompatible with the concept of breast-feeding? On the contrary, for these most vulnerable of our patients and their families, the exponentially increasing body of research supports that both the provision of human milk and breastfeeding are not only as important as they are in the full term population, but in fact may be more critical to the ultimate health and developmental outcome of these sick and premature babies. The AAP policy statement specifically recommends human milk as the preferred feeding not only for healthy term infants, but for sick and premature infants as well (1).

It is incumbent on us as practitioners to have the knowledge and the expertise to promote and successfully support lactation in the NICU population. Unfortunately, most of us received a cursory education on lactation, if at all, during medical school, residency and fellowship training. The same is true of nursing, nurse practitioner and physician assistant training. This is evidenced by the lack of physician knowledge of and confidence in the subject (11,12,13), the variable and non-evidence-based information present in current general pediatric textbooks (14) and the paucity of neonatal textbooks that even include it. This chapter presents our current

knowledge of the unique benefits of the use of human milk in a preterm and sick NICU population, supporting an evidence-based rationale for its important role in our therapeutic regimen. It will also detail the challenges to the provision of human milk, including the decision to express human milk and breastfeed, initiating and maintaining lactation with a breast pump, breast milk supply, the use of donor human milk, the developmental progression toward breastfeeding, the use of alternative feeding methods, and supporting breastfeeding in the NICU and after discharge.

BACKGROUND

Prior to the advent of NICUs and the technology that has made them possible, most premature infants did not survive. Those that were developmentally and physiologically mature enough did so if they could be kept warm, and nourished. The source of that nourishment was human milk. It would then not be an unreasonable leap of faith to say, that until this past century, the survival of premature infants was in large part dependent on the provision of human milk. As early as 1907, Pierre Budin, at L'Hôpital Maternité in Paris, encouraged mothers of premature infants to breastfeed to improve survival (15). Julius Hess, who in Chicago began the first continuously operating center for premature infants in the United States, wrote in 1922 "by far the best results are obtained in the premature infant weighing less than 1500 grams when it is fed human milk" (16). He advocated that human milk was the choice for feeding premature infants, with artificial milk a poor substitute, resulting in increased mortality. It is astounding that at that time there was even positive discussion about the survival of very low birth weight babies, let alone the association of improved survival with human milk feedings!

So why are we just now "re-discovering" the value of human milk in the neonatal unit? In 1947 Gordon showed that premature infants fed two different formulas based on bovine milk gained weight faster than infants who were fed human milk (17). It had also been previously shown that human milk did not support bone mineralization in premature infants unless supplemented with calcium and phosphorus (18). Based on studies like these, the use of human milk was abandoned in the United States for formulas that provided higher protein and mineral intakes. Although the latter was an important observation that needs to be considered today, what was not realized at the time, was how much was lost to obtain this gain.

INCIDENCE OF BREASTFEEDING OR PROVISION OF HUMAN MILK

Until very recently (19,20), the only on-going large-scale source of breastfeeding data in the United States has been the Ross Laboratories Mothers Survey (21,22), which was developed in 1954 and is periodically updated. Ross Products is a division of Abbott Laboratories, a manufacturer of infant formulas. Surveys are mailed to large numbers of mothers who have given birth within the previous year. Included among concerns of using this data to define breastfeeding rates and goals in the United States are low response rates (average 28% per month since 1997) (21), inability to determine exclusivity of breastfeeding, no differentiation between breastfeeding and breast milk feeding, and conflict of interest in a formula company monitoring breastfeeding rates. Although the population of NICU babies or premature babies per se are not analyzed, data is reported on the subset of babies with birth weights less than 2,500 grams, which would combine both premature babies and small for gestational age term babies. For 1990 the in-hospital breastfeeding rates in this weight category are given as 36.5% (compared to overall population breastfeeding rate of 51.5%) with steady increases to 62.7% (compared to overall increase to 69.5%) in 2001 (21,22). In comparison, recently published data from the Centers for Disease Control and Prevention (CDC), using questions added to the National Immunization Survey for the third quarter of 2001, showed a similar overall U.S. initiation of 65.1% (95% CI: 59.5%-70.7%) (19). The CDC has also looked at breastfeeding in 10 states using the Pregnancy Risk Assessment and Monitoring System (PRAMS). For 1993 they report 57% overall initiation, with 40.3% for babies less than 2500 grams, and 49.4% for babies admitted to the NICU. This improved in 1998 to 67.5% overall initiation, 57.9% low birth weight initiation, and 64.3% NICU initiation (20). These data, although less commercially biased, are still difficult to interpret and compare to other studies as a result of inconsistency of definitions. The definition of initiation of breastfeeding varies between studies, and often includes any attempt at putting a baby to breast or initiating lactation with a breast pump in the first several

P.415

days of life or during the initial hospitalization. It also does not indicate whether other liquids are given at that time.

These same reports have tried to look at duration of breastfeeding by surveying for any breastfeeding activity later in the first year of life. The Ross Mothers Surveys report continued breastfeeding at 6 months in babies less than 2,500 grams birth-weight increasing from 9.5% in 1990 to 22.1% in 2001 (with concomitant changes in

the entire population of 17.6% to 32.5%) (21,22). This data looked at babies with “any breastfeeding”; including only breastfed, breast milk/breastfeeding mixed with formula feedings (no quantification determined), and only occasional breast milk/breastfeeding (again no quantification). For 2001 they added the category of “exclusive” breastfeeding, reporting for all infants in-hospital as 46.3%, falling to 17.2% at 6 months; for babies less than 2,500 grams, 27.1% in-hospital falling to 8.4% at 6 months (21). Exclusive was defined as “fed only human milk; no supplemental formula and/or cow's milk.” No information on solid foods or other non-formula supplements (e.g., water, juices) fed to infants were collected (21). The PRAMS study looked at “predominant” breastfeeding at 10 weeks postpartum and showed decreases between 1993 to 1998 of 58.5% to 57.9% in the entire population, 47.9% to 45.1% in the low birth weight subgroup, and 55.1% to 47.3% in the NICU subgroup (20). When duration data is given, it has historically been *any* breastfeeding or breast milk consumption, with no differentiation made for whether other liquids or solids are ingested and in what quantities. This issue was addressed in 1988 by the Interagency Group for Action on Breastfeeding, who developed a set of definitions to standardize terminology. In the system they describe, full breastfeeding is distinguished from partial breastfeeding, with full subdivided into categories of exclusive and almost-exclusive breastfeeding, and partial differentiated into three levels (23). The hope was that consistent widespread implementation of these definitions would assist researchers and agencies to describe, interpret and compare breastfeeding practices accurately. Clearly, this has not occurred.

In March 2004, the Breastfeeding Committee for Canada issued a document on breastfeeding definitions. They used work previously done in this area, including the definitions from the Interagency Group for Action on Breastfeeding, to develop definitions in an algorithmic format that will facilitate data collection that is consistent, and can be used to compare breastfeeding practices between Canadian provinces and territories (Table 23-1) (24). These definitions are well thought out, and clearly delineate the amount of human milk vs. other liquids that are being consumed. The one thing they do not do, however, is to separate out *breast milk feedings* from *breastfeeding*.

When attempting to elucidate trends in breastfeeding and human milk consumption specifically in a NICU population, one can examine a number of reports from individual NICUs. For example, in one author's NICU (KM), breast-feeding rates have been tracked over a 15-year period. During this time, breast-feeding promotion and support has been greatly increased (which will be detailed later in this chapter). In the entire NICU population, only 20.2% of babies received any human milk (either by breastfeeding or alternative feeding method) in 1989, which steadily increased to 70.8% in 2002. Continuing to receive any human milk at discharge increased from 5.9% to 55.9% of all NICU discharges over this same time period. Even more striking is the data for the population less than 1,500 grams: initiation increased from 10.6% to 82.6% with continued provision of any human milk at discharge from 1.6% to 38.2% (25).

TABLE 23-1 BREASTFEEDING DEFINITIONS

Definition	Description
Exclusive Breast milk	No food or liquid other than breast milk, not even water, is given to the infant from birth by the mother, health care provider, or family member/supporter
Total breast milk	No food or liquid other than breast milk, not even water, is given to the infant from birth by the mother, health care provider, or family member/supporter during the past 7 days
Predominant breast milk	Breast milk, given by the mother, health care provider, or family member/supporter plus 1 or a maximum of 2 feeds of any food or liquid including nonhuman milk, during the past 7 days
Partial breast milk	Breast milk, given by the mother, health care provider, or family member/supporter plus 3 or more feeds of any food or liquid including nonhuman milk, during the past 7 days
No breast milk	The infant/child receives no breast milk
Breast milk includes breastfeeding, expressed breast milk or donor milk and undiluted drops or syrups consisting of vitamins, mineral supplements or medicines.	
From The Breastfeeding Committee for Canada Breastfeeding Definitions, March 2004, with permission.	

Although the numbers vary, overall trends show an increase in initiation and continuation of breastfeeding activity over the past decade, with significantly fewer babies in low birth weight or NICU categories than healthy, full term babies breastfeeding at any time point. Single institutional reports from the United States and

Canada have substantiated that NICU breastfeeding rates are lower than in their equivalent well-baby populations (26,27,28,29), with rapid attrition over the course of the hospitalization and after discharge (29,30,31,32,33). Factors often associated with continued lactation in this population are mothers who are older, married, of Caucasian race, with more than a high school education, a good social support system and having babies with increasing birth weight (27,30,33,34,35). An interesting recent multicenter study by Powers and associates used an administrative database to look at breastfeeding in 42,891 neonates admitted to 124 NICUs from January 1999 to December 2000 (36). They show that 50% of neonates discharged home from

NICUs are not receiving human milk, and they confirm that greater birth weight, older gestational age, white race, increasing maternal age, and married parents are associated with increased likelihood of receipt of at least some human milk at discharge. Of note, they also showed that site of care is a significant independent factor associated with human milk use. This raises questions regarding site differences that are more or less likely to promote successful breastfeeding in an intensive care setting.

It is also important to note that these trends in North American NICUs are not necessarily replicated in other parts of the world. As early as the 1980s, reports from European (37,38,39), Brazilian (40), and Australian (41) units demonstrate breastfeeding initiation rates, duration, and eventual exclusivity in premature babies that are equal to or higher than those we currently see in our term healthy population! Importantly, these countries have breastfeeding cultures, in which breastfeeding in the term healthy population is the norm, with close to 100% initiation.

ADVANTAGES OF HUMAN MILK FOR PREMATURE AND COMPROMISED BABIES

Human milk is a living, changing fluid. It contains over 200 known components, including live lymphocytes, macrophages, neutrophils; immunoglobulins, complement, and other host defense factors; lactoferrin; enzymes and hormones such as corticosteroids, erythropoietin, and insulin to name a few, in addition to its nutrients. There are complex interactions between these components, which likely enhance and contribute to their functions. It is ever-changing, from the beginning to the end of a feeding session, throughout the course of the day, and over the course of lactation. It can never be replicated, no matter how much advertising to the contrary is implied. Adding a "new" component to artificial formula that is present in human milk does not in any way guarantee that its function or performance will be identical. Human milk has changed and adapted over the course of human evolution to provide exactly what human infants need. It differs from the milk of other mammalian species, including bovines, which have concomitantly evolved to provide what the young of each of those species require to optimally grow and mature.

Accepting that human milk is the species-specific gold standard in nutrition for human babies, the outcomes associated with its use are then the norm to which other forms of nutrition are compared. That being the case, instead of a discussion of the "benefits of breastfeeding" as has been our habit, it is more accurate to look at the "risks of artificial feeding." There is a large evidence-based body of literature detailing improved health and developmental outcomes of human milk-fed term babies and their mothers, over artificially fed babies, which have been well reviewed elsewhere (1,2,3,4,42,43,44,45,46). The economic savings to families, health care payers, employers, and society have also been studied. Table 23-2 summarizes these disadvantages of using artificial formulas.

TABLE 23-2 SUMMARY OF THE DISADVANTAGES OF NOT BREASTFEEDING

Infant/Child:	Economic:
Increased incidence/severity of:	Families:
Diarrheal diseases	Cost of formula
Respiratory infections	Increased sick child visits
Otitis media	Increased medication use and costs
Urinary tract infections	Lost wages for sick child care
Infant botulism	Employers:
Sudden infant death syndrome	Employee absence for sick child care
Sepsis	Reduced productivity
Meningitis	Potential for higher health insurance rates
Allergic diseases	Payers:

Type 1 Diabetes mellitus	Increased physician fees
Celiac disease	Increased emergency room fees
Some childhood cancers (leukemias, lymphomas)	Laboratories/x-rays fees
Inflammatory bowel disease	Increased prescriptions
Mother:	Hospitalization costs
Increased potential risk for:	Society:
Postpartum blood loss	Use of natural resources in production of artificial feedings
Anemia	Environmental costs of production and wastes generated
Premenopausal breast cancer	
Ovarian cancer	
Osteoporosis	
Inability to take advantage of Lactational Amenorrhea Method (LAM) of family planning	

There is every reason to assume that these same advantages of human milk to term, healthy babies also apply to preterm and sick neonates. Additionally, there is increasing research-based evidence of both short- and long-term positive effects on prematurity-related conditions, including nutrition, gastrointestinal (GI) function, host defense, neurodevelopment, and physiological well-being.

Nutritional Advantages

Both the AAP (1) and the Canadian Paediatric Society (5) strongly recommend that breast milk is not only the preferred nutrition for healthy term infants, but for all infants, including premature and sick newborns, with rare exceptions (1). For an excellent in-depth examination of this topic please see Chapter 22. The reader is also referred to a recent review article of the use of human milk for premature infants (47).

There are several points that are worth reiterating here. Preterm milk is different than term milk (Table 23-3). Notably, preterm milk has higher concentrations of protein, fatty acids, sodium, and chloride (48,49), which interestingly, are all components required in higher amounts by babies born early. This phenomenon was initially attributed to lower milk volumes produced by mothers of preterm babies, thus causing a concentrating effect on these nutrients.

P.417

However, contrary to this theory, other components of preterm milk are present in the same concentrations as in term milk. It has subsequently been shown that preterm milk has similar volumes as term milk, so this is a true occurrence. Some have speculated that this is a maternal adaptation to the delivery of her premature baby, although others suggest that these differences are the end result of the interruption in maturation of the mammary gland during pregnancy. In a recent study looking at total nitrogen, fat, lactose and carbohydrate concentrations, gestational age at birth (GA) was inversely related to carbohydrate concentration; postmenstrual age (PMA; an indicator of autonomous developmental processes not affected by the moment of birth) was not related to milk composition; although postnatal age (PNA) was related to a decrease in total nitrogen and an increase in lactose concentration. This data was interpreted to indicate that PNA strongly influences the development of the composition of very preterm human milk, GA affects carbohydrate content with a negligible effect on the nutritional value of the milk, although PMA has no effect (50).

Increased in Preterm Milk	Unchanged in Preterm Milk
Total nitrogen	Volume
Protein nitrogen	Calories
Long-chain fatty acids	Lactose (?less)
Medium-chain fatty acids	Fat
Short-chain fatty acids	Linolenic acid
Sodium	Potassium
Chloride	Calcium
Magnesium (?)	Phosphorous
Iron	Copper

Zinc
Osmolality
Vitamin B1-12

Breastfeeding. A Guide for the Medical Profession, 1999:445.

The higher concentration of nutrients in preterm human milk all decrease to approximately term milk levels over the course of the first postnatal month, regardless of the gestational age of the baby at delivery, although the premature baby's increased needs continue until approximately term corrected gestational age. With the advantage the earlier higher concentrations, particularly of protein and electrolytes, that premature milk afforded no longer being present, we are often required to fortify human milk for the smallest babies. Babies less than 1,500 grams have been shown to require fortification with more calories, protein, calcium, phosphorus, sodium chloride and some vitamins to preclude poor growth rates, hyponatremia, hypochloremia, and osteopenia (47). Larger, more mature babies thrive on mother's milk alone. Because human milk content differs not only over the course of lactation, but during the course of a feed or milk expression session, at different times of the day, and for those babies requiring feeding by alternative methods, by the method used, it is critical to monitor these very low birth weight babies for growth rates, serum sodium levels, and bone mineralization status (see Chapter 22).

Protein

Human milk protein is 80% whey, as opposed to bovine milk protein, which is 80% casein. The whey in human milk, α -lactalbumin, is much more easily digested than bovine whey, which is β -lactalbumin, an important factor to consider for premature babies with immature gut function. Additionally, human milk protein also includes nucleotides, secretory immunoglobulin A (sIgA) and other immunoglobulins, and an enzyme, lysozyme, all of which are thought to aid in host defense; growth factors that stimulate gut growth and maturation; a variety of hormones; and enzymes (e.g., mammary amylase, lipases) that enhance the immature intestinal tract's ability to digest nutrients. The amino acid taurine, which serves many functions in the newborn including bile acid conjugation, osmoregulation, neurotransmission, and as an antioxidant and a growth factor, is present in high concentrations in human milk and is almost absent in bovine milk. Hence, it is added to artificial feedings. Unlike bovine milk, human milk is also low in phenylalanine and tyrosine, which the premature and newborn infant are poorly equipped to metabolize. For these reasons among others, human milk protein composition is well-adapted to the needs of premature babies (see Chapter 22) (51).

Lipids

Human milk lipids have sparked the greatest interest in milk components recently, with the increasing body of literature on the positive neuro-developmental effects of the long-chain polyunsaturated fatty acids (LC-PUFA's), in particular docosahexaenoic acid (DHA) and arachidonic acid (AA). They are found in phospholipids in the brain, retina and red blood cell membranes. These LC-PUFA's are not readily synthesized by preterm babies, and are normally delivered via the placenta. They occur naturally in human milk, but are not found in bovine milk. For premature babies, they must be delivered via an external source, in this case easily by human milk. Because of studies that show improved neuro-developmental outcome and visual function in breastfed preterm babies and in formula-fed preterm babies supplemented with exogenous sources of LC-PUFA's, DHA and AA have now been added commercially to most term and preterm infant formulas. Of concern is that these additives are of plant origin and are structurally different than human LC-PUFA's (see Neurodevelopmental Advantages).

Human milk lipids are an easily digested source of energy, in part as a result of their composition and in part as a result of their packaging with lipases in the milk, providing approximately 50% of the calories.

P.418

Additionally they provide cholesterol, which is an essential component of membranes. Human milk-fed babies show significantly higher plasma cholesterol levels than formula-fed babies (52). Although one might then expect them to have higher cholesterol levels than formula-fed babies as adults, the opposite has been found to be true (53). Additionally, coronary artery disease has been shown to be less frequent in persons up to 20 years of age who were initially breastfed (54). It has been postulated that this early exogenous exposure to cholesterol, a necessary nutrient, keeps endogenous cholesterol production down-regulated, thus resulting in lower cholesterol levels in adult life. The mechanisms remain to be elucidated.

Carbohydrates

The disaccharide lactose is the predominant carbohydrate in human milk. It is a ready source of energy, and is broken down by the enzyme lactase, located in the brush border of the intestinal mucosa, to galactose and glucose, necessary for energy supply to the rapidly growing brain. Lactase activity is low in premature babies, but is readily inducible by exposure to lactose, enabling them to absorb more than 90% from human milk. The remaining unabsorbed lactose contributes to softer stool consistency, and colonization of the gut by nonpathogenic fecal flora. It also enhances calcium absorption, critical to preventing nutritional rickets in prematures. Oligosaccharides, present in human milk as well, act in host defense by preventing bacterial attachment to intestinal mucosa, thus serving a protective role for the relatively immunocompromised preterm infant.

Energy

Several previous studies have suggested that human milk-fed term (55,56) and preterm (57,58) infants have lower sleeping energy expenditure compared with formula-fed infants. A recent randomized, cross-over study of gavage-fed preterm babies showed significantly lower energy expenditure in the human milk fed babies at prefeeding, during feeding, and postfeeding measurements (59). With the vast difference in composition of the nutrients and other factors between human and artificial milk, it is not possible to say what causes this difference, but it is an intriguing difference that remains to be investigated.

Gastrointestinal Advantages

In addition to the species specificity and superior digestibility of the nutrients in human milk for premature babies, human milk also favorably affects the function and maturation of the GI tract. It has been shown *in vivo* to decrease intestinal permeability in preterm infants when compared to preterm formula (60). Several studies have found that human milk promotes more rapid gastric emptying than artificial formula (61,62), with one revealing that on average, human milk emptied twice as fast as formula (62). This has implications for clinical practice. Delayed gastric emptying, which generally presents clinically as measured gastric residuals or vomiting, prevents advancement of enteral nutrition. Babies who cannot reach full enteral feeds require longer periods of parenteral nutrition, with the concomitant risks inherent in both prolonged intravenous catheter usage (e.g., infection, thrombosis, chemical infiltrates) and prolonged intravenous nutrition (e.g., mineral or electrolyte imbalance, hepatic damage). Any of these can impact length of stay, which in turn has economic and social/family implications, all of which are important to consider in the therapeutic plan in our NICUs today. In fact, other studies suggesting that human milk is better tolerated by the GI tract of premature babies than formula have looked at the marker "time to full feeds." Several have shown that infants fed human milk achieve full enteral feeds significantly faster than those fed artificial formulas (63,64). This would also be expected to have a positive impact on length of stay.

Another related finding is the induction of lactase activity by feedings. Lactase, the enzyme responsible for the digestion of lactose, is present in the fetal intestine early in gestation, but the greatest increase occurs during the third trimester. Hence, premature babies are lactase-deficient at birth. In one study, lactase activity was induced in preterm babies (26-30 weeks gestation) by the initiation of enteral feeds. Of greatest significance, the highest levels of enzyme activity were seen with the introduction of "early" feeds (4 days old) as opposed to "standard" feeds (15 days old) and in human milk-fed vs. formula-fed babies (65). There was also an inverse correlation between lactase activity at 28 days, and the time to achieve full enteral feeds. It appears that the level of lactase activity may be a marker of intestinal maturity, with human milk use being directly related to the progression of that maturity.

There are a large number of "bioactive components" in human milk that are not present in formulas. They variously provide antiinflammatory effects or protection from infectious agents; or are hormones and growth factors that influence development; or are immune function modulators (66). This is an active area of research with many questions remaining to be answered. At least a few of these factors have activity suggesting they may be involved in GI maturation, growth and motility (67). Epidermal growth factor (EGF) is a major growth-promoting cytokine that stimulates proliferation of intestinal mucosa and epithelium and strengthens the mucosal barrier to antigens (68,69). In an animal model, EGF isolated from human milk has been shown to facilitate gut healing after induced injury (69). Other factors identified in human milk, known as human growth factors I, II and III and insulin-like growth factor, have been shown to have growth-promoting functions, including stimulation of deoxyribonucleic acid (DNA) synthesis and cellular proliferation. *In vivo* studies in animal

species have shown remarkable increases in the mass of intestinal mucosa after feedings with colostrum, which contains these factors, but not after feedings with artificial milk (70,71). It is intriguing to postulate that

factors such as these in human milk may be important to the maturation and development of the premature GI tract, as well as being important to intestinal repair after damage as a result of disease processes such as necrotizing enterocolitis.

Host Defense Advantages

One of the single most extraordinary advantages of the use of human milk over formula in the preterm and NICU patient is the effect on host defense and infections. This reason alone is enough to make the use of human milk the gold standard in this population. The myriad of hormones, factors, cytokines, proteins, enzymes, nucleotides, antioxidants, immunoglobulins, and live, functioning leukocytes contained within human milk (72), their interactions and the milieu in which they effect action, is not and cannot ever be duplicated in an artificial milk. And our knowledge is just beginning to scratch the surface.

One can think of human milk as not only the perfect form of nutrition, but also as “baby's first immunization.” One type of immunization is the passive transfer of antibody. Examples include the use of intravenous immune globulin, tetanus immune globulin, rabies immune globulin, or respiratory syncytial immune globulin. The immunoglobulins represented in a mother's milk are a history of many of the infectious agents she has been exposed to, and developed antibody to, during her lifetime. By transferring these antibodies to her baby through her milk, she is then in effect “immunizing” her baby against those organisms. This process is a continuum from the one begun in utero by the passage of maternal antibody across the placenta. Taking this one step further is the concept of the enteromammary immune system, first proposed in 1979 by Kleinman and Walker (73) (Fig. 23-1). In this schema, antigen presented to the maternal mouth and gut is brought into proximity of lymphoid follicles in the maternal GI tract. The antigen's presence commits maternal lymphoblasts to specific IgA production against that antigen. These lymphoblasts migrate via the mesenteric nodes and the thoracic duct into the systemic circulation, in which they find their way into the active mammary tissue. There these cells manufacture sIgA, which is secreted into the milk. When the infant ingests the milk, the immunoglobulin present functions in the infant's gut as protection against that specific pathogen. Most sIgA is not absorbed in the infant's intestine, but rather plays an active role in mucosal defense. Although intact immunoglobulin has been found in infant urine, signifying some systemic absorption, most survives intact in the GI tract, and is excreted into the feces. The environment of the neonatal intensive care unit is full of potentially pathogenic organisms. What makes this concept of the enteromammary immune system even more appealing is that during skin to skin (kangaroo) care, a neonate is held by the mother at her chest, and is touched, kissed, and caressed. The mother exposes herself to any potential pathogens to which her baby has also been in contact. Through the enteromammary immune system, she makes antibody to those particular organisms, and then in subsequent feedings, she passes that antibody to her baby, to help protect him/her. Imagine—individually prepared immunizations to help protect each different baby in the NICU!

Similarly to our previous discussion of concentrations of specific nutrients, many of these immune modulators are in higher concentration in preterm milk than term milk, helping to compensate for the premature baby's immature immune function (Table 23-4). When major factors were quantified and compared between colostrum of mothers delivering both prematurely (28-36 weeks) and at term (38-40 weeks), mean concentrations of IgA, lysozyme, lactoferrin, and absolute counts of total cells, macrophages, lymphocytes, and neutrophils were found to be significantly higher in the preterm colostrum (74). The degree of prematurity did not influence the antiinfective levels in the colostrum. However, the total cells and macrophages were significantly higher in the colostrum of mothers delivering at 28-32 weeks of gestation compared to 33-36 weeks gestation ($p < 0.05$) (74). These differences make the use of early colostrum and human milk critical in the care of premature and sick babies, both as prevention and also possibly in treatment of infectious disease.

Another likely factor in improved immune defense with the use of human milk is the affect on fecal flora. The normal flora of the intestines of a breastfed infant is predominantly the gram positive bacteria *Lactobacillus bifidus*. Non-human milk-fed babies are colonized with many more types of bacteria, most of which are the potentially pathogenic gram negative bacteria. With establishment of *Lactobacillus* as the predominant bacteria inhabiting the premature infant's GI tract, the likelihood of a serious or life-threatening gram negative infection would be expected to decrease.

It has long been known that breastfed babies are at decreased risk of a number of infectious diseases—respiratory infections, otitis media, gastroenteritis, and diarrhea—and are at decreased risk of mortality. These

protections accrue in a dose-dependent fashion—i.e., the more breast milk a baby receives, statistically the better protected they are. Although much of the earlier work was done in Third-World countries, and commonly held beliefs are that breastfeeding does not make a difference in industrialized nations like the United States, there are now many studies that show significant impact in these populations as well (75,76,77,78). There has even been a study looking at breast-feeding and the risk of postneonatal deaths in the United States which shows promoting breastfeeding has the potential to save or delay about 720 postneonatal deaths each year (79)! It is probably fair to assume that babies admitted to NICUs, once attaining term corrected gestational age and discharged to home, will accrue similar advantages from breast milk/breastfeeding as their healthier term counterparts in these studies. But even more importantly for our population, an increasing body of research has been done looking at the effects of a diet of

P.420

human milk compared to preterm formula in premature and low birth weight babies, with respect to clinical infections. The data is clear—premature babies fed human milk are at significantly less risk of serious diseases, including necrotizing enterocolitis, urinary tract infections, sepsis, and meningitis.

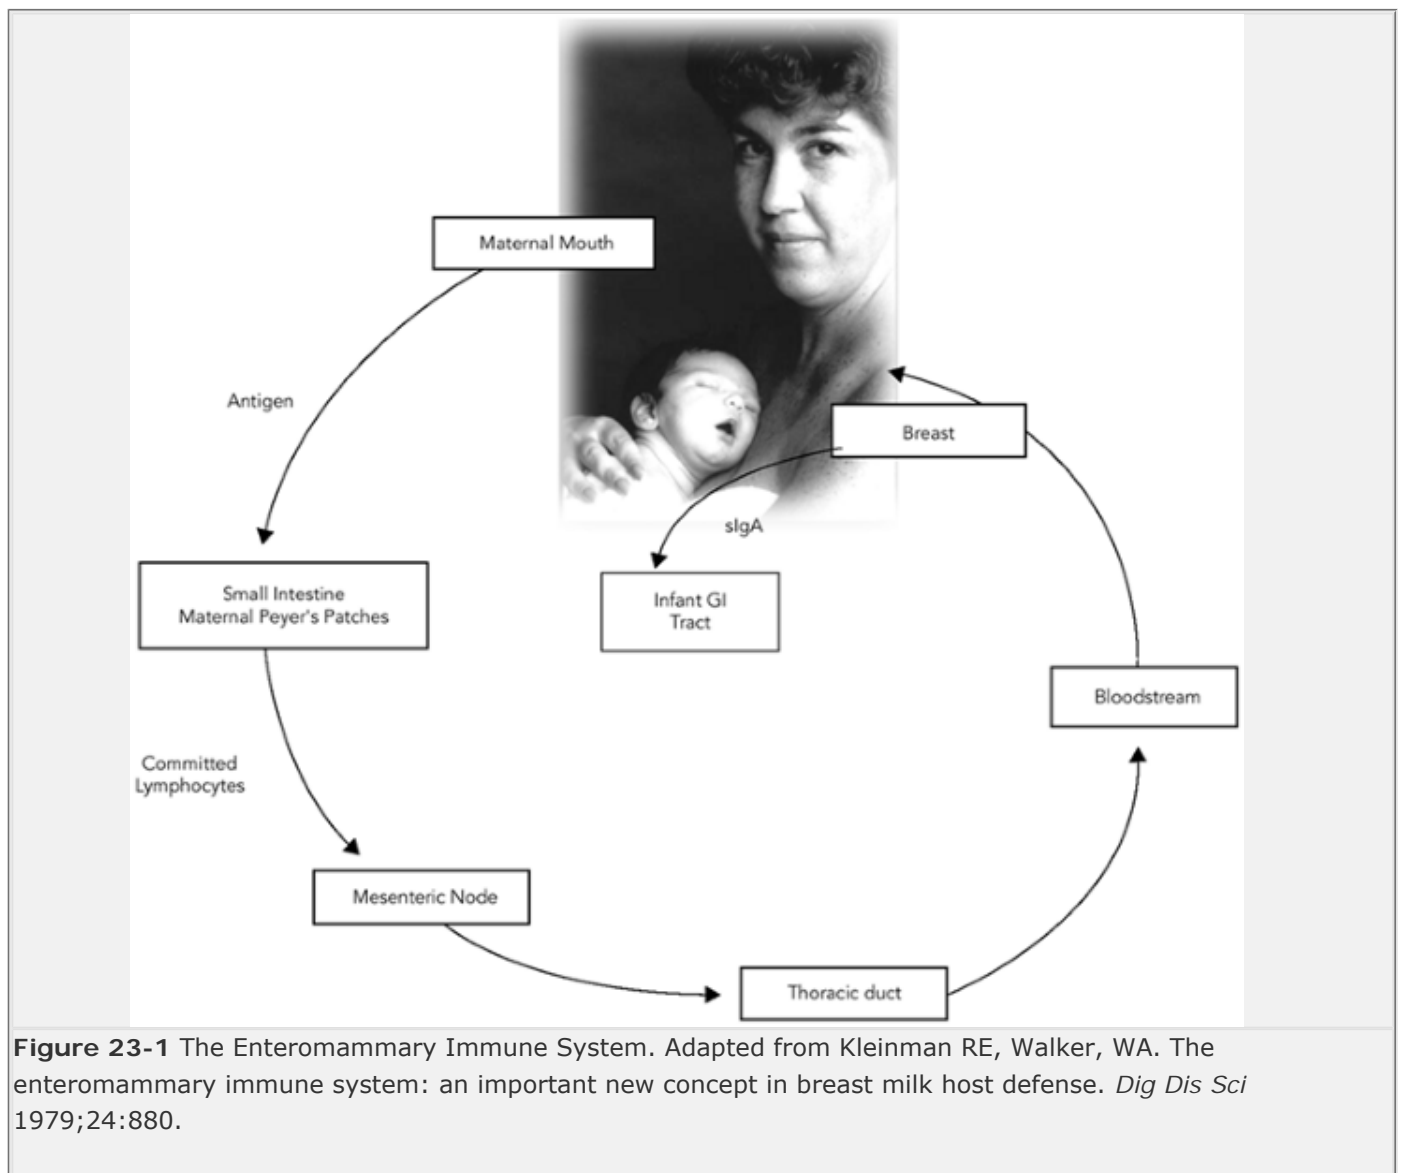

Figure 23-1 The Enteromammary Immune System. Adapted from Kleinman RE, Walker, WA. The enteromammary immune system: an important new concept in breast milk host defense. *Dig Dis Sci* 1979;24:880.

As early as 1971, a report from Sweden showed a protective effect of breastfeeding against sepsis in the newborn (80). Then in 1980, Narayanan and her group in India reported that even partial use of human milk (81), and subsequently exclusive use (82) could significantly decrease the incidence of infection in a premature and low birth weight population. In the first study, infants fed human milk supplemented with formula had a 6% incidence of sepsis, compared to a 21% incidence in those fed formula alone (81). In the second, in 62 infants studied, no sepsis occurred in those infants receiving human milk exclusively, although six episodes occurred in those fed formula (82). A further study by this group looked at the dose-response effect of human milk in the prevention of infection (83). Infections noted were sepsis, diarrhea, pneumonia, meningitis, conjunctivitis, pyoderma, thrush, and upper respiratory infections. The strongest effect was noted in those babies fed exclusive human milk, followed by partial feedings of human milk. In a United States study, a decrease in blood culture

proven sepsis was seen in those infants fed their own mothers' milk compared to those fed formula (27% vs. 58%, $p < 0.05$) (63) More recently in another U.S. neonatal unit, El-Mohandes and associates showed a significantly decreased incidence of sepsis, in each of three time periods through the first 38 days of life, for infants admitted to the NICU who received human milk vs. formula (odds ratio for sepsis in human milk-fed infants was 0.4, 95% confidence limits, 0.15 to 0.95, $p = 0.04$) (84).

TABLE 23-4 COMPARISON OF ANTI INFECTIVE PROPERTIES OF PRETERM AND TERM MOTHER'S COLOSTRUM

	Preterm Colostrum	Term Colostrum
Total protein (g/L)	0.43 ± 1.3	0.31 ± 0.05*
IgA (mg/g protein)	310.5 ± 70	168.2 ± 21*
IgG (mg/g protein)	7.6 ± 3.9	8.4 ± 1
IgM (mg/g protein)	39.6 ± 23	36.1 ± 16
Lysozyme (mg/g protein)	1.5 ± 0.5	1.1 ± 0.3*
Lactoferrin (mg/g protein)	165 ± 37	102 ± 25*
Total cells/ ml ³	6794 ± 1946	3064 ± 424*
Macrophages	4041 ± 1420	1597 ± 303*
Lymphocytes	1850 ± 543	954 ± 143*
Neutrophils	842 ± 404	512 ± 178**

P.421

Hylander and colleagues published an elegant study in 1998 in which they looked at 212 VLBW infants born at Georgetown University Medical Center (85). They not only looked at incidence of infection among these babies in relationship to their type of feeding, but they also controlled for confounding factors. Infection was documented as clinical signs of sepsis along with positive cultures for pathogenic organisms from one or more of the following sites: blood, spinal fluid, urine, stool, pleural fluid, nasopharyngeal, intravascular catheter, umbilicus, eye, or surgical wound. Additionally, pneumonia (by chest radiograph) and necrotizing enterocolitis (Bell's classification) were included. Human milk feeding was defined as receiving any human milk, with supplemental formula feedings when milk was not available. Formula-fed babies received only formula. They found that the incidence of infection (human milk 29.3% vs. formula 47.2%) and sepsis/ meningitis (human milk 19.5% vs. formula 32.6%) differed significantly by type of feeding (Fig. 23-2). Human milk was independently correlated with a reduced odds ratio of infection (OR = 0.43, 95% CI, 0.23-0.81), controlling for gestational age, 5-minute APGAR score, days on mechanical ventilation, and days without enteral feeds. Human milk feeding was also independently correlated with a reduced odds ratio of sepsis/meningitis (OR = 0.47, 95% CI 0.23-0.95), controlling for gestational age, mechanical ventilation days, and days without enteral feeds. And remember, the human milk-fed babies were supplemented with formula, so if they had been exclusively breastfed, one wonders if the difference would have been even more remarkable?

Figure 23-2 The incidence of all infections and of significant infections (sepsis/meningitis) in VLBW babies in formula vs. breast milk-fed groups, is significantly different even when controlling for confounding factors. Infection OR = 0.43; 95% CI 0.23-0.81; sepsis/meningitis OR = 0.47; 95% CI 0.23-0.95) $n = 212$. From Hylander MA, Strobino DM, Dhanireddy R. Human milk feedings and infection among very low birth weight infants. *Pediatrics* 1998;102:e38.

In 1999, Schanler and his colleagues showed that in a group of premature infants between 26 to 30 weeks gestation, those fed predominantly fortified human milk were discharged earlier (73 ± 19 vs. 88 ± 47 days) and had lower incidence of necrotizing enterocolitis (NEC) and late-onset sepsis than infants fed preterm formula (86). This data on NEC confirms a previous study by Lucas and Cole (87), who showed that in a cohort of 926 infants with birthweights below 1850 grams, formula fed babies were six to ten times more likely to develop NEC than those fed human milk exclusively; and three times more likely than babies who received a combination of human milk and formula supplements. Once again, this data shows a dose-response effect of human milk. While reviewing the data on NEC it is also important to point out that in addition to these significant clinical decreases in incidence of NEC, there are also concomitant significant savings in economic costs. This is an enormous issue to us as practitioners, to the health care system as a whole, and certainly to the individual families we care for. A reduction in the cases of NEC would engender significant savings in medical charges, and length of stay (LOS). Bisquera and associates (88) showed that infants with surgical NEC exceeded LOS by 60 days over matched controls, and medical NEC by 22 days over

P.422

controls. Based on LOS, the estimated total hospital charges per baby for surgical NEC averaged \$186,200 more and medical NEC \$73,700 more than controls. This translated into yearly additional hospital charges at their institution for NEC of \$6.5 million, or \$216,666 per survivor! When parents' time and wages and prevention of premature deaths are also considered, the total savings in the United States alone are more than \$3 billion if only 75% of preterm infants received human milk feedings and their incidence of NEC decreased from 7% to 1% (89)! The significance of these statistics cannot be ignored.

Just as the etiology of NEC is not completely understood, and is certainly multi-factorial, so the mechanism underlying the protection against NEC afforded by breast milk is also not completely understood, and most likely multi-factorial. One study showed a decreased prevalence of NEC in premature infants who were given enteral doses of a serum-derived IgA-IgG product, with IgA predominance, similarly to that found in human milk (90). This leads one to postulate that the immunoglobulins, in particular IgA, present in human milk have a role to play in NEC prevention. It is also known that platelet-activating factor (PAF) is one of the inflammatory mediators that is known to be higher in babies with NEC, and that in experimental models, it causes bowel necrosis similar to that seen in NEC, when injected intravenously. PAF is rapidly broken down by PAF acetylhydrolase, which has been shown to be not only present in human milk, but to be approximately 5-fold higher in preterm than in term milk (91). This may yet be another mechanism by which breast milk is protective. Additionally we have previously discussed the predominance of nonpathogenic fecal flora in breastfed infants. Could this not be another protective mechanism? There are certainly many other biologically active substances in human milk that may ultimately be found to have a role in the prevention of NEC.

It is unclear how much human milk is needed to see these effects. In the previously discussed Hylander study (85), the human milk-fed group also received supplements of formula and still showed significant benefit. Narayanan (83) showed a dose-response in that exclusive human milk was more protective than partial, which was still more protective than no human milk. And Lucas and Cole showed that in NEC, partial human milk feeding was protective, but less so than exclusive human milk feedings (87). Furman and colleagues, looking at 119 VLBW babies, identified a daily threshold amount of at least 50 ml/kg/day of maternal milk through week 4 of life as needed to decrease rates of sepsis in this group (92). These data are convincing that by providing human milk, we do make a difference in these serious morbidities in even the tiniest of our patients. And it certainly appears that there is a dose-response relationship. That being the case, with all the potential morbidities that our patients face, and the costs both economically and emotionally for these families and society, it is without a doubt worth our efforts to make human milk the gold standard in neonatal intensive care for these reasons alone. It has also been shown that upper respiratory symptoms are reduced for those low birth weight babies through seven months corrected age who continue to receive human milk after discharge from the NICU (93). Although not significant, a trend appears to exist for otitis media, bronchiolitis, and gastroenteritis as well. More studies with larger cohorts are needed to confirm these data.

Neurodevelopmental Advantages

Much press has been given to recent work that shows improved cognitive development in babies who receive human milk. In 1988 Morley and associates showed an 8-point cognitive advantage using the Bayley Scales of Infant Development for 771 infants with birth weights less than 1850 grams (94). After controlling for demographic and perinatal factors, a 4.3-point advantage still remained. When this cohort was followed up at 7.5 to 8 years of age, infants who had received human milk by tube (rather than breastfeeding) continued to show an 8.3-point IQ advantage (over half a standard deviation) even after adjustments were made for difference in mother's education and social class (95). They also showed a dose response relationship between the proportion of human milk in the diet and subsequent IQ. In a second randomized prospective study, these same researchers compared premature infants who received mature donor human milk with those who received premature formula as their early enteral nutrition. These diets were compared as sole enteral feeds or as supplemental feeding to their own mother's expressed milk. No differences in outcome were seen at 18 months between the two diet groups, despite the low nutrient content of mature donor milk in relation to preterm formula. Additionally, when they compared the infants from this study fed solely on mature donor milk with infants from a previous study fed solely standard term formula, the infants fed the mature donor milk had higher developmental scores, again supporting the positive role of human milk on cognitive development (96). Bier and colleagues have also looked at the effects of human milk on both cognitive and motor development. They found that in a cohort of 39 premature infants, those who received human milk had significantly higher motor scores at 3 and 12 months corrected ages than those fed formula. Additionally, when adjusting for oxygen requirement and maternal vocabulary scores, human milk-fed babies continued to show an advantage in both cognitive and motor scores at 12 months. There was also an association between the amount of human milk intake while in the special care nursery (dose response relationship!), and cognitive development at both 7 and 12 months corrected ages (97).

There has been one meta-analysis of controlled studies looking at the question of human milk and cognitive development (98). It demonstrated a 3.16-point higher score for cognitive development in human milk-fed babies compared with formula after adjustment for significant covariates. This difference was observed as early as 6

P.423

months and was sustained through 15 years of age, the last time of reliable measurement. Longer duration of breast-feeding was accompanied by greater differences in cognitive development (dose related response). Whereas normal weight infants showed a 2.66-point difference in IQ scores between breastfed and formula fed groups, the difference was even more remarkable, a 5.18-point difference, in low-birth-weight infants. The results of this meta-analysis suggest that not only does human milk contribute to higher neurodevelopment, but that the effect is even more striking in a much more high-risk population, the low-birth-weight infant.

Postulated to be responsible for at least a portion of these neurodevelopmental advantages of human milk is the presence of long-chain polyunsaturated fatty acids (LC-PUFAs), which until recently, were not present in formulas (Please see Chapter 22 for a more in-depth review). Docosahexaenoic acid (DHA), normally accounts for greater than one-third of the total fatty acids of the gray matter of the brain and the retina of the eye (99). Most of the prenatal accumulation of DHA in these tissues occurs in the third trimester—thus by definition, premature infants are deficient compared to their term counterparts. Animal studies have shown that deficiency of DHA in neural tissues during development leads to behavioral and retinal changes.

Other examples of the effects of human milk on neurological maturation have also been observed. Premature infants receiving human milk have been shown to have faster brainstem maturation than those on formula (100). Visual acuity and the development of retinopathy of prematurity have also been studied. A number of studies were performed before the routine addition of the LC-PUFAs to preterm formulas. In one, the researchers showed improved visual acuity of preterm infants up to four months of age in supplemented vs. nonsupplemented formulas (99). In another, improved retinal function was present in LC-PUFA sufficient VLBW neonates fed human milk or supplemented formula as compared to an unsupplemented formula group with lower LC-PUFA cell composition (101). Better visual evoked potentials and acuity in both preterm and term infants at 57 weeks postconception has been seen in those fed human milk as opposed to those fed formula (102). Additionally, another interesting study in which healthy term infants who breastfed to 4 or 6 months, and then were weaned, were randomly assigned to commercial formulas with or without DHA and arachidonic acid (ARA) supplements. At 1 year of age, the level of DHA as measured in the red blood cells was reduced by 50% from weaning level in the unsupplemented group, although there was an increase of 24% in the supplemented group (103). The conclusions drawn from this study were that the critical period during which a dietary supply of

DHA and ARA can contribute to optimizing visual development in term infants extends through the first year of life. This supports the AAP recommendation that breastfeeding continue through the first year of life (1), and begs consideration then of the length of time breastfeeding should be encouraged and supported for the baby born prematurely.

Physiological Advantages

Breastfeeding is widely assumed to be more stressful than bottle feeding for premature infants, an assumption that has led in many intensive care units to the introduction of bottle feedings as the first oral feeds, and postponing attempts at breastfeeding until babies "can prove themselves with the bottle." There are also often concerns for the small premature baby's ability to maintain temperature while breastfeeding, leading to "rules" restricting initiating breastfeeding until a certain weight is achieved. Additionally, there is the widely held belief that the "suck-swallow-breathe" mechanism is not mature until approximately 34 weeks gestation. Because of the fear that they will choke, desaturate and aspirate, this leads to more "rules" concerning not initiating oral feeds, including breastfeeding, until at least 34 weeks corrected gestational age. It is important to point out that there is no scientific evidence to back any of these statements. On the contrary, the exact opposite is the case as we will discuss. It is also important to understand that these policies, in addition to being unsupported scientifically, are also harmful in that they (a) preclude premature babies and their mothers from early breastfeeding experiences; (b) allow babies whose mothers want to breastfeed to learn to suck from a bottle, which then in many cases makes it hard for them to transfer to the breast at a latter time, as the sucking mechanisms are different; and (c) introduces breastfeeding so late in the hospital stay, that in addition to struggling to overcome what they have learned with an artificial nipple, the mother and baby are often discharged before they have had time to learn together and develop the confidence and skills necessary to allow successful breastfeeding in this population. It is important to re-emphasize our medical dictum in this circumstance: *Primum non nocere*.

Data does exist that enables us to develop breastfeeding policies that are physiologic, safe and supportive of breast-feeding. As early as the 1980s, Meier was publishing data concerning physiologic stability at breast compared to bottle-feeding. She was able to show that in babies less than 1,500 grams at the time of first feeding, different sucking mechanisms were employed for breast and bottle, with better coordination of suck-swallow-breathe during breastfeeding, particularly in the smaller less mature babies. Concomitantly, there are markedly different patterns of transcutaneous oxygen pressure (tcPO₂) for the two methods of feeding. TcPO₂ patterns suggest less ventilatory interruption during breastfeeding than during bottle-feeding with greater declines in tcPO₂ during bottle-feeding than during breast-feeding over the course of a feeding session. Additionally, babies became significantly warmer during breastfeeding than during bottle-feeding (104,105,106). Similar studies done by Bier and colleagues in first VLBW (107), and then ELBW (108) babies showed they could tolerate beginning breast- and bottle feedings at the same postnatal age; that they were

P.424

less likely to have oxygen desaturations to less than 90% during breastfeeding; and that they had lower intakes during breastfeeding. Given that there is no data supporting the safety of initiating bottles as first feeds, and that there is data to show that during breastfeeding premature babies are more physiologically stable, it would then seem reasonable, safe and scientifically sound to allow mothers to put their babies to nuzzle at breast and to begin early steps toward breastfeeding, once they are physiologically ready!

CHALLENGES TO THE PROVISION OF HUMAN MILK

The Decision to Express Human Milk and Breastfeed

Expressing human milk and subsequently breastfeeding a premature infant has been described as a contribution to the care of her infant that only the mother can make. This is a very powerful, tangible opportunity for these mothers. Additionally, this feeding choice has been considered the one aspect of natural caregiving that the mother does not have to forfeit when she delivers a sick or premature infant. In the past, the decision to provide expressed human milk for the premature infant was regarded as a matter of parental choice with professional responsibility limited to implementing the parent's decision. With increasing and irrefutable evidence that human milk supports the optimal health and nutrition of sick and premature infants, NICU care providers must actively encourage mothers to initiate lactation and provide milk to their infants, even if they do not plan to ultimately feed at the breast.

Parental decisions related to infant feeding must be based on informed choice. Emphasizing the importance of human milk to the health of the infant assists mothers in making an informed decision about feeding method. Health care providers should share research-based evidence about the superiority of human milk and the value of this intervention for the sick or premature infant. It is also important to communicate the maternal benefits of lactation to these mothers, both in terms of her immediate ability to be actively involved in the care of her baby, no matter how sick he or she is, and also in terms of the health benefits she will accrue (2,3). Optimally, this information should be discussed with the family as soon as the premature birth of their baby becomes a possibility. With the understanding that this is not always feasible, it must be discussed as soon after the infant's birth as realistic, so that milk expression can be initiated and colostrum expressed when the hormones of lactation are optimal. Even mothers who had indicated prior to the birth of their child that they desired to feed formula, are often more than willing to initiate milk expression to obtain colostrum for their babies when they understand all the advantages it confers. Written information should reinforce that early human milk is considered "medicine" that prevents infection in this vulnerable population. Although staff may worry that this approach is coercive or may make mothers feel guilty about initial feeding plans, mothers who are educated to make an informed choice to provide human milk for their infant report they are thankful for the information that assisted them to support the health of their infant. It is important that families understand that a decision to initiate milk expression does not commit them to breastfeeding. They can decide to stop at any point along the continuum. This is very empowering to these women, who with the birth of a baby who requires intensive care, acutely feel the loss of normal maternal control. Research has demonstrated that structured education and support programs within NICUs are effective in increasing lactation initiation rates, often in mothers who had intended to formula feed (109,110). The positive breastfeeding outcomes of such programs clarify the critical role of health care providers in sharing the science of human milk with mothers so that they can make an informed choice related to infant feeding.

Initiating and Maintaining Lactation with a Breast Pump

Mothers who provide breast milk and eventually breastfeed their premature infants must develop their milk supply through manual or mechanical milk expression techniques. These techniques may be suboptimal compared to actually breastfeeding in stimulating and maintaining a full milk supply. As a result, compromised milk production is a well-documented constraint to extended breastfeeding in the premature mother-infant dyad. An understanding of the physiology of lactogenesis and the effects of various pumps and pumping styles on milk production is critical to understanding this issue and supporting mothers to establish and maintain optimal milk volumes.

The transition from pregnancy to lactation is called lactogenesis. The first half of pregnancy is characterized by growth and proliferation of the mammary ductal system; during the second half of pregnancy, secretory activity increases and the alveoli become distended by accumulating colostrum (111). The capacity of the mammary gland to secrete milk after approximately 16 weeks gestation is referred to as lactogenesis I. The onset of copious milk secretion 2 to 8 days after birth is called lactogenesis II. Triggered by a rapid drop in serum progesterone levels after the delivery of the placenta, lactogenesis II results in a rapid increase in milk volumes from 36 to 96 hours postpartum. Ongoing lactation is dependent on a delicate interplay of hormones and effective stimulation and emptying of the breast. Interference with these processes can delay and/or suppress milk production (112).

Prolactin and oxytocin are the predominant hormones of lactation. Prolactin, the milk-making hormone, is essential for both initiating and maintaining milk supply. As progesterone and estrogen levels abruptly drop after birth, the anterior pituitary gland is no longer inhibited by these

P.425

hormones and releases pulsatile surges of prolactin in response to suckling at the breast. Frequent breastfeeding in early lactation stimulates the development of receptors to prolactin in the mammary glands and results in a faster increase in milk synthesis (113). The number of prolactin receptors increases in early breastfeeding and remains constant thereafter (114,115). Therefore, early breast stimulation during this critical period is a predictor of later milk production. Oxytocin is the hormone responsible for the removal of milk from the breast. Excreted by the posterior pituitary gland in response to suckling, oxytocin causes the myoepithelial cells surrounding the alveoli to contract and milk to be ejected into the ducts in which it is available to the newborn. The secretion of oxytocin is negatively affected by stress and pain. Therefore, the birth of a premature infant (often by cesarean delivery) and the subsequent stressors associated with this event can interfere with the milk ejection reflex or "let down" of milk from the breast.

After the first few days postpartum, lactation shifts from endocrine control (hormone driven) to autocrine control (driven by milk removal). Galactopoiesis (the maintenance of milk production) is driven by the quality and quantity of milk removal. As long as milk is being removed from the breasts, the alveolar cells will continue to make milk. This supply-demand phenomenon regulates milk production to match intake by the infant (112).

The birth of a premature infant can negatively influence milk production. If a mother has delivered very prematurely, mammary development may be poor because the mother may not have received the full component of pregnancy related hormones to prepare the breasts for lactation (116,117). Additionally, the close infant contact most frequently experienced by mothers following term delivery is limited or absent after premature delivery. As a result, the neurohormonal stimulus of the lactogenic hormones is impaired. An additional barrier to optimal milk expression is the fact that anxiety, fatigue and emotional stress, all powerful inhibitors of lactation, are experienced almost universally in mothers of premature infants (118). As a result, for mothers of premature infants, concerns related to milk production and transfer of adequate milk to the infant are primary reasons for discontinuing breastfeeding or providing supplements. Early, frequent and optimal stimulation of maternal milk supply must replace the natural breastfeeding process to ensure adequate milk production and duration of breastfeeding in this population.

Current research points to three factors that are independently associated with optimizing milk production in mothers who are pumping for a preterm baby. After controlling for maternal age, race, marital status and maternal education, factors significantly associated with ongoing milk supply and breastfeeding at term include initiating breast pumping before 6 hours postpartum, pumping more than 6 times a day, and skin-to-skin contact with the infant (119,120,121). An additional factor that optimizes ongoing milk production is expressing milk for an adequate duration of time to completely empty the breasts (120). The degree of breast emptying is a strong stimulus for milk synthesis and may be even more important than the frequency of pumping. Clinical advice therefore should include early (<6 hours postpartum), frequent (8-10 times in 24 hours) and effective pumping to achieve milk volumes between 800 and 1000 ml per day by 2 weeks postpartum (112) (Table 23-5). This oversupply of milk provides a reserve against diminishing milk production later in lactation.

TABLE 23-5 OPTIMAL INITIAL MILK EXPRESSION REGIME

Lactogenesis I—Establishing initial milk supply

- Begin milk expression as soon after birth as possible (optimally within 6 hours)
- Pump frequently (no less than 8 times in 24 hours)
- Pump at least once at night (between 1 AM and 4 AM)
- Use a full-sized (hospital grade) electric breast pump with the ability to pump both breasts simultaneously
- Increase pump suction until milk is flowing and comfort maintained
- Hold infant skin-to-skin prior to pumping if possible
- Use breast massage prior to and during milk expression
- Pump for 10 to 15 minutes and/or until all milk droplets cease flowing
- Maximize rest and minimize stress as much as possible

Lactogenesis II—Maintaining milk supply

- Continue with above regime
- To ensure breasts are emptied, do not pump a specific amount of time, but pump until milk stops flowing, for 2 to 3 minutes

Mothers who initiate long-term milk expression require a hospital grade electric breast pump; the clinical challenge is ensuring that these pumps are available. Although hospital-grade electric pumps are available through pharmacies, lactation consultants and home health agencies, many mothers are unable to incur this expense. Support and advocacy from health care providers related to the necessity of this equipment for the health of the infant may assist with payment from third party payers. Although some researchers advocate simultaneous pumping as a significant predictor of eventual milk volumes (122,123), other studies have not supported the necessity of pumping both breasts simultaneously (119). However, simultaneous (double) pumping requires less time and effort than sequential (single) pumping; this difference may influence ultimate maternal commitment and ongoing willingness to continue pumping over time.

Human Milk Supply

Despite their best efforts, mothers of premature infants may experience persistent low milk volumes or milk production that decreases over time. Researchers have described a frequent phenomenon of a decreasing milk supply during the second month of pumping (124), which is very often seen by these authors. Because a breast pump does not mimic the physical contact and closeness of an infant during breastfeeding, suboptimal hormonal stimulation

P.426

may play a role in decreasing milk supply. Little is known about the physiologic response of mechanical milk expression to milk production. Therefore strategies to manage low milk volumes in mothers of premature infants have focused on pharmacological and nonpharmacological enhancement of prolactin secretion (112,125,126,127).

Kangaroo Care, also called skin-to-skin Care, is an effective nonpharmacological method to enhance maternal milk production through skin-to-skin contact. This intimate contact stimulates the release of the hormones of lactation and positively influences maternal milk supply (128,129). Mothers who engage in Kangaroo Care frequently note feelings of milk-ejection and report pumping larger volumes immediately following holding their infants skin-to-skin. Hurst and colleagues report that mothers who held their infants in Kangaroo Care for 30 minutes per day had significantly greater milk volumes both early (2 weeks) and later (4 weeks) in the postpartum period (128). Breast massage has also been demonstrated to increase volumes of pumped milk. It is done similarly to a breast self-exam. Using the palmar surface of her three middle fingers, a mother starts close to the chest wall and slowly massages in a circular motion, moving toward the areola. Mothers should be instructed to palpate each breast after pumping and subsequently massage the firmer areas to promote complete breast emptying (117).

Ongoing clinical observation of pumped milk volumes will ensure timely intervention to prevent significantly inadequate milk production. Because most premature infants require a minimum of 500 mL per day at discharge, intervention to increase milk volumes should be put into place when milk volumes fall below this level (112). Nonpharmacological interventions to increase milk volumes include increasing pumping frequency and resuming and/or increasing pumping at night, pumping at the infant's bedside, or while holding a picture or an article of baby's clothing or bedding; alternatively pumping in a quiet, low-stress environment; and covering the milk collection bottles with a receiving blanket or towel while pumping (decreases anxiousness, stress hormones? It really works!). Pharmacological measures however should be considered if alternative strategies to increase milk volumes have been employed unsuccessfully for 7 days, milk supply is not fully established despite optimal breast stimulation, and/or milk supply has decreased significantly (by 50% or <500 mL/day) after optimal initiation.

Pharmacological prolactin enhancers are another strategy to assist with increasing milk supply. Dopamine inhibitors such as Metoclopramide and Domperidone have been used to induce lactation in clinical situations with varying results (125,126,130). Both increase circulating prolactin levels and, with accompanying breast stimulation, are postulated to cause an increase in prolactin receptors and subsequent milk production (113). As a result, these medications are most effective in the early postpartum period when the breast tissue is sensitive to the formation of prolactin receptors. Companies that manufacture these drugs do not endorse their use as galactagogues, so they are used off label for this purpose (Use of Galactagogues in Initiating or Augmenting Maternal Milk Supply, Appendix C-1). When other strategies to increase milk supply have been applied, however, pharmacological alternatives may be considered to optimize milk production and support ongoing breastfeeding.

THE USE OF MOTHER'S MILK IN NEONATAL INTENSIVE CARE

Guidelines for the collection and storage of human milk ensure optimal quality of human milk that is collected and fed to premature infants. Milk storage and handling are slightly different for the term healthy baby/infant compared to the hospitalized/sick/premature infant (131, 132). Collection technique, collection container and storage conditions play a role in maintaining the unique constituents of human milk and reducing bacterial colonization. Even with meticulous technique, no mother's milk is sterile. Attention to hand washing and cleaning of expression equipment, however, is extremely important in reducing colonization by pathogens other than normal skin flora. Mothers require instruction to ensure that anything coming in contact with the milk or the breasts be cleansed thoroughly prior to each pumping session. Each mother must have her own personal kit. Instructions should include washing all pump parts with hot soapy water after each pumping and sterilizing all

equipment once a day. Most NICUs provide sterile hard plastic containers for the collection of human milk in the hospital and at home. These containers provide for the stability of water-soluble constituents and immunoglobulins. Plastic milk bags are not recommended for the collection of milk for hospitalized infants as a result of loss of milk constituents and chance of leakage and contamination during storage and handling. The temperature at which milk is stored determines the duration of storage. Fresh milk, considered optimal for premature infants, must be used or refrigerated, within one hour of expression. If the infant is not fed immediately, expressed milk can be safely kept in the refrigerator for 48 hours. If the milk will not be used within this time frame, it should be frozen. Milk that has been fortified with additives should be used with 24 hours, and should never be frozen (Appendix C-2).

All milk that is used for infant feeding should be stored in the hospital under controlled conditions. Environmental issues are an important aspect of quality control. This includes monitoring refrigerator/freezer temperatures, and routine cleaning and maintenance of storage units and milk preparation areas. All milk should be clearly identified with infant's name, medical record number and date and time of collection and kept in an environment that eliminates the potential for tampering (Appendix C-2).

Human milk, like blood, is a living fluid and should be handled as such. Proper handwashing and/or wearing gloves during preparation and administration prevents potential bacterial contamination. Stringent quality control standards,

P.427

including a two-nurse check system of identification, minimize potential administration errors (Appendix C-2).

The Use of Donor Human Milk

No chapter on the use of human milk in the NICU is complete without a discussion of donor human milk and its uses. It is beyond the scope of this chapter to present this subject in great depth—for that the reader is referred to more comprehensive discussions (133,134,135,136).

If human milk is the perfect food nutritionally, immunologically and developmentally for the sick or premature infant, what happens when that milk is not available? What if the mother died in the postpartum period? What if the mother, despite her best efforts, is not providing adequate volumes to cover the baby's needs? What if the mother is HIV positive in North America? What if the mother was delivered prematurely because she had a diagnosis of breast cancer made during pregnancy, and she must now undergo chemotherapy? What if the mother, despite being optimally informed, decided not to provide breast milk, and now her baby has a severe allergic colitis and is not thriving on any of the expensive hypoallergenic formulas? What if...? Do these questions sound far-fetched? They are not. They have all occurred within recent memory in one intensive care unit. The answer has always been "provide formula"—or "keep changing formulas around until you find one that works." But is this the best answer? The World Health Organization (WHO) and the United Nations Children's Fund (UNICEF), in their 2003 *Global Strategy for Infant and Young Child Feeding*, recommend banked donor milk as the next option when mother's own milk is not available (137). Although the AAP fell short of endorsing the use of donor milk in its 1997 statement (1), the AAP's 2003 Red Book does contain a section on human milk banks and donor milk (138). The international physician breast-feeding organization, the Academy of Breastfeeding Medicine, supports donor human milk as the preferred human milk supplement in its published clinical protocol for supplementing healthy, term infants in the hospital (139). Many other countries in Europe and South America have donor milk banks and make extensive use of donor human milk.

In North America, the Human Milk Banking Association of North America (HMBANA) developed guidelines that are now mandatory for all member milk banks (140). They require thorough donor screening and testing (similar to that required for organ donors), pasteurization of all milk, and bacteriological quality control of all dispensed milk. The pasteurization process kills all known viruses (including CMV and HIV) and bacteria known to date. Most of the immunologic factors remain intact. IgA is reduced by 20% to 30%; lysozyme activity is only minimally affected; lactoferrin iron-binding capacity is reduced by as much as 60% (141). Even with these reductions, donor milk still has more immunoglobulin, lysozyme, and lactoferrin than formula! There is little effect of pasteurization on the long chain polyunsaturated fatty acids (141). In 2002 the six milk banks belonging to HMBANA dispensed 501,100 ounces of milk, approximately half of which went to premature or ill NICU babies (when surveyed in 1994) (142).

The benefits of using donor milk are the same as have been discussed for mother's own milk. In fact, many of the studies from Europe on the prevention of NEC and neurodevelopmental outcomes were done using donor milk when own mother's milk was not available. In addition to prematurity and low or nonexistent maternal milk

supply, other uses in the NICU include formula intolerance/allergy; short bowel syndrome; other issues of malabsorption such as gastroschisis; multiple births; recovery from NEC; supplementation of the hypoglycemic baby; and supplementation of the dehydrated, hyperbilirubinemic breastfed baby.

Donor milk requires a doctor's prescription. Although the milk is donated to the milk banks and not sold, there are processing fees charged to help defray the costs of donor screening and processing of the milk. That fee is currently approximately \$3.50 an ounce plus shipping fees. In Canada, the use of donor milk is covered by the national health plan. In the United States, its coverage by insurance and health plans is variable. It often requires an extra effort by the physician to speak to the medical director of the health plan and educate him or her on the benefits of using donor milk. Although the cost may seem exorbitant, it has been estimated that for every \$1 spent on donor milk, \$11 to \$37 in NICU costs are saved (136). Arnold calculated the cost of supplying donor human milk and fortifier to a hypothetical preterm infant as being \$1350 (134). Using the previously discussed (86) estimated additional costs of surgical NEC averaging \$186,200 more and medical NEC \$73,700, the potential for preventing a case of NEC by the use of donor human milk seems more than economical! Most milk donated to milk banks comes from mothers who have delivered at term. However, they do receive milk from preterm mothers—mothers who have large milk supplies, and even mothers who have ultimately lost their baby, but donate their milk as part of working through the grieving process, to help another baby. Preterm and full term milk is processed separately. Donor preterm milk can be specifically requested, and if available, it will be shipped to you. It is shipped frozen overnight. It is worth having a policy in place for the timely transport of the milk from your receiving area to your unit, where it must be transferred to the freezer on arrival. For a sample donor human milk policy, please see Appendix C-3.

FORTIFICATION OF HUMAN MILK FOR VERY LOW BIRTH WEIGHT BABIES

There are many times when babies in the NICU do not show adequate growth and good weight gain. For babies who are receiving breast milk, there are a number of things that can be done. One of the most obvious, and most frequently overlooked, is increasing the volumes. As neonatologists, we have firmly entrenched in our minds that we cannot exceed

P.428

160 cc/kg/day. For some babies this is true—in particular those who are fluid restricted, on diuretics, or for those who do not tolerate advancing beyond that volume enterally. However as we also know, term babies, when allowed to feed ad libitum, often exceed 200 to 220 cc/kg/day. So it is worth remembering that at least in some of our population, we do not have to adhere to such tight fluid control. When we cannot advance volume any further, there are generally two ways to advance calories with breast milk: using hind milk and using commercial fortifiers.

Hind Milk

The fat content of human milk increases throughout the course of a feeding or a milk expression session. We can take advantage of that to provide higher caloric milk to a baby who is either receiving breast milk through an alternative feeding method or who is breastfeeding. Hind milk refers to the milk at the end of the feed that is higher in fat content; foremilk is the milk from the early part of the feed that is lower in fat. Because the fat changes along a continuum, this is in some ways an artificial construct, but one that is useful to this concept. For a mother to provide hind milk, she must be producing more than the baby's requirement in milk per day. Essentially it consists of having her pump off a specified volume of milk at the beginning of a session, change containers, and then continue to pump until she is "empty." If these containers are then compared, the foremilk will look thin and bluish (lower fat content) and the hind milk will look whiter and creamier. The decision regarding how much is foremilk and how much is hind milk is based on how much milk mother makes, and how much is needed for a feed. For example, if she generally pumps 4 ounces of milk total, and the baby receives 2 ounces at a feeding, we would have mom pump off approximately 1 ounce from each breast as her foremilk, and the remaining 2 ounces total as her hind milk. The containers need to remain separate and be labeled as foremilk and hind milk respectively. If a baby is receiving some or all of his/her nutrition at the breast, this method can still be used. Mother can express the initial one ounce from her breast, and then let the baby drain the breast to receive the higher fat content milk. This method has been used successfully in a developing country to improve growth when commercial fortifiers were not available (143). A word of caution—hind milk is only higher in fat and therefore calories. It does not provide the extra protein, vitamins or minerals that many of our babies need. These are provided by the commercial fortifiers. However, if a baby on fortified milk is not

showing acceptable rate of weight gain, one can successfully use fortified hind milk (144).

Commercial Fortifiers

Either liquid or powdered commercially manufactured substances generally provide fortification. Powdered fortifiers add the additional nutrients without diluting out any of the substances in the human milk. Liquid fortifiers are added in equal volume to the human milk, thus diluting out its components by half. Traditionally, when a mother's milk production has equaled or exceeded her baby's requirements, powdered fortifier has been used. When her production has not met her baby's needs, liquid fortifier has been used in an attempt to "extend" her milk. There have recently been a number of reports of significant *Enterobacter sakazakii* infections in neonates, including sepsis, meningitis and necrotizing enterocolitis, with premature and sick babies being at highest risk (145,146,147,148,149,150). They are associated with the use of complete milk-based powdered infant formula products from a variety of manufacturers. Powdered milk-based infant formulas are not sterile; they are heat treated during processing, but unlike liquid formula products, not subjected to the high temperatures for sufficient time to make the product commercially sterile (145,151). Recommendations from the CDC included that "formula products should be selected based on nutritional needs; alternatives to powdered forms should be chosen when possible" (145). At the time of this writing, there have been no reports of infection following the use of powdered human milk fortifiers. However, based on these reports and the CDC recommendations for powdered "formula products," many NICUs are preferentially using the liquid fortifiers, unless there is a cogent reason for using the powdered.

The protein in these fortifiers, which is derived from cow's milk, is of concern to many neonatologists and nutritionists. One of the risks of artificial feedings compared to human milk is the development of allergic GI symptoms to the bovine protein they contain. The ideal fortification of milk for preterm babies could be obtained by a process known as lactoengineering, in which specific components are removed from either excess own mother's milk, or donor milk, and then added to the human milk feeding to increase those needed nutrients. Studies have shown babies fed own mother's milk fortified with human milk protein (152) or with human milk protein plus human milk fat (153) grow comparably to both intrauterine growth curves and to other premature babies who have been exclusively fed fortified preterm formulas. This is an expensive process, but is feasible, and has been under investigation in several European countries (154,155,156). The ideal may well become human milk proteins packaged with other components for use as fortifiers for preterm babies. In the meantime, for these very low birthweight babies, human milk with added fortification is the ideal nutrition available.

It is a widely held belief by staff at all levels in NICUs that the addition of commercial human milk fortifiers increases feeding intolerance; there is, however, no evidence for this. Numerous controlled clinical trials have shown no difference in signs of feeding intolerance, increased gastric residuals, bilious gastric residuals, abdominal distention, or blood in the stools when compared to human milk alone or preterm formulas (157,158,159,160,161,162).

P.429

There has also been concern that nutritional additives to human milk may in fact alter its complex system of antiinfective/host defense properties. In one clinical study fortified human milk has been shown to increase, but not to a significant degree, the incidence of necrotizing enterocolitis (5.8% compared with 2.2%, $p = 0.12$), and infections (suspected plus proven; 43% compared with 31%, $p = 0.04$) over human milk alone (163).

Laboratory research in this area has shown that fortification does not affect total IgA content (164,165), or inhibition to *E. coli*, although it does decrease lysozyme activity by 19%, which was not considered significant (164). When fortified human milk was evaluated under simulated nursery conditions, bacterial colony counts did not rise appreciably for the first 20 hours under refrigeration, but did increase approximately 10-fold in the following 4 hours under incubator conditions (165). More recently, Chan evaluated the effect of addition of powdered fortifiers to human milk on antibacterial activity. Human milk alone inhibited the growth of *E. coli*, *Staphylococcus aureus*, *Enterobacter sakazakii*, and Group B Streptococcus. Fortifier that contains iron, and iron alone, affected the antimicrobial activity of the milk, causing no zone of inhibition for any of these organisms (166). The fortifier containing no iron had similar inhibitory effects to human milk alone. It was postulated that the iron may have saturated the lactoferrin in the milk, thus decreasing its antibacterial activity. Another *in vitro* study looked at the effect of human milk fortifier added to human milk on the concentration of transforming growth factor- α (TGF- α). TGF- α is a gut peptide found in human milk that is believed to exert a maturational effect on the neonatal gut. They found that the addition of fortifier did not affect the whole milk or aqueous portion of TGF- α , but significantly decreased its concentration in the fat fraction, in addition to altering its

molecular mass profile characteristics (167). Thus far, the data does not suggest a change in our current practice of fortification. Whether these laboratory findings are of clinical significance remains to be seen. But it is worth keeping in mind that the addition of exogenous substances to human milk, although our intent is good, may in fact be found later to alter and compromise the balance of nutrients, enzymes, hormones, immunological and other factors and thus their effects.

One final note on fortification—mothers of NICU babies are already dealing with many stresses, not the least of which are the circumstances that brought her and her baby to the NICU. We must always be very cautious when talking about “inadequate growth” and “fortification” with her. Remember—providing breast milk is the one thing only she can do for her baby. If we are careless when we broach these subjects, the message she will take away is that her milk is not adequate, and that her infant's slow growth relates to something she is not doing right. It is important to point out to her that her milk is the best possible nutrition for her baby, and helping the baby to fight infections, and that she is doing an excellent job providing it. The issue at this time is that her small baby has enormous nutritional needs, which can be met by using hind milk and/or commercial fortifiers. It is important as well to emphasize that this is a time-limited issue, and that as her baby grows, matures, and becomes healthier, her milk alone will provide all her baby needs.

Colostrum Oral Care

It is well known that sIgA is present in large quantities in premature colostrum (Table 23-4). Almost 75% of ingested IgA from human milk survives passage through the intestinal tract and is excreted in the feces (168). This immunoglobulin provides passive protection against antigens (including viruses and bacteria) crossing the immature, permeable mucosal barrier (169). As early as 1983, Narayanan and colleagues from India reported that small quantities of colostrum (10 cc three times a day) administered to low birth weight infants resulted in a significantly decreased incidence of infection compared to solely formula-fed controls (170). It is common practice in NICUs to provide oral care to babies who are not being orally fed—including the new, ventilated ELBW and VLBW infants, and those with significant cardiovascular instability. This is generally accomplished using sterile water applied to a cotton-tipped swab, or to a piece of gauze. In our unit, we have instituted a practice of “colostrum oral care” in which any baby who is not being enterally fed can be provided with oral care using mother's expressed colostrum instead of sterile water. The reasoning behind this is that knowing the sIgA is active in protecting the mucosal surfaces of these immunocompromised babies, by swabbing the oral cavity with colostrum, we are providing some of that protection to the oral mucosa and possibly the upper GI tract if any is swallowed. Additionally, it accomplishes another very important purpose. In the early days before a mother can hold a very small or sick baby, before the milk she is working so hard to express can be used for feeds, she is playing a vital role in the care of her infant. This procedure can be initiated within hours of birth, even in the most premature babies. NICU staff or parents dip a sterile swab in the colostrum container, and swab over the tongue and oral mucosa. The swab should not be dipped back into the container. This may be done as frequently as every 4 hours, generally in conjunction with hands-on care. Once minimal enteral feedings are begun, remaining colostrum should be used for those early feedings, and oral care continued according to standard routine.

THE DEVELOPMENTAL PROGRESSION TOWARD BREASTFEEDING

In hospital breastfeeding management, the process of establishing breastfeeding in the preterm population begins with the facilitation of frequent skin-to-skin contact

P.430

through Kangaroo (skin to skin) care (Fig. 23-3). Originally proposed by Rey and colleagues in Bogota Columbia (171), subsequent studies in developed nations illustrate that the practice is safe, beneficial and an essential component of high-quality neonatal intensive care (172,173,174,175). Kangaroo care has also been consistently associated with improved milk production, enhanced maternal breastfeeding competence and extended lactation (175,176,177,178). Mothers who provide skin-to-skin contact report that their infant makes rooting and sucking movements toward the nipple, note feelings of milk ejection and leaking, and often express larger amounts of milk immediately following a Kangaroo Care session (179,180). Kangaroo care provides the mother with the opportunity to become more confident in handling her small infant. Mothers who engage in Kangaroo Care report a sense of efficacy, increased self-esteem, and confidence in caring for their babies (181). Kangaroo care also provides the infant with frequent access to the breast, increases opportunity for nonnutritive sucking, and assists in the gradual transition to breastfeeding. It is the optimal position for an infant to receive gavage feedings prior to the establishment of breastfeeding and during supplemental feedings. Tornhage and colleagues

report that infant plasma cholecystokinin levels increase when receiving nasogastric feedings during Kangaroo Care (182). This stimulates GI function and infant growth.

Figure 23-3 Mother and 600-gram 23-week infant engaging in skin-to-skin contact.

The transition from breast milk feedings to breast-feeding is critical. When successful breastfeeding is established in the hospital setting, breastfeeding is more likely to continue at home. However, the process of breastfeeding the premature infant can be challenging for the infant, the mother and the health care professional. The transition phase from providing expressed human milk to nutritive breastfeeding has not been extensively studied. Factors to consider in transitioning the premature infant from breast milk feedings to feeding at the breast include assessment of feeding readiness, optimizing opportunity for early breast-feeding, encouraging increased breastfeeding as the infant nears discharge and ensuring post discharge support based on the individual needs of the mother and infant.

Assessment of feeding readiness is determined by the maturation of the infant, measured chronologically as corrected gestational age and influences the development of feeding skills. The bottle-feeding skill of the premature infant has been positively correlated with the development of sucking skills and is a function of maturation (183). The infant must be able to coordinate bursts of sucking interspersed with pauses for breathing to manage the bottle-feeding skills. This ability is variable but often occurs by about 34 weeks' gestational age.

Restrictions in breastfeeding policies for preterm infants are commonly based on studies of bottle-feeding, in which it has been established that infants with immature cardi-respiratory control show less coordinated suck-swallow-breathe pattern, resulting in apnea, hypoxia, and bradycardia (184). However, at the breast the preterm infant coordinates sucking, swallowing, and breathing with minimal fluctuations in transcutaneous oxygen pressure (104,106), and as discussed earlier, is more physiologically stable.

There is no scientific evidence linking gestational age, growth/weight milestones, or the ability to drink from a bottle as evidence for breastfeeding readiness in a premature infant. Although maturation plays a role in the premature infant's ability to breastfeed, clinicians observe a wide range of variability related to breastfeeding readiness and competence among premature infants, with infants as young as 34 weeks gestation fully breastfeeding although some term infants take several weeks to effectively breast-feed. This suggests that the emergence of breastfeeding competence in preterm infants is a multifactorial process that is dependent on both infant and maternal factors. The role of experience and learning in acquiring breastfeeding skills has recently been investigated (185). Nyquist and colleagues suggest that the development of nutritive sucking is not solely maturational but a result of learning and extrinsic factors such as maternal-infant interaction and the frequency and time spent breastfeeding (185). The same investigators examined early oral behavior of preterm infants during breastfeeding via electromyographic study (186). Data provided evidence of early sucking competence during breastfeeding, with wide individual variations. The authors concluded that preterm infants are capable of suckling at the mother's breast at low maturational levels and that both maturation and experience play a role in breastfeeding success (186). With experience and maturation, preterm infants will demonstrate increasing competence in latching onto the breast and maintaining a latch. Over time, they will subsequently engage in more efficient suckling and demonstrate gradual increase in vigor, intake velocity and volume at the breast (187). Research also indicates that breastfeeding is less stressful for premature infants than bottle-feeding with less hypoxia, apnea, bradycardia, and oxygen desaturation experienced during breastfeeding than during bottle

attained, neonatal staff should encourage early and frequent opportunities to breastfeed.

Figure 23-4 Premature infant at the breast.

Readiness criteria for early breastfeeding sessions include individual assessment of physiological stability during Kangaroo Care or holding, wakeful periods during feeding, rooting when hungry, and periods of nonnutritive sucking. The goal of early breastfeeding for a premature infant is to promote an enjoyable experience for both mother and baby although simultaneously teaching proper position and latch at the breast. Some oral feeding is possible at the breast between 28 to 30 weeks gestation; by 32 to 34 weeks gestation, some infants may be able to take a full breastfeed once or twice a day, while others may become proficient at breast; from 35 weeks onward, efficient breastfeeding that maintains growth is possible (Fig. 23-4).

Early breastfeeding sessions provide opportunity to introduce breastfeeding as the first oral feeding experience for the premature infant. These are in effect, practice sessions. Mothers do not feel the pressure to "make it work" because their baby's nutrition does not depend on their success. So they become comfortable handling the baby, and working on the skills of positioning and latching, while enjoying this process and the time spent with their baby. These sessions are also excellent times to give the baby a gavage feed, in effect teaching the baby as well. Over time the baby becomes "imprinted" with "this is the position I am in, this is the taste and smell of my mother (and maybe even a little taste of the milk that can be expressed onto her nipple!), and this is the nice feeling I get when my stomach becomes full." During this early breastfeeding stage, mothers should be encouraged to put baby to the breast one to two times per day. Making the mother and baby as comfortable as possible is key. Chairs used for these postpartum women should be padded and give the mother good support with enough room to maneuver and provide support to the infant's body. The large reclining chairs used in geriatric wards or dialysis units make perfect breastfeeding or skin to skin chairs. Mothers often maintain better position if a small stool is used under their feet to raise their legs somewhat. Pillows may be necessary to help support her arms in correct position. The baby needs to be supported as well. Commercial breastfeeding pillows, made of hospital grade materials that can be wiped off with disinfectant between babies, are available and work well. They can be covered with a towel or receiving blanket for comfort. Alternatively, some come with removable, washable covers that can be changed between babies. In our experience they seem to work better than using bed pillows, which are another option. Neonatal staff should provide a constant presence to reassure the mother, point out the positive aspects of this early breastfeeding, ensure infant stability, and optimize the latch of the premature infant at the breast.

The premature infant has unique characteristics that may interfere with latch at the breast. These include low muscle tone, limited energy, and the propensity to fall asleep at the breast from fatigue rather than satiety (188). Compared to a full-term infant, physical characteristics include a proportionately larger head, weaker neck muscles, and a mouth that is smaller in relationship to the areola and breast. These characteristics require breastfeeding positions that assist in placing the infant's mouth over the areola. Failure to support the infant in this optimal position will result in inability to compress the lactiferous sinuses, decreased milk transfer and nipple trauma. Additionally, failure to provide adequate support for the premature infant at the breast can result in the baby slipping away from a good latch and tiring easily as a result of the additional effort expended during breastfeeding to try and stay latched. Mothers may become discouraged because of some of these issues. It is important to reassure them that these are time-limited concerns. As the baby grows and develops, the hypotonia will improve. Early on for many of these dyads, the problem of "trying to fit a quarter-sized nipple into a dime-sized mouth" is a real problem. It is easy to point out to a frustrated mom, that although her nipple is not expected to grow any more, her baby's mouth will!

Effective techniques to assist the premature infant to latch vary and depend on the configuration of the breast and the strength and skill of the infant (188). Data from nonnutritive sucking and bottle-feeding reveal that the amount of suction that the premature infant generates

P.432

while at the breast is maturationally dependent (189). Because of this limitation, small premature infants need to be "placed" and "kept" on the nipple/areola, because limited suction inhibits their ability to bring and keep the nipple /areola in the correct position for milk extraction. Mothers of small premature infants require instruction to place and support the baby at the breast. This includes supporting the baby's head at the nape of the neck during latch and throughout breastfeeding. Additional head support assists weak neck musculature of the premature infant to maintain neck stability and prevents undirected head movement that can lead to airway collapse, apnea, and bradycardia (190). For some mothers with large breasts, it is helpful to roll a towel or blanket to place under the breast to hold it up, to make it easier for mom to see as she is placing the baby, and easier for the baby to stay latched because the breast is being supported. Supportive positions for breastfeeding the premature infant include the underarm/football hold or cross-cradle (across the lap) positions. These positions support the infant's head and torso, guide the infant to the nipple/areolar area, ensure optimal latch, and subsequently maintain the baby in a close flexed position throughout the feeding. To maintain the airway and to help in swallowing in the cross-cradle position, it is important to maintain the infant's body facing the mother, keeping the baby's ear, shoulder and hip in a straight line, and then flexing their legs around the mother's body (Fig. 23-5). In the football hold, care should be taken to ensure that the baby's neck is not overly flexed (Fig. 23-6). The typical breastfeeding Madonna hold, which most mothers have seen so will naturally try, in which the baby is held with her arm on the same side of her body as the breast she is feeding from, is not appropriate for premature or other low tone babies. The baby's head, which is supported in the crook of the mother's arm, tends to fall through, and is poorly supported for optimal feeding.

Figure 23-5 Cross-cradle position at the breast.

When optimal position is attained, the infant's head can be moved toward the breast, by the hand supporting the neck and head. The mother's nipple can then be lightly brushed against the infant's mouth. The infant will spontaneously open his mouth when ready. The mother should then gently guide the infant onto the nipple/areolar area. The mother with everted, elongated nipples may find it easier to elicit a sucking response at the

breast as her nipple will automatically stimulate the roof of the baby's mouth and elicit the sucking response. Mothers with flatter nipples may require additional assistance to achieve latch. This may include manipulating the nipple to make a "teat" which will then stimulate the infant suck reflex. It can be done by either having the mother use the electric pump briefly right before the feed to draw the nipple out, or by having the mother roll her nipple between her thumb and forefinger. This requires additional assistance from nursing staff or a lactation consultant during the first several breastfeeding sessions or until the infant has demonstrated effective latch.

Figure 23-6 Football hold with a premature baby at breast, demonstrating compression of the breast to increase milk flow during the feed.

It is important here to discuss the concept of "on-cue" feedings. In neonatal units, we are very entrenched in calculating, ordering, measuring and reporting the exact input and the intervals at which it must occur. It is critical to our care when our patients are very small or very sick. However, we need to learn to relax that somewhat as we begin to introduce feedings at breast. If the baby is due for an interval feeding at a specific time but is asleep, it often will prove fruitless to try to put the baby to breast at that time. However, an hour later, before the next feed is due, when the baby is awake and the mother is at the bedside, it is the right time to allow them to practice breastfeeding. If the baby takes nothing or if the baby actually ingests a few ccs, it really does not matter. But the dyad have had the perfect opportunity to learn—that is what matters. As the baby

P.433

matures, bedside staff will often notice a pattern to their wakeful periods. It is not unusual for them to be at night. So a mother who comes in every afternoon to put the sleeping baby to breast may have gotten nowhere. But if she changes her pattern, and manages to come in at night when the baby is often active, their breastfeeding skills may take off and amaze everyone. From there, we often see the babies becoming more wakeful for feeds, so on-cue breastfeeding times can advance in number. If the baby is awake 2 hours after the last feed, and is giving feeding cues, it is perfectly reasonable to have her put the baby to breast again, even though it is "too early" based on our feeding orders. That is what the mother will do once she is home—that is what we must ultimately aim for before discharge.

Mothers must be taught indicators of milk transfer/ swallowing at the breast. This includes the soft "caw" sound of swallowing. This also includes the open-pause-close pattern of suckling during which the wide-open pause of the infant's mouth during breastfeeding indicates that the infant is swallowing a mouthful of milk. When evidence of milk transfer diminishes during a feed, switching breasts and using breast compression may increase volume of milk ingested. During breast compression, the mother uses her "free" hand, which has been supporting her breast, to grasp the breast in a C-hold (fingers on one side, thumb on the other) and when the baby is suckling, compresses her breast between her fingers to eject more milk (Fig. 23-6). This will often keep the baby interested and actively suckling. When bursts of these indicators are evident during breast-feeding,

and accuracy of intake is important, intake at the breast can be estimated by the use of prefeeding and postfeeding weights (191,192). The difference between pre- and post-weights in grams equals the amount of milk transferred in cc's. Volume of intake at the breast can be extremely variable. It is, however, virtually impossible to estimate by observing the feed, even by experts in lactation. Most premature infants will experience marginal intake during early breastfeeding. However some infants can consume adequate quantities of milk during early breastfeeding because mothers have copious milk supply and it flows readily. Thus milk volume and ejection can compensate for a marginally effective suck in some small premature infants. Test weighing or prefeeding and postfeeding weights under identical conditions may be helpful in determining the ability of the infant to stimulate milk transfer, amount of supplements required, and maternal milk supply. The scale used must be an accurate electronic scale. "Under identical conditions" means the baby must be weighed immediately before and after the feeding session, with the same clothing, diaper, blankets, leads, tubes, and so on at both of these times. Using this data, instead of trying to guess how much supplementation must be given for that feed, the difference between the ordered feeding amount and the amount taken at breast can be calculated and given via gavage. Prefeeding and postfeeding weights may also provide an indicator of breastfeeding progress and therefore reassurance for mother and staff. Test weighing should be introduced when it appears that milk transfer is occurring or when discharge is imminent. This information can assist in tailoring ongoing breastfeeding support and discharge preparation.

ONGOING BREASTFEEDING SESSIONS

The Use of Alternative Feeding Methods

The goal of ongoing breastfeeding sessions is to support the infant to consume adequate volumes of milk from the breast in anticipation of discharge. Research indicates that premature infants are able to coordinate the suck, swallow and breathe pattern of breastfeeding before bottle-feeding (104). This data also illustrates that mean volumes of milk transfer/intake during early breastfeeding sessions is often minimal but that the range for intake at the breast is variable and may be quite high. Early breastfeeding sessions are almost always supplemented by gavage feedings, which optimize this early learning experience. Typically, other methods of supplemental and/or complementary feedings are initiated when the maturity, energy and ability of the infant to suckle increases. These include bottle-feeding, cup feeding, finger feeding, and feeding tube at the breast. Currently there is limited evidence to guide hospital practice related to transitioning the premature infant to the breast. Although protocols to eliminate or minimize bottle feeds have been published and used clinically (193), the majority have not been tested in randomized controlled trials. Hospital policies and practices related to the use of supplemental or complementary feedings however can potentially interfere with breastfeeding outcomes (194,195).

The majority of neonatal units introduce bottle-feeding as a supplementation method for the preterm infant who is not exclusively breastfed during neonatal hospitalization. The degree that bottle-feeding may interfere with the acquisition of breastfeeding skills is controversial. Most experts would agree that the oral dynamics of breastfeeding and bottle-feeding are significantly different (196,197). Breast-feeding is dependent on the massaging action of the tongue and jaw while bottle-feeding depends more on suction. Additionally, the characteristic of milk flow from the bottle is different from the flow of milk from the breast. A quicker flow that provides immediate reward for minimal sucking may be another factor in the preference of bottle over breastfeeding. Therefore the suckling pattern learned through bottle-feeding may result in infants resisting latching to the breast, refusing the breast, or having difficulty with latch-on (198,199). Research indicates that the use of artificial nipples interferes with breastfeeding success in term infants and that they may be detrimental in preterm infants as well (194,200,201). Consequently, for preterm infants whose supplementary feedings are provided by bottle, subsequent breastfeeding may be difficult. Alternative feeding methods that do not adversely affect breastfeeding duration in this population are highly desirable. This need, coupled with recommendations emerging from the 1991

P.434

WHO/UNICEF Baby Friendly Initiative (202,203) that no artificial nipples or pacifiers be used if breastfeeding is to be established, has resulted in an increased use of alternate feeding methods in neonatal units. Methods that may foster the transition of preterm infants to full breastfeeding include continued tube feeding, cup feeding, finger feeding, or a nursing supplementer tube (feeding tube device). A nipple shield may also be a consideration at this stage of breastfeeding. Currently there is no agreement on the best method of supplementing the preterm infant or the timing of transitioning the preterm infant to the breast. Supplementation method and timing are based on a combination of maternal and infant factors. Various levels

of evidence support each strategy.

Until the preterm infant establishes a pattern of nutritive oral feeding, periodic gastric tube feedings are required. Although guidelines and protocols for gastric feeding differ, continuous nasogastric tube placement is the most common protocol and tube sizes include numbers 5, 6.5, and 8 French (204). Nasogastric feedings have been associated with negative impacts on breathing, sucking, irritation, and delayed transition to oral feeding. A prospective randomized trial evaluated the impact of an indwelling smaller bore feeding tube (3.4 French) during the transition to breastfeeding as an alternative to supplementation by bottle. Infants who received nasogastric supplementation were 4.5 times more likely to be partially and 9.4 times fully breastfeeding at discharge compared to the bottle-fed group (205). Method of supplementation continued to be predictive of long-term breastfeeding as well (205). Although there were risk and stressors associated with continued nasogastric feeding (greater numbers of apnea and bradycardia requiring stimulation) the authors suggest that this method can be used safely during hospitalization to support ongoing breastfeeding.

Cup feeding has been used primarily in full term infants as a short-term method of providing a supplement to a breastfeeding baby. Early reports suggested that cup feeding is a safe alternative method of supplementation for preterm infants 30 weeks gestational age and older (206). Breastfeeding rates were increased when cup feeding replaced bottle-feeding and replaced or supplemented tube feedings in this early study (206). More recently, the safety of cup feedings and bottle feedings were compared in a prospective randomized cross-over study of 56 infants ≤ 34 weeks at birth by Marinelli and colleagues (207). Results indicate that a 10-fold increase in desaturations occurs during bottle-feeding compared to cup feeding. Although volumes taken were lower and duration of feeds longer during cup feedings, the study supported the use of cup feeding as a safe alternative feeding method for premature infants learning to breast-feed (207). The mechanics and safety of cup feeding were also evaluated by Dowling and colleagues through observation of 18 cup feeding sessions by 8 preterm infants with a mean gestational age of 30.7 weeks (208). Data indicate that the infants remained physiologically stable during cup feeding but that low volume of intake may account for this stability and is also cause for concern (208). Spillage was a common occurrence during cup feeding, indicating that cup feeding may not be as easy for the infant or caregiver as previously described. Therefore, the efficacy and efficiency of cup feeding as an alternative method of supplementation is questioned and requires further study (208) (Fig. 23-7).

Figure 23-7 Cup feeding.

Finger feeding is another alternative feeding method that eliminates the need for bottle-feedings while the premature infant is learning to breastfeed and/or nearing discharge. Finger feeding is proposed as a method of feeding that assists with the development of appropriate tongue position and movements of sucking. Finger feeding is considered more similar to breastfeeding than bottle-feeding and can be used while the infant is learning to breastfeed, is too tired to breastfeed or when mother is not available (194). Little data exists to evaluate finger feeding as an alternative feeding method. Oddy and Glenn assessed the effectiveness of finger feedings in encouraging a breastfeeding-type suck and breastfeeding outcomes in preterm infants who required supplementation (209). Data was collected on rates of breastfeeding at discharge before and after this alternative feeding method was introduced. Results indicated higher rates of breastfeeding on discharge in preterm infants who were supplemented with finger feeding vs. bottle-feeding (209). One of the concerns with finger feeding is that it is introducing a hard surface into the baby's mouth, and may not ultimately fair any better than the use of artificial bottles with nipples. It is a tool that is used widely and successfully in "suck-training" babies with dysfunctional sucking mechanisms (210). Although further research is required to evaluate

this strategy, finger feeding may provide an option to support breastfeeding learning in this population.

Alternative methods of transitioning the premature infant to the breast can be used when the mother is present; these include a nipple shield and a feeding tube device at the breast (supplemental nurser). Recent literature supports the use of a thin silicone nipple shield to assist the premature infant to latch when the infant cannot draw in enough nipple/areola, the areola is too puffy or the nipple

P.435

is very large (211,212). Because the nipple shield is less pliable than the maternal nipple, it can stimulate a stronger sucking reflex. It has been hypothesized that the nipple shield functions to increase the effectiveness of infant suck by remaining in the correct position within the infant's mouth in the absence of strong suck pressures. A nipple shield maintains its shape when the infant pauses, keeping him/her on the breast with little effort, minimizing the tendency to slip off during feedings. Additionally, once the baby begins to suckle, negative pressure appears to be generated in the empty space between the nipple and the tip of the shield. These pressures have been postulated to compensate for the weaker suck of the infant, allowing milk to accumulate in the chamber, and thus making it more readily available (212). In these circumstances, the nipple shield may make it easier for the premature infant to maintain attachment to the breast and extract milk. As a result, temporary use of a nipple shield may increase both the duration of suckling and volume of milk consumed during breastfeeding (211,212) (Fig. 23-8). In the past, nipple shields were considered taboo in the lactation field. They were made of thick rubber, and mothers often developed decreasing milk supplies as a result of less sensory stimulation to the breast, ultimately leading to cessation of breastfeeding. The newer thin silicone nipple shields are less likely to precipitate these negative outcomes. Premature infants who may benefit from the use of a thin silicone nipple shield include those with short inefficient bursts of sucking, limited energy and low suction at the breast, who fall asleep quickly at the breast, or whose mothers have flat or ill-defined nipples that make grasp and sustained latch difficult. A nipple shield is often well accepted by mothers because it allows the infant to feed at the breast with increased vigor, alert periods and intake at the breast (112,212).

Figure 23-8 Silicone nipple shield with feeding tube device.

Figure 23-9 Feeding tube device at the breast.

Attempts should be made to wean the baby from the nipple shield prior to discharge. However, if the baby can only maintain total enteral intake with the shield, discharge home can be considered, but only if there is experienced lactation support available. The dyad must have close follow-up with intent to wean from the shield when the baby is able to suckle well without it. Additional research is required to continue to explore the use of a silicone nipple shield as a temporary milk transfer device for premature infants.

A feeding tube device at the breast (supplemental nurser) can be beneficial for a mother with a limited milk supply or for an infant who achieves a good latch but is unable to transfer adequate milk volumes (214). This device reinforces the position and latch of breastfeeding, provides for additional infant intake at the breast without supplementary time and energy expenditure, and increases maternal milk supply through optimal breast stimulation (Fig. 23-9). Mothers often feel initially awkward with placing the tube and then latching the baby, but with assistance from staff and a little practice, it will become much easier for her. The tube should be placed so that the tip is close to, but not at or past the end of the nipple. If that occurs, babies often figure out quickly how to use it like a straw instead of latching correctly! A feeding tube device can be placed inside a nipple shield to aid a baby with milk transfer, especially if the mother has low milk supply, or the baby has limited energy and needs help with efficiently transferring milk (Fig. 23-8).

It is important to recognize that the safety, efficacy and breastfeeding outcomes of all methods of supplementing

P.436

the premature infant during the transition to full breast-feeding have not been studied systematically in controlled trials. Therefore, the method, timing and duration of supplementation should be based on individual assessment of the infant and mother and follow informed consent.

DISCHARGE PLANNING

Transition to cue-based full breastfeeding occurs over time with the majority of premature infants able to achieve this milestone by the time they are equivalent to term. This process is facilitated by increasing the frequency of breast-feeding as the infant's ability to transfer milk at the breast improves. Several protocols to facilitate this outcome are documented in the literature. All require ongoing assessment of breastfeeding adequacy and intervention as required.

Breastfeeding assessment should include regular visual assessment of the baby at the breast by staff with knowledge and experience in the care of breastfeeding families. Several "breastfeeding tools" are available to promote an objective assessment of latch, milk transfer and other attributes associated with optimal breastfeeding (215,216,217,218,219,220). The Preterm Infant Breastfeeding Behavior Scale specifically measures the maturational steps in breastfeeding progress and is useful in the clinical setting (220). Utilization of an objective breastfeeding assessment tool has the potential to identify early breastfeeding issues and assist staff to intervene in a timely and consistent manner. These tools are also excellent teaching tools for families which assist mothers in assessing progress toward successful breastfeeding.

As the infant matures, mothers should be given opportunity to breastfeed not only on cue, but ad libitum. Frequent on-demand or cue-based breastfeeding ad libitum provides information about the infant's energy level to engage in full breastfeeding, rate of growth with this plan, and assists with setting realistic goals for discharge preparation and feeding at home. Feeding options should be discussed with mothers and fathers to ensure they

participate in and are fully informed about individualized breastfeeding plans. An individualized transition to home plan should be put into place for each mother-infant dyad based on the skills of the infant, the mother's milk production and the infant's caloric needs. Because the behavioral feeding cues of the preterm infant are less distinct than the full-term infant, mothers require time and learning to interpret correctly (185). The availability of a parent suite for overnight stays facilitates this learning, allowing maximal access to the infant and a trial of breastfeeding on cue. This opportunity can also provide valuable information related to maternal milk supply and the adequacy of infant intake at the breast. Prior to discharge, if the facilities are available, parents should be offered and encouraged to room-in with their baby for at least 24 hours. This is helpful in both troubleshooting any concerns or issues that arise, and for building parental confidence that they will be able to manage once home.

Many premature infants are otherwise ready for discharge before reaching term. Lack of maturity may continue to interfere with their ability to fully breastfeed. Other premature infants are discharged at term but have size and energy limitations that preclude full breastfeeding. Mothers therefore may need to modify their expectations about their infant's breastfeeding potential at discharge. All mothers require a detailed feeding plan at discharge that addresses the ongoing nutritional needs of the infant while supporting ongoing breastfeeding. This plan must support the mother's knowledge of expected feeding patterns, assessment of adequate intake, supplementation (method, frequency and amount) to ensure adequate intake, and the need for continued pumping to ensure full milk production until the baby is fully breastfed. It is optimal that this plan be not only developed collaboratively with the parents, but also given to them in written format to refer to once home. It must also be communicated to the primary care provider and the lactation expert who will be following and managing this dyad closely at home (Appendix C-4).

SUPPORTING BREASTFEEDING IN THE NEONATAL INTENSIVE CARE UNIT AND AFTER DISCHARGE

It is critical to have a "breastfeeding friendly" NICU to optimize a dyad's chances of successfully breastfeeding. One of the largest roadblocks to this is the inaccurate and inconsistent advice and assistance that is given to these mothers and families by the health care professionals (relatives and friends as well) they come into contact with. Much of that is based on knowledge deficits in lactation, attitudes and beliefs that influence what we say and how we present it, and personal factors such as age, education and own breastfeeding experiences (221,222). Additionally, nurses, who spend more time at the bedside than any other caregivers, are viewed by families as breastfeeding authorities, regardless of their knowledge or expertise. Although a number of studies have looked at the effect of education on caregiver attitudes on breastfeeding, one has examined this approach in the NICU. Siddell, Marinelli, and colleagues examined the change in breastfeeding knowledge and attitudes in their NICU staff after a structured mandatory 8-hour educational intervention (223). Nurses' breastfeeding knowledge and some attitudes improved significantly, with indication that other attitudes were changed as well. Although more study is necessary, it appears that the time and effort placed on educating a NICU staff so that advice and assistance can become more consistent, has the potential to make a difference.

The environment also must be breastfeeding friendly. Many mothers are very shy about breastfeeding openly, and their privacy must be respected. Because milk volume is often increased when a mother pumps at her baby's bedside, pumping is another activity that requires some

P.437

privacy. Portable screens in sufficient numbers are an easy way to cordon off a small area. It is interesting to observe that once pumping and breastfeeding become the cultural norm in a given unit, it is not unusual to see mothers request the screens less. Having enough portable hospital-grade electric breast pumps, comfortable chairs for skin to skin and breastfeeding, breastfeeding pillows, and stools are equally as important. If space permits, small rooms in which mothers can rest between feeding sessions, express milk, or take their babies to as discharge nears are ideal, as are rooms for overnight/rooming-in.

Another major issue is the influence of the formula/ drug companies on our NICU culture, and that of medicine as a whole. The giving out of free formula samples and discharge gift packs have been associated with decreased duration of breastfeeding in the less vulnerable well-baby population (224,225). The Baby-Friendly Hospital Initiative was designed by the United Nations Children's Fund (UNICEF) and the WHO as an intervention to increase breastfeeding rates (202,203). One of the issues it addresses is the negative influence of these products, and other informational materials provided by these companies for our patients—for example booklets on breastfeeding. Two recent U.S. studies, one in a NICU, have shown that these interventions can improve

breastfeeding initiation rates (226,227). Instead of discharging a vulnerable breastfeeding NICU family with a discharge gift pack from a formula company, some units have put together their own packs with noncommercial information and supplies to support them.

The period immediately following discharge from the neonatal unit is a time of extreme vulnerability for mothers and may precipitate a breastfeeding crisis (188). Follow up care in the community is critical and must be arranged and provided prior to discharge home. Access to a telephone support number and referral to a lactation consultant or a breastfeeding clinic has been shown to increase the transition to home and support ongoing breastfeeding in this vulnerable group (Appendix C-4).

SPECIAL CIRCUMSTANCES

The Near-Term Infant

Infants born at 35 to 37 weeks gestation are considered near term. In the past, these small but physically stable infants were cared for in a special care nursery until close to 40 weeks gestation. Currently, most stable near-term infants are placed on the postpartum unit with their mothers and treated as though they are full-term. Many of these infants appear deceptively vigorous at first glance but have subtle immaturities that may compromise their outcomes. Clinical challenges in temperature control and glucose/ metabolic stability are examples of this immaturity. Potential difficulties in establishing and maintaining breast feeding present an additional challenge in this population.

Common breastfeeding problems experienced by term infants and their mothers are magnified in infants who are born before term. These include the ability to latch to the breast, the incidence of jaundice, weight loss in the first few days to weeks of life, and the establishment of maternal milk supply. As a result, the near term infant is at risk of hypoglycemia, dehydration and slow growth/failure to thrive. Recent literature has reported an increased incidence of kernicterus among breastfed infants; this literature identifies breastfed infants born at less than 37 weeks gestation at increased risk for this devastating and preventable morbidity (228,229). These issues are more likely to occur in near term infants who are breastfeeding.

The predominant characteristic of the near term infant that interferes with breastfeeding is decreased stamina. This characteristic results in less effective suckling at the breast, decreased milk transfer and suboptimal breast stimulation. Additionally, the suck, swallow, breathe cycle of the near term infant may not be fully developed, further compromising intake at the breast. Poor muscle tone also contributes to fatigue and suboptimal breastfeeding. A common pattern among these infants is to latch and suckle for a short time and then pause to rest with subsequent difficulty resuming a nutritive sucking pattern. The inability of these infants to sustain a suck/swallow/breathe pattern limits milk transfer and contributes to insufficient intake at the breast. This scenario predisposes the near term infant to morbidity in the early newborn period (230).

The two basic principles in breastfeeding support of the near term infant are to ensure adequate infant nutrition and to assist with establishing and maintaining maternal milk supply. The near term infant requires adequate nutrition with minimal calorie/energy expenditure. Early frequent breastfeeding should be accompanied by assessment of latch and intake at the breast. Once lactogenesis II is established, measurement of intake at the breast with an electronic scale can provide information about the infant's ability to transfer milk effectively and maternal milk supply. The infant may need to be supplemented after breast-feeding with small quantities of expressed breast milk or formula. A full/generous milk supply assists the infant to receive adequate intake at the breast with minimal effort. Because the near term infant may not have the ability to optimally stimulate milk production, mothers should be encouraged to use a full-sized electric breast pump after breastfeeding to ensure early and ongoing milk supply. Discharge from the hospital must be accompanied by a discharge plan that is communicated to the family and care providers. Early and ongoing follow up is required to ensure infant health and nutrition and maternal health and milk supply. With continuing support, the majority of near term infants will transition to full breastfeeding at term.

Other infants who have decreased energy and potential for poor breastfeeding may also benefit from this approach. The NICU graduate may be discharged before term or at term but not displaying term characteristics. Infants born to diabetic mothers, term infants who have been ill at

birth, and term infants with physical or neurological issues that interfere with energy or feeding may have compromised breastfeeding ability similar to the near term infant. Similar to the near term infant, these vulnerable infants should be carefully assessed for breastfeeding competency and supported until the transition

to full breastfeeding is made. For more information see the Academy of Breastfeeding Medicine Protocol #10. Breastfeeding the Near-Term Infant at <http://www.bfmed.org>.

Hypoglycemia and the Breastfeeding Infant

It is important to briefly touch on the issue of hypoglycemia and the breastfeeding infant, from the standpoint of prevention and maintaining the breastfeeding relationship. The topics of metabolic adaptation to extra-uterine life, glucose homeostasis, and causes of hypoglycemia are well covered in other venues (231,233). As described by Williams (231) there are two principles to guide us in preventing hypoglycemia: (a) early and exclusive breastfeeding meets the nutritional requirements of healthy, full-term newborn infants; and (b) healthy full-term infants do not develop symptomatic hypoglycemia simply as a result of underfeeding. An excellent guide to the prevention and management of hypoglycemia is the Academy of Breastfeeding Medicine Clinical Protocol Number 1: Guidelines for Glucose Monitoring and Treatment of Hypoglycemia in the Breastfed Neonate (233). In brief, this is put into practice by putting babies skin to skin, which facilitates normal temperature and metabolic adaptation, to initiate breastfeeding within 30 to 60 minutes of delivery, and allowing them to room-in, and feed on cue as frequently as every 10 to 12 times in 24 hours or more. Given these tenants, there is no need to "routinely" monitor blood glucose levels in healthy, full-term breastfeeding infants (1,233). If hypoglycemia does develop, asymptomatic babies can continue to breastfeed frequently with careful follow-up and monitoring. If a need for intravenous glucose develops, once the baby is stable and able to feed, breastfeeding should resume as weaning from the i.v. glucose occurs.

Jaundice and the Breastfeeding Infant

It is beyond the scope of this chapter to cover this topic in detail. The reader is referred to in-depth articles on jaundice (234,235) that cover the pathophysiology and prevention of "lack of" breastfeeding jaundice. With increasing cases of kernicterus being reported, the importance of good management and frequent follow-up of breastfeeding babies, especially those who are feeding poorly, whose mothers have not developed a good milk supply, or who develop jaundice, cannot be over-stated. It is critical that when a breastfed baby needs intervention or is admitted to the hospital for treatment of dehydration or jaundice, that it be emphasized to the mother and the family that breastfeeding is not harmful or dangerous to the baby. This can not be emphasized enough. Mothers immediately get the message that they have done something wrong to cause their child to have this problem. As often health care providers, in their explanations of the pathophysiology, lay blame on the failure of breastfeeding, mothers immediately assume enormous guilt. With that comes pressure from within themselves or their families to stop breastfeeding and begin formula feeding. It is critical that these mothers be supported to continue breastfeeding through this family crisis. That support in the hospital setting includes continuing breast-feeding; having a qualified person (lactation consultant, trained staff member) immediately evaluate and begin working on fixing the mother's milk supply and the baby's latch and transfer of milk, and allowing the mother to room-in with her baby. If supplements are needed, and the baby can latch, consider use of a feeding tube device at breast, so the mother will continue to stimulate her breasts to produce more milk, and her feedings can continue at breast. If milk supply is at issue, evaluate possible causes. Most commonly one finds a baby with a poor or inadequate latch; a mother with sore nipples; and a vicious cycle of less stimulation to the breasts resulting in inadequate milk supply. If the mother's nipples are significantly painful and traumatized because of poor latch, she may need a rest from breastfeeding. In either of these scenarios, it is critical that she be given the use of a hospital-grade electric pump in the hospital to use, and that she initiates frequent expression (see Table 23-5) to empty her breasts and increase her milk supply. The gentle support of this mother and her family are as important as the diagnosis and treatment of the dehydration and the jaundice.

CONTRAINDICATIONS TO BREAST FEEDING

There are surprisingly few contraindications to the provision of breast milk and breastfeeding. We will cover a few of the most important here (for a more in-depth review the reader is referred to 236,237,238,239).

Infections

Human Immunodeficiency Virus

The one clear infectious contraindication to breastfeeding, in developed countries, is maternal HIV (138,240).

HIV can be transmitted through human milk, with rates varying from 5% to 20% depending on many contributing factors, and up to 29% when the infection is acquired just before or during the breastfeeding period (236). In developed countries in which sanitary affordable replacement feedings are readily available, women should be counseled strongly not to breastfeed. In developing countries in which safe and affordable substitutes are not readily available, and in which malnutrition and infectious diseases cause high infant and child mortality, breastfeeding remains the nutrition of choice. These recommendations will continue to be re-evaluated as more study is done on

P.439

the specifics of the transmission of HIV and the possible affects of maternal and infant antiretroviral therapy.

Human T-Cell Lymphotropic Virus

HTLV-1 and HTLV-2 are retroviruses similar to HIV. The virus is transmitted in human milk, so women with this infection are advised not to breastfeed. Recommendations in developed countries are the same as for HIV (138).

Hepatitis

The risk of transmission of Hepatitis A is rare, so breast-feeding is encouraged. Breastfeeding does not increase the risk of transmission of Hepatitis B. Babies born to mothers who are positive for hepatitis B should be treated according to recommended guidelines. There is no need to delay initiation of breastfeeding. Hepatitis C transmission via breast milk has not been documented. Mothers should be advised it is theoretically possible, but maternal hepatitis C is not a contraindication to breastfeeding (138).

Cytomegalovirus

Cytomegalovirus (CMV) maternal infection is a bit more complicated. It is a ubiquitous virus, and is transmitted via breast milk. Acquisition in healthy full-term infants does not result in clinical disease, leading to the term "natural vaccination" (241). Recent reports of transmission, thought to be through breast milk to premature infants, some of whom developed significant disease, have caused some concern (242). Some units use only frozen milk, which has been reported to kill the virus, in the smallest, most immunosuppressed babies. No authoritative guidelines have been issued.

MEDICATIONS AND DRUGS

The vast majority of medications are compatible with lactation. Many health care providers will tell a mother to stop breastfeeding when a medication is prescribed. This is rarely indicated, and it is always worth looking up the drug in a reliable source. If a drug is found to be contraindicated, it is almost always possible to find another that will be efficacious and is compatible with breastfeeding. Drugs that require cautious use when used in breastfeeding mothers of newborns or preterm infants include: sulfonamides (jaundice possible; do not use in G6PD deficiency); ergotamine and bromocriptine (reduce milk supply); pseudoephedrine and estrogens (may inhibit milk supply); meperidine (neonatal sedation reported); fluoxetine (tremulousness, colic, crying and hypotonia reported); angiotensin-converting enzyme inhibitors (may predispose to neonatal hypotension) and anticancer agents (239). Drugs of abuse—marijuana, cocaine, heroin, phencyclidine—are contraindicated in lactation. When in doubt—do not tell a mother to pump and dump or discontinue breastfeeding—go to a good source and find out! Medications that are found in breast milk are shown in Appendix H-1a, H-1b, H-1c, H-1d and H-1e.

CONCLUSION

In today's high-tech world of neonatal intensive care, there is one relatively low tech intervention that we as neonatologists can give with just a little effort, understanding, and education—the gift of mother's milk. The research supports it. The cost/benefit ratio is very appealing. The advantages to our patients and their mothers and families are high. The drawbacks are very low. Promoting, encouraging, and supporting mothers to succeed is a very small price to pay. We just need to remember, and to embrace, that *all babies were born to be breastfed*.

Acknowledgment

With deep gratitude to Ms. Linda Kaczmarczyk, Pediatric Clinical Librarian at Connecticut Children's Medical Center, for her invaluable aid in preparing this chapter.

Chapter 24

Thermal Regulation

Michael Friedman

Stephen Baumgart

A HISTORICAL PERSPECTIVE

Tarnier was an obstetrician in Paris who first applied modern concepts of incubation to human infants starting around 1830 (1,2). Tarnier's incubator, the *couveuse*, has been widely recognized as the first one designed specifically to care for premature babies. Tarnier and his student, Budin, studied premature human incubation into the next century, reporting almost doubled survival in infants born at less than 2 kg. In the United States, commercialization of Tarnier's and Budin's designs occurred, and the Rotch Incubator appeared at the Colombian Exposition in Chicago in 1893 (3,4,5). Thereafter, in 1933 Blackfan and Yaglou (6) provided humidity along with air warming within incubators, which improved the stability of infant temperature control. In the 1940s Chappel in Philadelphia added air isolation techniques to incubator care to prevent neonatal septic infections recognized to occur more frequently in humid environments (7,8). In 1958, Silverman and associates (9) challenged the need for humidity in incubators and used higher air temperatures than previously reported to care for an ever smaller premature population surviving with modern techniques.

Toward Defining the Optimal Thermal-Neutral Environment

In 1959 Cross and Hill from the United Kingdom described a metabolically neutral temperature for achieving the optimal environmental care of newborn animals and humans, suggesting that poor temperature maintenance resulted in increased metabolic rates of oxygen and substrate consumption (10,11,12) (Fig. 24-1). Physiologic responses to environmental temperature during incubation of premature newborn infants were investigated systematically in 1962 by Brück and coworkers (13,14) from Germany. In 1969 Hey and associates (15,16,17) from the United Kingdom defined the best operational incubator temperatures for preterm babies by describing an algorithm of air and wall temperatures, taking humidification and swaddling (insulation) into account as well. The Hey and Katz nomograms for regulating incubators following preterm birth, growth, and maturation remain the benchmark standard for modern human incubation to date (Fig. 24-2).

THERMAL BALANCE AT THE BEGINNING OF LIFE

Fetal Thermal Regulation

The fetus generates heat during metabolism with cellular proliferation and differentiation, maintenance of intra- and extracellular ion gradients, and transport of nutrients and wastes across cell membranes. Cardiac and skeletal muscle work also generates heat *in utero* (18). Fetal ovine and human studies suggest that the rate of fetal heat production is about 33 to 47 cal/kg/minute (18,19). Fetal-maternal temperature gradients in mammals and humans have demonstrated that a difference in temperature of only 0.45°C to 0.50°C between the umbilic arterial and venous blood is sufficient to eliminate the majority of metabolic heat via the placental circulation (i.e., by forced convective transfer into the mother's uterine circulation) (20,21,22). Probably less than 10% to 20% of heat is dissipated from the fetal skin into the amniotic fluid (natural convection and conduction from the uterine wall). The mother additionally serves as a heat reservoir for the fetus, favoring the dissipation of heat as a byproduct of fetal metabolism. Fatal hyperthermia may occur with an elevation of maternal temperature or if the mother is unable to dissipate the excess heat produced during pregnancy. Therefore, pregnant women are advised to avoid prolonged hot baths and exertion on hot and humid days. Maternal fever should be treated aggressively with environmental cooling and with antipyretics and antibiotics when indicated.

Transition in the Delivery Suite

At birth, a newly born infant is immediately exposed to a wet and cold environment. Without intervention, rapid cooling by convection from the neonate's skin into the cold delivery room air (at least a 10.0°C drop) and by

evaporation at a tremendous rate (0.58 kcal/mL of water loss) may result in a drop of the infant's body temperature at a rate of 0.2°C to 1.0°C/minute. Although fetal response to cold stress is relatively insensitive prenatally (22,23), increased infant activity (crying with agitated movement characteristic of cold exposure upon birth), vasoconstriction, and nonshivering thermogenesis (shivering is not active in the human newborn) occurs the instant the baby hits the cold air, mediated by the sympathetic nervous system (24). Triggered by temperature sensation of the skin, infant metabolic rate may increase by two- to threefold and thus maintain body temperature for a period of several hours in the term subject before thermogenic reserves of glycogen and brown fat become depleted.

Figure 24-1 Basic concepts for defining neonatal thermal-neutral environmental temperature (horizontal axis) as the minimal observed metabolic rate (vertical axis, measured indirectly as oxygen consumption). The shaded region of this graph (the relatively narrow thermal-neutral zone) is bounded by upper and lower critical temperatures for nonmetabolic or physical regulation of normal body temperature (e.g., by vasoconstriction, vasodilatation, or changes in posture). Variation of environmental temperature outside this limited range results in a metabolic rate increase, in which infant core temperature may remain normal, but at the expense of increased metabolic expenditure (e.g., cold stress). Outside the thermal regulatory range of metabolic heat production, inevitable body cooling or heating results, with eventual death at environmental extremes. (From Baumgart S. Incubation of the human newborn infant. In: Pomerance JJ, Richardson CJ, eds. *Neonatology for the clinician*. Norwalk, Conn: Appleton & Lange, 1993:139-150, with permission.)

Figure 24-2 Range of temperatures needed to provide neutral environmental conditions for babies lying naked on an insulated mattress in draft-free surroundings (at about 50% relative humidity) with equal mean radiant wall temperature and air temperature. The top graph represents a 1-kg infant at birth and the bottom graph a 2-kg infant. Optimum temperature probably approximates the lower limit of each neutral range as defined here. Approximately 1°C should be added to these operative temperatures to derive the appropriate neutral air temperature for a single-walled incubator when room temperature is less than 27°C (80°F), and more should be added if room temperature is very much less than this. (From Hey EN, Katz G. The optimum thermal environment for naked babies. *Arch Dis Child* 1970;45:328-334, with permission.)

Physiology of Neonatal Thermal Response

Brown fat is especially thermogenic in the term newborn, with large reserves located between the scapula, in the axillae and perithymic region, and in the paraspinal and peri-nephric areas. Penetrated extensively by blood vessels, which give it the brown appearance and which conduct heat generated into the central circulation, these adipocytes are laden with excess triglyceride stores and numerous mitochondria. With cold stress, the sympathetic surge acts directly upon cell surface receptors, which stimulate

P.447

cyclic-AMP-mediated lipoprotein lipase. Thyroid hormone also surges at birth and augments this effect (5,25,26). β -Oxidation is uncoupled in brown adipocytes, however, resulting in triglyceride breakdown and resynthesis producing heat (27).

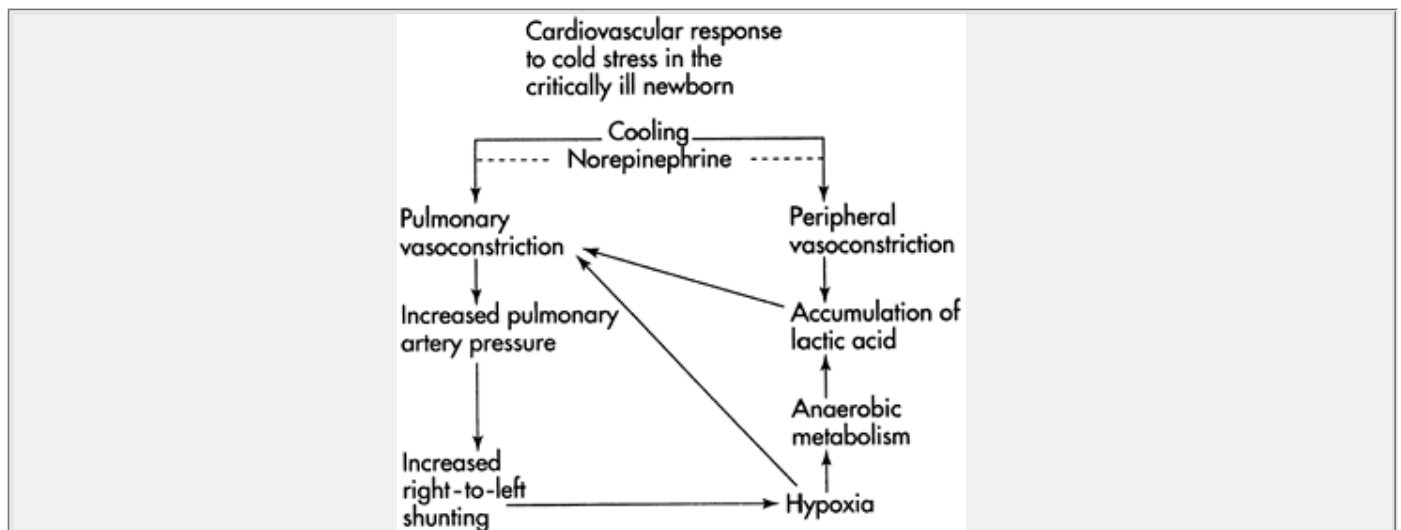

Figure 24-3 Immediate and potentially detrimental cardiovascular response to a sympathetic surge in norepinephrine released after birth upon exposure of the neonate's temperature-sensitive skin to a cold extrauterine environment (convection and evaporation). (From Baumgart S. Incubation of the human newborn infant. In: Pomerance JJ, Richardson CJ, eds. *Neonatology for the clinician*. Norwalk, Conn: Appleton & Lange, 1993:139-150, with permission.)

Preterm infants with immature thermogenic response and without metabolic substrate reserves deposited over the last trimester of pregnancy fare worse. As shown in Fig. 24-3, a sympathetic surge occurs at birth, with massive neurohumoral secretion of noradrenaline from paraaortic nodes and the fetal adrenal (28). Systemic and pulmonary vasoconstriction result, which may end in poor oxygen uptake and relative peripheral tissue hypoxia. Lactic acid production ensues, with demise ultimately occurring secondary to cold stress. Tarnier in the 1800s recognized this in Paris, where there was no central heating and poor home and hospital insulation.

Early Intervention

Drying infants in the delivery suite interrupts the process of evaporation, and bundling infants in cotton blankets to prevent exposure to cold air interrupts convective heat loss and provides insulation to retain the infant's metabolic heat. Placing infants at the mother's breast and cradled into her axillary fold engenders conductive heat transfer from the mother to the infant. Alternatively, and especially if early intervention is required to aid transition (e.g., suctioning or oxygen administration), the infant is dried first and then placed onto dry bedding under a radiant warmer while these procedures are performed. A convectively warmed incubator enclosure with air temperatures ranging from 35.0°C to 37.0°C and a variety of plastic swaddling heat shields have been advocated to prevent excessive cold exposure, especially during transition and hospital transport of premature infants (29,30,31).

Once in the nursery or mother's room, bundled infants may be placed into either an open bassinet or incubator (naked or bundled) and provided close monitoring of either axillary (preferred, 36.0°C to 36.5°C) or rectal (37°C to 37.5°C) temperatures through the first few hours of life. Slightly premature infants (32 to 35 weeks) or small-for-gestational-age babies may appear to have normal body temperature at the expense of metabolically generated heat (9). Glass and associates (32) demonstrated that premature infants nurtured in dry incubator environments of either 35.0°C (slightly cool) or 36.5°C in the first few days of life maintained a normal body temperature, but experienced more weight loss in the cooler environment.

Kangaroo Care

Skin-to-skin care, now termed kangaroo care, has been promoted for nurturing premature infants who are held naked between the mother's breasts as if in a kangaroo's pouch. The infant is in contact with the mother's warm skin and is close to the breast for unlimited feeding. Fathers also can provide thermal support in this way. Kangaroo care was first reported from Bogotá, Columbia, where use of conventional incubators was limited and mortality in nonincubated preterm births high. A large randomized trial from this country recently showed that infants less than or equal to 2.00 kg placed under kangaroo care shortly after birth for prolonged periods achieved transition safely and grew normally, had fewer nosocomial infections, and were discharged earlier, particularly at less than or equal to 1.80 kg (33). Significant reduction in early mortality also has been observed. During the 1980s the kangaroo technique was promoted for nurturance of nonmechanically ventilated, growing premature infants in Scandinavian and some other European countries. Randomized clinical trials also have demonstrated enhanced mother-infant attachment, greater maternal self-esteem, prolonged and enhanced lactation, increased infant alertness, and better weight gain (34). Physiologic studies have focused on demonstrating thermal-neutral metabolic response (minimal observed oxygen consumption) and temperature stability in stable growing premature babies during kangaroo care. Moreover, vital signs and oxygenation parameters were demonstrated to be more stable in preterm infants recovering from bronchopulmonary dysplasia, with absence of periodic breathing and reduced apnea and bradycardia. Behavioral studies demonstrate more homogenous sleep patterns, less irritability later in infancy, and more direct social eye contact with caregivers (35).

In the intensive care nursery, kangaroo care may be initiated even during mechanical ventilation with uncomplicated patients. Mothers are instructed to wear front-opening shirts, maintain careful hygiene without open sores or rashes, and avoid use of lotions, oils, or perfumes. Maximum skin surface area contact is desirable with a covering blanket to avoid outward convective and evaporative heat losses. Privacy and quiet must be provided by the nursery staff for periods of 0.5 to 1 hour initially, and careful temperature monitoring by surface

along with cardiorespiratory and noninvasive oxygen monitoring when indicated. Temperature deviation of more than 0.5°C of normal skin temperature (36.5°C to 37.0°C) should result in termination of the session and return to incubator care. Periods up to 4 hours may be achieved. Mothers are encouraged to pump their breasts before and after sessions because milk production is enhanced. Parents are empowered with the care of their infants, and kangaroo care integrates the family into the neonatal intensive care team. Presently, no adverse reports have been published, and the use of kangaroo care in modern intensive care settings is on the rise.

CONVECTION-WARMED INCUBATORS

A modern incubator consists of an optically transparent, plastic hood (≥ 3 mm thick) covering the infant, with sidewall and hand-access ports. The infant lays on a bed platform, underneath which a tungsten element electronically heats the air. Air is forced over this element by a fan, circulating heated air within the hood. Temperature may be controlled thermostatically to regulate either the air or infant skin temperature (15,36).

Thermodynamics of Incubation

The physiology of mammalian (homeothermic) thermal regulation (37) may be summarized by the equation:

$$\dot{Q}_{\text{metabolic}} = \dot{Q}_{\text{convection}} + \dot{Q}_{\text{conduction}} + \dot{Q}_{\text{evaporation}} + \dot{Q}_{\text{radiation}} + \dot{Q}_{\text{stored}}$$

in which [Q with dot above] is the rate of either metabolic heat production (left side of the equation) or of heat loss and heat stored (right side of the equation), generally expressed in kcal/kg/hour or in W/m² (J/sec/m²). By convention, heat production and heat losses (or storage) are expressed as positive values. When a mammal is successfully maintaining normal body temperature, heat storage is zero, otherwise body temperature either increases or decreases until a new thermal equilibrium is established at another temperature. Also, when an environmental heat loss becomes a heat gain (e.g., under a radiant warmer), the gain is expressed as a negative loss.

Convection

The rate of heat transferred from an infant's skin into the incubator environment depends in part on the insulation provided by the dermis and subcutaneous fascia (comprised primarily of white fat deposited late in gestation). Preterm babies have almost no fatty fascia and, therefore, are more vulnerable to heat loss through air (and skin blood flow) convection (37). Air convection is heat loss that takes place from the skin's surface into the surrounding environment and is summarized by the equation:

$$\dot{Q}_{\text{convection}} = k_1(T_{\text{mean skin}} - T_{\text{air}}) + k_2(T_{\text{mean skin}} - T_{\text{air}})V^n$$

in which two forms of skin-to-air convective heat loss occur, depending on the gradient between skin and air temperatures (ΔT), the complex geometry of surface area exposed and air thermal density k , and air movement velocity V^n (38). The first is natural convection, which results from the gradient of temperature between the skin surface and surrounding air (38,39). Natural convection cells form as warm air rises from the skin, conveying heat and body moisture away from the surface of the baby. Air thus warmed subsequently cools and falls back toward the baby, forming the convection cell. Such cells form over the curvature of the baby's exposed body surface area. An infant in flexion leaves less surface area exposed (38). An infant extended and flaccid is able to dissipate more heat. Posture may be a valuable observation in deciding the thermal comfort or discomfort of even a preterm infant.

The second form of convection is forced convective air movement, usually occurring at air velocities ≥ 0.27 m/sec. Forced convective heat loss is roughly proportional to an exponential power (n) of the velocity (V) of air movement. Within forced convection-warmed incubators, manufacturers strive to render still the air near the baby. Recent estimates of natural and forced-air convective heat loss from premature neonates nursed within incubators indicate success in this strategy because natural convection was the only major loss observed to occur (40). Heat also is lost to a lesser degree by respiratory convection and evaporation.

An example of different incubator convection designs affecting skin-to-air heat transfer is shown in Fig. 24-4,

adapted from a study of partitional calorimetry performed by Okken and associates (41). The left incubator partition in this figure represents a natural convection-warmed incubator with no circulating fan. Air rose passively from heating elements underneath the baby's mattress to warm the interior of the incubator hood. The second partition on the right represents a more standard, fan-forced convection incubator as described previously. Nonevaporative heat loss in the passive device (non-E, the sum of convection, radiation, and conduction) was 60% compared to 47% in the forced convection-warmed incubator, whereas evaporative heat loss (E) was 13% higher in the forced convective environment. These authors attributed this increased evaporative loss to disturbance by the incubator's fan of a microenvironment of humid air layered near the baby's skin.

Figure 24-4 Partitional calorimetry performed for premature infants in two different types of convection-warmed incubators, natural and forced air. The rate of evaporative heat loss (E) is greater proportionally for babies nurtured in a conventional forced-air warmed environment than nonevaporative heat losses (non-E) from convection, conduction, and radiation. Heat balance is regulated by metabolic rate (M) and nonmetabolic mechanisms for thermal conservation (e.g., vasoconstriction). (Adapted from Okken A, Blijham C, Franz W, et al. Effects of forced convection of heated air on insensible water loss and heat loss in preterm infants in incubators. *J Pediatr* 1982;101:108-112, with permission.)

TABLE 24-1 CALCULATED BODY SURFACE AREA: BODY MASS RATIO FOR ADULTS, LOW-BIRTH-WEIGHT NEONATES, AND VERY-LOW-BIRTH-WEIGHT NEONATES

	Body Mass (kg)	BSA (m ²)	BSA/Mass (cm ² /kg)
Adult	70	1.73	250
LBW premature	1.5	0.13	870
LBW premature	1.0	0.10	1,000
VLBW	0.5	0.065	1,300

LBW, low birth weight; VLBW, very low birth weight. (Adapted from Costarino AT, Baumgart S. Neonatal water metabolism. In: Cowett RM, ed. *Principles of perinatal neonatal metabolism*. New York: Springer-Verlag, 1991:623, with permission.)

Figure 24-5 Transepidermal water evaporation from the skin of premature neonates of gestations ranging from 25 to 40 weeks, followed longitudinally from birth over the first month of life. Dehydration is most dangerous in the most immature babies less than 28 weeks of gestation in the first week of life before skin keratinization occurs. (From Sedin G, Hammarlund K, Nilsson GE, et al. Measurements of transepidermal water loss in newborn infants. *Clin Perinatol* 1985;12: 79-99, with permission.)

Evaporation

The premature neonate loses large amounts of water (and, therefore, latent heat at 0.58 kcal/mL) through evaporation from the skin for several reasons (42,43,44,45,46,47,48,49). First and most important is the premature neonate's thin epidermis lacking keratin, which normally serves as a vapor barrier for older infants, children, and adults. Very immature skin is associated with reduced survival, and evaporative rates from infants less than 700 g may be likened to those of severe burn victims. Second, premature neonates lose excessive amounts of water and heat due to an increased body surface area:body mass ratio as demonstrated in Table 24-1 (50). The very-low-birth-weight premature infant of less than or equal to 500 grams exposes six times the area of the adult subject per kilogram of the largely water body mass. Third, the proportion of the extracellular water mass in the very-low-birth-weight infant, which is exposed to the external environment through the nonkeratinized epidermal layer, is significantly larger (51).

Hammerlund and Sedin (45) (Fig. 24-5) summarized the rate of transepidermal water loss in premature newborn infants nurtured in incubators throughout the first month of life at different gestational ages. This figure demonstrates that the newborn at 26 weeks of gestation may lose as much as 60 grams of water per m²/hour (more than 180 mL/kg/day or 100 kcal/kg/day). Additional amounts of water may also be lost from upper airways during respiration of nonhumidified air in incubators.

P.450

Incubator Humidification

Humidification inside modern incubators is accomplished by the evaporation of water from a reservoir located in the air path over the heating element beneath the incubator mattress (52). Earlier descriptions of humidification in incubators cited the use of nebulized mist to saturate the infant's environment ($\geq 80\%$ to 90% relative humidity) (53,54). These latter techniques resulted in the proliferation of *Pseudomonas* infections and were rejected resoundingly by a number of reports (53,54,55,56). Unfortunately, abandoning all use of vapor (invisible humidification) based on infection risks encountered with particulate mists (visible humidification) has resulted in running incubator hoods completely "dry." Relative humidity levels inside dry incubators at 36°C to 36.5°C may drop to less than 10% to 15%, promoting large insensible water and latent heat losses (52). In response to these concerns, the American Academy of Pediatrics recommended only moderate use of air humidification 50% relative humidity in the vapor phase (i.e., gaseous), and not a particulate mist (liquid phase) (57). Put simply, if water circulating near an infant is visible, infection may be more likely.

A more recent reevaluation of incubator humidification was conducted by Harpin and Rutter (52) in 1985. Thirty-three infants less than 30 weeks of gestation and less than 2 weeks of age were nurtured in vapor-humidified incubators saturated at between 80% and 90% relative humidity. Two infants acquired *Pseudomonas* sepsis and one died. Twenty-nine babies of similar gestation and maturity were nurtured in dry incubators: one suffered an episode of *Pseudomonas* sepsis and died. Those who died with *Pseudomonas* infections did so after the study had ended after the first 2 weeks of life. The authors recommended that humidification be used routinely in the first 2 weeks of life to prevent evaporative losses and prevent skin desiccation. Humidification early in life may be prudent for incubation of the very-low-birth-weight infant, in whom heat and water losses are excessive and probably pathologic. Modern incubators now may be equipped with sophisticated solid-state temperature and humidity control devices to prevent condensation at higher relative humidity levels between 60% and 80%. Although verification is yet lacking, hopefully a reduced risk of infection will occur by maintaining humidity without visible condensation.

Conductive Heat Loss and Warming Mattresses

Conductive heat loss results from contact of a baby's body with the solid surface of a bed platform:

$$\dot{Q}_{\text{conduction}} = k(T_{\text{core temp}} - T_{\text{mean skin}})/D$$

in which k is contact surface area and the bed's heat conductivity constant, and (ΔT) represents the temperature gradient between the infant's body core (containing heat) and mean skin contact surface. D is the thickness of the bed's conducting material. In general, insulating foam rubber (about 2.5-cm thickness) and double cotton blanket batting results in negligible conductive heat loss by providing insulation from the metal or plastic bed table (i.e., reducing the value of k). Recently, however, incubator manufacturers and water mattress companies have provided evidence that exogenous heat application through carefully conducted bed surfaces maintained at less than or equal to 39°C to prevent burn injury to areas of skin contact may reduce environmental heat requirements from incubators or radiant warmers for very-low-birth-weight subjects (58,59). Moreover, application of warmed mattresses during extreme environmental conditions encountered in infant transports also may prove beneficial (59,60).

Radiant Heat Loss

Radiant heat loss is the least intuitive aspect of newborn incubation. Radiant heat loss occurs as a transfer of infrared electromagnetic energy virtually instantly from one warm body to another of lesser warmth:

$$\dot{Q}_{\text{radiation}} = (\beta)(\epsilon_1)(\epsilon_2)(T_{\text{mean skin}} - T_{\text{walls}})$$

in which a radiant heat transfer constant β (Stefan-Boltzmann), the physical emissivity of the infant's skin and incubator's plastic walls (ϵ_{skin} , ϵ_{walls}), the absolute temperature gradient (ΔT), and the infant's exposed surface area and posture determine the rate of radiant heat loss within incubators (37). In a single-walled incubator, heat transfers from the infant's skin (36.5°C to 37.0°C) to the mean temperature of the cooler walls of the incubator's plastic interior (approximately 28.0°C to 36.5°C). The incubator walls then reradiate heat to the nursery walls and windows, which are even cooler (18.0°C to 27.0°C). A massive heat sink is represented by the nursery walls, which may determine 60% of the operant environmental temperature perceived by the skin in room air conditions:

$$T_{\text{operant environment}} = 0.60(T_{\text{walls}}) - 0.40(T_{\text{air}})$$

Double-Walled Incubators

The importance of radiant heat transfer within incubators is demonstrated in Fig. 24-6 (40). Two incubators of different designs are compared. Partitional calorimetry for a single-walled incubator is shown on the left, whereas a double-walled incubator design is depicted on the right. The double-walled incubator constitutes a plastic chamber similar to the single-walled incubator with an additional inner wall suspended several centimeters interior to the outer wall of the incubator. Warmed air is circulated between these two incubator walls, warming both the outer and inner surfaces of the inner wall, as well as the inner surface of the outer wall of the incubator. The result is an elevated inner wall plastic temperature exposed to an infant's skin. Radiant heat loss to the inner wall of the incubator exposed to the infant's skin is significantly reduced. Convective heat loss is higher in the double-walled incubator because a cooler air temperature is

required to maintain the infant when radiant heat loss is thus conserved. Because vapor pressure is constant, evaporative heat loss is the same in both incubator devices.

Figure 24-6 Partitional calorimetry performed for preterm infants at steady-state, thermal-neutral temperature in two forced-air, convection-warmed incubators, either with only a single wall between the infant and surrounding nursery's environmental air and wall temperatures, or with an inner wall (double-walled incubator) interposed between the infant and incubator's outer wall. Forced-air warming of both sides of the inner wall reduces radiant heat loss, resulting in lower servocontrolled incubator air temperature (higher infant convective heat loss). Evaporative loss was not altered by insertion of the double wall. (Adapted from Bell EF, Rios GR. A double-walled incubator alters the partition of body heat loss of premature infants. *Pediatr Res* 1983;17:135-140, with permission.)

Skin Surface Servocontrol Temperature

As a result of the difficulties encountered in measuring and controlling the whole environment defined by all of the parameters described previously, Silverman and associates (36) proposed that any set of environmental conditions that rendered a normothermic skin surface temperature would provide a thermal-neutral environment. They defined a skin temperature servocontrol set point between 36.2°C to 36.5°C over the anterior abdominal wall for thermostatic control of incubator air temperature warming (with or without humidification, mattress warming, or radiant walls protection) to guarantee a minimal observed metabolic rate of oxygen consumption and, therefore, a thermal-neutral environment. Proportional response, servocontrolled skin temperature now has become the standard of care for regulating convection-warmed incubator heating over much of the world.

Servocontrolled Incubator Homeothermy

All incubator studies demonstrating a thermal-neutral environment under a variety of conditions evaluating air temperature, convection, and humidity; incubator wall temperature; and nursery temperature were performed at steady-state conditions. Infant metabolic rates often were determined in noncritical subjects at rest. Such steady-state conditions are theoretical, however, in critically ill premature neonates in thermostatically servocontrolled incubators, subjected to the many variations encountered in the modern neonatal intensive care nursery. Hand ports and doors may be opened and closed several times a day for access to nursing and minor surgical procedures, as well as radiographic, ultrasound, and echocardiographic examinations. Incubators may be invaded as often as once an hour for delivery of intensive care. This can result in overshooting and undershooting of air temperature for as long as 1 hour after the door has been closed.

THE RADIANT WARMER BED

The radiant warmer bed is a variable-level, waist-high platform with a mattress surface (which may be either heated or may incorporate an electronic scale), upon which the critically ill newborn lies without an encumbering plastic enclosure. Suspended about 80 to 90 cm above this platform is a radiant heat source with an electrically heated metal alloy wire coiled within a quartz tube. A thermostatic skin servocontrol device regulates the radiant heat, which is distributed across near and far wavelengths of the infrared spectrum (Fig. 24-7). At full power, the sum of infrared

P.452

irradiance is less than 100 mW/cm² of surface area on the bed platform. The heat delivered in the near portion of the infrared spectrum (less than 1,000 nm) is less than 10 mW/cm² of surface area irradiated. These levels of radiant exposure recently have been judged as biologically safe for the developing skin and eyes in the prematurely born newborn infant when exposed briefly. The servocontrolled warmer generally operates at about one-half this peak power, and radiant power density delivered at bed level usually is well below the 50 to 60 mW/cm² felt to be potentially deleterious at longer periods of exposure. The head, foot, and sides of the radiant warmer bed platform receive less radiant power and, therefore, less warming than is delivered to the center of the bed platform. Optimally, infants are positioned in the center of this device.

Figure 24-7 Spectral irradiance measured at bed level with increasing power from a radiant warmer's heating element. Note two peaks of energy indicating the wire element's emission (near infrared wavelength spectrum at the left) and the quartz containment tube's reemission of absorbed heat from the wire (far spectrum at the right). The notch in the near peak probably indicates infrared adsorption by water vapor. Integrated over the entire peak emissions, levels of near and far infrared exposure are felt to be safe for the developing skin and eyes. (From Baumgart S, Knauth A, Casey FX, et al. Infrared eye injury not due to radiant warmer use in premature neonates. *Am J Dis Child* 1993;147: 565-569, with permission.)

Figure 24-8 Partitional calorimetry for infants nurtured naked under radiant warmers servocontrolled to maintain anterior ab-dominal wall skin temperature at 36.5°C. Shown on the left are convective, evaporative, conductive, and radiant heat losses (from the infant's sides), and on the right are radiant heat gain (facing the warmer) and heat generated by the infant's metabolism. (Adapted from Baumgart S. Radiant heat loss versus radiant heat gain in premature neonates under radiant warmers. *Biol Neonate* 1990;57: 10-20, with permission.)

Figure 24-8 demonstrates experience with complete partitional calorimetry for critically ill premature infants nurtured under radiant warmers (61). Both radiant heat losses under a radiant warmer as well as heat gains are demonstrated. The effects of evaporation, convection, and conduction and of infant metabolic heat production are demonstrated for infants nurtured naked and supine under these devices. Heat loss comprised 64% toward convection to the surrounding cool air of the nursery's environment. The majority of convective heat loss occurred naturally, whereas a minor component was composed of forced convective air movement from doors opening and closing within the nursery, nursery personnel bustling near the bedside, as well as the cycling of heating and cooling vents supplying the nursery's ambient air control. These turbulent convective air movements contributed to evaporative heat loss, which comprised 30% of total heat loss in this figure. Thermal equilibrium is maintained under a radiant warmer by replacement of heat losses through convection, evaporation, conduction, and radiation, by radiant heat gain directly from the warming element. Almost 58% of heat replacement is derived from the servocontrolled radiant warmer. Metabolic heat production M comprises 42% of the thermal balance and is overpowered by the radiant heating element.

Thermal-Neutral Radiant Warming

Le blanc (62) summarized a meta-analysis comparing radiant warmers to convectively heated incubators. The thermal-neutral environment was defined for each warming device as the minimal observed metabolic rate of oxygen consumption (MOMR measured in oxygen consumption, $\dot{V}O_2$, in mL/kg/minute) when skin temperature was servocontrolled between 36.0°C and 36.5°C and at steady-state conditions. Eleven of 16 infants demonstrated slightly higher rates of oxygen consumption when nursed at similar temperatures under radiant warmers ($\dot{V}O_2$ 6.84 ± 0.37 [standard error of the mean] vs. 7.45 ± 0.44 mL/kg/minute), an increase of 8.8% in metabolic rate under radiant warmers.

A more recent meta-analysis compiled by Flenady and Woodgate (63) again compared radiant warmers to incubators using MOMR to define the thermal-neutral environment. This review found that nursing under radiant warmers caused a statistically significant increase in insensible water loss and a nonsignificant trend toward higher oxygen consumption when compared to incubators. When a heat shield was added to the radiant warmer and compared to the incubator, there was a trend toward higher insensible water loss that was not statistically significant and there was no difference in oxygen consumption.

The assumptions involved in the calculation of MOMR are that the infant is (a) at rest and asleep, (b) postprandial at least 2 to 3 hours, and (c) at thermal-neutral temperature conditions. Typically premature infants demonstrate slightly higher oxygen consumptions than term infants, and small-for-gestational-age infants manifest oxygen consumptions slightly higher than premature and term infants. The minimum requirement for oxygen consumption in these studies demonstrates a metabolic rate of caloric expenditure of roughly 60 to 75 kcal/kg/day. Above this amount, 9 to 10 kcal/kg/day may be required for growth. However, intensive care conditions provided to critically ill neonates rarely approximate those of a growing premature baby at rest and at steady-state.

Figure 24-9 shows results of oxygen consumption measurements from studies conducted in an intensive care nursery in a 1.2-kg infant nurtured naked and supine under a radiant warmer while intubated endotracheally and receiving ventilatory support (64). During a 90-minute period of relatively mild cold stress (servocontrol skin temperature 35.5°C), oxygen consumption fluctuated

P.453

between 5.5 and 8.5 mL/kg/minute, paralleled closely by the infant's heart rate and behavior. These observations of preterm infant behavior linked to metabolism are typical, even in critically ill infants. Criteria for determining MOMR suggest that oxygen consumption for this subject is 5.5 mL/kg/minute. However, the integrated sum of behavior over the entire study period reflects a higher rate of global metabolism. Such observations led Schulze and associates (65) to speculate that a thermal-neutral environment should be evaluated over periods considerably longer than 10 to 30 minutes of MOMR at steady state. Figure 24-10 shows oxygen consumption over three 90-minute periods for the same infant as shown in Fig. 24-9 at three different radiant warmer servocontrol skin temperatures—35.5°C, 36.5°C, and 37.5°C (66). From these studies over longer study periods, it seems clear that infant behavior may constitute a significant part of metabolic rate determination, affecting the thermal-neutral zone. Figure 24-11 shows 18 premature infants nurtured under radiant warmers demonstrating a thermal-neutral environmental temperature (between 36.2°C and 36.5°C servocontrolled anterior abdominal wall skin temperature) in which all infant behavior was incorporated (66). Approximately 7.2 mL/kg/minute VO_2 at the warmer's 36.5°C skin temperature set point represented optimal control under intensive care circumstances. Increasing anterior abdominal wall skin temperature above this point by 1°C resulted in no significant additional reduction in metabolic rate, and when servocontrolled to 37.5°C, the gradient for heat loss (from the infant's core to the skin) narrowed sufficiently for a number of them to become hyperthermic (38.2°C to 38.5°C). It is therefore recommended to avoid skin control temperatures above

P.454

36.7°C and 37.0°C for infants in the weight range studied (between 0.87 and 1.60 kg).

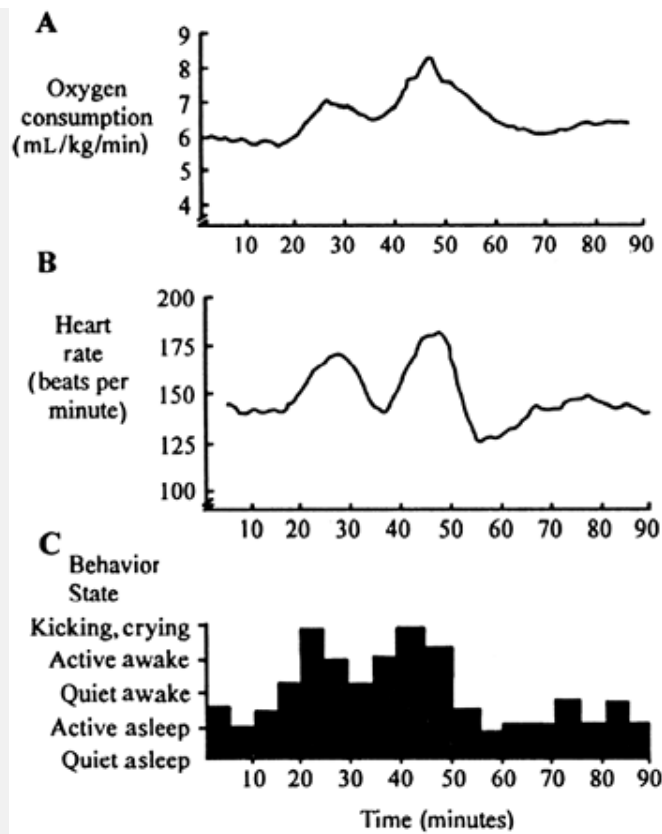

Figure 24-9 Metabolic rate of oxygen consumption (A) parallels heart rate (B) and infant activity (C) with the performance of indirect calorimetry in a premature baby weighing approximately 1.2 kg. Variation with infant behavior is demonstrated in this relatively cool condition (servocontrol 35.5°C). (From Baumgart S. Partitioning of heat losses and gains in premature newborn infants under radiant warmers. *Pediatrics* 1985;75:89-99, with permission.)

Figure 24-10 The metabolic rates of oxygen consumption from the same infant shown in Fig. 24-9 are compared at 35.5°C, 36.5°C, and 37.5°C servocontrol skin temperature. Behavioral activity is attenuated, and basal metabolism is significantly reduced at warmer temperatures. (From Malin SW, Baumgart S. Optimal thermal management for low birth weight infants nursed under high-power radiant warmers. *Pediatrics* 1987;79:47-54, with permission.)

Figure 24-11 Significantly lower oxygen consumption is demonstrated at 36.5°C compared to 35.5°C servocontrol temperature for a series of 18 infants under radiant warmers. No additional significant reduction in oxygen consumption is achieved by increasing servocontrol temperature to 37.5°C, and several infants demonstrated deep rectal hyperthermia at 37.5°C. (From Malin SW, Baumgart S. Optimal thermal management for low birth weight infants nursed under high-power radiant warmers. *Pediatrics* 1987;79:47-54, with permission.)

HEAT SHIELDING

Rigid, Plastic Heat Shields

A 1- to 2-mm thickness of plastic used as a miniature incubator hood and placed over infants on open radiant beds has been proposed by several authors. Yeh and associates (67) reported that insensible water loss was reduced by more than 25% for infants nurtured under a plastic hood. Bell and associates (68) failed to replicate any difference in water loss using a rigid plastic body hood under radiant warmers. The configuration of the plastic hoods used in each of these studies was different, in some cases permitting free air exchange at the open ends of the hood. Moreover, the interposition of radiantly opaque plastic between infant and the radiant element may have interfered with the delivery of radiant heat to the baby's skin (69). Disruption of the servocontrol mechanism by interposition of a radiant opaque plastic heat sink between the infant and the warmer seems to be a futile strategy.

Occlusive Plastic Blankets or Bags

A flexible plastic blanket made of saran seems more efficient than the body hood, particularly under a radiant warmer (Fig. 24-12) (39,70). Saran is thin, permitting free heat exchange without excessive evaporation (70). The flexible plastic blanket reduces the effect of forced convection, which disrupts the microenvironment of warm, humid air near the infant's skin (39). The reduction in both convective and evaporative heat losses is about 30% (70). Insensible water loss is diminished from about 2.0 to 1.2 mL/kg/hour. Oxygen consumption is reduced from 9.0 to 8.0 mL/kg/minute in this study. The net effect of saran blanket heat shielding under radiant warmers renders the environment more homeothermic, with lower power required to achieve thermal equilibrium, both from the radiant warmer and the baby's rate of metabolic heat production.

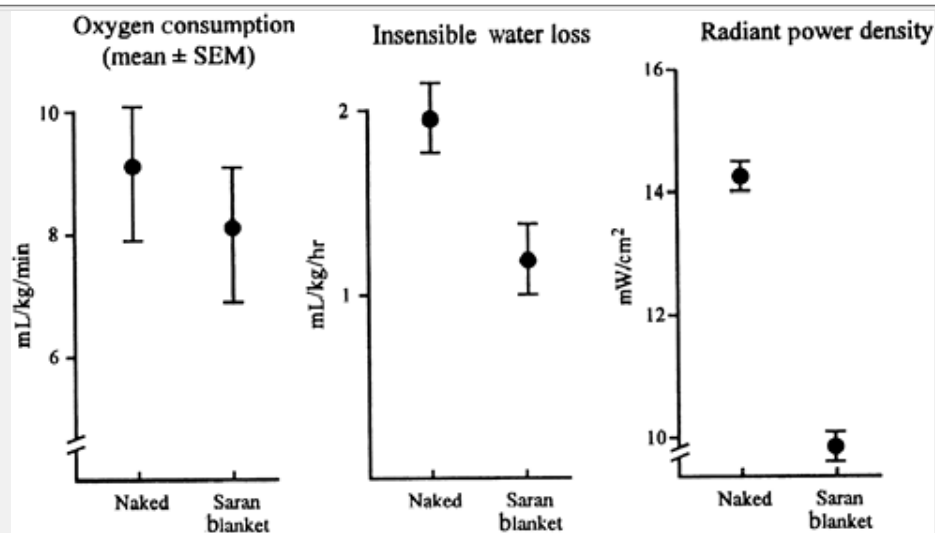

Figure 24-12 Comparison of radiant power density delivered (right), insensible water loss (middle), and oxygen consumption (left) in preterm neonates nurtured either naked or covered by a saran plastic blanket under radiant warmers. The blanket significantly reduced all three measurements in all babies tested, suggesting better environmental maintenance under saran. SEM, standard error of the mean. (From Baumgart S. Reduction of oxygen consumption, insensible water loss, and radiant heat demand with use of a plastic blanket for low-birth-weight infants under radiant warmers. *Pediatrics* 1984;74:1022-1028, with permission.)

A polyethylene plastic body bag was proposed by Vohra and associates (71) for use during delivery room resuscitations in premature neonates. Significantly higher core temperatures and survival was reported for babies less than 28 weeks of gestation. A multicenter randomized trial of this device has been proposed by the authors.

Adverse effects with plastic blankets or bags have been cited. In extremely low-birth-weight infants, the immature skin may stick to the plastic, causing maceration. Moreover, if the servocontrol thermistor fails or becomes detached, serious hyperthermia may result and deaths have been reported. Nursing management of thermal care should prevent plastic from directly contacting the skin wherever possible. Infant core temperatures (axillary or rectal) should also be monitored frequently without relying on the skin servoprobe. Finally, infection control risk with plastic blankets/bags has not been adequately documented. With careful regard to these complications, however, these techniques are presently the most effective under radiant warmers for more consistent thermal-neutral temperature regulation.

EPIDERMAL BARRIER PROTECTION

Semiocclusive Artificial Skin

A novel strategy for thermal protection is covering the exposed surfaces of immature skin with semiocclusive polyurethane dressings (Tegaderm and Opsite) (72). In early studies using this technique, insensible water loss from days 1 to 4 of life was reduced by 30% to 50%. Upon careful removal of the artificial polyurethane dressing, skin moisture barrier development (keratinization) was consistent with development over the adjacent naked skin sites tested. A report by Porat and Brodsky (73) indicated that applying an adherent polyurethane layer over the entire torso and extremities early in very-low-birth-weight infants under 800 g improved fluid and electrolyte balance, reduced patent ductus arteriosus and intraventricular hemorrhage, as well as improved survival. Mancini and associates (74) found a similar result and reported a decrease in bacterial growth on skin guarded by a semipermeable dressing.

Emollients and Aquaphor

Rutter and Hull (76) originally reviewed topical agents for reduction of transepidermal water loss. They found high water content creams ineffective in this regard, whereas paraffin produced a modest effect. Calculated evaporative rate was initially halved in preterm infants less than 30 weeks of gestation; however, this effect was transient, with return to a higher rate of water loss within 4 to 8 hours (75,76). Nopper and associates (77)

conducted a randomized trial investigating barrier effects of a topical, petroleum-based, preservative-free ointment (Aquaphor) applied twice daily for 2 weeks to the skin of preterm infants. Transepidermal water loss was decreased by 67% initially compared to control infants and remained at 34% below controls after 4 to 6 hours. Dermatologic scores of skin integrity were improved in treated infants, and there was a decline in bacterial colonization of axillary skin, with a significantly lower incidence of positive blood and spinal fluid cultures. The authors also suggested better temperature control and fluid balance in treated subjects. Commentary by Rutter (76) on this work suggests, however, that temperature control may not benefit babies weighing less than 1 kg early after birth, and only high humidity incubators eliminate this problem in the smallest infants.

Aquaphor results early on were encouraging for improving skin care and reducing insensible water loss (77); however, the findings of a multicenter randomized trial are still awaiting publication (Vermont Oxford Network 2001) (78). One preliminary study, however, implies that bacterial infection may be more likely (79). Until complications of any shielding technique are better defined, nurses and doctors should remain cautious adopting them for routine care of extremely low-birth-weight patients.

HYBRID INCUBATOR/RADIANT WARMER DESIGN

One new incubator design recently marketed is the hybrid design. The accessibility of a radiant warmer is combined with the protection of an incubator enclosure. In the incubator mode, plastic walls surround the baby, and temperature is regulated by convection air warming. In the radiant warmer mode, these plastic walls are rotated down below the bed platform to facilitate handling with procedures. An overhead radiant heater switches on automatically to regulate servocontrolled skin temperature. No plastic is positioned between the infant and radiant warming element. Although expensive, these devices are an alternative to moving fragile infants requiring procedural interventions.

FEVER

Generally, fever may be defined as a core body temperature greater than 37.5°C. Depending on the limits chosen, approximately 1% to 2.5% of all newborns admitted to the normal nursery are febrile by rectal or axillary temperature (80). Although relatively more uncommon, the most life-threatening cause of fever in the neonate is bacterial sepsis. Fever, however, is an unreliable marker for infection in the newborn as less than 10% of all febrile neonates have culture-proven sepsis, and many more infected infants demonstrate normothermia or most commonly, hypothermia.

PHYSIOLOGIC CONTROL OF BODY TEMPERATURE

Central control of body temperature occurs at the level of the hypothalamus, where a set point temperature defines normothermia. When body temperature falls below this set point, the hypothalamus initiates heat conservation mechanisms that include peripheral vasoconstriction and nonshivering thermogenesis. If body temperature rises above the set point, heat dissipation mechanisms are activated; in the neonate, these consist mainly of peripheral vasodilation and to limited degree, sweating. It is thought that fever occurs when this set point is displaced to a higher level.

MECHANISMS PRODUCING NEONATAL FEVER

Bacterial and viral toxins, like endotoxins of bacterial membranes, are examples of exogenous pyrogens that can initiate an immunologic cascade resulting in fever (80). Exogenous pyrogens stimulate granulocytes and macrophages to produce endogenous pyrogen (interleukin-1). Endogenous pyrogen then activates phospholipase A₂, which ultimately results in the production of prosta-glandins. One of these prostaglandins, PGE₂, is thought to be one of the mediators that raises the hypothalamic set point producing the fever seen with infection.

In addition, exposure to excess heat or insulation (excessive swaddling) can quickly increase core temperature of newborn infants due to their poor heat dissipation mechanisms, particularly the inability to effectively sweat. Such overheating commonly occurs when term babies are nursed in uncontrolled incubators or under radiant warmers. Temperature elevation may also occur with increased infant metabolic rate, as seen with skeletal muscle rigidity and status epilepticus. Another cause of temperature elevation is occasionally observed in well, breast-feeding newborn infants on the third to fourth day of life and is felt to result from dehydration due to insufficient maternal milk production. Finally, there are more recent reports of an increased incidence of

Chapter 25

The Extremely Low-Birth-Weight Infant

Apostolos Papageorgiou

Ermelinda Pelausa

Lajos Kovacs

Tremendous progress in the survival of newborn infants has resulted in the need for population descriptors other than "premature" or "low birth weight." Such descriptors require subdivision by both gestational ages and birth weights to have meaningful diagnostic and prognostic value.

In the 1960s, the term "low birth weight" (LBW) defined all infants with a birth weight less than 2,500 g. With improved survival of infants born weighing less than 1,500 g in the 1970s and 1980s, the term "very low birth weight" (VLBW) was introduced to better express the problems and outcomes unique to this group of infants.

In the 1990s, it became clear that a new category was necessary to reflect the prevailing reality, namely, the large number of surviving infants born weighing less than 1,000 g. Thus, the term "extremely low birth weight" (ELBW) was added to identify these infants.

In the start of the millennium, we have witnessed the survival of a new cohort of infants who weigh less than 500 grams at birth, i.e., below the weight limit which the World Health Organization had designated for reporting live births. These infants, referred to by some authors as "fetal infants" or "micropremies," are rarely treated in our neonatal units but, nevertheless, reflect a new reality of modern Neonatology. Although their care showcases the tremendous clinical and technological progress achieved in recent years, their survival has also brought a substantial additional demand on human and financial resources, and major ethical dilemmas. Most of the fetal infants who do survive are small for gestational age (SGA) and, at this point in time, their long-term prognosis is not reassuring, which makes their neonatal intensive care unit (NICU) management a hotly contentious issue (1,2,3).

In recent years, few medical specialties have demonstrated as much progress and success as has neonatology. With regionalization of perinatal care, improved technology, and better understanding of their pathophysiology and specific needs, the survival of ELBW infants has improved dramatically (4,5,6,7,8,9,10,11,12). In fact, in most well organized perinatal centers in North America and Europe, neonatal deaths are uncommon for infants with birth weights more than 1,000 g, in the absence of congenital anomalies. Recent reports demonstrate the improvement in overall perinatal and neonatal mortality and the increasing survival of VLBW and ELBW infants over time. Joseph and colleagues describe the reduction in infant mortality rates in Canada between the years 1985 to 1987 and 1992 to 1994, with the magnitude of reductions ranging from 14% (95% CI, 7-21) at 24 to 25 weeks gestation to 40% (95% CI, 31-47) at 28 to 31 weeks (13). Data in Table 25-1 reflect the progress as experienced in our own perinatal center over the last 15 years for infants born weighing less than 1,000 g. Our own perinatal mortality statistics at the Sir Mortimer B. Davis-Jewish General Hospital, a McGill University tertiary care perinatal referral center with near 4,000 deliveries per year and a catchment area of 12,000 deliveries, show a neonatal mortality consistently between 0.3 and 0.5 per 1,000 live births for infants weighing more than 1,000 g, including those who died from lethal congenital anomalies.

Thus, the care of VLBW infants, and particularly of ELBW infants, occupies an important part of the daily activities of all NICUs and contributes heavily to the cost of neonatal care (14,15,16,17).

As mortality has much decreased, concerns have been expressed regarding whether morbidity has followed the same rate of improvement (12,16,18,19,20,21,22,23,24). There is current evidence that for infants born weighing more than 750 g, the decline in morbidity is a significant one, although not parallel to mortality. However, for infants with birth weights less than 750 g, their long-term prognosis remains less favorable. Although the incidence of cerebral palsy and other physical impairments is relatively low, the incidence of later-appearing cerebral dysfunction is quite elevated, with requirement for additional resources to manage behavioral and school difficulties in later childhood.

TABLE 25-1 DECLINE IN MORTALITY BY BIRTHWEIGHT AT THE JEWISH GENERAL HOSPITAL, MCGILL UNIVERSITY, FROM 1984 TO 2002

Birth Weight(g)	1984–1985		2001–2002		Percent Improvement
	Births	Mortality	Births	Mortality	
500–750	25	14 (56.0%)	41	18 (43.9%)	22
751–1,000	36	10 (27.8%)	40	4 (10.0%)	64
500–1,000	61	24 (39.3%)	81	22 (27.2%)	31

Major problems related to ELBW infants are listed in Table 25-2.

The aim of this chapter is to present a global approach to the care of ELBW infants, with emphasis on the problems and management issues particular to them. The reader is referred to the specific chapters in the textbook for a more comprehensive review of each problem.

Much of what is written in this chapter is based on our own experience in the management of ELBW infants, with appropriate reference to the most recent published data. We expect that our experience may be different from many in other parts of the world. It is important to appreciate that the Canadian health care system, which provides universal access to health care, emphasizes prevention and has a very successful antenatal referral policy, with the vast majority of VLBW infants being inborn. Table 25-3 indicates the number of infants weighing less than 1,500 g born in the five level III maternity hospitals in the province of Quebec in comparison with the number born in levels II and I (25). The success of the regionalization of perinatal care can be better appreciated by knowing the size of the province (approximately four times the size of France) and the weather conditions.

 Poor defense to infection

EPIDEMIOLOGY

Until recently, statistics on ELBW infants were analyzed exclusively by birth weight. Although this method offers the advantage of an objective measurement, it does not take into account the effect of gestational age (26). In other words, many infants born weighing less than 1,000 g are more mature than their birth weight may indicate, hence denoting the problems of intrauterine growth restriction (IUGR) superimposed on prematurity. The neonatal problems and long-term prognosis can be quite different for the more mature, SGA infant than for the less mature, appropriate for gestational age (AGA) infant of the same birth weight. The distinction between AGA and SGA infants born before 28 weeks of gestation became possible only in recent years, thanks to the introduction of early pregnancy ultrasonography. In Canada, and particularly in the Province

P.461

of Quebec, systematic ultrasonography between 16 and 18 weeks of gestation has permitted not only the early detection, and the potential for termination of major congenital anomalies but, at the same time, it has provided a reasonably accurate dating of almost all pregnancies. Precise gestational age assignment, along with the birth weight of premature infants, has made it possible to relate specific problems, diagnoses and prognoses to the degree of immaturity, and to recognize the implications of IUGR at a very early gestational age (26). In our perinatal center, in the last 6 years, the incidence of IUGR, defined as a birth weight beyond two standard deviations (2SDs) below the mean for a given gestational age, has been 24.5% for infants born weighing less than 1,000 g (Table 25-4). It is hoped that as gestational age dating becomes universal and more accurate, the current method of reporting perinatal statistics based on birth weight will be complemented by the gestational age, thus reflecting both the degree of maturity and the degree of appropriateness of intrauterine growth. Hence, neonatal pathology and prognosis can be based on both gestational age and birth weight.

Gestational Age	Weight (g)	Mortality
24 wk	<700	63.3%
n = 241	>700	37.2%
25 wk	<760	43.3%
n = 364	>760	35.9%

From SB Effer, unpublished data.

Although mortality rates of VLBW and ELBW infants are declining, the incidence of these births has not changed significantly. In the province of Quebec, the rate of live births for infants weighing 500 to 999 g has increased slightly from 0.3 in 1992 to 0.4% in 1998 and for those weighing 1,000 to 1,500 g from 0.4 to 0.5%. Similarly, the incidence of births less than 26 weeks increased from 0.1 to 0.2% and that of births between 26 and 28 weeks from 0.4 to 0.5% (25).

Factors that have long been recognized as being associated with prematurity include extremes of maternal age, socioeconomic status, low level of education, adverse social habits, maternal diseases, gynecologic infections and, more recently, multiple pregnancies secondary to *in vitro* fertilization (27).

Significant predictors for the survival of ELBW infants are older gestational age, heavier birth weight, female gender, African American race, singleton birth, and the absence of severe fetal growth restriction (28). The importance of birth weight for the survival of infants born at 24 and 25 weeks of gestation has been demonstrated clearly in a multicenter study of Canadian tertiary care centers (Table 25-5). In this particular study, all infants were inborn, and the gestational ages were confirmed by early ultrasonography. Likewise, maturity by only a few days has been shown to add significant chances of survival, as shown in Table 25-6. Whether analysis is done by increments of 100 g or by increments of a few days, the impact of these two factors on the survival of ELBW infants is very important. Tables 25-4 and 25-7 indicate the survival rate of infants born weighing less than 1,000 g in our institution between 1995 and 2002, analyzed by weight and gestational age. In our experience, infants born before 27 weeks of gestation with a birth weight beyond 2SD below the mean are at a disadvantage compared to appropriate-for-gestational-age infants of the same gestational age in terms of acute and chronic problems, the most striking complication being the higher incidence of retinopathy of prematurity (ROP) (26).

TABLE 25-5 IMPACT OF GESTATIONAL AGE ON SURVIVAL OF 533 INFANTS AGED 24 TO 25 WEEKS IN THE CANADIAN COLLABORATIVE STUDY

In terms of global epidemiologic evaluation of outcomes for ELBW infants, many factors contribute to the inaccuracy of data. A number of countries, and particularly some developing ones, do not keep statistics for infants born before 28 weeks of gestation. In other countries,

P.462

when death occurs rapidly in the first day of life, the death is not recorded as a neonatal death. Also, information originating from small private institutions may be inaccurate and difficult to control. National and regional data can also be seriously affected by the ratio of inborn to outborn infants and the number of extremely premature infants who are resuscitated. Indeed, great variations do exist in terms of intervention and resuscitation in the delivery room between institutions and countries, and they reflect not only differences in the capacity of some institutions to manage newborns near the limits of viability, but also differences in philosophy. Tables 25-4, 25-7 to 25-9 indicate the survival, management, and complications of infants weighing less than 1,000 g born in our center over a 8-year period (1995-2002).

PERINATAL MANAGEMENT

Prenatal

With the advent of routine early ultrasonography, the gestational age is fairly well established on admission to the Obstetrics unit for the vast majority of women presenting with premature labor, premature rupture of membranes or other problems diagnosed in the second trimester of pregnancy. Such patients need to be immediately placed in the charge of a specialist in high risk Obstetrics (Obstetrical Perinatologist or Specialist in Maternal Fetal Medicine) to coordinate the evaluation and management plans and to ensure appropriate communication and counseling. Based on the investigation for the causes of the problem at hand, the evaluation of the degree of cervical dilatation, the condition of the membranes, the presence or absence of chorioamnionitis and, if possible, the most recent evaluation of fetal well-being by bedside or formal ultrasonography, the Perinatologist can decide on the best course to be taken, such as an estimate of the likelihood of controlling labor with tocolysis to allow adequate time for antenatal corticosteroid therapy (7,29), often with consultation with their colleagues in neonatology.

The prospective parents should receive accurate information regarding all facets of the proposed management, including the possible need for cesarean delivery, and information regarding the subsequent management of the newborn infant, including the potential risks related to both the degree of prematurity and the therapeutic interventions that may be necessary to keep the infant alive.

P.463

Ideally, this information should be provided conjointly by both the obstetric perinatologist and the neonatologist and should be based not only on general statistical information, but also on the specific institutional experience with outcomes of newborn infants of similar gestational age. In our center, the attending neonatologist provides a written consultation on all patients admitted to the obstetric high-risk unit. We meet with the family, offer an extensive review of our experience with similar cases, and answer their questions regarding risks and outcomes. The father and mother are invited to visit the NICU and to familiarize themselves with the environment and the personnel. If the mother is not able to visit for medical reasons, we show her a book with pictures explaining each step of the baby's treatments, from the delivery room to the time of discharge.

The lowest gestational age at which resuscitation should be initiated has long been the subject of debate. Guidelines are available from both the American and the Canadian Fetus and Newborn Committees (30,31). Based on our experience, we offer an optimistic opinion in terms of survival and potential morbidity for pregnancies of 25 weeks' gestation and over. Between 24 and 25 weeks, although we underline that the chances of survival are quite good, we also emphasize the increased risk of potential complications, such as intraventricular hemorrhage (IVH), periventricular leukomalacia (PVL), retinopathy of prematurity (ROP), chronic

lung disease (CLD), neurosensory impairments, and later school and behavioral difficulties. For pregnancies between 23 and 24 weeks of gestation, we describe the higher incidence of complications previously mentioned, and the lower survival rate; however we also mention the possibility of intact survival or survival with minimal handicaps. Finally, for pregnancies below 23 weeks of gestation, we do not recommend intervention. For parents who request full intervention, we strongly advise that resuscitation will be undertaken only if the newborn has at least the degree of maturity predicted by dates and/or ultrasonography, and if, in the judgment of the neonatologist present in the delivery room, the newborn has reasonable chances of responding to resuscitation. We always make it clear to the parents that initiation of resuscitation and subsequent treatments in the NICU do not preclude discontinuation of therapy if a major complication such as severe IVH is detected in the hours or days following birth. The presence of a staff neonatologist in the delivery room is an integral part of our protocol for the management of ELBW infants.

One of the most difficult questions that parents ask, and which our obstetric colleagues continuously debate, is the safest route of delivery in the presence of either a breech presentation or evidence of fetal distress (32). In our institution, based on our own results, we advise cesarean delivery in such situations as of 25 weeks' gestation. Between 24 and 25 weeks, we feel less inclined to recommend cesarean delivery, particularly in view of the fact that many may require a classical incision. The decision to proceed with such an intervention is taken with a clear understanding by the parents of all the medical implications for both the mother and the infant. Finally, at less than 24 weeks of gestation, cesarean delivery is performed strictly for maternal indications. Our incidence of cesarean section by gestational age is indicated in Table 25-10. It is obvious that a large number of cesarean deliveries, and particularly those between 22 and 24 weeks of gestation, are performed strictly for maternal indications, i.e., severe abruption, preeclampsia, etc.

TABLE 25-10 CESAREAN SECTION RATE IN 352 INFANTS WEIGHING 500–1,000 g AT THE SMBD-JEWISH GENERAL HOSPITAL, MCGILL UNIVERSITY, 1995–2002

GA by Wks	No. Deliveries	No. C/Sections	%
<23	10	0	0

25–26	129	71	55.0
27–28	76	39	51.3
29–30	25	20	80.0
31–32	7	7	100
All ages	352	168	47.7

Another difficult management situation relates to ruptured membranes between 18 and 22 weeks of gestation, resulting in severe oligohydramnios, with the inherent risk of lung underdevelopment (33,34). Serial ultrasound studies can evaluate the degree of reaccumulation of amniotic fluid and allow for a better-educated decision regarding whether continuation of pregnancy is advisable (35). However, in the vast majority of these cases, the outcome is very poor, and termination of pregnancy constitutes reasonable advice, particularly if rupture of membranes occurred before 20 weeks of gestation with poor reaccumulation of amniotic fluid. Amnioinfusion has been proposed and attempted as a means of overcoming the problem of chest compression, with limited success thus far (36).

Impending Delivery

The management of a patient with impending premature delivery should include the following: evaluation of gestational age by dates and/or early ultrasound, fetal size and position, condition of the fetal membranes, amniotic fluid volume, and evidence of chorioamnionitis and other obstetric complications such as bleeding, toxemia, and so on. Vagino-rectal cultures for the detection of group B streptococcal colonization and initiation of therapy with penicillin are also in order (37). If culture results return negative, penicillin can be discontinued. In all patients from 24 weeks of gestation who are not infected and for whom there is no maternal indication for immediate delivery, such as massive bleeding, and in whom the cervix is

dilated less than 5 cm, we propose tocolysis with magnesium sulfate and administration of betamethasone (29,38). Our experience over the years with the combination of tocolysis and betamethasone has been fully supported by the 1994 NIH Statement on Antenatal Use of Corticosteroids (39). For patients between 24 and 34 weeks' gestation, we administer two doses of 12 mg of betamethasone, 24 hours apart. Beyond 34 weeks, we use steroids only when an amniocentesis indicates lung immaturity. Multiple pregnancies are offered similar therapy (40). We also monitor body temperature and changes in leukocyte count, keeping in mind the possible transient leukocytosis after the administration of betamethasone.

If a patient has fever or demonstrates other signs of chorioamnionitis, broad-spectrum antibiotics are initiated. In the presence of ruptured membranes, a number of obstetricians use a combination of ampicillin and erythromycin in an attempt to temporarily stop labor and administer steroids (41,42,43). This seems a reasonable approach, because between 30% and 50% of premature births are believed to be precipitated by common genital tract infections.

Delivery Room Management

The successful management of the ELBW infant begins in the delivery room (Table 25-11). A well-organized and equipped delivery room and the presence of a competent team headed by an experienced neonatologist are essential ingredients to the proper reception of these very fragile newborns. The basic principle guiding successful management is directed toward prevention of any physiologic deviation from normality, such as hypothermia, acidosis, or hypoxia. At the same time, it is important that each intervention during the resuscitation process be carefully adapted to the size and to the needs of the tiny infant. Brisk maneuvers, excessive positive pressure with bagging, or inappropriate administration of drugs and fluids may induce permanent central nervous system (CNS) or lung injuries.

TABLE 25-11 THE FIRST 60 MINUTES OF LIFE

1. **Expert resuscitation in the delivery room.**
2. **Good thermoregulation.**
 - a. Keep the infant warm and dry in the delivery room
 - b. Provide high-humidity environment in the incubator
3. **Minimum handling and avoidance of brisk maneuvers.**
4. **Expert cardiorespiratory support.**
 - a. Liberal use of nasopharyngeal CPAP.
 - b. Intubation when indicated, avoiding excessive ventilatory pressures.
 - c. Continuous monitoring of oxygenation with pulse oximetry.
 - d. Monitoring of blood pressure. Prudent administration of volume expanders.
 - e. Catheterization of umbilical vessels, when indicated.
 - f. Close monitoring of blood gases, Hb, WBC + diff, blood glucose.
 - g. Radiographic evaluation of lung pathology and position of catheters.
 - h. Administration of surfactant, when indicated. Rapid adjustment of ventilatory support.
5. **Intravenous D₁₀W and antibiotics when indicated.**
6. **Parental information**

It seems particularly inappropriate when high-risk mothers are referred to a tertiary care center for specialized perinatal care, to have their premature newborn infants cared for in the delivery room and during the critical first hours of their lives by unsupervised and inexperienced in-training personnel. Major decisions, such as whether to initiate resuscitation and for how long, often need to be made in extremely short periods of time and under heavy pressure for infants at the limit of viability. This can be done only by experienced personnel (44).

In our center, the birth of an ELBW infant is always attended by a neonatologist in addition to the pediatric house staff and a trained delivery room nurse. Appropriate equipment is used according to the American Heart Association and American Academy of Pediatrics (AAP) guidelines for neonatal resuscitation, with particular emphasis on temperature control i.e., radiant heater set at maximum temperature and prewarmed blankets (45).

During the initial steps of stabilization, the condition of the infant is rapidly assessed. After drying, positioning on warm blankets, and suctioning, most ELBW infants require immediate initiation of positive pressure ventilation with a bag and mask. Resuscitation is initiated using an inspired oxygen concentration of 100%, which is rapidly reduced as the infant's condition improves. Although concerns have recently been raised that such a practice

may result in potential exposure to oxygen free radical species (46,47), the available data is limited to asphyxiated newborn infants at term, and there is currently insufficient evidence to support a change in practice. We found that, for ELBW infants, ventilation is more effective if performed at a higher ventilatory rate than for the term infant. We use anesthesia bags and ventilate at a rate of 60 to 80 breaths per minute, adjusting the pressure to provide adequate bilateral air entry and chest wall excursion. For extremely premature infants, intubation in the delivery room may rapidly follow.

With proper ventilation, in our experience, rarely will an infant require chest compressions or epinephrine. The prognosis of ELBW infants requiring this extent of resuscitation is very guarded, particularly if their birth weight is below 750 g. Fluid resuscitation is reserved only for those infants in which significant blood loss is suspected.

Even following optimal resuscitation, the Apgar scores of ELBW infants rarely exceed 6 or 7 in view of their decreased tone and reactivity, poor respiratory effort, and initially poor peripheral perfusion (48). The infant's heart rate is thus the best measure of the effectiveness of resuscitation efforts.

The topic of delivery room management would not be properly covered without mentioning the ethical dilemmas faced by the neonatologist when parental and

P.465

medical opinions regarding resuscitation differ, or when an ELBW infant is severely asphyxiated and requires prolonged resuscitation. It is our view that reasonable parental opinions must be respected after full and honest discussion of the infant's chances of meaningful survival.

Admission to the Neonatal Intensive Care Unit

Expert management in the delivery room and during the first hours after admission to the NICU is of paramount importance to prevent immediate and long-term complications in the ELBW infant. It is well established that the majority of cerebral injuries occur around the time of delivery or in the immediate postnatal period. Acute changes in cerebral blood flow may predispose the very fragile network of periventricular vessels to rupture. Hence, it is essential to handle these very fragile infants with extreme care, avoiding unnecessary disturbances, and preventing, rather than correcting physiological deviations in acid-base balance, blood gases, blood pressure, or body temperature. Also, overly aggressive ventilation either in the delivery room or in the NICU may predispose to significant acute or chronic pulmonary problems such as hyperinflation and loss of elasticity of the alveoli, pulmonary interstitial emphysema, pneumothorax, and eventually CLD.

The vast majority of our ELBW infants who require assisted ventilation are intubated in the NICU. Only in exceptional situations, when the infant does not respond to bag and mask ventilation, is intubation performed in the delivery room. We use the nasotracheal route, and an endotracheal tube (ETT) of 2.5 mm for infants with a birth weight less than 1000 g. We believe that it is important to use a low-caliber ET tube to avoid subglottic trauma, strictures, and eventually stenosis. We have never had to perform a tracheostomy in an infant, and stridor has been very rare among our patients.

If the newborn infant is in distress, an umbilical arterial catheter is inserted. The arterial line is used exclusively for blood sampling. We favor the "high" position of the tip of the catheter, just above the level of the diaphragm. After each blood sampling, the catheter is flushed with a heparinized solution of 0.45% saline. In infants weighing less than 750 g, we also insert an umbilical venous line. We use the venous line to infuse fluids, thus avoiding excessive handling and disturbance to the newborn infant during the first 24 to 48 hours of life. The tip of the catheter is positioned at the junction of the inferior vena cava and the right atrium, hence avoiding the liver. This is important, particularly when infusing hypertonic solutions, such as sodium bicarbonate or calcium gluconate.

Blood is analyzed for glucose, electrolytes, blood gases, hemoglobin, and leukocytes. An intravenous with 10% dextrose is initiated at a rate of 65 to 85 mL/kg/d and the infant is placed in a high humidity closed incubator. Serum glucose levels are closely monitored, and the concentration of dextrose administered is adjusted accordingly. In very tiny babies, when more than ten percent of the baby's blood volume has been removed, we replace it with packed red cells. We use a single donor, collecting the blood in small packs, which may be used for up to several weeks (49). Donors are extensively screened for all viral illnesses. We encourage parents who wish to donate blood to their infants to do so, as long as they are of a compatible blood group and are free of viral and other infections. Very sick infants receive 1:1 nursing care until the condition is stabilized, at which point the ratio of nurse-to-baby becomes 1:2.

A percutaneous central venous catheter is usually inserted between the second and third day of life for

intravenous alimentation (50,51). As portal of entry, we use the upper extremities of the infant, and we aim for the tip of the catheter to be in the superior vena cava, being careful to avoid intracardiac positioning, with its attendant risks of erosion into the pericardial space (52,53). In case of failure to properly position a central line, peripheral venous access is maintained using an extremity or scalp vein. Parenteral nutrition (TPN) is generally introduced within the first 24 hours of life. When the mother receives intravenous fluids during her labor, a baseline electrolytic profile of the newborn shortly after birth appears to be the proper way to follow subsequent changes. Electrolytes are repeated between 12 and 18 hours of age. During the first 72 hours, the body weight is recorded every 8 hours, and fluid intake is adjusted accordingly. The new incubators have incorporated scales, allowing recordings without excessive handling and disturbance of the newborn infant. One other major advantage of the new incubators is that they can provide a high level of humidity, hence substantially reducing the need for large volumes of fluid.

To establish prognostic criteria, it is important to obtain a cranial ultrasound in the first 24 hours of life (54,55). This ultrasound needs to be repeated at least one week later, or as often as necessary, depending on the pathology detected on admission or, if the infant's condition has deteriorated, suggesting CNS involvement. It is also important, before discharge from the hospital, to repeat the cranial ultrasound to evaluate the presence or absence of periventricular leukomalacia (PVL) (56). Ideally, this last ultrasound should be performed at 35 to 36 weeks of postmenstrual age.

Respiratory Support

The vast majority of infants with a birth weight less than 1,000 g will need some form of respiratory assistance to survive. For vigorous infants, nasal continuous positive airway pressure (CPAP) or recently, nasal ventilation, is the preferred mode of support (57). Some controversy surrounds the timing and criteria for the initiation of assisted ventilation. Likewise, controversy also exists regarding whether these tiny infants should receive prophylactic exogenous surfactant in the delivery room (58,59,60,61,62). We do not systematically intubate infants born weighing less than 1,000 g, and we do not administer surfactant unless the infant requires assisted ventilation and a minimum FiO_2 of 0.30.

P.466

The introduction of exogenous surfactant therapy has reduced significantly the mortality of all newborns suffering from respiratory failure secondary to respiratory distress syndrome (RDS), but its impact has been particularly important among the most premature infants (63,64,65,66,67,68,69). Administration of surfactant in these very tiny infants requires extra care, as rapid changes in lung compliance may not only damage the lungs by creating overinflation and overdistention, but also may predispose to acute changes in ductal circulation which, in turn, could lead to both cerebral and/or pulmonary hemorrhage. With rapid improvement in oxygenation, persistent hyperoxia also may be detrimental to the eyes. Hence, the administration of surfactant should be performed by an experienced person, under close monitoring of ventilatory parameters, and with rapid reduction of peak inspiratory pressures (PIP) and oxygen concentrations. If necessary, a second dose of surfactant may be administered as soon as 6 hours after the first. However, in our experience, if the response to the second dose is not satisfactory, it is highly unlikely that the condition will improve with additional administration of surfactant. In our center, 64% of the babies improved rapidly, requiring only a single dose of surfactant. Natural surfactant preparations are nowadays practically the only ones used (70).

Mechanical ventilation has dramatically improved the survival of infants weighing less than 1,000 g. In the 1970s, very few infants born weighing less than 1,000 g survived. In the early 1980s, survival of infants weighing 500 to 750 g varied from 3% to 25%, and that of infants weighing 750 to 1,000 g ranged from 30% to 70% (71). In initiating mechanical ventilation, it is imperative that minimal effective settings be used (72). Studies have shown that hyperventilation and overinflation of the lungs increase the loss of surface active phospholipids (73). Also, overinflation predisposes to air leaks and particularly to pulmonary interstitial emphysema (PIE). The latter is a serious complication in the tiny infant, and is a relatively frequent one. It is probably related to structural immaturity of the lungs, particularly to the relative lack of elastic tissue, which normally increases progressively throughout gestation (74). Also, the interstitium is larger in the more immature infant as a result of poor alveolization. Although drainage of a pneumothorax may lead to rapid improvement, management of PIE is far more complicated. As lung compliance is reduced, there is a need for increased PIPs to maintain adequate ventilation. This results in increased barotrauma to the small airways. Chorioamnionitis has been reported as a risk factor predisposing to PIE (75). The highest incidence of PIE in tiny infants has been observed when intrauterine pneumonia complicates the RDS. To overcome the problems related to PIE, a number of strategies have been devised. These include acceptance of higher levels of partial pressure of CO_2

(PCO₂) and lower levels of potential of hydrogen (pH), reduction of the positive end-expiratory pressure (PEEP) to between 2 and 3 cm water (H₂O), selective intubation of the contralateral lung, positioning the infant on the affected side, increasing the expiratory time, and systemic corticosteroid therapy. The combination of the above strategies can occasionally produce quite spectacular recovery from this condition. However, high frequency oscillatory or JET ventilation is probably the most effective therapy (76,77).

A variety of ventilatory strategies have been promoted to maintain satisfactory ventilation and to reduce the risk of complications (78), such as high PIP-low rates, low PIP-high rates, variation in the I:E ratio, variations in the flow, permissive hypercapnia, tolerance of lower pH and, more recently, high-frequency oscillation and even ventilation via nasal prongs. In recent years, however, the general trend is to use the lowest possible PIP to achieve acceptable ventilation and oxygenation. Of course, the question is what is considered "acceptable"? Some neonatologists will tolerate a pH as low as 7.20 and a PCO₂ as high as 65 mm Hg. Most centers also aim for PaO₂ values between 50 and 70 mm Hg. Our own approach to the ventilation of tiny infants over the years has been to favor nasotracheal intubation with a 2.5-mm ET tube. Our PIPs rarely exceed 14 to 15 cm H₂O, and we set the PEEP at 5 cm H₂O, with initial rates of 65 to 75 per minute. We aim for arterial oxygen pressure (PaO₂) values between 45 and 50 mm Hg, which is enough to abolish production of lactic acid and, at the same time, remains relatively close to intrauterine values. Our pulse oximeters (79) are set to alarm at a lower limit of 80% and an upper limit of 93% for the first few weeks of life. We believe that this modest degree of oxygenation offers the advantage of reducing the need for administration of elevated oxygen concentrations, thus minimizing lung toxicity, and may help to avoid retinal damage. Our incidence of bronchopulmonary dysplasia (BPD) and ROP are shown in Table 25-9. We believe that by using the lowest possible PIP and initially, a relatively rapid respiratory rate, we reduce overdistention and barotrauma and minimize the risk of lung injury. Because, in RDS, there are compartments in the lung with relatively normal ventilation perfusion ratios and others with poor ventilation and adequate perfusion, it seems reasonable to attempt to improve ventilation of the poor ventilation perfusion (V-Q) compartment without overdistention of the normal V-Q compartment. Raising the ventilatory rate, which raises the mean airway pressure without changing the PIP, appears to accomplish this (80). We also have observed that with initially higher respiratory rates, the tiny infant very rapidly stops fighting the respirator, thus making the gas exchange smoother and possibly decreasing the incidence of air leaks. Relatively high respiratory rates also seem to be more physiologic for the very immature infant, as observed by Greenough and collaborators (81). For toilet of the airways, we use the Ballard closed suction circuit, thus avoiding disconnecting the infant from the ventilator (82). We suction sparingly during the first few days of life, when the volume of secretions is minimal. Analgesia/sedation is given for nonemergent intubation and for infants who remain agitated while on mechanical ventilation.

Most of our ventilated babies have their umbilical vessels cannulated for blood sampling and for fluid infusion.

P.467

As soon as the procedures of intubation and catheterization of the umbilical vessels are completed, we perform chest and abdominal radiography to assess the position of the ET tube and the umbilical catheters and, at the same time, to evaluate the severity of lung pathology. Fifteen minutes after the initiation of ventilation, we obtain an arterial blood gas and adjust the ventilatory parameters accordingly. We generally aim for a pH above 7.25 and a PCO₂ between 45 and 55 mm Hg, but when the PIPs are elevated or in the presence of PIE, we tolerate partial pressure of CO₂ (PCO₂) values up to 60 mm Hg as long as the pH is at least 7.20. Our ET tubes are sutured to the tape placed on the upper lip. We record the level at which sutures were placed on the ET tube, thus avoiding the need to repeat a chest radiograph to evaluate the tube position when reintubation is required. Actually, we take very few radiographs, and we rely extensively on clinical assessment, blood gases, and pulse oximetry. However, a chest radiograph should be taken if there are concerns about the position of the endotracheal tube or the development of any form of air leak.

Avery and associates (83) reported in 1987 that the incidence of BPD varied between neonatal units. The unit with the lowest incidence used CPAP much more frequently than did the other units. Epidemiologic data from 36 units in the Vermont-Oxford Trial Network also indicate large differences in the incidence of BPD, from 16% to 70% for infants weighing between 501 and 1,500 g (84). The incidence of BPD was lower in units allowing higher PCO₂ values. More evidence of the association of BPD and PCO₂ was provided by Kraybil and associates (85). More recently, Garland and associates (86) reported the highest incidence of BPD among infants with the lowest PCO₂ before the administration of surfactant.

The concept of permissive hypercapnia for patients requiring mechanical ventilation gives priority to the prevention or limitation of severe pulmonary hyperinflation over the maintenance of normal ventilation. The principle consists of allowing the PCO_2 to rise by minimizing ventilator pressures and tidal volume (87). Potential risks of high PCO_2 values include increased cerebral perfusion, increased retinal perfusion, increased pulmonary vascular resistance, and reduction of pH. Based on epidemiologic observations, it appears that respiratory acidosis, unlike metabolic acidosis, is not associated with poor neurologic outcomes. Vannucci and associates (88) demonstrated similar findings in animal studies involving rats.

Flow rate also can affect ventilation and increase airway injury. We generally use a flow rate between 3 and 5 L/min. Only when we need very high pressures, for instance, in the presence of pulmonary hemorrhage, do we allow the flow rate to exceed 5 L/min.

Several reports in the literature have expressed concern about potential side effects of low PCO_2 values (89).

Graziani and associates (90) reported that, along with other factors, marked hypocarbia during the first 3 postnatal days was associated with increased risk of periventricular white matter injury in premature infants. The theoretical model of ischemic brain injury has been described by Wigglesworth and Pape (91). These authors hypothesize that cerebral blood flow could be decreased by several factors, including hypotension, hyperoxia, hypocarbia, and increased venous pressures. Concern also has been expressed in the literature about high-frequency ventilation, which may lead to low PCO_2 values as a result of effective alveolar ventilation (92).

However, the data regarding the development of PVL among infants managed with these devices remain controversial. Most authors agree, however, that for hypocarbia to be dangerous for the brain, it has to reach levels below 30 mm Hg. Our policy is to avoid PCO_2 values below 40 mm Hg by first reducing PIP before reducing respiratory rates.

High frequency oscillatory ventilation (HFOV) has been used in recent years in an attempt to reduce the incidence of early ventilatory complications and to prevent bronchopulmonary dysplasia. Published reports are often contradictory and, so far, there is no clear evidence that HFOV offers an advantage over conventional ventilation (93,94). HFOV, however, offers an advantage when treating infants with PIE, pulmonary hypertension, or diaphragmatic hernias (95).

More recently, the effects of patient-triggered ventilation with volume-guarantee have been explored in the management of preterm infants (96). This novel technique calls for an automatic adjustment of the peak inspiratory pressure to ensure a minimum set mechanical tidal volume.

The timing of extubation of ELBW infants is very important, because they are prone to develop severe apnea, with the potential risk of cerebral injury. Nowadays, with early administration of surfactant and improvement in lung compliance, rapid extubation and placement on nasal CPAP or nasal ventilation is possible in the majority of ELBW infants. However, some extremely premature infants develop severe episodes of apnea and desaturation, requiring frequently reintubation. For this reason, for the tiniest infants, we often favor a more progressive weaning process by maintaining them for a few extra days at a very low PIP of 10 to 12 mmHg and rates of 15 to 25 per minute, although providing maximum intravenous and oral alimentation (97). When the infant is stronger and starting to gain weight, we administer caffeine and proceed directly to extubation. The infant then is placed on nasal CPAP. The CPAP is discontinued when, after periodic trials, the infant can maintain good oxygenation without significant apnea, bradycardia, and desaturations. If an infant on nasal CPAP shows signs of fatigue manifested by recurrent apnea and retention of CO_2 , we try nasal ventilation prior to reintubation. In many circumstances, this approach provides the extra help that these tiny infants require to avoid reintubation (98,99).

Cardiovascular Support

By far, the major cardiovascular problem in ELBW infants is the presence of a patent ductus arteriosus (PDA). More than 50% of infants born weighing less than 1000 g will

P.468

have a PDA diagnosed during the first few days of life (100,101). The onset of clinical manifestations of the PDA is related to the timing of improvement of the infant's respiratory status, which is associated with a decreasing pulmonary vascular resistance and a predominantly left-to-right shunt. The patency of the ductus arteriosus can be easily documented in the first hours of life, with the help of echocardiography. At this early stage of life, the shunt is either right-to-left or bidirectional, depending on the severity of the infant's respiratory condition. In our

center, the incidence of clinically significant PDA requiring therapy has been around 65% of all infants weighing less than 1,000 g. The left-to-right ductal shunting can be diagnosed as early as in the first day of life in infants with RDS who improved following surfactant therapy (102). An active precordium, with bounding pulses and visible carotid pulse, will often precede auscultation of a murmur. If left untreated, the infant may develop left-sided heart failure and pulmonary edema or hemorrhagic pulmonary edema, with significant deterioration of the respiratory status. Significant left-to-right ductal shunting may cause decreased peripheral perfusion and oxygen delivery. ELBW infants with significant PDA are at risk for IVH, necrotizing enterocolitis (NEC), renal failure, CLD, and metabolic acidosis (103). The size of the ductus arteriosus, and the ratio of the left atrium to aortic root can be easily measured by echocardiography (104). We consider as significant a PDA of diameter greater than 1.5 mm and/or a ratio of left atrium to aortic root greater than 1.3 for ELBW infants.

The ductus arteriosus of the premature infant is less responsive to the vasoconstrictive effect of oxygen and is less likely to close spontaneously than that of term infants, especially in infants with RDS. The classic management of PDA first involves medical and supportive measures, i.e., fluid restriction, diuresis, distending airway pressure, transfusion of packed red blood cells to keep the hematocrit above 0.4. If these measures fail to close the ductus arteriosus, pharmacologic closure is possible with a cyclooxygenase inhibitor, namely indomethacin (105,106,107). In ELBW infants, because closure of the ductus arteriosus is unlikely to occur spontaneously, the infant is at risk for the short- and long-term complications mentioned previously. Hence, therapy with indomethacin has become standard practice for the majority of these infants. Different protocols of treatment have been proposed. We treat most infants with 0.2 mg/kg of indomethacin every 12 hours for three doses. For infants developing clinical and/or biochemical signs of renal failure, we subsequently use 0.1 mg/kg per dose (108). A reduction in fluid intake is advisable prior to administration of indomethacin. In our experience about 80% of the treated infants will respond with a functional closure of the ductus. However, about 30% of these may reopen, in which case, further indomethacin is administered. If the ductus arteriosus fails to close after three courses of indomethacin, or if indomethacin cannot be administered because of significant renal dysfunction on previous treatment, then surgical ligation is necessary. In the last 8 years, 16.7% of ELBW infants required surgical ligation of the ductus after repeated failures of pharmacologic therapy. The more premature the infant, and the greater the postnatal age at the time of treatment, the greater the failure of indomethacin (109). A group particularly resistant to indomethacin therapy is ELBW infants with severe IUGR (26). Suggested hypotheses for this high failure rate of indomethacin therapy among this group of infants include chronic hypoxia, altered levels of prostaglandin, and altered number or sensitivity of their receptors (110).

Contraindications to indomethacin therapy include renal failure, active bleeding, and thrombocytopenia. The presence of IVH does not appear to be an absolute contraindication to the use of indomethacin. Recent studies indicate that there is no progression of the severity of IVH after administration of indomethacin for PDA closure (111). Until additional data are available, it is prudent in the presence of IVH to verify the platelet count prior to the administration of indomethacin and to eliminate any bleeding diathesis.

The optimal timing of administration of indomethacin has been a matter of debate. Although early or prophylactic use of indomethacin may result in a higher initial PDA closure rate and in a reduction in the incidence of severe IVH, it does not appear to ultimately reduce the need for surgical PDA ligation, does not confer any long-term respiratory advantage, and does not change the rate of survival without neurosensory impairment at 18 months (112,113).

Another cyclooxygenase inhibitor that seems very promising is ibuprofen (114). It has the theoretical advantage over indomethacin that it may increase the range of blood pressure at which cerebral blood flow is autoregulated, but has little effect on cerebral blood flow during normotension (115,116). In a Phase I study carried out in our center, we observed a dramatic response in 12 ELBW infants treated with ibuprofen within 3 hours of birth (117). All twelve infants had their PDA permanently closed after three doses of ibuprofen. We also observed a significant trend in the reduction of IVH and practically no side effects. These findings have since been confirmed by other groups of investigators. The efficacy of ibuprofen for the treatment of PDA appears to be equivalent to that of indomethacin, with a lower likelihood of oliguria (118). Furthermore, in a series of patients evaluated by near-infrared spectroscopy and Doppler ultrasonography, ibuprofen therapy did not result in a significant reduction in cerebral perfusion and oxygen availability (119). One reported side effect of ibuprofen, namely the development of transient severe pulmonary hypertension and hypoxemia in a few infants treated within six hours of birth, may still require further evaluation (120).

Finally, in the presence of a clinically significant ductus that fails to respond to pharmacologic closure or in the presence of contraindications to the use of indomethacin, surgical ligation should not be delayed, as the presence of a continuous left-to-right shunt may contribute to ventilator and oxygen dependency with well-

Regarding early management of low blood pressure, with the exception of hypovolemic shock, when volume replacement is an urgent matter, we rarely use volume expanders and β -adrenergic drugs to maintain blood pressure. We pay particular attention to skin perfusion. As a rule of thumb, we aim for a mean blood pressure that is numerically slightly above the gestational age of the infant.

FLUIDS AND ELECTROLYTES

The management of fluids and electrolytes remains one of the most challenging aspects in the care of the ELBW infant. Knowledge of the body composition of these infants and better understanding of their renal function has helped to determine their requirements (121,122).

It is important to remember that the body of the ELBW infant is made up of 85 to 90% water, which is distributed as one-third intracellular water (ICW) and two-thirds extracellular water (ECW). Immediately following birth, glomerular filtration rate and fractional excretion of sodium (FENa) are low and urine output is minimal. This is followed by a diuretic phase, which results in a decrease in the ECW compartment. Furthermore, because of the large body surface area to body weight ratio and the underdeveloped epidermis of the ELBW infant, evaporative losses, if uncontrolled, may be of very significant magnitude, i.e., 5.7 mL/kg/h (123,124). Additionally, the immature kidney, having a limited concentrating ability (less than 700 mOsm), produces large amounts of diluted urine. Thus, without close control of fluid intake and the infant's environment, the infant is very vulnerable to dehydration and hypertonicity, which may predispose to IVH. One has to be also careful not to overload the infant with fluids, because this may have an impact on PDA, with possible congestive heart failure, pulmonary edema, worsening pulmonary function and CLD (125).

Shortly after admission, once the infant's respiratory status has stabilized and the need for ready access to the infant is not as essential, the infant is transferred from a radiant warmer to an incubator, maintaining 75 to 80% humidity for the first few days of life. This approach significantly reduces water and heat loss and allows limitation of fluid intake to between 65 and 85 mL/kg/d for the first day of life. Additionally, we monitor the infant's weight every 8 hours during the first days of life, and adjust fluid intake consequently. Under these described conditions, there is rarely a need to exceed an intake of 170 to 180 mL/kg/d even for infants with a birth weight less than 600 g.

Electrolyte abnormalities such as hypernatremia, hyponatremia, and hyperkalemia are frequently seen in ELBW infants. Hypernatremia is usually the result of severe insensible water loss, but can be secondary to the treatment of metabolic acidosis with large amounts of sodium bicarbonate. Hyponatremia (less than 130 mmol/L) is more frequently seen because of the high FENa during the diuretic phase. It may also be noted during the first day of life if the mother has received large amounts of hypotonic intravenous fluids. Hyponatremia is also seen following therapy with indomethacin without prior proper reduction of fluid intake, and later on when diuretics are used for the treatment of CLD.

On admission, infants receive only a 10% dextrose solution in water. We monitor blood glucose and electrolytes closely and we test all urine for glucose. We subsequently adjust the intravenous dextrose according to the blood glucose values. Protein and lipid intake is generally initiated during the first 24 hours of life in the form of parenteral alimentation. We begin sodium supplementation only when its serum value is less than 140 mmol/L, which usually occurs between the second and third day of life.

Hyperkalemia (K^+ greater than 7 mmol/L) is a severe acute problem in this ELBW group of infants, even in the absence of oliguria and potassium intake (126). A rapid rise in serum potassium may be seen during the first 24 hours of life, especially in the most immature infants. A few mechanisms have been proposed for this hyperkalemia, i.e., relative hypoaldosteronism, immaturity of the renal distal tubules, and internal potassium shift from the intracellular space to the extracellular space. Hyperkalemia is also more severe in infants with intraventricular or pulmonary hemorrhage, extensive bruising, or renal failure. It is prudent to obtain a baseline measurement of electrolytes following birth, particularly when the mother has received intravenous fluids. We routinely repeat the electrolytes every twelve to eighteen hours during the first couple days of life, or more frequently if indicated, especially for the smallest infants.

We treat hyperkalemia when it exceeds 7 mmol/L with insulin and sodium bicarbonate to allow an intracellular shift of potassium and calcium gluconate for stabilization of the myocardium. Potassium supplements are introduced only after the serum level has stabilized below 4.5 mmol/L.

We also monitor urine output, and use the urine specific gravity and osmolality as an additional guide to assess the renal function and hydration status of the infant. Typically, the urine pH of the ELBW infant is greater than 7 in the first few of days of life, then decreases as the tubular reabsorption of bicarbonate increases. Microscopic hematuria is consistently seen in the ELBW infant during the first few days after birth, regardless of the health status of the infant. Monitoring for the presence of glucose in the urine can be a good indicator of the carbohydrate homeostasis of the newborn infant. Some extremely premature infants have a low glucose renal tubular threshold and may be predisposed to osmotic diuresis.

Management of fluids in the ELBW infants is very much dependent on securing an intravenous line. Intravenous access may, at times, become very difficult, thus compromising fluid, electrolyte, and glucose homeostasis, thermoregulation, and physiologic stability as a result of the pain induced by multiple attempts to insert a venocath. The umbilical vessels usually provide an easy access route for the first days of life. Subsequently, small neonatal infusion needles (IMP Group International Inc.) are inserted in

P.470

the scalp, or a venocath is inserted in one of the extremities. In our center, we favor the insertion of a percutaneous central venous catheter, which gives continuous venous access for as long as necessary (50). In our experience, this technique has not increased the incidence of infection when compared to peripheral catheters used for prolonged parenteral alimentation. (51)

The Skin of the Extremely Low Birth Weight Infant

The skin of an infant born at 23 to 26 weeks of gestation is extremely immature. Maturity of the epidermis is present at birth only in infants born after 32 weeks of gestation (127). Prior to this time, the epidermis is underdeveloped, especially the stratum corneum, predisposing to very high transepidermal water loss, and to the risk of trauma and percutaneous absorption of toxic agents. The skin also is permeable to gases, allowing for diffusion of oxygen and carbon dioxide. The tremendous transepidermal water loss of the ELBW infant predisposes to dehydration, electrolyte imbalance, and evaporative heat loss. Trauma to the skin may provide a portal of entry for infectious organisms. Fortunately, after birth, there is acceleration of epidermal maturation, such that, by 2 weeks of age, the skin of the premature infant almost resembles that of the term infant. Preservation of skin integrity and prevention of transepidermal water loss have been, and still are, areas of challenge in neonatology. Under a radiant warmer, water loss is extensive. Plastic shields have been used to decrease this loss, with variable success. When the infant is placed in an incubator, increasing the ambient humidity to 80% reduces total extracellular loss to a minimum. Initial studies using the topical ointment Aquaphor;[®] had shown reduced losses for up to 6 hours following application, improved skin condition and decreased skin bacterial colonization, thus possibly reducing the risk of nosocomial infection (128). However, more recent studies indicate no advantage with this approach. (129)

Nutrition

Nutrition is an essential part of the care of the ELBW infant. These tiny infants are born with very low reserves of fat and carbohydrates, and they rapidly develop nutritional deficiencies in calcium, phosphorus, iron, trace minerals, and vitamins. Their endocrine and enzymatic capability is limited as a result of immaturity. Postnatally, they rapidly enter a catabolic state unless provided with sufficient nutrients. On the other hand, reversal of this catabolic state often is difficult because of limited feeding tolerance. The gastrointestinal (GI) tract is immature in terms of digestive pathways and motor function, increasing the risk of developing NEC.

The first goal of nutrition is to prevent catabolism. Usually, this will be achieved by providing a minimum of 50 kcal/kg/d. Growth will require additional caloric intake. Achieving steady growth is essential for the ELBW infant, because the intrauterine growth velocity at 25 to 30 weeks' gestation is relatively higher than at term. If reasonable caloric intake cannot be provided, catch-up growth may never be achieved.

In the early days of life, satisfactory nutrition can never be achieved exclusively with milk. Parenteral nutrition provides the additional calories (130). In contrast to enteric nutrition, parenteral administration starting at 80 to 85 kcal/kg/d can provide the necessary calories for growth. When the infant no longer is receiving intravenous nutrition, 100 to 120 kcal/kg/d are needed to maintain growth. However, this level of caloric intake may not be sufficient in infants suffering from CLD and other high-energy-requiring conditions (131). Appropriate growth, if one wants to mimic intrauterine growth, should be a 2% daily increase in body weight, slowing to 1% near term.

Both parenteral nutrition and enteral nutrition are not without difficulties and complications in the ELBW infant.

TPN requires intravenous access and, this can be associated with a variety of infections, with *Staphylococcus epidermidis* being the most common. The composition of TPN has been, and remains, an area of active research, especially regarding the composition of essential amino acids and fatty acids. Exclusive intravenous nutrition affects the mucosal lining of the GI tract, which is bypassed and eventually may lead to villus atrophy. TPN also requires regular metabolic monitoring for glucose, electrolytes, urea, lipids, and acid-base balance. Cholestatic jaundice is a frequent complication of TPN (132). In the vast majority of cases, this is a self-limited condition, the exact etiology of which is not completely understood, but appears to implicate both amino acids and lipids.

Enteral nutrition may consist of either breast milk or premature formulas. During fetal life, the fetus constantly swallows amniotic fluid, promoting intestinal development. Enteral feeding, even in small amounts, has been demonstrated to stimulate trophic factors and hormonal maturation of the GI tract, thus improving overall intestinal function and potentially improving feeding tolerance and preventing mucosal atrophy (133,134). Whether early introduction of feedings and stimulation of the GI tract could prevent or decrease the incidence of NEC has not yet been established.

The current standard for postnatal nutrition is to duplicate as much as possible in utero fetal growth rates (135). To achieve this goal, high intravenous amino acid and lipid intake are necessary. Recent studies indicate that more aggressive amino acid intakes up to 3 g/kg/d from the first days of life not only are well tolerated, but they also suppress protein breakdown and provide increased protein accretion and synthesis. (136)

In our center, we start TPN from day one, as soon as the infant is metabolically stable, with 1 g/kg/d of amino acids, 1g/kg/d of lipids, and glucose according to tolerance. Calcium, phosphorus, vitamins, and trace minerals also are added. Sodium and potassium are added according to the electrolytic profile. The intake of amino acids and lipids is rapidly increased to a maximum of 3 to 3.5 g/kg/d. Lipids

P.471

are restricted in the presence of severe indirect hyperbilirubinemia. We also adjust the amino acid intake according to urea, pH, and the degree of TPN-related cholestasis. Monitoring of urea, creatinine electrolytes, glucose, and bilirubin is performed daily for the first 3 to 4 days of life and then is reduced to twice a week. When the oral intake is half of the total caloric requirement, monitoring is performed only once a week. During the past 8 years, the mean duration of any amount of TPN administration among 253 survivors born weighing less than 1,000 g was 31.5 ± 15 days (median 28.5 days, range 9 to 121 days).

In terms of enteral nutrition, we attempt to introduce minimal feedings, starting in stable infants as early as 48 hours of life. In the vast majority, we use breast milk or, if necessary, a premature formula (68 kcal/100 mL). However, tolerance varies widely from one infant to the other. We encourage mothers to pump their own milk, which is used exclusively for their own babies. The progression of enteral feedings and the addition of a breast milk fortifier varies from one neonatal unit to the other. For the smallest infants, we increase the volume per feeding by 1 mL every 24 hours, up to 10 mL, and then by 1 mL every 12 hours. Generally, we add a fortifier to the breast milk, thus increasing its caloric content to 81 kcal/100 mL when oral intake is between one-quarter and one-half of the total daily intake. For those infants on premature formula, we also advance to a more calorie dense formulation (81 kcal/100 mL). Intolerance to milk feeds is not an infrequent occurrence. Tolerance of full enteral feeding, in our experience, usually is achieved between 20 and 30 days of life. In the 192 survivors mentioned previously, birth weight was regained at a mean of 12.2 ± 6.8 days (median 13 days, range 2 to 48 days). These data are comparable to that reported by Berry and associates (137).

Glucose, Calcium, and Phosphorus Homeostasis

Early hypoglycemia frequently is seen in this group of infants, because of poor glycogen reserves and the immaturity of the postnatal adaptive mechanism of endocrine and enzymatic control of glucose. In particular, ketogenesis and lipogenesis, which lead to the production of alternate fuels, are limited in very premature infants, making the infant more dependent on glucose (138,139). Hence, an infusion of dextrose at a rate of 8 to 10 mg/kg/min is necessary to maintain normoglycemia.

Hyperglycemia is a frequent and challenging complication, particularly in extremely immature infants of 23 to 24 weeks' gestation and in those with IUGR. This condition is usually the result of high glucose infusion rates, but may also occur because of incomplete suppression of hepatic glucose production in the presence of hyperglycemia, reflecting the immaturity of the regulatory mechanisms mentioned previously (140). Hyperglycemia poses the risk of osmotic diuresis, and thus of increased water loss, which eventually may have cerebral implications. Insulin can be used to control hyperglycemia. Although the exact mechanism of its action in the extremely premature infant is not completely clear, it is thought to work by decreasing hepatic production

of glucose and increasing glucose utilization by peripheral tissues.

We monitor blood glucose within 1 hour of birth and as often as required, until stabilization. We also test all urine for glycosuria. We tolerate blood glucose values up to 8 or even 10 mmol/L, provided there is no glycosuria. If an insulin infusion is used, one must remember to preflush the tubing with the infusate, because insulin adheres to plastic and, unless the binding sites are saturated prior to infusion, a very erratic infusion of insulin may occur, making the interpretation of glucose values difficult (141,142). The sudden onset of glycosuria in a previously stable infant may be an early sign of infection. Hyperglycemia also is seen frequently with initiation of dexamethasone therapy for BPD (143). Because of the slow metabolic adaptation of the ELBW infant, rapid and significant changes in glucose intake should be avoided to prevent episodes of hypo- or hyperglycemia, which can become difficult to control. Finally, for the treatment of acute and severe hypoglycemia, a bolus of no more than 200 mg/kg of dextrose can be administered as needed, although, at the same time, increasing the concentration of the intravenous glucose infusion.

Additional calcium is necessary in ELBW infants both in the early days of life and later, when their limited calcium reserves are rapidly depleted during this period of rapid growth. However, it is important to appreciate that, because of the low serum albumin of the immature infant, total serum calcium rarely exceeds 1.75 mmol/L. Measurement of ionized calcium is, of course, the ideal way to evaluate hypocalcemia. Because hypocalcemia also can induce apnea, we always verify calcium levels after the first 24 hours of life. It is important to remember that metabolic acidosis can give falsely reassuring values of serum calcium, which decline rapidly with the improvement of acid-base balance. Mechanisms involved in the early manifestations of hypocalcemia include parathyroid dysfunction, renal immaturity, and calcitonin stimulation. Treatment of hypocalcemia consists of administering 500 mg/kg/d of calcium gluconate. As soon as we introduce TPN, 300 mg/kg/d of calcium gluconate is added daily to the solution, together with multivitamins. Because maternal milk has an inadequate mineral and vitamin content, we use a human milk fortifier and vitamins. In the presence of persistent hypocalcemia, it is important to verify the levels of magnesium. The daily recommended dose of Vitamin D in ELBW infants is between 800 and 1,000 IU. (144)

Acid-Base Balance

No other investigation is ordered more frequently in ELBW infants than measurements of acid-base balance. Both the respiratory and metabolic components need frequent adjustments. Acid-base homeostasis varies in relation to the degree of renal maturity. The renal threshold of bicarbonate can be as low as 15 mEq/L. Hence, in ELBW infants,

P.472

there is often a need for additional buffering with sodium bicarbonate. The need for supplemental sodium bicarbonate also is frequent with high amounts of amino acids in the TPN. We initiate correction of the acid-base balance as soon as the base deficit exceeds 5 to 6 mEq/L. Because TPN contains calcium, the addition of sodium bicarbonate may induce precipitation. For this reason, we have elected to administer sodium bicarbonate via slow push of 0.5 mEq/kg every 2 to 6 hours, according to the severity of the metabolic acidosis, while evaluating the progress of correction and adjusting the frequency of administration accordingly. With this approach, we do not need to discontinue intravenous alimentation, nor do we need to start a second intravenous line. Sodium acetate added to the TPN as an additional buffer, is an alternative treatment to acidosis (145). The late metabolic acidosis of prematurity also is related to a combination of increased nitrogen load and low renal threshold.

Although acidosis is the main concern in the early days of life, later on, many of these tiny babies may develop a metabolic alkalosis as a result of the administration of diuretics, in combination with fluid restriction, as part of the management of CLD. On occasion, we have found it helpful to administer acetazolamide at a dosage of 2.5 mg/kg every 12 hours to overcome a significant metabolic alkalosis (pH more than 7.45).

Jaundice

Rarely will an infant weighing less than 1,000 g escape the need for phototherapy. Hepatic immaturity and reduced erythrocyte lifespan, blood group incompatibilities, extensive extravasation of blood, and increased enterohepatic circulation as a result of poor bowel motility all contribute to the fact that ELBW infants are very prone to develop jaundice. Because the serum bilirubin binding capacity is decreased in premature infants as a result of the lower serum albumin, the level at which toxicity for the brain and acoustic nerves may occur is much lower than that of the more mature infant. Guidelines for the initiation of phototherapy have been

proposed in the past and have undergone frequent revisions. However, some basic principles are universally accepted and govern the management of jaundice. These include age of the baby in hours or days from birth, gestational age, presence of a hemolytic disorder, degree of bruising or other extravasation of blood, and level of serum albumin. We find it helpful in our decision to initiate or discontinue phototherapy to estimate the serum binding capacity from the level of serum albumin (146). Based on this principle, we have not seen a single case of kernicterus clinically or on autopsy material. Although we do not initiate phototherapy immediately after birth, we believe that relatively early phototherapy can decrease significantly the need for exchange transfusion, which incidentally is poorly tolerated in the very immature infant. We generally initiate phototherapy when the bilirubin level has reached 80 micromol/L in the first 24 hours of life, or if we note an increment of more than 40 micromol/L/d. When phototherapy is used, it is important to increase the fluid intake by 15% to 20% to avoid excessive insensible water loss. When the bilirubin level approaches the exchange transfusion level, it is important to avoid variations in acid-base balance, high levels of lipid infusion, hypothermia, and certain medications, which may compete with and displace bilirubin from albumin, thus precipitating kernicterus.

MAJOR MORBIDITIES OF THE EXTREMELY LOW-BIRTH-WEIGHT INFANT

Neurologic Disorders

The neurologic examination of the newborn infant is related to gestational age and is affected greatly by any disturbance in the CNS. The ELBW infant is typically hypotonic. The primitive reflexes are absent but brain stem function (corneal, gag, oculocephalic reflexes, facial grimacing, nasal tickle) can be tested. Neuronal migration usually is completed by 24 weeks of gestation, but synaptic development and myelination are just beginning at this age.

Intraventricular Hemorrhage

IVH is a major morbidity for the ELBW infant, with serious potential sequelae in surviving infants, which include hemorrhagic periventricular infarction, posthemorrhagic hydrocephalus, seizures, PVL, and in the long-term, neurosensory and neurodevelopmental impairments. Despite modern advances, this remains a common problem, with an incidence of up to 44% of ELBW cohorts (147,148). Fortunately, the majority of ELBW infants develop less severe IVH (Grade I or II). There is evidence that the overall incidence of IVH may be declining in recent years (149). In a study of a large cohort of infants with birth weight of 500-1500 g from the National Institute of Child Health and Human Development (NICHD) Neonatal Network, Shankaran and associates (147) observed a significant decrease in severe intracranial hemorrhage (Grades III and IV) from 19% to 15% over a 3-year period. Significant variation in the rates of all grades of IVH has been observed between centers.

The degree of prematurity is a very strong predictor for IVH, with gestational age and birth weight inversely correlated with the incidence and severity of IVH. Thus, the smallest and youngest infants are at greatest risk for more severe IVH. Recent reports described the incidence of Grades III and IV IVH at 9% to 13% for ELBW infants, in contrast to 2% to 5% for infants with birth weights greater than 1,000 g. Severe IVH was found in 16% of infants with gestational age at birth less than 25 weeks, in contrast to about 1% to 2% in which gestation was greater than 25 weeks.

In our center, among 253 ELBW infants born between 1995 and 2002, we observed an overall incidence of 24.4%

P.473

for any IVH and 7.6% for severe IVH (Grades III and IV) (Table 25-8). It is important in assessing the incidence of IVH to know whether it is representative of the whole population born weighing less than 1,000 grams or only among survivors, in which the incidence of IVH would be much lower. Indeed, among our survivors, the incidence of IVH was 16.6% and for grades III and IV, 4.7% (Table 25-9).

The variations in the incidence of IVH could also be explained by the multifactorial pathogenesis proposed by Volpe (150,151), describing intravascular, vascular and extravascular factors, superimposed on the fragility of the germinal matrix and the limited cerebral blood flow autoregulation in ELBW infants.

We are particularly attentive to rapid stabilization, avoidance of hypo- and hyperoxia, and hypo- and hypercarbia, maintenance of normoglycemia, and control of the environment with the use of high humidity in the first few days of life to prevent excessive water loss, hypernatremia and hyperosmolarity. We attempt to

maximize synchronization of the ventilator breaths to the infant's own respiratory efforts. We use the Ballard closed suction circuit, thus avoiding frequent disconnection of the infant from the ventilator. We avoid volume expanders, unless there is documented blood loss or significant hypotension. We favor early medical PDA closure. Finally, we minimize handling of the infant, with clustering of care or use of sedative/analgesics as warranted to decrease significant discomfort and pain. We also avoid significant apnea by initiating prompt supportive management, such as early nasal CPAP/ventilation, methylxanthines or mechanical ventilation, as necessary, and by rapid diagnosis and treatment of causative factors, such as infection, hypoglycemia, and hypocalcemia.

IVH may present acutely, leading to shock and death. It may be clinically silent or, more commonly, it may present with worsening cardiorespiratory instability. The time of occurrence of IVH has been well investigated and our experience is similar to published data. About 50% of bleeds occur during the first day of life, 25% during the second day, and 15% on the third day of life. (152). It is unusual for an infant to develop IVH after 7 days of life.

Ultrasonography is the most reliable and safest neuroimaging technique to diagnose IVH in premature infants (153). We obtain a cranial ultrasound in the first 24 hours of life. If no IVH is detected, the study is repeated 1 week later, or sooner if the infant suffers from any acute event in the interim. If pathology is present, ultrasonography may be repeated at intervals of 48 to 72 hours, until stabilization of the intracranial pathology and as clinically warranted to facilitate parental counseling and decisions for care.

The immediate management of IVH involves stabilization of the cardiovascular system, correction of any bleeding diathesis, and monitoring for hyperbilirubinemia and hyperkalemia. Careful neurologic examination and serial measurements of the head circumference along with serial cranial ultrasounds must be planned for the early detection and management of progressive posthemorrhagic hydrocephalus. If there is rapid dilatation of the ventricles, neurosurgical intervention may be necessary for temporary or permanent drainage of the cerebrospinal fluid. We have not found repeated lumbar punctures to be effective as a temporizing technique to control progressive posthemorrhagic hydrocephalus.

Prognosis for mortality and long-term morbidity is related to the extent of the brain injury, hallmarked primarily by the extent of the bleed. Severe IVH with periventricular hemorrhagic ischemia in the ELBW cohort has a mortality of more than 50% and leads to progressive ventricular dilatation in 80% of infants. Many studies have confirmed the significant association between Grade IV IVH, periventricular leukomalacia and ventriculomegaly with cerebral palsy. One study gave an odds ratio (OR) of 15.4 (95% CI, 7.6-31.1) for a diagnosis of CP at 2 to 9 years of age in the presence of Grade IV IVH, PVL, or ventriculomegaly. Furthermore, Grade IV IVH and moderate to severe ventriculomegaly were strongly associated with the risk of mental retardation or neuropsychiatric disorders at 2 to 9 years, with the odds ratio ranging from 9.97 to 19.0 (154,155).

We believe that transport *in utero*, antenatal steroids, judicious obstetrical management, and expert delivery room stabilization and NICU care are important preventative measures against IVH. Pharmacologic strategies, specifically indomethacin administered within the first 12 hours of birth in ELBW infants, can reduce the incidence of severe IVH (112), but without significant long-term benefit at 18 months and hence is not current or recommended practice in our center (148). Further innovative research is needed to impact this serious complication for ELBW infants.

Periventricular Leukomalacia

PVL is the other significant injury of the developing premature brain, with an incidence estimated to range from 4% to 15%. In our center, PVL is uncommon, with an incidence of 5.5%. It is believed to be a consequence of hypoxic-ischemic events, leading to necrosis of the white matter (156). The most commonly affected areas are the white matter near the trigone of the lateral ventricles and around the Foramen of Monro. Although often diagnosed in association with IVH, PVL may also occur independently as an isolated lesion. Sometimes, the origin is clearly intrauterine. Chorioamnionitis is recognized as a risk factor for PVL (156). Postnatally acquired PVL is seen more frequently in male infants, in infants with severe RDS, in infants with septicemia, and in those with significant cardiovascular instability or apnea (156).

Cystic PVL among preterm infants is the single best predictor of adverse long-term neurologic outcomes (157). The frequency of cerebral palsy developing after cystic PVL has been reported to vary between 62 and 100%. (158). Its characteristic manifestation is a spastic paresis involving predominantly the lower extremities (spastic diplegia), and it is usually diagnosed in the first 2 years of life.

Although uncommon, severe disability with spastic quadriplegia, strabismus and impaired visual acuity, developmental delays, cognitive impairment, and seizures may be observed in early childhood.

The diagnosis of PVL is made primarily by cranial ultrasonography. When the lesions have occurred in utero, it is possible to make the diagnosis soon after birth, with the first or second studies. However, prenatally or postnatally acquired PVL is usually diagnosed by 3 to 6 weeks or later, as time is necessary to develop the cavitation of the injured periventricular white matter. This ultrasound, usually performed prior to discharge home, provides important prognostic information for the neurodevelopment of the infant, facilitating parental counseling and planning for long-term multidisciplinary follow-up.

Magnetic resonance imaging (MRI) may allow greater detection of white matter abnormalities than ultrasound. However, there have been insufficient follow-up studies to indicate whether the additional findings provide more information about neurodevelopmental prognosis. Therefore, the routine use of MRI and other techniques of neuroimaging for the detection of PVL and other brain injury in the ELBW is not yet a recommendation, and should be an avenue for future research. (155). Because of the later appearance of cystic lesions or residual ventricular dilatation secondary to involution of the periventricular white matter and resorption of the cysts, it is important to repeat the cranial ultrasound study between 36 and 40 weeks' postmenstrual age (155).

Seizures

Seizures are relatively rare in the ELBW infant, despite many potential risk factors, such as intracranial hemorrhage, hypoglycemia, and electrolyte disturbances. Compared to full-term infants, seizures in very premature infants are even more challenging to diagnose, due primarily to cortical immaturity coherent with the gestational age. Subtle, tonic or myoclonic seizures may be difficult to differentiate from the general uncoordinated movements, tremulousness and myoclonic jerks often seen in extremely premature infants. The etiologies of seizures in the ELBW infant, as for the term infant, include CNS pathology, metabolic derangements (e.g. hypoglycemia, hypocalcemia, severe hyponatremia), infection, and drug withdrawal.

The investigation and management of seizures is described comprehensively elsewhere. Suffice it to say that the electroencephalogram (EEG) can be difficult to interpret, because a conventional surface EEG may not detect the electrical activity of deeper cortical and subcortical structures. The treatment of seizures in ELBW infants involves correction of any metabolic derangements, appropriate antibiotic therapy for infection as warranted, and control of seizure activity to avoid brain injury as a result of alteration in cerebral energy metabolism. As for term infants, the prognosis in the face of neonatal seizures depends primarily on the underlying cause. However, the prognosis is generally worse for ELBW with seizures, compared to term infants. Our preference for medical control of seizures is with phenobarbital at a loading dose of 20 mg/kg, which can be increased by another 10 mg/kg if control is not achieved (maximum loading dose 30-40 mg/kg). If control is not achieved, phenytoin is added, at a loading dose of 15 mg/kg (maximum loading dose 30-40 mg/kg). Rarely, the use of sedative-hypnotic anticonvulsants, such as lorazepam (0.05-0.1 mg/kg/dose) or diazepam (0.1-0.2 mg/kg/dose), and rectal paraldehyde (0.3 ml/kg, diluted 1:2 in mineral oil) may be considered for resistant seizures. There should be proper attention to adverse effects of these agents on very premature infants, such as the potential exacerbation of jaundice secondary to bilirubin displacement from its albumin-binding site by the sodium benzoate in diazepam and the abnormal movements (muscle twitchiness, myoclonus) seen with lorazepam (159,160).

Hearing Impairment

ELBW infants are at increased risk for hearing impairment because of multisystemic illness and the frequent use of potentially ototoxic medications, such as aminoglycosides and diuretics. The estimated prevalence of hearing impairments in extremely immature (< 26 weeks gestation) survivors ranges from 1.7% to 3.8%. (161). In the TIPP study, the prevalence of hearing loss requiring amplification for surviving ELBW infants was 2% (20/876 infants). (162)

Reporting on the outcomes of VLBW infants at age 19 years, Ericson and Kallen found high rates of persistent hearing impairment, with the odds ratio for severe hearing loss being 2.5 (95% CI, 1.2-5.0) (163). In 1994, the Joint Committee on Infant Hearing issued a Position Statement recommending that all infants born with birth weight less than 1500 grams undergo auditory screening. (164). Early diagnosis of hearing loss and amplification with hearing aids as early as 6 months of age, together with speech therapy, are essential to reduce the progressive disability in speech and language development caused by hearing impairment. The tests commonly used to detect hearing loss in the ELBW include the evoked auditory brainstem responses (ABR) and

otoacoustic emission (OAE). (165). In our unit, a hearing screen is obtained prior to discharge using the OAE, with a diagnostic ABR confirming abnormal screening results.

Hematologic Disorders

Anemia

Low iron stores, multiple blood tests, blood loss as a result of either organ hemorrhage or hemolysis, and rapid growth are some of the factors that make anemia a practically unavoidable hematologic complication for any ELBW infant. The ELBW infant usually has a hemoglobin concentration of 140 to 160 g/L at birth. Those who have suffered from IUGR may have a hemoglobin concentration as high

P.475

as 200 g/L. Their blood volume is 85 to 90 mL/kg. However, these values can be affected by the extent of placental transfusion at delivery (166). We generally allow for a 10-second placental transfusion in ELBW infants not suffering from IUGR.

The need for transfusion of blood products is a source of anxiety for parents. Any measure that can decrease the frequency and severity of anemia should be implemented. These measures include limiting blood tests to those essential for appropriate management of the infant, use of microtechniques, and use of pulse oximetry and other transcutaneous devices to monitor partial pressure of oxygen (PO₂) and PCO₂.

Although the administration of erythropoietin with iron supplementation does not eliminate completely the need for blood transfusion, it can reduce the number of transfusions (167,168). The lack of universal use of erythropoietin is probably as a result of the fact that it is expensive and that, at least in sick infants, it does not eliminate the need for blood transfusions.

To decrease the risk of infection, one unit of packed red cells from a single, properly screened donor, divided into several small bags (satellite bags), could be used for the same infant for several weeks (169). We have found this approach useful and more reassuring to parents.

We also have implemented a protocol for direct blood donation from compatible parents (father or mother) who are cytomegalovirus, human immunodeficiency virus, and hepatitis B and C negative. Blood is irradiated prior to transfusion to avoid graft-vs.-host disease. However, preparation of such blood requires time. The issue of blood transfusion is discussed with the family, antenatally whenever possible, or soon after admission of the infant to the NICU, and the parental decision is documented in the chart.

Our guidelines for the management of anemia with blood transfusion in ELBW infants are as follows: (a) infants born with severe anemia and/or hypovolemic shock; (b) replacement of blood taken from an umbilical line in the first days of life for frequent blood monitoring and exceeding 10% of the baby's blood volume; (c) maintenance of hematocrit between 0.35 and 0.40 during the first week of life and between 0.30 and 0.35 during the second week; (d) maintenance of hematocrit greater than 0.35 in infants with PDA and in those still having severe lung disease in the second week of life; (e) in infants with CLD, we maintain the hematocrit between 0.30 and 0.35; (f) after the second week of life, the hemoglobin is allowed to decrease as long as the baby has no signs of symptomatic anemia such as poor feedings, high output cardiac failure, apnea, edema, failure to gain weight, tachycardia, and tachypnea. Finally, 4 to 6 mg/kg/d of elemental iron is commenced at 4 to 6 weeks of life.

When transfusion is necessary, it should be administered slowly, especially during the first weeks of life, when any acute change in blood volume may be translated into changes in cerebral blood flow, thus predisposing to IVH, and when there is cardiorespiratory instability. We usually transfuse a volume of 10 mL/kg of packed red blood cells, which may be repeated at 12 hours, according to the need. Furosemide 1 mg/kg can be given with transfusions.

Hemostasis and Bleeding Diathesis

Vitamin K and vitamin-K-dependent coagulation factors are present at low concentrations at birth (170). As a result, all of our ELBW infants receive 0.5 mg of vitamin K intramuscularly immediately after delivery. Additionally, parenteral nutrition is supplemented with vitamin K.

Conditions requiring immediate administration of additional vitamin K include hemorrhagic pulmonary edema, pulmonary or gastric hemorrhage, and disseminated intravascular coagulation. The management of these

conditions often will require, additionally to vitamin K, administration of fresh frozen plasma, transfusion of platelets, and treatment of the underlying condition.

Thrombocytopenia (platelet count less than $100 \times 10^9/L$) is commonly observed in ELBW infants and, if severe enough, may put the infant at risk for IVH. Thrombocytopenia is more frequent in infants born to preeclamptic mothers and infants with IUGR (171). Accelerated platelet destruction is seen in infants with sepsis, indwelling catheters, or active bleeding, or following exchange transfusion. In practice we transfuse platelets to infants with a platelet count below 30 to $40 \times 10^9/L$. However, in case of active bleeding and a platelet count less than $60 \times 10^9/L$, transfusion of platelets should be considered.

Chronic Lung Disease

A large number of ELBW infants continue to require oxygen supplementation at one month of life, and many of them will remain oxygen dependent beyond 36 weeks of postmenstrual age. Both dates have been proposed in the literature to define CLD. It is also not rare to see a number of infants discharged on home oxygen programs. Up to 70% of infants weighing less than 1000 g have been reported to develop CLD, and an important number of survivors are discharged home on supplemental oxygen (172). Thus, for many ELBW infants, CLD seems practically unavoidable.

It is beyond the scope of this chapter to discuss the pathogenesis and pathophysiology of CLD, and we refer the reader to the appropriate chapter. Hence, we will limit our discussion to a few aspects of the problem that are more specific to the ELBW infant. CLD encompasses more than the classic BPD described by Northway and associates in 1969 (173). Over the years, we have observed two distinct groups of infants developing CLD (97). The first group consists of infants with severe RDS, who require early intubation and mechanical ventilation. In our center, close to 65% of these infants receive exogenous surfactant. This is followed by a rapid decrease in oxygen requirement and need for ventilatory support. By day 3 of life, the majority of these infants are breathing room air or require a minimal amount of supplemental oxygen. However, in most of these

P.476

infants, this improvement is transient, as ventilatory support and oxygen supplementation become necessary after 7 to 10 days of life, with eventual resolution of the respiratory problem over the ensuing weeks. The period of deterioration is usually accompanied by the presence of increased airway secretions, which require frequent toilet of the airways. The second group is composed of infants who had no initial lung pathology, and who required intubation for immaturity and/or apnea, but needed only minimal oxygen supplementation, if any. A number of these infants go on to develop clinical and radiological signs of CLD. They follow the same pattern of deterioration, and eventual improvement as the group with initial lung pathology. Fig. 25-1 indicates the bimodal fluctuation in oxygen requirement among 120 survivors of birth weight less than 1000 g in our center between 1993 and 1997.

Figure 25-1 Variation in O₂ requirement in 120 survivors. RA, room air. 500-1000 g (1993-97).

In our population of ELBW survivors, 63.6% required oxygen supplementation at 28 days of age, and 31.2% at

36 weeks' postmenstrual age, with 5.9% of infants requiring supplemental oxygen after discharge home (Table 25-9).

The proposed management of the infant with CLD is based on a combination of the following interventions:

Respiratory support.

Acceptance of a PCO₂ value up to 65 mm Hg, provided that the pH is at least around 7.25. Once the infant attains a postmenstrual age of 35 weeks, we aim for a steady oxygen saturation above 90% on pulse oximetry to prevent cor pulmonale. The hematocrit is generally kept above 0.35.

Prevention of fluid overload.

Early closure of the PDA, fluid restriction to 120 to 130 mL/kg/d, or even less in some cases, administration of diuretics on a chronic basis, i.e., hydrochlorothiazide 1 mg/kg/dose and spironolactone 1 mg/kg/dose every 12 hours. Additional diuresis can be obtained with furosemide, when necessary.

Nutritional support.

It has been increasingly recognized that infants with CLD require particular attention to nutritional support. These infants may fail to thrive as a result of an increase in energy expenditure associated with an increased work of breathing, and their enteric intake may be suboptimal as a result of frequently associated feeding intolerance and gastroesophageal reflux. Lung growth and repair of damaged pulmonary tissue requires an adequate intake of all nutrients (174). We thus aim for an energy intake of 120 to 140 kcal/kg/d, encourage early initiation of enteral feeds, and use diuretics as needed to eliminate excess fluid.

Control of nosocomial infections.

As ETT tubes frequently become colonized, it is important to periodically send secretions for culture and sensitivity to antibiotics. However, we do not treat the colonized infant if the condition remains stable, but rather monitor the infant carefully for clinical and laboratory signs compatible with infection. We may treat, however, infants colonized with ureaplasma, mycoplasma, or chlamydia with erythromycin if the respiratory status presents an unusual progression.

Control of inflammation.

Because an inflammatory response seems to be an important mechanism leading to CLD, corticosteroids had been used extensively during the 1990s to decrease pulmonary edema, prevent inflammation, and increase surfactant and antioxidant production. Systemic dexamethasone had been the drug of choice, and various protocols were proposed in terms of onset and duration of treatment (175,176). Most infants responded favorably, with rapid extubation and a significant decrease in oxygen requirement. Initially, the side-effects of this therapy were believed to be limited to transient hypertension and hyperglycemia, an increased risk of infection, reversible hypertrophic cardiomyopathy, and a flattening of the growth curve.

With the onset of the new millennium, new data became available regarding the long-term outcomes of steroid-treated infants. Of note were some serious concerns that corticosteroid therapy may be independently associated with poor brain growth and with the

P.477

development of cerebral palsy (177). This new information has resulted in a joint statement by the AAP and Canadian Pediatric Society, in which the routine use of systemic dexamethasone for the prevention or treatment of CLD in VLBW infants is no longer recommended (178). We currently limit the administration of systemic steroids to the most unstable ventilator-dependent infants with severe, life-threatening CLD, and the duration of therapy is limited to a three-day pulse of dexamethasone of 0.1 to 0.2 mg/kg/day, after parental consultation.

It remains to be clarified whether less potent systemic corticosteroids, such as hydrocortisone, administered at very low doses, may have a role to play in the future treatment of CLD (179). The same can be said of inhaled steroid preparations such as budesonide, the efficacy of which has likely been limited to date by inadequate methods of pulmonary delivery (180,181).

Bronchodilators.

In infants with decreased air entry and wheezing, we have found that the administration of nebulized salbutamol at a dose of 1.25 mg diluted in 2.5mL physiologic saline solution, can be helpful (182). We have often observed that, immediately after a treatment, air entry improves and clearance of secretions becomes easier, particularly in combination with chest physiotherapy.

Home Oxygen Therapy

Despite maximum therapy, some infants remain dependent on supplemental oxygen beyond 40 weeks' postmenstrual age. In our center, such infants are evaluated and followed after discharge by a pediatric pulmonologist. The parents undergo specific training for home oxygen therapy. Prior to discharge, participation is organized with a multidisciplinary follow-up program, which include in its membership the pediatric pulmonologist, nutritionist and occupational therapist. For the years 1995 to 2002, the incidence of home oxygen therapy in our surviving ELBW infants was 5.9%. In comparison, the incidence of supplemental oxygen at discharge to home in the TIPP study was 18% to 20% (148).

Necrotizing Enterocolitis

NEC is the major GI disorder that selectively affects the sick premature infant. Its etiology is multifactorial and includes suspected predisposing factors such as intestinal immaturity, poor intestinal motility, hypoxemia, ischemia, PDA, umbilical catheter placement, IUGR, feeding practices, exchange transfusion, and systemic infections (183).

Antenatal administration of steroids appears to accelerate intestinal maturation and provides additional protection against NEC to the prematurely born infant (184). The incidence of NEC varies widely, from center to center, and is estimated at between 9% and 25% for ELBW infants (185). Our incidence of surgical NEC between 1995 and 2002 was 2.6% (Table 25-8). Variation in the incidence probably reflects differences in diagnostic criteria and clinical practices. Indeed, the successful reduction in the incidence of NEC is related essentially to prevention, by avoiding all known predisposing factors and by intervening and interrupting the cascade of progression of the disease at the earliest signs, which many of us like to call "pre-NEC." These signs include increased gastric residuals, abdominal distension, cardiovascular instability, deterioration of skin perfusion, clusters of apneic spells, and unexplained glycosuria and lipemia. In the presence of these signs and depending on their severity, it is our practice either temporarily to discontinue feedings or to decrease the volume by 50% and reevaluate the situation in a few hours. In the presence of further abdominal distension, we do not hesitate to discontinue oral feeds and insert an orogastric catheter under continuous low suction. In the majority of cases of benign distension, the intestinal decompression reestablishes the intestinal vascular supply and, within 2 to 4 hours, the abdomen returns to normal. In an otherwise healthy looking and active infant, we do not necessarily initiate therapy with antibiotics unless there is blood in the stools or the abdominal radiograph demonstrates, besides dilated bowel loops, signs compatible with evolving NEC, such as pneumatosis intestinalis. In these cases, a septic workup is performed and antibiotics are begun immediately. Our initial treatment is a combination of gentamicin and ampicillin, to which clindamycin is added in case of additional deterioration, or when the presentation is that of overwhelming NEC. One of the most distressing situations in neonatology occurs when a previously stable premature infant, in whom milk intake has progressed well, suddenly develops fulminant abdominal distension accompanied by sepsis, profound metabolic acidosis, neutropenia, thrombocytopenia, and cardiovascular shock followed by rapid death. Fortunately, this dramatic clinical presentation is rare, as it is difficult to anticipate or to prevent, let alone to treat.

The management of NEC, besides antibiotics and orogastric suction, requires close monitoring of vital signs, frequent abdominal radiographs, with lateral views to visualize the possible presence of free air in the peritoneal cavity, correction of metabolic abnormalities, and cardiovascular support with volume expanders and vasopressors. Many infants with NEC may require assisted ventilation, as apnea frequently complicates the situation. TPN is also an integral part of the management of these infants. Persistent intractable metabolic acidosis, severe neutropenia and thrombocytopenia are ominous prognostic signs and usually reflect extensive intestinal necrosis.

For infants managed medically, the time of reintroduction of oral feeds is a critical one. We usually reinstate enteric feeds after 7 to 14 days of therapy, depending on the rapidity of resolution of clinical and radiologic signs. The presence of bowel sounds, a stable condition, and a well-perfused infant without significant apnea are the basic requirements for starting oral feeds. We initially use an elemental formula and progress slowly to full

present several weeks after the initial episode, with milk intolerance, vomiting, and abdominal distension. Strictures may also be the result of subclinical injury of the intestine and can be seen in infants in whom the diagnosis of NEC was never made before.

In summary, much still needs to be learned about NEC, its prevention, and its management. In the meantime, every neonatal unit needs to develop its own philosophy and approach to reduce the risks of NEC. In our view, strategies that decrease the risk of NEC include antenatal administration of steroids, use of mother's own milk, early priming of the GI system with a very small volume of milk prior to the advancement of feedings, and, above all, careful observation of the infant's condition, with reduction or temporary discontinuation of feeds and intestinal decompression at the earliest suspicion.

Inguinal Hernias

Inguinal hernias occur frequently in ELBW infants, with a reported incidence between 14 and 30% (186,187). In our center, the incidence of inguinal hernia diagnosed prior to discharge home ranges from 10% to 15%. Predisposing factors are weakness of the abdominal musculature and tissues of the inguinal canal and increased intraabdominal pressure, especially in the presence of CLD. They can present as early as 2 weeks of age, often becoming very large and causing intermittent feeding intolerance, abdominal distension or bouts of crying and irritability. Surgical repair must be planned in consultation with a Pediatric Surgeon, preferably prior to discharge home where appropriate. Recurrence in the first year of life is a common observation.

Retinopathy of Prematurity

ROP remains a frequently diagnosed morbidity for ELBW infants and may result in significant visual impairment, ranging from correctable myopia and astigmatism to bilateral blindness. The incidence and severity of ROP is inversely proportional to birth weight and gestational age (188,189). Thus, as survival has increased, so has the number of surviving ELBW infants with severe ROP, particularly in infants born at the limits of viability at 23 and 24 weeks. Severe ROP is defined as unilateral or bilateral stage 4 or 5 disease or disease requiring laser or cryotherapy in at least one eye. Schmidt et al found an incidence of about 7% in a surviving ELBW cohort (162). However, blindness has become a rare outcome, with an estimated prevalence of 2% in ELBW survivors (162). The incidence and severity of ROP in our center is shown in Table 25-9.

The etiology and pathogenesis are complex and discussed in greater detail elsewhere in this book. Arterial oxygen tension remains a great risk factor, despite the introduction of noninvasive continuous O₂ monitors, such as pulse oximetry, and the presumed tighter control of the arterial pO₂. In addition to immaturity, we have recently reported that the combination of IUGR and severe prematurity further increases the risk of developing severe ROP (26).

Based on current knowledge of predisposing factors and years of careful observation, we have developed a policy of keeping stringent control of the PaO₂ below 50 mm Hg for all infants with birth weight less than 1,000 g in the first weeks of life. We have established guidelines for pulse oximetry, primarily based on gestational age and birth weight. Our long-standing practice to accept lower limits of arterial oxygen saturation (SaO₂) and to avoid brisk variations is in keeping with recent publications supporting the safety of this practice in an attempt to decrease the incidence of ROP (190). Furthermore, avoidance of swings from normoxemia to hyperoxemia and hypoxemia has been reported to decrease the incidence of ROP (191). For ELBW infants, the upper limit of SaO₂ is set at 93% and we try to avoid rapid fluctuations in PaO₂. We favor permissive hypercapnia, although we avoid prolonged hypercapnia, with values of pCO₂ greater than 55 mm Hg in the first weeks of life. We have a low tolerance of recurrent apnea associated with significant oxygen desaturation. In such cases, we do not hesitate to use respiratory support (nasal CPAP/ventilation; endotracheal ventilation) if the episodes are not readily controlled by respiratory stimulant medication, e.g. caffeine.

Early diagnosis and treatment of prethreshold and threshold ROP is required to preserve maximal visual acuity and prevent progression to blindness. This is achieved by expert serial ophthalmologic examinations as described by the joint statement of the AAP, the American Association of Pediatric Ophthalmology and Strabismus, and the Academy of Ophthalmology, such that all ELBW infants should be screened for ROP, with

the first examination at 4 weeks of postnatal age or between 31 and 33 weeks postmenstrual age (192).

Like others, we have observed a few unpredicted cases of "rush" disease developing early, between 30 and 33 weeks, or progressing at later corrected gestational ages after a period of quiescence at stage 1 or 2. Consequently, in our center, we schedule the first ophthalmologic screen at 4 weeks after birth or at 30 weeks of postmenstrual age, whichever comes first. This practice is coherent with a recent publication by Subhani and associates (193), which recommended earlier screening in ELBW infants, beginning by 5 to 6 weeks of age using the postnatal age criterion and not waiting for the corrected postmenstrual age. Follow-up examinations are scheduled depending on the findings (e.g., degree of vascularization, zone and stage of retinal changes, tortuosity, plus disease) at intervals of 1 to 2 weeks. If the disease process seems to accelerate, examinations are performed twice a week. Infants with threshold and plus disease are candidates for laser therapy. In our center, 6% of ELBW underwent laser therapy in the past few years with satisfactory results.

Apnea of Prematurity

Apnea of prematurity is a feature of nearly all infants with a birth weight less than 1,000 g. Its incidence and frequency decrease with advancing gestational age, but at

P.479

times it may be seen up to 42 weeks of postmenstrual age (194). In the ELBW population, it is a frequent indication for mechanical ventilation, thus exposing these infants to potential complications related to respiratory support.

Apnea usually is defined as a cessation of breathing for 20 seconds or more, or of a shorter duration if associated with cyanosis or bradycardia. Different patterns have been observed in premature infants: central apnea (absent breathing movements), obstructive apnea (breathing movements, but no airflow) or mixed apnea (central and obstructive) (195). ELBW infants are particularly prone to obstructive apnea, especially when in supine position with the neck in the midline, because of the weakness of the muscles of the oropharynx. Apnea as a result of obstruction of the lower airways also has been reported, suggesting immaturity of lung mechanics. The cessation of gas exchange during a significant apneic episode is manifested by hypoxemia and/or bradycardia. Recurrent episodes of apnea may affect neurodevelopmental outcome. Although it is difficult to relate frequency and severity of apnea to outcome, one can only stress the importance of monitoring these infants by pulse oximetry. Because apneic episodes can occur in premature infants as a result a variety of underlying diseases, investigation of other pathologic causes must be undertaken before diagnosing apnea of prematurity.

Patient management will depend on the severity and frequency of apneic episodes. Methylxanthines, which stimulate the respiratory center, are the most effective pharmacologic treatment for apnea of prematurity. Methylxanthines, aside from reducing the frequency of apneic pauses, have other actions that are equally important. They increase respiratory rate, tidal volume, and minute ventilation, and they decrease diaphragmatic fatigue. They also increase the sensitivity of the chemoreceptors to carbon dioxide and improve blood pressure and cardiac output (196,197,198). Treatment with either aminophylline or theophylline is effective but needs to be repeated two to four times per day. In our center, we treat apnea of prematurity with caffeine, which is the metabolite of theophylline (199). We found that caffeine has fewer GI side effects and causes less CNS irritability. It also has a much broader therapeutic index and achieves more stable plasma levels. In view of its long half-life, it only needs to be given once daily. We use caffeine base at a loading dose of 10 mg/kg, followed 24 hours later by a single daily dose of 2.5 mg/kg. Caffeine can be administered intravenously or orally. When given intravenously, the injection should be performed slowly, as it may otherwise be quite painful. We verify the serum level of caffeine in cases of intractable apnea or in the presence of clinical signs of toxicity. Caffeine is also the drug of choice when we start weaning an infant from the mechanical ventilator. The therapeutic range of serum caffeine levels is very broad, between 23 and 104 micromol/L, and the mean half-life is 102 hours.

If we cannot control apnea in a satisfactory manner with caffeine, we rapidly initiate nasal CPAP or nasal ventilation, which, in combination with caffeine, offers very good stabilization in the vast majority of cases. Finally, if apnea persists, we do not hesitate to intubate and ventilate such an infant with low pressures and rates. In infants with persisting apnea and desaturations after 40 weeks' postmenstrual age, we perform a respirogram prior to discharging them home on xanthines and a home monitoring program. It is important, before closing the discussion on apnea, to underline the fact that pharmacologic treatment of apnea should be considered only after proper investigation has eliminated any underlying condition requiring specific treatment, such as anemia, infection, or metabolic disorders.

Neonatal Infections

The ELBW infant is particularly vulnerable to bacterial, viral, and fungal infections. A significant number of premature labors are likely precipitated by infection. Chorioamnionitis is a frequent finding after a premature birth, particularly in the presence of prolonged rupture of membranes. As the clinical signs of infection are often nonspecific, the index of suspicion and the concern about the possibility of intrauterine infection should be very high in the presence of a premature birth. Hence, screening for infection should be an integral part of the evaluation of the ELBW infant. The diagnosis of neonatal infection can sometimes be difficult, as early neonatal infection often manifests with respiratory symptomatology, which is also the overwhelming pathology of prematurity. This is particularly true in the presence of group B streptococcal pneumonia, which is often indistinguishable clinically and radiologically from RDS (200). However, early appearance of recurrent apnea, poor perfusion, hypotension, and significant metabolic acidosis, often in the presence of an abnormal leukocyte count, are very strong elements in favor of infection.

In symptomatic infants, we obtain a skin surface culture, blood culture, and leukocyte count, and we initiate broad-spectrum antibiotic coverage with ampicillin and gentamicin. We do not routinely perform a lumbar puncture on admission. However, if the blood culture is positive or if there is clinical evidence of deterioration compatible with meningitis, then a lumbar puncture is performed. If the result suggests the presence of meningitis, we adjust the duration of therapy, antibiotic coverage and dosage accordingly. If the infant's condition improves rapidly, the blood culture is negative, and the acute phase reactants are normal, we discontinue antibiotics after 2 to 5 days.

Nosocomial infections are not rare among infants whose hospitalization can be as long as 3 to 4 months. Aside from the immaturity of the immune system, predisposing factors include ventilator care, intravenous alimentation via central or peripheral lines, and exposure to extensive handling. In recent years, *S. epidermidis* has emerged as the most common organism (201,202). However, in ventilated infants and in those with CLD, *Pseudomonas*, *Klebsiella*, and *S. aureus* are the predominant organisms found. Fungal infections are not rare and should be suspected in the presence

P.480

of unexplained thrombocytopenia, hyperthermia (203), and clinical signs of progressive deterioration.

It is common practice to initiate intravenous therapy with vancomycin and a third-generation cephalosporin on suspicion of nosocomial sepsis, particularly when the infant is critically ill. One must, however, bear in mind that the widespread use of antibiotics in any neonatal intensive care unit may rapidly result in the development of drug-resistant bacterial strains (204,205,206). Another acceptable approach in more stable infants is to use a combination of cloxacillin and an aminoglycoside such as gentamicin, with subsequent adjustment of antibiotic therapy according to bacterial susceptibility testing results.

It is our policy not to treat colonization of ET tubes with antibiotics unless there are signs of pneumonia or systemic infection. In the absence of signs of infection, the vast majority of our ventilated infants are left without antibiotic coverage under close observation, with weekly monitoring of ETT colonization and sensitivity to antibiotics. This information can be used in case of clinical deterioration suggesting infection.

Concern has been expressed regarding the risk of infection in infants treated in incubators with high humidity. Our experience, using the new incubators providing up to 80 percent humidity, has generally been positive. However, after the first 48 hours of life, we do reduce the humidity level to 60% to 65%.

In the past, considerable effort was placed on measures believed to protect the newborn infant from nosocomial infections. These efforts included the restriction of visitors, and the use of gowns, gloves, masks, and hair nets. However, no studies have shown any evidence supporting these measures (207). In our unit, despite no longer using gowns for several years, we have not observed any change in the incidence of infection. We recommend gowning only when parents handle their babies in their arms or in cases requiring strict isolation. Parental visiting is unrestricted, and siblings are allowed to visit if they are healthy. In our view, the cornerstone of a relatively low incidence of nosocomial infection has been the enforcement of a very strict program of hand hygiene for both visitors and staff. In addition to routine hand-washing before and after patient contacts, an alcohol-based hand gel is also available at the bedside for unanticipated interventions (208).

Pain Control, Sensory Overload, and Developmental Care

During their NICU stay, preterm infants are exposed to external stimuli that are very different from those experienced by the fetus *in utero*: noise, lights, frequent disturbances, a nonliquid environment promoting different body movements and postures, and pain. Although neonatal pain was largely ignored in the past, it is now widely accepted that all newborns, including the ELBW, do experience pain. Furthermore, because ascending pain pathways are well developed by 24 weeks, but because descending pathways with endogenous opiates that may modulate incoming pain impulses are not present before 32 weeks, it is probable that the pain experienced by the very premature infant may actually be more intense. (209). Appropriate management of neonatal pain and stress is a very important aspect of modern neonatal care (210). Many nonpharmacologic strategies have been proposed to minimize the pain and stress experienced by infants for minor and major procedures, such as bundling, nonnutritive sucking, clustering of interventions and expertise in performing the procedures. Pharmacologic options include the use of opiate and nonopiate analgesics and local anesthetics. Topical anesthetics have not been fully evaluated for use in ELBW infants. Sedation and analgesia for elective intubation maintains physiologic stability for the neonate and facilitates the procedure for both the neonate and the operator (211). The safety of continuous opiate infusion early in life and for prolonged periods of time in very premature infants is still in the phase of evaluation (212). Although oral sucrose does attenuate the pain response for less invasive procedures such as heel sticks, i.v. insertion, and endotracheal suctioning, it remains unclear if there are adverse long-term effects secondary to repeated sucrose treatments of premature infants (213). Clearly, further research is required to better manage the stress and pain experienced by premature infants, to understand the long-term effects on the growth and development of the premature brain from episodes of stress and pain and exposure to exogenous opiates, and to demonstrate the long-term safety and utility of strategies to control neonatal stress and pain. Our efforts to reduce neonatal pain should succeed without inadvertent harm to the infants.

How the *ex utero* sensory input experienced by the premature infant affects the development of cerebral pathways and systems, including programmed cell death or apoptosis, is not known. These pathways are established after the period of neuronal migration, which is often completed around the 24th week of gestation. Unfortunately this time is often marked by clinical instability in the newborn very premature infant, e.g., from RDS, electrolyte disturbances, PDA, and limited energy and nutrient intakes, which may compound an adverse effect on the development of the premature brain.

These concerns have been the impetus for the wide implementation by most NICUs of global developmental care practices (e.g., control of light and noise, kangaroo care, massage and music therapy) and individualized developmental care (e.g. Newborn Individualized Developmental Care and Assessment Program [NIDCAP]) to minimize the stress, limit the sensory overload, and thereby optimize the health and neurodevelopment of each infant and facilitate parent-child bonding (214). Many studies have been published about developmental care, but because most have been limited by small samples, differing reported outcomes and other methodological problems, there continues to be controversy regarding the utility of these practices. Systematic reviews of the effectiveness of developmental care do confirm short-term benefits, such as improved growth outcomes, shorter duration of

P.481

mechanical ventilation and oxygen supplementation, decreased length of stay and cost of hospitalization, and improved neurodevelopmental outcomes to 9 to 12 months corrected age, but not at 24 months; effects at older ages have not been reported (215,216).

In our nursery, the medical and nursing personnel have been sensitized to these issues over the years. The bedside nurse is responsible for implementing and maintaining the developmental care and comfort of the infant, with clustering of care to minimize external interventions and eliminate unnecessary disturbances, although promoting close parent-infant bonding. Particular attention is given to the parents' needs during hospitalization. Preparation for discharge involves the multi-disciplinary NICU and Neonatal Follow-Up teams, in collaboration with the family. Parents' group meetings are held regularly, allowing free discussion of common problems and concerns, and providing a ready support group.

Planning for Hospital Discharge

Preparing for hospital discharge is a momentous time for ELBW infants and their parents. This very much anticipated step is also fraught with emotional upheavals, with some parents pushing for early discharge and other parents clearly afraid to take their child home. It is the role of the NICU staff not only to judge the medical readiness of the infant for discharge, but also the readiness of the parents and family, and to support and educate the parents such that they are well prepared to take their infant home and that the discharge process is

orderly. The AAP recently published guidelines for hospital discharge of high-risk infants (217). Discharge planning should be a multidisciplinary process with participation of the Neonatal Follow-Up team. The medical complications should be reviewed with the parents and plans for specific follow-up organized. Parents should be clear about who will be involved in their infant's care after they leave the NICU, who to call in emergencies, and should be taught about worrisome signs that should prompt assessment of their infant by a health care professional. Children with special needs, such as home oxygen therapy, will require even more planning, preparation and clear instructions for the parents. We plan the first Follow-Up Clinic visit within 1 to 2 weeks of discharge mainly to reassure parents that they are doing well, as we review the infant's weight gain, feeding problems, and check the hemoglobin for late anemia. Thus, transition from the NICU to home should be planned such that parents do not feel cut off from the security of the NICU, and such that they feel confident in their ability to safeguard and nurture their precious infant.

FOLLOW-UP OF THE EXTREMELY LOW BIRTH WEIGHT INFANT

The ultimate goal of neonatal intensive care for ELBW infants is to improve survival without impairment or disability attributable to the very premature birth. Fortunately, as survival has improved, follow-up studies have not shown an increase in the rates of neurodevelopmental delays or neurosensory impairments, such as cerebral palsy, blindness, deafness, or mental retardation (218,219,220). Although the majority of survivors do well, the improved survival rate translates to an increase in the absolute number of infants with neurodevelopmental and/or neurosensory problems and for whom long-term follow-up would be of benefit. Recent studies of outcomes of ELBW and VLBW infants at school age, adolescence and early adulthood reveal high rates of school difficulties, persistent neurosensory impairments, and health-related problems (221,222,223,224). Other studies describe the positive perceptions and values of these survivors and their families (225,226,227,228,229,230).

In 1993, Allen and associates reported the 36 month corrected age survival and morbidity rates for infants born between 22 and 25 weeks gestation (7). There were no survivors at 22 weeks, whereas 15%, 56%, and 80% of infants survived at 23, 24, and 25 weeks, respectively. Only 2% of those born at 23 weeks survived without severe intracranial abnormality. Intact survival was 21% at 24 weeks and 69% at 25 weeks. The authors concluded that aggressive resuscitation is warranted for infants born at 25 weeks or greater, but not for those born at 22 weeks or less. The Canadian Pediatric Society forwarded similar recommendations, with great deference to parental wishes at 23 and 24 weeks gestation (231). The Neonatal Resuscitation Program (NRP) emphasizes that the limit of viability is a moving target and up-to-date outcome data will assist in decision-making and care (232). An example of this is the change in the limit of viability in Japan, as stipulated in the Eugenic Protection Law, from 24 to 22 completed weeks of gestation. Nishida and associates reported that ELBW infants treated at the Tokyo Women's Medical College from 1984 to 2001 had a survival rate of 82%, with 50% survival for infants with birth weights of 400 to 499 grams (9/18 infants), 50% survival at 22 weeks gestation (3/6 infants) and low rates of neurosensory complications, such as cerebral palsy in 6.3% and mental retardation in 17.3%, at the 6-year follow-up (233).

There are many publications about the early neonatal outcomes based on birth weight, which encompass inborn, outborn, center-specific, and regional or population-based cohorts. With a regionalized perinatal program and population-based data from Australia, Yu described significant improvements in the survival of ELBW infants, increasing from 25% in 1979 to 56% by 1992 (234). Decreases in neurosensory deficits at 2 years of age were also observed, with severe disability reduced from 18 to 11%, severe cerebral palsy from 3 to 1%, blindness from 7 to 3% and deafness from 6 to 0.5%. The TIPP study described 1202 infants with birth weights of 500 to 999 grams. Survival to 18 months of age corrected for prematurity was 80%, with the following rates of neurosensory impairments: cerebral palsy 12%, severe cognitive delay 27%, hearing loss requiring amplification 2%, and bilateral blindness 2%. Death after a postmenstrual age of 36 weeks occurred in 4% of the sample (148). A review of the current literature by

P.482

Msall and associates provides a general summary of the rates of the major neurodevelopmental outcomes of ELBW infants in the first 2 to 3 years: cerebral palsy 9% to 26%, blindness 1% to 15%, deafness 1% to 9%, and cognitive disability 10% to 42% (235).

Early outcome data by gestational age is less encouraging. A regional study from Ontario, Canada, published in 1993, observed an absence of any handicap at 2 years of age in 50% of surviving infants born at 23 weeks, 41% of those born at 24 weeks, and 59% of those born at 25 weeks (6). In the same year, a regional study from Oxford, England reported moderate-to-severe functional handicaps at 4 years of age in 80% of surviving infants born at less than 25 weeks of age and in 66% of those born at 25 weeks (236). The large EPICure study

described the outcomes of infants born at 25 or fewer completed weeks in the United Kingdom and Ireland in 1995 (237,238). This study added more fuel to the controversy regarding care of the extremely premature infants as they reported dismal survival and neurodevelopmental outcomes based on total births by gestational age, including stillbirths and cases not resuscitated in the delivery room. The outcomes of 283 surviving infants (92% follow-up rate) were described at a median age of 30 months: 49% had any disability, 23% had severe disability, and 18% had cerebral palsy.

Studies at school age consistently show significant difficulties for the ELBW population. Hack and Fanaroff (219) described the school-age outcomes in infants born weighing less than 750 grams, found that 56% of these extremely small infants required special education classes, and concluded that infants with birth weights less than 750 grams are expected to have significant problems with cognitive ability, psychomotor skills and academic achievements. Gross and associates (239) found that ELBW at 10 years did less well in school than term controls. They found that family factors, such as stable family units, were stronger predictors of school performance than were perinatal complications. This study illustrates the importance of variables other than prematurity and perinatal events on eventual cognitive outcome and also points to new directions for potential intervention to impact on behavior and learning for ELBW infants.

Studies of outcomes into early adulthood primarily describe VLBW cohorts. Consistent findings were persistence of chronic health problems and neurosensory impairments, smaller and lighter stature with an impact on physical work capacity, difficulties in educational attainment and lower IQ even in the absence of neurosensory impairment. (240,241) Bjerager and associates (228) describe the quality of life (QoL) at 18 to 20 years of age for VLBW cohort born in Copenhagen between 1971 and 1974 and found that VLBW subjects free of handicaps had a quality of life comparable to normal birth weight controls. Dinesen and associates (229) found that the VLBW cohort born in 1980 to 1982 achieved higher QoL scores in comparison to the VLBW cohort born in 1971 to 1974.

Mazurier and associates (242) described a Canadian ELBW cohort at 16 to 21 years of age. They found that ELBW subjects had a mean intelligence quotient (IQ) in the normal range (95 +/- 11) but lower than that of the control group (107 +/-14), had significantly more school failures, and a lower rate of completion of secondary school education (61% vs. 87%).

Monset-Couchard (243) and associates reported on the mid- and long-term outcomes of 166 premature SGA, ELBW infants born in Paris, France. Language delays were observed at some stage in 31% of cases; behavioral disturbances in 42% (with 12% having severe problems); cerebral palsy in 2%; visual deficits increased to 68% with age; hearing losses after otitis media in 8%; 47% entered high school at their proper age and only 50% of the older individuals obtained their "baccalaureate" in their 19th/20th year.

The limited number of studies describing outcomes of ELBW and VLBW infants into adolescence and adulthood indicate that problems with health, education and adaptation may persist. It is unclear if the long-term outcomes of ELBW and VLBW individuals without neurosensory impairment, whether SGA or not, differ significantly from those of the normal-birth weight population. Furthermore, the current studies describe the outcomes of infants born in the 1970s and 1980s, prior to the current innovations in neonatal practices such as surfactant, alternative ventilation strategies, intensive nutrition and developmental care, and recent changes in obstetrical practices that may have a positive impact on neonatal outcomes, which include higher utilization of antenatal steroids, planned maternal transfers to tertiary care perinatal centers and intrapartum antibiotics. Whether the current ELBW and VLBW graduates have the same risks of long-term difficulties as their predecessors is not known. The importance of longitudinal follow-up of ELBW and VLBW infants and long-term follow-up studies cannot be overstated.

Our own longitudinal follow-up of infants born between 22 and 25 weeks of gestation is on-going. From April 1988 to March 1994, 110 infants born between 22 and 25 weeks gestation were admitted to our NICU. There were 58 survivors (survival rate 53%). In the first two years of life, problems with growth and general health were noted, with 56% requiring at least one rehospitalization for hernia repair, ear tubes, eye surgery, bronchiolitis-asthma or pneumonia. Reactive airway disease was seen in 59% and recurrent otitis media in 57%, with the need for hearing aid in 6%. The Griffiths Scales of Mental Development scores at a corrected age of 24 months were in the normal range (mean GQ 96 ± 4) and no infant scored in the mentally retarded range of less than 70. Outcomes at 5 years of age were available for 53 infants. For this cohort of 53 infants (91% follow-up rate), the mean gestational age was 24.9 ± 0.7 weeks and the mean birthweight was 715 ± 112 gms. There was a progressive improvement of their general health, as shown in Table 25-12. The rates of neurosensory impairments at 5 years of age were as follows: 5.2% had significant visual impairment, 5.5% required hearing aids and 9.4% were diagnosed with cerebral palsy (1 child had quadriplegia and 4 had monoplegia). Normal

and 5 children (9%) having severe deficits. Behavioral difficulties such as hyperactivity and attention-deficit features were present in 28%, and speech delay in 37%. Overall, a higher incidence of deficits was present among SGA children compared to AGA (67% vs. 37%). Microcephaly (head circumference <5th centile) was found to be an important prognostic factor and was a predominant finding in SGA children (244).

TABLE 25-12 HEALTH IMPROVEMENT OVER 5-YEAR PERIOD AMONG 53 CHILDREN BORN BETWEEN 22–25 wks GA

	NICU Discharge to 2 Years	2–5 Years	Difference	p Value
Re-hospitalization	56%	10.5%	-44	0.01
Asthma	56%	31%	-25.5	0.04
Otitis media	53%	31%	-25	0.06

The overall experience to date with ELBW infants allows us to come to the following conclusions:

- The vast majority of the surviving ELBW infants can hope for a very meaningful life.
- As survival of infants born less than 26 weeks has increased, there is an increase in the absolute numbers of ELBW infants who are healthy, and also of infants with long-term complications.
- A substantial number of ELBW infants will have physical, intellectual and behavioural impairments resulting in significant functional disability, which may persist into adolescence and adulthood.
- Because of the sequelae of extremely premature birth, it is important to have an organized, long-term Follow-Up Program as part of the postdischarge care of ELBW infants, to insure appropriate diagnosis and assist with therapy, resources and support to the child and family.
- Evidence of significant brain injury, such as Grade III or IV IVH, cystic PVL and ventricular dilatation, is an ominous predictor of future handicaps. Concomitant diagnosis of chronic lung disease at 36 weeks corrected age and severe retinopathy of prematurity increase the likelihood of neurodevelopmental problems. These provide important information to counsel the parents during care in the NICU and prior to discharge home.

One of the on-going challenges for Neonatal Follow-up of ELBW infants is to advocate for appropriate resource and service supports to these high-risk children and their families, and to insure longer-term follow-up, ideally into school entry.

In the past, the exceptional circumstances of birth at extreme prematurity offered no chance for survival. Although a very difficult road, fraught with major medical complications, parental stress and unanswerable ethical dilemmas, modern neonatal care for these extremely premature and ELBW infants has afforded many parents the opportunity to realize their hope of taking home a healthy infant with the potential for a good future.

FUTURE DIRECTIONS AND ETHICAL ISSUES

Although the birth weight barrier of 500 grams has been broken (2), the debate regarding the lower limit of viability remains open (30,31).

Early follow-up of infants born with a weight less than 500 grams is not very reassuring (1). It is obvious that beyond the heavy cost in human and financial resources in the NICU, these children will require extensive and careful long-term evaluation and support. Their performance at school age and as young adults is not yet clear.

However, it seems unlikely at this point that their management will cease. Therefore, it is our responsibility as neonatologists to provide short-and long-term accurate information to both parents and society, if we want to defend our interventions with credibility. We need to establish general and institutional guidelines and to address the ethical, financial and philosophical issues related to our interventions. Parental decisions need to be respected, but parents need also to be well informed of the potential risks. It is likely that with improved medical knowledge and technology, avoidance of major complications, and with better

P.484

nutrition, the outcome of all ELBW infants will improve. However, as we follow with great interest the future of these children born at the limit of viability, it is important to focus our attention on improving their management in our NICUs rather than on trying to break new barriers.

TABLE 25-13 MEASUREMENT OF DEVELOPMENT AND COGNITIVE FUNCTION OVER TIME FOR INFANTS BORN BETWEEN 22–25 WEEKS GA

^a Age corrected for prematurity; Griffiths GQ: Griffiths Mental Development Scales General Quotient

It is also evident that not all neonatologists, nor all NICUs, should undertake the treatment of ELBW infants. The management of these infants requires great expertise and ample resources. A critical mass is essential to maintain high medical and nursing standards. Ideally, only regional perinatal centers should be involved in the care of ELBW infants, and treatment should be undertaken only when adequate resources are available, without compromising the care of more mature infants having better chances of intact survival. Finally, the ultimate decision regarding the management and degree of intervention in the delivery room remains the responsibility of the neonatologist because, very often, there may not be time for multiple consultations and because, after all, the neonatologist is the person with the wider experience to make such decisions. However, it is also important that neonatologists involved in the care of the ELBW infant be sensitive to the wishes of the family and be objective in their presentation of information and interpretation of outcome data to the family. The neonatologist also should be prepared to advise parents when therapy has reached its limits, and should avoid heroic interventions when the expected outcome, based on current scientific knowledge, is definitely unfavorable. In our view, as we enter the new millennium, the moving target in the management of the ELBW infant should no longer be the gestational age or the birth weight, but rather the condition of the infant at birth, his or her potential to survive, the parents' desire, and our own honest evaluation of the capabilities, commitment, and resources of our own environment to provide lengthy support to the infant and to his or her family.

ACKNOWLEDGMENTS

We would like to express our profound gratitude to the NICU nursing personnel for many years of competent and devoted care of our ELBW infants. Our deep appreciation to Mrs. Judi Garon for her dedication and secretarial expertise.

Chapter 26

Intrauterine Growth Restriction and the Small-For-Gestational-Age Infant

Marianne S. Anderson

William W. Hay

INTRODUCTION

Much of the interest in infants who are small for gestational age (SGA) at birth, and much of the impetus for studying intrauterine growth restriction (IUGR) that produces SGA infants, began with the observation by pediatricians and neonatologists that newborn infants who were classified according to birth weight as small, average, or large for gestational age (SGA, AGA, and LGA, respectively) showed specific morbidities and rates of death that were unique to each of these birth weight-gestational age classifications (1) (See Appendix D for intrauterine growth charts). SGA infants were recognized as having more frequent problems with perinatal depression ("asphyxia"), hypothermia, hypoglycemia, polycythemia, long-term deficits in growth, neurodevelopmental handicaps, and higher rates of fetal and neonatal mortality (2) (Fig. 26-1). Although there have been tremendous improvements in perinatal diagnosis and treatment, severe IUGR and the birth of markedly SGA infants continue to be frequent problems, and the perinatal morbidity and mortality rates of IUGR fetuses and SGA infants continue to exceed those of normal fetuses and infants.

DEFINITIONS

Small for Gestational Age

SGA infants are classically defined as having a birth weight that is more than two standard deviations below the mean or less than the 10th percentile of a population-specific birth weight vs. gestational age plot. Broader definitions include less than normal anthropometric indexes, such as length and head circumference, and marked differences between growth parameters, even when they are within the normal range. For

example, an infant can be considered “relatively” SGA when its weight is at the 25th percentile, but its length and head circumference are at the 75th percentile. In this case, the weight/length ratio (or the Ponderal index = [weight (g)]/[length (cm)]³) is less than normal, indicating that growth rates of adipose tissue and skeletal muscle, the principal determinants of weight, were less than normal (Fig. 26-2) (3).

Intrauterine Growth Restriction

IUGR is defined as a rate of fetal growth that is less than normal for the population and for the growth potential of a specific infant. IUGR therefore produces infants who are SGA. SGA infants can be the result of normal but slower than average rates of fetal growth, such as those constitutionally small but not abnormal infants whose parents, siblings, and more distant relatives are small (4). SGA infants also can be the result of abnormally slow fetal growth that is caused by pathophysiologic conditions or diseases. Because growth is one of the essential features of the fetus, nearly any aberration of biologic activity in the fetus can lead to growth failure. Thus, small size at birth can be either a normal outcome or one that is a result of intrinsic or extrinsic factors that limit fetal growth potential.

Birth Weight Classification of Growth

Many terms are used to describe variations in fetal growth. For example, human newborns are classified as having normal birth weight (greater than 2,500 g), low birth weight (LBW, less than 2,500 g), very low birth weight (VLBW, less than 1,500 g), or extremely low birth weight (ELBW, less

P.491

than 1,000 g). Obviously, classification by weight alone says little about fetal growth rate, as most infants with less than normal birth weights are the result of a shorter than normal gestation, i.e., they are preterm. Similarly, classifying newborns as preterm or term on the basis of birth weight is erroneous, as infants with IUGR are smaller than normal at any gestational age.

Figure 26-1 Morbidities specific to small-for-gestational-age infants. (Adapted from Lubchenco LO. The high risk infant. In: Schaffer AJ, Markowitz M, eds. *Major problems in clinical pediatrics*, volume XIV. Philadelphia: WB Saunders, 1976:6.)

Normal Variations and the Assessment of Fetal Growth

Normal fetal growth varies almost twofold. For example, mean birth weight for neonates born in New Guinea is 2,400 g (5), whereas normal birth weights in other populations can exceed 4,000 g (6). Such variations are related to genetic and environmental factors, the latter usually reflecting local diets (e.g., the relatively obese infants of Polynesian women who eat relatively large amounts of starchy foods in their normal diet). These and other normal anthropometric variations

must be considered in relation to the diagnosis of IUGR in fetuses and SGA status of newborns.

Symmetric and Asymmetric Growth

Restriction

SGA infants have been classified as having symmetric or asymmetric IUGR. Symmetric IUGR implies that brain and body growth both are limited. Asymmetric growth indicates that body growth is restricted to a much greater extent than head (and thus, brain) growth. In such cases, brain growth is considered "spared." Mechanisms that allow brain growth to continue at a faster rate than adipose tissue and skeletal muscle are not completely known. Contributing factors may include an increased rate of cerebral blood flow relative to the umbilical and systemic circulations, which has been observed in some of these infants (7). In some experimental models, cerebral glucose transporter concentrations are preserved despite fetal hypoglycemia, indicating preservation of cerebral glucose uptake capacity (8). The most severely affected infants have marked reductions in both brain and body growth. Even moderately IUGR infants have growth restrictions of both brain and body, but to varying degrees that depend on the duration and severity of the insults that inhibit growth. Asymmetric and symmetric growth restriction are best thought of, therefore, as extreme examples (Fig. 26-3). Asymmetric fetal growth differentially affects organs other than the brain. As shown in Fig. 26-4, the heart also is larger for body weight in these infants, whereas the liver, probably representing glycogen deficit, and thymus, perhaps indicating a response to stress but also showing a potential for immunologic inadequacy, are smaller for body weight.

In general, factors intrinsic to the fetus cause symmetric growth restriction, whereas external factors cause asymmetric growth. Patterns of symmetric growth restriction develop early during fetal life, reflecting their intrinsic nature. Asymmetric patterns also can develop as early as the second trimester (9) and as much as 30% to 50% of extremely preterm neonates (less than 1,000 g) are SGA, probably reflecting pathology that produced growth restriction and led to preterm birth. Factors that limit the growth of both the fetal brain and body include chromosomal

anomalies (e.g., particularly trisomy conditions), congenital infections (toxoplasmosis, rubella, cytomegalovirus), dwarf syndromes, some inborn errors of metabolism, and some drugs (10). The mechanisms by which these factors limit fetal growth are multifactorial.

Asymmetric growth restriction classically develops during the late second and third trimesters when fetal nutrients, particularly glucose and lipids, increasingly contribute to energy storage in the form of glycogen and fat (in both brown and white adipose tissue) (11). Slight reductions of energy substrate supply to the fetus limit fat and glycogen storage and the growth of skeletal muscle, but allow for continued bone and brain growth. More extreme limitations of energy substrates, for longer periods, affect both growth and energy storage. Timing is important; with decreased nutrient supply early in gestation, growth of all body organs is restricted, whereas decreased fetal nutrient supply later in gestation primarily restricts growth of glycogen content, adipose tissue, and skeletal muscle.

INTERPRETATION OF FETAL GROWTH CURVES

Growth Curves Based on Neonatal

Measurements

Cross-sectional growth curves have been developed from anthropometric data in populations of infants born at

P.492

different gestational ages (12). Such curves have been used to demonstrate whether an infant's weight is within the normal range for a given gestational age and thus to estimate whether that infant's in utero growth was greater or less than normal. The normal range is defined as birth weights between the 10th and 90th percentile of the population-specific birth weight vs. gestational age relationship. Fetuses and neonates who are within the 10th and 90th percentiles for weight vs. gestational age are considered AGA. Those who are less than the 10th percentile are considered SGA. Those who are greater than the 90th percentile are considered LGA. Other terms for SGA infants include light for dates and small for dates.

Colorado Intrauterine Growth Charts

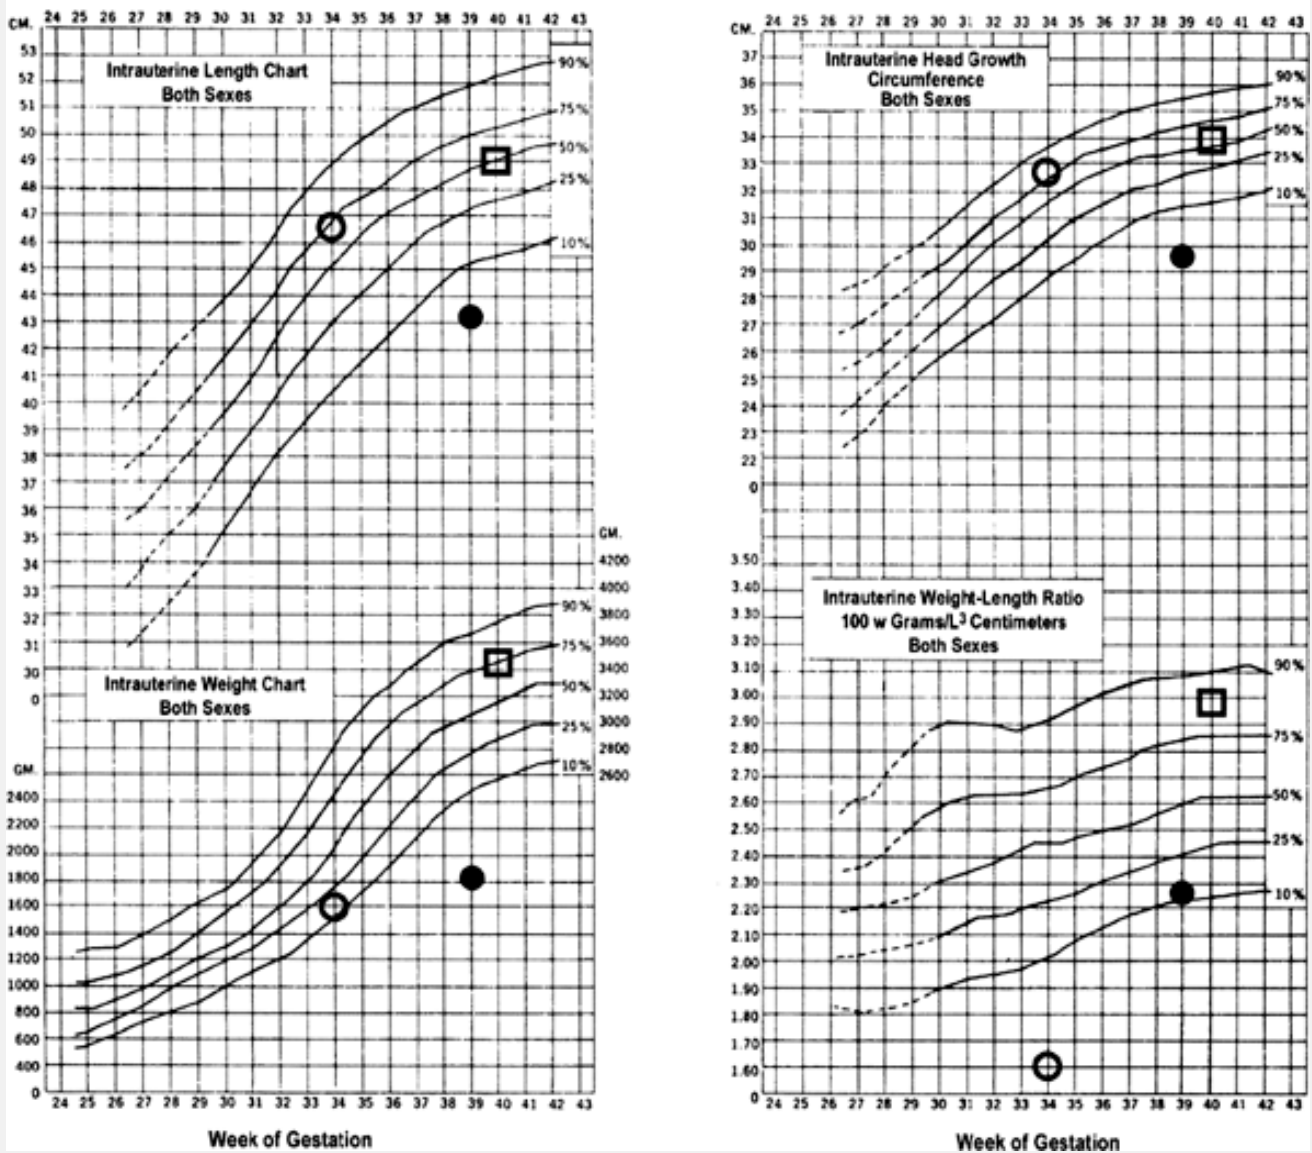

Figure 26-2 The Colorado Intrauterine Growth Charts, including symbols that define the anthropometric measurements for the three infants shown in Fig. 26-2. (O) Preterm infant at 34 weeks of gestation, showing asymmetry of weight (15th percentile) versus length and head circumference (75th percentile) and weight-to-length ratio (85th percentile); (•) severely but symmetrically small-for-gestational-age infant at 39 weeks, showing weight, length, head circumference, and weight-to-length ratio all about equally and markedly (<10th percentile); and (□) symmetric average-for-gestational-age infant at 40 weeks, showing weight, length, head circumference, and weight-to-length ratio about the 65th to 75th percentile. (Growth charts from Lubchenco LO, Hansman C, Boyd E. Intrauterine growth in length and head circumference as estimated from live births at gestational ages from 26 to 42 weeks. *Pediatrics* 1966;37:403 (ref. 13).

Most growth curves usually are confined to the third trimester. Each curve is based on local populations with variable composition of maternal age, parity, socioeconomic status, race, ethnic background, body size, degree of obesity or thinness, health, pregnancy-related problems, and nutrition,

P.493

and the number of fetuses per mother, the number of infants included in the study, and by what methods and how accurately measurements of body size and gestational age were made. Estimating gestational age, in particular, has considerable error. Such error is derived from variability in dating conception because of maternal postimplantation bleeding and irregular menses, wide variability in the development physical features of maturation in the infant, and interobserver variability in assessing an infant's developmental stage. The growth curves shown in Fig. 26-2 are those of Lubchenco and colleagues (13) in Denver, Colorado, published in 1966. They are biased to slightly lower birth weights compared with many other growth curves, especially close to term, as a result of the unique mix of racial and ethnic groups in the population of babies who were born at Colorado General Hospital, Denver, Colorado, at the time the data were collected. Although the higher altitude of Denver (5,280 feet or $\sim 1,600$ m) has been considered a factor in the smaller birth weights shown in these curves, the independent effect of high altitude on restricting fetal growth is not clearly demonstrable at 1 mile (1.6 km). In fact, growth curves similar to those of Lubchenco et al. have been produced at sea level among lower socioeconomic groups with a high proportion of blacks and Hispanics in the population (Fig. 26-5).

Mathematical analyses of various fetal growth curves have been used to determine growth rates over relatively short gestational periods or at discrete gestational ages (12). For example, the data used in the Lubchenco growth curves (Figs. 26-2 and 26-5) can be approximated by a simple exponential function showing fetal weight increasing at about 15 g/day/kg. This rate will vary from the smallest to the largest infants. For a given weight percentile, however, there are only differences of 1% to 2% for this exponential function among different populations and studies.

Figure 26-3 Preterm, small-for-gestational-age infant at 34 weeks of gestation (**left**), severely small-for-gestational-age infant at 39 weeks (**middle**), and average-for-gestational-age infant at 40 weeks (**right**).

Growth Curves Based on Fetal Measurements

Fetal growth curves also have been developed from serial ultrasound measurements of fetuses who subsequently were born at term in healthy condition and with normal

P.494

measurements, providing continuous rather than cross-sectional indexes of fetal growth. These curves can be better correlated with the expected fetal growth rate of a particular fetus than can cross-sectional, population-based growth curves. Serial ultrasound measurements of fetal growth also can more accurately determine how environmental factors, such as severe maternal illness and under nutrition, can inhibit fetal growth. Figure 26-6 shows an example of ultrasound data for fetal growth curves, including evidence for a particular fetus whose growth

rate clearly was affected adversely by poor maternal health and beneficially by improved maternal nutrition. Further, fetal ultrasound-derived growth curves show less of the midgestational exponential increase in fetal growth rate that is typical of cross-sectional growth curves derived from neonatal measurements at different gestational ages. This observation strengthens the concept that, because preterm birth is not a normal outcome, one must be suspicious of growth parameters and growth curves derived from cross-sectional measurements of preterm infants assessed at birth. The intrauterine growth of these preterm infants probably was affected adversely by the same pathologic factors that led to their preterm birth. Thus, there probably is no ideal fetal growth curve derived from postbirth, cross-sectional measurements. Future growth curves to assess in utero growth of a specific newborn should be based instead on more thoroughly and accurately determined fetal growth parameters from ultrasound measurements in pregnancies with definitely known dates of conception and birth at term of normally grown and developed infants.

Figure 26-4 Body length and selective organ weight percent changes from normal preterm infants of similar birth weights in necropsy series of IUGR fetuses. (After Gruenwald P. Growth patterns in the normal and deprived fetus. In: Jonxis JHP, Visser HKA, Troelstra JA, eds. *Aspects of*

prematurity and dysmaturity. Springfield: Charles C. Thomas, 1968:43.)

INTRAUTERINE GROWTH RESTRICTION AND PRETERM BIRTH

Most cases of fetal growth restriction represent only minimal growth delay and are natural, reproductively successful, although not perfect, adaptations to nutrient limitation. Most cases of IUGR, therefore, are not major causes of preterm delivery, and fetal growth rate and length of gestation usually are not related. In cases of severe IUGR, the pathophysiologic processes causing the IUGR also can lead to preterm labor and preterm delivery. Thus, IUGR frequently occurs with a variety of maternal conditions that are associated with preterm delivery (Table 26-1) (14,15,16,17).

Established maternal conditions that are associated with both IUGR and preterm delivery include very low maternal prepregnancy weight, prior preterm delivery, cigarette smoking, indirect effects of very young or advanced maternal age, and lower maternal socioeconomic status (14). Regarding race, African-American women who were born in the United States have a twofold greater incidence of both preterm birth and IUGR than do white women from the United States or African-American women who emigrated from Africa. Reasons for this are multifactorial and include nearly all of the generally associated risks

P.495

P.496

and causes of IUGR and preterm delivery (15). Stretch-activated mechanisms probably induce preterm labor in cases of multiple gestation, uterine and placental space-occupying anomalies (e.g., fibroids), and polyhydramnios. Insufficient endometrial surface area for placental invasion and growth, plus abnormal placental perfusion, also combine to restrict nutrient delivery to the fetus, leading to IUGR. Poor placental growth and function limit placental supply of growth promoting hormones to the fetus, e.g., human placental lactogen (hPL), steroid hormones, and insulin-like growth factor-I (IGF-I) (18,19,20), and limit effective maternal-fetal nutrient exchange. In cases of polyhydramnios, IUGR often is related to the primary pathologic processes such as fetal infection, anemia, cardiac failure, and neuromuscular disorders.

Intrauterine fetal infections can limit fetal growth by damaging the fetal brain and the neuroendocrine axis that support fetal growth via insulin-like growth factors (IGFs) and insulin. Intrauterine infections also can damage the fetal heart, leading to diminished cardiac output, poor placental perfusion, and inadequate nutrient substrate uptake. Fetal infections and ascending infections of the membranes from the vagina also are associated with preterm delivery. They probably do this by enhancing the fetal supply of prostaglandins, which causes fetal and uterine production of various cytokines that are associated with or cause the onset of labor (21). Chronic placental and fetal infections also limit placental perfusion, in some cases by inhibition of nitric oxide production, which leads to uteroplacental vasoconstriction, placental

insufficiency, and IUGR (22). Preeclamptic women have poor endometrial vascular support for growth of the placenta, leading to placental growth failure, fetal nutrient deficit, and IUGR (23). Fetal hypoglycemia, hypoxemia, and acidosis usually are present in such cases of poor placental development and perfusion. These factors lead to increased production of prostaglandins and the activation of labor-promoting cytokines, leading also to preterm delivery (24). Many of these cases are delivered preterm to protect the mother from eclampsia or the fetus from hypoxic-ischemic injury. Very young and very old women both produce IUGR infants who often are born prematurely. Nutritional, uterine, and vascular mechanisms may be common in these situations. Young still-growing adolescent girls appear less capable of mobilizing fat reserves in late pregnancy, apparently reserving them instead for their own continued development (25). Failure to mobilize such reserves can limit nutrient supply to the fetus and the rate of fetal growth (26). IUGR in cases of maternal smoking and substance abuse may be as a result of reduced placental blood flow, inhibition of uteroplacental vascular development, or direct fetal toxicity.

These examples illustrate that IUGR is commonly associated with conditions that also are related to preterm delivery. It is not surprising, therefore, and important to note, that IUGR is an increasingly common finding among infants born at earlier gestational ages. Whereas at term 10% of infants are classified as SGA, at less than 28 to 30 weeks gestational age, 30% to 40% of infants may be the result of IUGR (27).

FETAL GROWTH

The period of fetal growth is from the end of embryogenesis, at about the end of the first third of gestation, until term. During the embryonic period, growth occurs primarily by increased cell number (hyperplasia) (28). In the middle third of gestation, cell size also increases (hypertrophy), although the rate of cell division becomes stable. In the last third of gestation, the rate of cell division declines, although cell size continues to increase. Thus, insults that limit fetal growth in the embryonic period result in global reduction in fetal growth, whereas insults in the third part of gestation usually limit growth of fetal adipose tissue and skeletal muscle with less effect on the growth of other organs, especially the brain and heart (29).

GROWTH OF BODY COMPONENTS IN THE FETUS

Water

Fetal body water content, expressed as a fraction of body weight, decreases over gestation as a result of relative increases in protein and mineral accretion (Fig. 26-7) (30) and in humans because of the development of relatively large amounts of adipose tissue in the third trimester. Fetuses with marked IUGR and SGA neonates who have decreased body fat content have even lower fractional contents of body water. Extracellular water also decreases more than intracellular water as gestation advances, primarily because of increasing cell number and increasing cell size rather than the intracellular concentration of osmotic

P.497

substances. Measurements of extracellular space in SGA infants usually are normal for gestational age, as adipose tissue, skeletal muscle, and mineral accretion all are decreased to about the same extent (31).

Figure 26-7 Composition of weight gain in normal human fetuses. From Ziegler EE, O'Donnell AM, Nelson SE, et al. Body composition of the reference fetus. *Growth* 1976;40:329.

Minerals

Fetal calcium content in SGA and AGA fetuses increases exponentially with a linear increase in length, because bone density, area, and circumference increase exponentially in relation to linear growth (12). Accretion of other minerals varies more directly with body weight and according to the distribution of the minerals into extracellular (e.g., sodium) or intracellular (e.g., potassium) spaces (Table 26-2).

Nitrogen and Protein

There are very few chemical composition studies of normal human infants. Based on data from 15 studies accounting for 207 infants, Sparks has shown that nonfat dry weight and

P.498

nitrogen content (predictors of protein content) have a linear relationship with fetal weight and an exponential relationship with gestational age (Fig. 26-8) (12,32). Table 26-3 shows nitrogen, protein, and selected amino acid composition and accretion rates for normal human fetuses. About 80% of fetal nitrogen content is found in protein; the rest is found in urea, ammonia, and free amino acids. The data for fetal protein content and accretion in Table 26-3 thus may be high, as they are based solely on nitrogen content.

Nitrogen and Protein Accretion in Small-for-Gestational-Age Infants

Among SGA infants, nitrogen and protein contents are reduced for body weight, primarily as a result of deficient production of muscle mass. In

fact, they often are reduced below that of fat as a fraction of body weight (33).

Glycogen

Many tissues in the fetus, including brain, liver, lung, heart, and skeletal muscle, produce glycogen over the second half of gestation (34). Liver glycogen content, which increases with gestation (Fig. 26-9), is the most important store of carbohydrate for systemic glucose needs, because only the liver contains sufficient glucose-6-phosphatase for release of glucose into the circulation. Skeletal muscle glycogen content increases during late gestation and forms a ready source of glucose for glycolysis within the myocytes. Lung glycogen content decreases in late gestation with change in

P.499

cell type, leading to loss of glycogen-containing alveolar epithelium, development of type II pneumocytes, and onset of surfactant production. Cardiac glycogen concentration decreases with gestation, owing to cellular hypertrophy, but cardiac glycogen appears essential for postnatal cardiac energy metabolism and contractile function. Glycogen synthesis rates are low in human fetuses, about 2 mg/d/g of liver, accounting for less than 5% of fetal glucose utilization (35). Net synthesis, degradation, and accumulation rates of fetal glycogen are controlled by the functional states of two enzymes, glycogen synthase, which promotes glycogen formation, and glycogen phosphorylase, which promotes glycogen degradation (34,36,37). The total liver content of these two enzymes is relatively constant over gestation. Their functional states are regulated by hormone and substrate concentrations. For example, insulin acts synergistically with glucose to build hepatic glycogen stores, whereas close to term, cortisol, epinephrine, and glucagon develop the capacity to promote glycogenolysis and glucose release into the plasma.

^aFrom Widdowson EM. Chemical composition and nutritional needs of the fetus at different stages of gestation.

In: Aebi H, Whitehead R, eds. Maternal nutrition during pregnancy and lactation. Berne: H. Huber, 1980:39–48, with permission.

Glycogen Deficiency in Small-for-Gestational-Age Infants

Glycogen content is markedly reduced in SGA infants, both in the liver and in the skeletal muscles (34). This is as a result of lower fetal plasma concentrations of glucose and insulin, which are the principal regulators of glycogen synthesis. If the SGA fetus also experiences repeated episodes of hypoxemia, epinephrine secretion in response will further deplete glycogen by activating glycogen phosphorylase and increasing glycogenolysis.

Adipose Tissue

At term, fetal fat content, expressed as a fraction of fetal weight, varies markedly among species (Fig. 26-10) (37). The fat content of newborns of almost all land mammals at term is 1% to 3%, which is considerably less than the 15% to 20% fat content of human term infants. Even in those species, such as the human, that take up fat from the placenta and deposit fat in fetal tissues, the rate of fetal fatty acid oxidation is presumed low. This condition occurs because plasma concentrations of fatty acids (and keto acid products, such as β -hydroxybutyrate and acetoacetate) are low, and because the carnitine palmitoyl transferase enzyme system is not sufficiently developed to deliver long-chain fatty acids to the respiration pathway inside the mitochondria. Fat accretion for the human fetus is shown in Fig. 26-11. Between 26 and 30 weeks of gestation, nonfat and fat components contribute equally to the carbon content of the fetal body (12,38). After that period, fat accumulation exceeds that of the nonfat components. By term, the deposition of fat accounts for more than 90% of the carbon accumulated by the fetus. The rate of fat accretion is approximately linear between 36 and 40 weeks of gestation, and, by the end of gestation, fat accretion ranges between 1.6 and 3.4 g/d/kg. At 28 weeks of gestation, it is slightly less and ranges between 1.0 and 1.8 g/d/kg.

P.500

Adipose Tissue Deficiency in Small-for-Gestational-Age Infants

By term, fat content in human fetuses with IUGR may be less than 10% of body weight (33). In these cases, the smaller placenta limits fetal fatty acid and triglyceride supply. Similarly, the smaller placenta decreases fetal glucose supply, which reduces glycerol production and triglyceride synthesis. Insulin deficiency, a result of decreased glucose and amino acid supply to the fetus, also limits fat synthesis. The insulin activation of peripheral lipoprotein lipase is thereby reduced, which normally is necessary to release fatty acids from circulating lipoproteins for adipocyte uptake and triglyceride synthesis, and to decrease the normal insulin stimulation of fatty acid synthase within adipocytes.

Figure 26-10 Fetal fat content at term as a percent of fetal body weight among species. Reproduced with permission from Hay WW Jr. Nutrition and development of the fetus: carbohydrate and lipid metabolism. In Walker WA, Watkins JB (Editors), *Nutrition in Pediatrics*, Second Edition. Hamilton: BC Decker, 1966, p. 376, with permission.

Calories (Total Energy Storage)

The energy value of various tissue components is shown in Table 26-4. Fat has a high energy content, 9.5 kcal/g, and a very high carbon content, approximately 78%. Thus, differences in fetal fat concentration lead to large differences in calculated caloric accretion rates and carbon requirements of the fetal tissues for growth. The caloric concentration of nonfat dry weight is fairly consistent at different developmental stages, indicating that the ratio of protein to nonprotein substrates in the tissues is relatively constant (Table 26-5). Thus, caloric accretion rate of any fetus can be estimated from the growth curve of the fetus and the changing fat and water concentrations (38).

Caloric Accretion Deficiency in Small-for-Gestational-Age Infants

Growth of fat and nonfat (protein plus other) tissues is metabolically linked through energy supply that is used for protein synthesis and the production of anabolic hormones (39). These promote positive protein,

fat, and carbohydrate growth. Thus, restriction of nutrient supply is likely to produce growth deficits of all tissues, not just fat. Indeed, growth restriction involves limitation of muscle growth and fat and glycogen (33). For example, chronic selective caloric (glucose) restriction in the experimental fetal sheep model leads to increased protein breakdown and lower rates of fetal growth and lipid content (40). Some growth curves, such as those shown in Figs. 26-8 and 26-11 from human

P.501

infants born prematurely at different times over the last third of gestation, show a bias toward thinner SGA infants with less fat relative to nonfat weight and nitrogen content (32). These infants, however, were stillborn and may have suffered extensive wasting and IUGR. Other studies have shown that human SGA infants can be markedly deficient in muscle mass, even more than for fat (33,41).

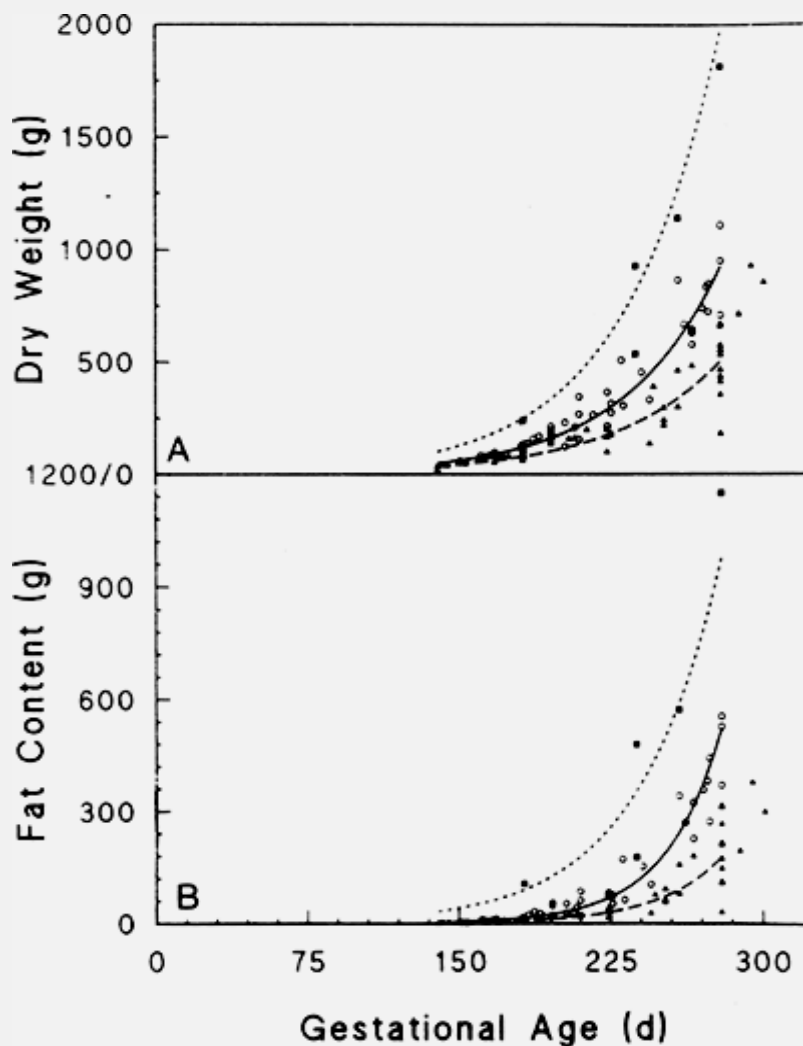

Figure 26-11 Dry weight (**A**) and fat content (**B**) plotted against gestational age in the same newborn human infants shown in Fig. 26-8 for LGA (▪, ...), AGA (O, — — —), and SGA ([black down-pointing triangle], — — — —) infants. Saunders Co., 1992:184, with permission.

REGULATION OF FETAL GROWTH

Fetal growth is regulated by maternal, placental, and fetal factors, representing a mix of genetic mechanisms and environmental influences through which genetic growth potential is expressed and modulated.

Epidemiologic Considerations

The major maternal risk factors for IUGR that vary among populations and among individuals within populations include small maternal size (height and prepregnancy weight) and low maternal weight gain during pregnancy. Low maternal body mass index (the degree of thinness or fatness, defined as $[\text{weight (kg)}]/[\text{height (cm)}]^2$) is a major predictor of IUGR. This characteristic interacts with other risk factors, such as diet, smoking, illnesses, and so forth, to affect fetal growth, especially in thin women. For example, smoking has only half the impact on fetal growth in obese vs. thin women, and in black vs. white women (42). Low blood pressure has a detrimental impact on fetal growth, mostly in thin women (43). Moderate obesity,

P.502

therefore, protects against most growth-inhibiting risk factors except for black race and female gender. This pattern also holds for certain therapies. For example, zinc supplementation has a major impact on fetal growth in black women who have relatively low plasma zinc levels early in pregnancy, with all of the impact occurring in relatively thin women (44). Also, low-dose maternal aspirin treatment has been shown to improve fetal growth primarily in thin women (45).

Genetic Factors

Many genes contribute to fetal growth. Table 26-6 lists estimates of the quantitative contribution of fetal and parental factors to fetal growth and birth weight at term. Maternal genotype is more important than fetal genotype in the overall regulation of fetal growth. However, the paternal genotype is essential for trophoblast development, which secondarily regulates fetal growth by the provision of nutrients. More specific gene targeting studies have shown the importance of genomic imprinting on fetal growth. For example, normal fetal and placental growth in mice require that the IGF-II gene be paternal and the IGF-II receptor gene be maternal, whereas maternal disomy producing IGF-II under-expression results in fetal dwarfism (39).

Nongenetic Maternal Factors

Under usual conditions, fetal growth follows its genetic potential, unless the mother is unusually small and limits fetal growth by a variety of factors considered collectively as “maternal constraint.” Maternal constraint represents a relatively limited uterine size, including placental implantation surface area and uterine circulation, and thus the capacity to support placental growth and nutrient supply to the fetus. A clear example of maternal constraint is the reduced rate of fetal growth of multiple fetuses in a species—human—that optimally supports only one fetus (Fig. 26-12). Obviously, small fetuses of small parents do not reflect fetal growth restriction; in fact, their rates of growth are normal for their genome and for the size of the mother. Unless maternal constraint is particularly prominent, such fetuses would not grow faster or to a larger size if more nutrients were provided, although they might grow somewhat larger if the maternal uterine endometrial surface area, and thus placental implantation and growth area, were increased. The nongenetic, maternal nature of this effect has been demonstrated by embryo transfer and cross-breeding experiments (29). For example, a small-breed embryo transplanted into a large-breed uterus will grow larger than a small-breed embryo remaining in a small-breed uterus. Furthermore, partial reduction in fetal number in a polytocous species, such as the rat, produces greater than normal birth weights in the remaining offspring. Conversely, embryo transfer of a large-breed embryo into a small-breed uterus will result in a newborn that is smaller than in its natural large-breed environment. Such

P.503

evidence supports the concept that fetal growth is normally constrained, and this constraint comes from the maternal environment, i.e., the size of the uterus.

Figure 26-12 Mean birth weight of single and multiple human fetuses related to duration of gestation. Adapted from McKeown T, Record RG. Observation on foetal growth in multiple pregnancy in man. *J Endocrinol* 1952;8:386, with permission.

Maternal Nutrition

The single most important environmental influence that affects fetal growth is the nutrition of the fetus. Normal variations in maternal nutrition, however, have relatively little impact on fetal growth and the severity of IUGR. This is because changes in maternal nutrition, unless extreme and prolonged, do not markedly alter maternal plasma concentrations of nutrient substrates or the rate of uterine blood flow, the principal determinants of nutrient substrate delivery and transport to the fetus by the placenta (46). Human epidemiologic data from conditions of prolonged starvation, and nutritional deprivation in experimental animals, indicate that severe limitations in maternal nutrition limit fetal growth only by 10% to 20%. Epidemiologic data from the Dutch during the Hunger Winter of 1944 showed an average reduction in fetal weight at term of 300 g (47), whereas birth weight at term was reduced by 500 g in women who suffered a more severe and prolonged famine in wartime Leningrad (48). Interestingly, second-generation daughters of women who suffered extreme nutritional deficit

during gestation in turn tend to produce SGA infants who are 200 to 300 g less than normal at term with their first pregnancies (49). However, attempts to limit weight gain in pregnancy with a 1,200-kcal diet (50% of what is now recommended to prevent preeclampsia) increased the incidence of fetal growth restriction up to tenfold (50). Restrictions of calorie and protein intakes to less than 50% of normal for a considerable portion of gestation are needed before marked reductions in fetal growth are observed. Such severe conditions often result in fetal loss before the impact of fetal growth rate in late gestation and fetal size at birth are manifested.

Attempts to increase fetal weight gain with maternal nutritional supplements have produced mixed results. Higher caloric feeding usually increases fetal adiposity, not growth of muscle mass or gain in length or head circumference. In contrast, high protein supplements tend to produce delayed fetal growth (51). Mechanisms responsible for this phenomenon are not known.

Maternal Chronic Diseases

Chronic hypertension, pregnancy-induced hypertension, and preeclampsia, like other vascular disorders including severe and long-standing diabetes mellitus and serious autoimmune disease associated with the lupus anticoagulant, have a common effect of limiting trophoblast invasion, placental growth and development, uteroplacental blood flow, and fetal oxygen and nutrient deficiency (52). Maternal cyanotic congenital heart disease can limit fetal oxygen supply, which can limit fetal growth (53). High-altitude hypoxia also can limit fetal growth (54), but usually this is only clinically significant for nonindigenous women who move to altitudes above 10,000 feet. Severe sickle cell crises can damage uterine vasculature, leading to placental growth and transport capacities (55).

Maternal Drugs

Specific effects of drugs on fetal growth (Table 26-7) are often difficult to sort out clinically, as many women who abuse drugs do so with many drugs taken intermittently, at different doses, and at different periods of

fetal vulnerability. These women also frequently suffer from other disorders

P.504

that could lead to poor fetal growth, such as poor nutrition, recurrent acute illnesses, and chronic diseases (56). Fetal growth restriction does appear to be a major part of the fetal alcohol syndrome. It is not clear when during gestation the specific effects of alcohol on fetal growth rate occur. Alcohol may exert its nonteratogenic effects by limiting placental-to-fetal amino acid transport (57). Cocaine probably exerts its primary effects on producing fetal growth restriction by causing uterine and perhaps umbilical vasoconstriction and reduced placental perfusion (58). The most consistent drug reducing fetal growth is cigarette smoking (41). Deficits of at least 300 g (about 10% of normal term weight) are not uncommon. A likely common mechanism is the effect of nicotine, and of catecholamines released in response, to constrict the uterine and perhaps the umbilical vasculature, reducing placental perfusion. Carbon monoxide, cyanide, and other cellular toxins may limit oxygen transport to fetal tissues and cellular respiration.

TABLE 26-7 DRUGS ASSOCIATED WITH INTRAUTERINE GROWTH RESTRICTION

Amphetamines
Antimetabolites (e.g., aminopterin, busulfan, methotrexate)
Bromides
Cocaine
Ethanol
Heroin and other narcotics, such as morphine and methadone
Hydantoin
Isotretinoin
Metals such as mercury and lead
Phencyclidine
Polychlorinated biphenyls (PCBs)
Propranolol

Steroids
Tobacco (carbon monoxide, nicotine, thiocyanate)
Toluene
Trimethadione
Warfarin

Placenta

The size of the placenta and its directly related nutrient transport functions are the principal regulators of nutrient supply to the fetus and thus the rate of fetal growth (36). Nearly all cases of IUGR are associated with a smaller-than-normal placenta. Figure 26-13 shows a direct relationship between fetal weight and placental weight in humans, demonstrating that LGA, AGA, and SGA infants are directly associated with LGA, AGA, and SGA placentas (59). Placental growth normally precedes fetal growth, and failure of placental growth is directly associated with decreased fetal growth. Variable limitations in placental nutrient transfer capacity modulate this primary effect of placental size on fetal growth. In some cases of experimentally reduced placental size, for example, fetal weight is not reduced proportionately (60). This indicates that either the capacity of the smaller placenta to transport nutrients to the fetus increases adaptively or the fetus develops increased capacity to grow. More characteristically, though, fetal growth fails first, or in direct relation to decreased nutrient supply. With primary fetal growth failure, placental growth can increase disproportionately, resulting in a larger than normal placental-to-fetal weight ratio for gestational age. This is characteristically seen under chronic hypoxic conditions of high altitude exposure or maternal anemia and has been seen in certain experimental situations of maternal undernutrition in early gestation (61). A variety of placental pathologic conditions are associated with IUGR (Table 26-8). In most of these cases, the placenta is simply smaller than normal. In many, there also is abnormal trophoblast development, including abnormal vascular growth in the

trophoblast villi, frequently associated with limited uterine vascular perfusion of the intervillous spaces.

Figure 26-13 Mean placental weights for large-for-gestational-age (O), average-for-gestational-age (•), and small-for-gestational-age (Δ) human infants at each gestational age. \pm SEM given for AGA infants alone. From Molteni RA, Stys SJ, Battaglia FC. Relationship of fetal and placental weight in human beings: fetal/placental weight ratios at various gestational ages and birth weight distributions. *J Reprod Med* 1978;21:327, with permission.

Placental and fetal growth both depend on an adequate supply of maternal blood to the placenta. IUGR is associated with inadequate development of the uteroplacental circulation, and radioisotope studies have demonstrated more than a twofold blood flow reduction in P.505

comparison with normal pregnancies (62). IUGR in the second half of gestation is due primarily to a failure of the normal villous vascular tree, mainly in the phase of nonbranching angiogenesis, because terminal villi

are critical for oxygen and nutrient transport to the fetus (63). This angiogenesis in turn depends on cytotrophoblast invasion of the uterus and its arterioles. Cytotrophoblast invasion is actually a differentiation process whereby the cells lose the ability to proliferate and modulate their expression of state-specific antigens. These antigens include members of the integrin family of cell-extracellular matrix receptors that are required for migration and invasion of the endometrium and decidua of the uterus (64). Preeclampsia, which is associated with IUGR, is characterized by shallow cytotrophoblast invasion (65). Abnormal cytotrophoblast differentiation also occurs, evidenced by the cells' inability to switch on their integrin repertoire (66). The same observations have been made on cultured normal cytotrophoblast cells in a hypoxic environment (67). These in vitro results indicate that whatever leads to hypoxia of the invading cytotrophoblast cells increases cytotrophoblast proliferation over differentiation and invasion, thus setting the stage for deficient placental development that can result in deficient nutrient and growth factor supply to the fetus, producing fetal growth restriction.

TABLE 26-8 PLACENTAL GROWTH DISORDERS THAT LEAD TO OR ARE ASSOCIATED WITH INTRAUTERINE GROWTH RESTRICTION

Abnormal umbilical vascular insertions (circumvallate, velamentous)
Abruptio (chronic, partial)
Avascular villi
Decidual arteritis
Fibrinosis, atheromatous changes, cytotrophoblast hyperplasia, basement membrane thickening
Infectious villitis (as with TORCH infections)
Ischemic villous necrosis and umbilical vascular thromboses
Multiple gestation (limited endometrial surface area, vascular

anastomoses)

Multiple infarcts

Partial molar pregnancy

Placenta previa

Single umbilical artery

Spiral artery vasculitis, failed or limited erosion into intervillous space

Syncytial knots

Tumors, including chorioangioma and hemangiomas

At more advanced stages of placental development, placental production of growth factors and growth regulating hormones develops, leading to significant autocrine regulation of placental growth and placental regulation of fetal growth processes. Human placental lactogen is synthesized and secreted by the syncytiotrophoblast cells of the placenta (68). Fetal growth-promoting actions of placental lactogen are mediated by stimulation of IGF production in the fetus and by increasing the availability of nutrients to fetal tissues (69). Obviously, placental growth failure and/or nutrient deficit to the placenta can result in decreased placental production of growth factors that then would lead to fetal growth failure.

FETAL NUTRIENT UPTAKE AND METABOLISM AND REGULATION OF FETAL GROWTH

In general, decreased rates of fetal growth represent an “adaptation” to inadequate nutrient supply. IUGR that results from decreased nutrient supply can be interpreted, therefore, as a successful, if not perfect, adaptation to maintain fetal survival. Fetal undernutrition also appears to affect rapidly growing fetuses more than slowly growing fetuses who may have been programmed to grow more slowly for genetic or embryonic and early fetal pathologic reasons (70). Reintroduction of nutrients can return fetal growth to normal in those fetuses whose rapid growth rate was decreased by undernutrition, but too rapid an

introduction of nutrients has often caused fetal pathology, including hyperlactatemia (70) and occasionally even acidosis and hypoxemia.

Glucose Uptake, Metabolism, and Regulation of Fetal Growth

Nearly all IUGR fetuses, whether studied experimentally in animal models or in women by cordocentesis (direct umbilical blood sampling), have relatively lower plasma glucose concentrations compared with normally grown fetuses (71,72). Fetal "hypoglycemia" has several consequences important to fetal adaptation and survival when maternal glucose supply is limited. First, relative fetal hypoglycemia is an important and natural compensatory mechanism that helps to maintain the maternal-to-fetal glucose concentration gradient and thus the transport of glucose across the placenta to the fetus (73). Despite this compensation, fetal hypoglycemia limits tissue glucose uptake directly by diminished mass action and indirectly by limiting fetal insulin secretion and thus the effect of insulin to promote tissue glucose uptake by skeletal muscle, heart, adipose tissue, and liver. Insulin also normally suppresses hepatic glucose production and release, and it acts as an anabolic hormone that increases net protein balance by inhibiting protein breakdown. Thus, a decrease in fetal plasma insulin concentration initially may allow fetal glucose production to take place, thereby providing glucose for both fetal and placental needs, but subsequently, combined with hypoglycemia, results in increased protein breakdown and decreased protein accretion (39,74,75).

Circulating concentrations and tissue-specific expression of growth factors such as IGF-I and IGF-II (see Fetal Amino Acid Metabolism) also are decreased during fetal hypoglycemia (76), which may contribute to increased fetal protein breakdown and decreased rates of fetal growth. Thus, fetal hypoglycemia in response to a decrease in maternal glucose supply acts to maintain fetal glucose supply, but it also leads to lower anabolic hormone concentrations, which limit the rate of fetal growth, thereby decreasing fetal nutrient needs.

Fetal Amino Acid Metabolism

The placenta contains a large variety of amino acid transporters, most of which use energy to actively concentrate amino acids in the trophoblast, which then diffuse into the fetal plasma, producing higher concentrations than in the maternal plasma (77). With small placentas, fetal amino acid supply is reduced, as are fetal amino acid concentrations, fetal protein synthesis, fetal protein and nitrogen balance, and, ultimately, fetal growth rate. Reduced energy supply to the placenta also reduces amino acid transport to the fetus. This is especially the case for oxygen deficit, either from primary hypoxemia or from reduced uteroplacental blood flow, and glucose deficit from chronic maternal and fetal hypoglycemia (78,79). Of course, hypoxemia and hypoglycemia could reduce fetal growth independently of reduced amino

P.506

acid transport, for example, by limiting anabolic hormone and growth factor production or by decreasing energy supply, both of which are necessary to produce protein synthesis and to limit protein breakdown in fetal tissues.

The reason why amino acid and energy supplies are so important for fetal protein and nitrogen balance and for fetal growth is illustrated in Fig. 26-14. This figure shows results of experiments in fetal sheep over the second half of gestation, comparing fractional protein synthesis rates derived from tracer amino acid data and fractional body growth rates derived from carcass analysis data. The fractional rate of protein turnover per unit wet weight of fetus is several fold higher at 50% to 60% of term gestation (equivalent to about 20 to 24 weeks of human gestation). Such high rates of protein turnover require a much greater rate of amino acid supply and energy than at term, when fetal protein turnover rate is much lower. Indeed, in midgestation fetal sheep, glucose utilization rates per whole fetal weight and oxygen consumption rates per dry fetal weight are much higher in the early fetus than at term (80). These conditions result in a 50% higher rate of net protein accretion and fractional rate of fetal growth at midgestation than at term. Clearly,

amino acid and energy deficits will affect the growth rate of the fetus at earlier stages of gestation, when fetal growth normally is very rapid much more than at term, when fetal growth rate is slower.

In the normally growing fetus, net protein synthesis exceeds net protein breakdown, resulting in net protein accretion. The mechanisms underlying the reduction in protein synthesis rate over gestation appear to be intrinsic to the fetus, and not to limitation of nutrient supply by the placenta. These mechanisms include changing proportions of the organs as fractions of body mass (Table 26-9).

Figure 26-14 Fractional rate of protein synthesis (K_s) over gestation in fetal sheep studied with leucine (\bullet) and lysine (O) radioactive tracers compared with the fractional rate of growth (K_G) in the lower portion of the figure (—). Fetal Endocrine and Autocrine/Paracrine-Acting Growth Factor Effects on Fetal Growth

Table 26-10 lists those hormones whose deficiency results in a reduction in fetal growth supported by experimental evidence (81). These fetal hormones promote growth (and development) in utero by altering both

the metabolism and gene expression of fetal tissues. These hormonal actions ensure that fetal growth rate is commensurate with nutrient supply.

Insulin

Insulin has direct mitogenic effects on cellular development and thus can regulate cell number. It also enhances glucose consumption by many cells, particularly in muscle, and limits protein breakdown (75). The latter effects are associated with reduced fetal growth when insulin concentration is low. This has been produced directly by experimental surgical (82) and chemical (83) ablation of the pancreas and/or the function of the pancreatic beta cells to secrete insulin, and has been observed clinically in infants who suffer pancreatic agenesis (84). Figure 26-15 shows reduced rates of growth in fetal sheep that underwent surgical pancreatectomy and a return to normal rates of growth with insulin replacement. Much of the growth reduction with hypoinsulinemia from pancreatectomy is caused by a release of insulin's normal inhibitory role on glucose production, resulting in fetal hyperglycemia, a secondary decrease in the maternal-fetal glucose concentration gradient, and thus a decrease in glucose transport to the fetus. Without this glucose, fetal growth decreases, as has been shown by a direct decrease in glucose uptake by the fetus following the production of chronic maternal hypoglycemia (85). Fetal amino acid uptake decreases under the same circumstances. Thus, insulin deficiency, directly and indirectly, results in a decrease in fetal nutrient supply. Initially, fetal protein breakdown results in fetal

P.507

amino acid release for energy (via direct amino acid oxidation in the tricarboxylic [citric] acid cycle) and glucose production. Later on, the reduced rate of fetal growth during conditions of low insulin, glucose, and amino acid concentrations is sustained by increased protein breakdown (40); however, amino acids are used to maintain protein turnover rate and not for protein accretion, oxidation, or glucose production.

TABLE 26-10 EFFECTS OF SPECIFIC ENDOCRINE DEFICIENCIES ON BODY WEIGHT AND CROWN—RUMP LENGTH, AND INDIVIDUAL TISSUES ADVERSELY AFFECTED BY TREATMENT IN SHEEP FETUSES DELIVERED NEAR TERM (>95% GESTATION)^a

Endocrine Deficiency	Procedure	Gestational Age at Onset (d)	Body Weight	Crown-rump Length	Tissues with Specific Developmental Abnormalities
Insulin	Streptozotocin	70-85	↓50%	↓20%	None
	Pancreatectomy	115-120	↓30%	↓15%	None

P.508

Insulin-Like Growth Factor-I

IGF-I is positively regulated by glucose supply in the fetus. Infusion of IGF-I into fetal sheep decreases protein breakdown, especially when protein breakdown is increased by fasting-induced hypoglycemia. Metabolic effects of a decreased plasma concentration of IGF-I have not been studied, although, as for insulin, such effects might be difficult to

separate from simultaneous changes in nutrient substrate supply and concentration. Thus, IGF-I probably can regulate metabolic processes that affect fetal protein balance and growth, but these have been difficult to measure.

Plasma IGF-I concentrations are positively related to fetal size at birth. A causative role for IGF-I has been shown by the production of transgenic models of mice that have shown that decreased expression of IGF-I results in markedly reduced rates of fetal growth. Other transgenic models with increased expression of IGF-I have been associated with increased brain growth (86,87), and this growth can be inhibited by overexpression of IGF binding protein-1 (IGFBP-1) (88). IGF-I stimulates an increase in oligodendrocytes and neuronal number, and neuronal outgrowth with increased dendritic arborization and axon terminal fields (89). Because IGF-I is decreased directly by reduced nutrient supply, particularly glucose, and IGFBP-1 is decreased under these circumstances, the smaller, more densely packed neuronal structure of the undernourished brain that is seen in some infants with severe IUGR may have been mediated by nutrient regulation of IGF-I and IGFBP-1 expression. Such developmental limitations might underlie the poorer neurodevelopmental outcome of severely SGA infants who have relative microcephaly.

Insulin-Like Growth Factor-II, Insulin-Like Growth Factor Binding Protein-2, Insulin-Like Growth Factor Binding Protein-3, and Vasoactive Intestinal Polypeptide

Although serum concentrations of IGF-II do not correlate with fetal size at birth in human infants, it has been shown conclusively that targeted mutation of the IGF-II gene reduces fetal size in mice (90,91).

Furthermore, IGF-II is the predominant IGF expressed in the tissues of embryos and fetuses of all species. As with IGF-I and IGFBP-1, transgenic overexpression of IGF-II and IGFBP-2 shows that cellular growth is dependent on the balance between the binding protein and the IGF molecule itself. IGFBP-3 is the predominant IGF binding protein in

several mammalian species including humans (92,93) and is reduced in cord blood of infants with IUGR (94). Vasoactive intestinal peptide (VIP) is another growth factor in the fetus that affects neuronal and whole body growth (95,96,97). Antagonists to VIP in pregnant mice produce smaller fetuses that are particularly microcephalic (98), with central nervous system neurons that show reduced mitosis and migration. These effects of VIP occur in the first half of gestation, coincident with transiently high VIP concentrations in the maternal plasma (99).

Thyroid Hormones

In all species, fetal thyroid hormone deficiency produces developmental abnormalities in certain tissues. When maternal thyroid hormones cannot compensate, as in the sheep, which does not transport maternal thyroid hormones to the fetus, fetal growth restriction develops, primarily reflecting deficient carcass growth (skin, bone, and muscle) (81). This growth restriction results from both hypoplasia (in muscle) and hypotrophy (in lung). More generally, fetal hypothyroidism decreases oxygen consumption and oxidation of glucose, thereby potentially decreasing fetal energy supply for growth. Hypothyroidism also can decrease circulating and tissue concentrations of IGF-I.

Glucocorticoids

Glucocorticoids do not have strong effects on fetal growth rate, but they are important in the maturation of many fetal enzymatic pathways (39). These include glycogen deposition, gluconeogenesis, fatty acid oxidation, induction of surfactant production and release, structural maturation of alveoli, structural maturation of the gastrointestinal tract, increased expression of digestive enzymes, increased adrenal function, switch from fetal to adult hemoglobin synthesis, and others. Many IUGR fetuses have increased cortisol concentrations that appear to result from intermittent hypoxic stress. This may account for much of the apparent increased maturation of IUGR fetuses, even when born preterm.

Growth Hormone

Growth hormone, which is the major hormonal regulator of postnatal growth, has no demonstrable effect on fetal growth (39,81).

ANTENATAL CARE OF THE INTRAUTERINE GROWTH-RESTRICTED FETUS

Diagnosis of Intrauterine Growth Restriction

Antenatal diagnosis of IUGR is difficult and often inaccurate. Despite careful attention to gestational dating by maternal history and early and serial fetal ultrasound evaluation, frequent maternal physical examinations, and repeated assessment of risks for IUGR, more than one-half of infants with IUGR may not be identified before birth (100). Serial ultrasound evaluation of fetal growth rate and fetal body proportions and Doppler velocimetry of the uterine, placental, and fetal circulations are now the standard diagnostic approaches to determining the severity of IUGR. In particular, Doppler velocimetry has provided increasingly accurate prognostic evidence of worsening fetal condition and impending fetal death (101,102,103,104,105,106). Chronic fetal distress resulting from placental insufficiency, hypoxia, and ischemia (with or without acidosis) is

P.509

associated with increased Doppler arterial waveform amplitudes that indicate increased vascular resistance and reduced systemic flow in the descending aorta and umbilical artery. Various ratios of systolic-to-diastolic flow velocity (amplitude) waveforms have been used, including the systolic-to-diastolic ratio, systolic-diastolic/systolic ratio (resistance index), and systolic-diastolic/mean ratio (pulsatility index). Ratios or indexes greater than two standard deviations from the mean are associated with IUGR, whereas reversed or absent diastolic waveforms represent severe fetal hypoxia and increased risk of fetal death. The most severely affected IUGR fetuses with the greatest risk of death demonstrate absent or reversed diastolic flow in systemic fetal arteries (104), along with increased umbilical venous pulsation and reversed flow in the abdominal vena cava. Interestingly, these same fetuses often have decreased cerebral (internal carotid artery) pulsatility index, indicating increased cerebral blood flow (105). This flow pattern has been

interpreted as one way in which brain growth is spared, as body growth rate slows as a result of placental ischemia and/or placental growth failure. Doppler waveform abnormalities usually precede less specific signs of fetal distress, such as abnormal changes in fetal heart rate, spontaneously or in response to oxytocin challenge testing.

The fetus also should be examined by ultrasound for anatomic abnormalities that indicate congenital malformations, genetic syndromes, and deformations. Amniotic fluid index also is useful to identify oligohydramnios. The latter is a risk factor for congenital anomalies, severe IUGR with reduced urine production, pulmonary hypoplasia, variable decelerations from cord compression, and intrauterine fetal death in as many as 5% to 10% of affected fetuses.

Future Diagnosis and Treatment of Intrauterine Growth Restriction

Altered fetal growth rate, and pathophysiology associated with IUGR, usually develop insidiously, such that once these conditions are clinically obvious, injury has already taken place. It is important, therefore, to develop and apply diagnostic techniques to the fetus that would establish accurately even minimal changes in growth rate and physiologic function. Currently, Doppler ultrasound measurements of fetal cardiac output, systemic blood flow, and organ blood supply are close to achieving this goal, particularly with respect to the placental circulation (107). Other recent research trials have focused on quantifying placental transfer functions in pregnant women who are carrying a severely IUGR fetus. For example, women carrying an IUGR fetus can be given stable isotopes of nutrients normally transported across the placenta, such as glucose and selected amino acids, followed by timed cordocentesis to measure placental transfer characteristics of these substrate isotopes (108). This information can be compared with that from normal pregnancies with normal placental function and fetal growth rates.

It is also important that diagnostic techniques are developed to assess what damage is being done in the more extreme cases of IUGR. Current techniques include magnetic resonance imaging, Doppler measurements of blood flow to specific organs (107), cordocentesis (109,110,111,112),

and neurologic and neuromuscular response to vibroacoustic stimulation (113). Based on such advances in fetal diagnosis, it soon may be possible to assess whether detected changes in fetal growth rate and measured fetal pathophysiology associated with IUGR are, in fact, as serious and indicative of future handicap as current postnatal follow-up studies have indicated.

Considerably more research is necessary to determine when and how damage to the fetus can be reversed or ameliorated. Some efforts have been made in animal models to improve maternal and fetal nutrition (114) and to enhance development by organ-specific hormone targeting (115). Examples of the latter include glucocorticoids that have been administered (such as betamethasone) to both the mother and the fetus to increase lung surfactant maturity (116), with additional potential benefits to the maturation of other fetal organs including the gut, heart, adrenals, and kidneys (115). Also, thyroid-releasing hormone has been administered along with corticosteroids to increase lung maturity, although currently there are mixed reports of its effectiveness (117). Continued work is necessary to assess brain development with such treatments, and long-term growth and development of all affected organs. More philosophically, it is important to consider whether it is wise to change normal developmental relationships among organs by using organ-specific hormone therapy; more information is needed to determine how altered patterns of organ development during fetal life are beneficial and how they may promote, or hinder, normal fetal development (118).

Antenatal Management

There are few, if any, proven treatments of IUGR. Bed rest and treatment of acute and chronic illnesses appear beneficial. Having the mother breathe supplemental oxygen improves fetal oxygenation, and in a few studies of severe IUGR fetuses with signs of chronic distress this has been associated with improved rates of fetal growth and reduced fetal aortic blood flow velocity (increased flow) (119). Trials of low-dose aspirin therapy, aimed primarily at treating preeclampsia, have not consistently improved fetal growth (120). Correction of maternal

nutritional deficiencies also is useful, particularly when the mother is markedly undernourished. Maternal dietary zinc supplements have improved fetal growth when zinc deficiency was prominent. High protein intakes have not helped and, in fact, have been associated with worse IUGR and perinatal morbidity and mortality.

Fetal surveillance techniques should be instituted to determine whether the fetal condition is beginning to fail and if delivery would be more likely to result in a successful pregnancy outcome. Traditional fetal surveillance techniques have included fetal activity recordings, the oxytocin challenge test, which measures fetal heart rate changes after oxytocin-induced uterine contractions, and the nonstress test, which measures the acceleration and beat-to-beat

P.510

variability of the fetal heart rate after spontaneous fetal movement. These tests, although still done, have been replaced by Doppler velocimetry and the biophysical profile, which combine analyses of fetal breathing movements, gross body movements, fetal heart rate, fetal heart rate reactivity to movement, and estimated amniotic fluid volume. The combined use of Doppler velocimetry and the biophysical profile has improved the antenatal management of IUGR (121,122). A low biophysical profile correlates with fetal hypoxia determined by absent or reversed diastolic flow in the umbilical artery and fetal blood gas and acid-base measurements obtained by cordocentesis, and with impending fetal demise.

Most obstetricians avoid labor when combined fetal surveillance techniques show severe fetal growth restriction and evidence of severe chronic distress (123,124), including absent or reversed diastolic flow in the fetal aorta, increased pulsations and/or reversed flow in the umbilical veins, and a low biophysical profile score. Fetuses with these conditions also usually have a nonreactive nonstress test result and a flat baseline fetal heart rate variability pattern. Such fetuses tolerate labor poorly and readily develop signs of acute distress. Saline amnioinfusion may be beneficial in the presence of oligohydramnios and an amniotic fluid index of less than 5 cm (125). Amnioinfusion to an index greater than 8 cm

may decrease the incidence of meconium-stained fluid, variable decelerations in the fetal heart rate, end-stage bradycardia, and acute fetal acidosis. In all such severe cases the delivery should be coordinated with the neonatology service to provide prompt postnatal evaluation and care and to prepare for resuscitation of a depressed or asphyxiated neonate.

In the absence of repeated observations of severe or progressively worsening IUGR and signs of fetal distress, the moderately affected IUGR fetus should be left in utero, although providing good nutrition, perhaps bed rest, and optimal health care to the mother, and continuing fetal surveillance. Decisions to deliver these fetuses prematurely to prevent fetal death should be tempered by the difficulties of accurately diagnosing the worsening of fetal condition and successfully managing all potential neonatal problems of a preterm infant. Although lung maturity may be present, the many other problems associated with preterm delivery should add caution to a decision for early delivery, especially before 31 to 32 weeks of gestation.

CLINICAL EVALUATION AND TREATMENT OF THE SMALL-FOR-GESTATIONAL AGE INFANT

General Evaluation in the Delivery Room

SGA infants often present a variety of clinical problems immediately after birth in the delivery room. Because of their large surface area relative to body weight, SGA infants lose heat rapidly. To prevent hypothermia, they should be dried quickly and completely, placed under a radiant warmer, and protected from drafts with warmed blankets. Severely SGA infants who suffered marked oxygen and substrate deprivation in utero may have cardiopulmonary difficulties at birth. Closer to term they may pass meconium and present with meconium aspiration syndrome, signs of asphyxia, including hypoxemia, hypotension, mixed metabolic and respiratory acidosis, and persistent pulmonary hypertension.

Immediately after birth, these infants need prompt and careful attention to their airway, breathing, and oxygen needs.

Brief Physical Examination in the Delivery

Room

SGA infants have several characteristic features, even when those infants with obvious anomalies and syndromes and those born to mothers with severe illness or malnutrition are excluded (126,127,128). Severely SGA infants who had marked IUGR have relatively large heads for their undergrown trunks and extremities. The abdomen often appears shrunken or "scaphoid" and must be distinguished from infants with diaphragmatic hernias. The extremities appear scrawny with thin skinfolds, with evidence of decreased subcutaneous fat and skeletal muscle. The skin is loose and often rough, dry, and peeling. In term and postterm severely SGA infants, the fingernails may be long, and the hands and feet tend to look large for the size of the body. The face appears shrunken or "wizened." Cranial sutures may be widened or overriding, and the anterior fontanelle may be larger than expected, representing diminished membranous bone formation. The umbilical cord often is thinner than usual. When meconium has been passed in utero, the cord is yellow-green stained, as are the nails and skin.

Gestational Age Assessment of the Small-for-Gestational-Age Infant

Gestational age assessment based on physical criteria often is erroneous. Vernix caseosa frequently is reduced or absent as a result of diminished skin perfusion during periods of fetal distress or because of depressed synthesis of estriol, which normally enhances vernix production. In the absence of this protective covering, the skin is continuously exposed to amniotic fluid and will begin to desquamate. Sole creases appear more mature as a result of increased wrinkling from increased exposure to amniotic fluid. Breast tissue formation also depends on peripheral blood flow and estriol levels and will be reduced in SGA infants. The female external genitalia will appear less mature because of the absence of the perineal adipose tissue covering the labia. Ear cartilage also may be diminished. Specific organ maturity often continues at normal developmental rates despite diminished somatic growth in most IUGR

infants. Cerebral cortical convolutions, renal glomeruli, and alveolar maturation all relate to gestational age and are not delayed with IUGR. P.511

Neurologic Examination of the Small-for-Gestational-Age Infant

Neurologic examination for gestational age assessment may be little affected by IUGR. These infants often appear to have advanced neurologic maturity, although this observation is derived mostly from comparisons with infants of similar birth weight, not similar gestational age. Peripheral nerve conduction velocity and visual- or auditory-evoked responses correlate well with gestational age and are not impaired as a result of IUGR. These aspects of neurologic maturity are not sensitive to nutritional deprivation. Active and passive tone and posture are usually normal in SGA infants and are reliable guides to gestational age, assuming that infants with significant central nervous system and metabolic disorders are excluded.

Behavioral Observations

SGA infants demonstrate specific abnormal behaviors. They often have a "hyperalert" appearance and generally look "starved and hungry," and they often are described as being jittery and hypertonic, even without simultaneous hypoglycemia. They may be hyperexcitable, showing aberrations in tone from hypertonia to hypotonia and, in many cases, apathy. The Moro response is increased, with exaggerated extension and abduction of the arms, windmill motions, and prolongation of the tonic neck posture (129,130). When IUGR is particularly severe, SGA infants tend to show abnormal sleep cycles and a more consistent picture of diminished muscle tone, deep tendon and facial tactile reflexes, general physical activity, and excitability. These more severe changes indicate that functional central nervous system maturity is impaired, despite the presence of electrical neurologic maturity (131,132,133). Such severely SGA infants often appear floppy and develop exhaustion more easily after handling (134). The behavioral disorders occur even in the absence

of significant central nervous system disease. The hypoexcitability indicates an adverse effect on polysynaptic reflex propagation and implies that central nervous system functional maturity does not necessarily proceed independently of the intrauterine events that result in IUGR.

Deferred Physical Examination to be Done in the Neonatal Intensive Care Unit

Careful evaluation is important as there is an increased incidence of severe malformation, chromosomal abnormality, and congenital infection among SGA infants (135,136). Dysmorphic features, "funny-looking facies," abnormal hands and feet, and the presence of palmar creases, in addition to gross anomalies, suggest congenital malformation syndromes, chromosomal defects, or teratogens. Ocular disorders, such as chorioretinitis, cataracts, glaucoma, and cloudy cornea, in addition to hepatosplenomegaly, jaundice, and a blueberry-muffin rash, suggest a congenital infection. Toxoplasmosis, other (syphilis, hepatitis, Zoster), rubella, cytomegalovirus, and herpes simplex (maternal infections) (TORCH) infections resulting in IUGR are unusual in the absence of other clinical signs of chronic congenital infection; however, screening cord blood for antibodies and antigens specific to certain infections (which can be augmented by polymerase chain reaction techniques), and a urine culture for cytomegalovirus may be indicated. Radiographic examination of the long bones, looking for possible anomalies and for the quality of mineralization, may be useful. Examination of the head with ultrasonography to establish the presence of congenital anatomic abnormalities or evidence of congenital infection also may be helpful in making a diagnosis.

CLINICAL PROBLEMS OF THE SMALL-FOR-GESTATIONAL-AGE NEONATE (TABLE 26-11)

Mortality

The consequences of small size for gestational age depend on the etiology, severity, and duration of growth restriction. There continues to

be much debate on this subject. Previous studies have included heterogeneous groups of infants with respect to the degree and cause of IUGR, the degree of prematurity, and the severity of clinical problems in the early neonatal period. By now, many studies have been conducted over extended periods of changing perinatal management and increasing survival rates of smaller, more preterm infants, many of whom have been classified differently at different times and among different studies regarding their degree of IUGR. Some studies have indicated that the fetus responds to the "stress" of growth restriction with an acceleration of maturity, which ultimately is protective for the infant. Others have found no evidence of improved survival after perinatal stress, and SGA status has been shown to be an independent predictor of increased fetal, perinatal, and neonatal death (137). On balance, there is little evidence to support the concept of improved survival after perinatal stress in SGA infants, and the perinatal mortality rate for SGA infants with relatively severe IUGR is 5 to 20 times that of AGA infants of the same gestational age (136,137). Particularly when adjusted for maternal neonatal risk factors of IUGR, including birth weight percentile, gestational age at birth, maternal height, prepregnancy weight, gestational weight gain, race, and parity, a subgroup of SGA infants is defined that has consistently and markedly higher perinatal mortality and morbidity rates than normally grown infants (138).

Intrauterine Growth Restriction/Small-for-Gestational-Age Status vs. Preterm Birth, and Effects on Mortality and Morbidity

Preterm and growth-restricted infants have independent and overlapping problems. Constitutionally small infants are not likely to have increased risks of mortality or morbidity. As gestational age decreases, the problems of

P.512

prematurity have a larger role in the outcome of both SGA and AGA infants. In contrast, the more mature preterm or term infant may suffer

more from the impact of growth restriction. When IUGR has been severe and prolonged, these infants have a higher perinatal mortality rate than their AGA peers. Intrauterine fetal death from chronic fetal hypoxia, immediate birth asphyxia, the multisystem disorders associated with asphyxia (hypoxic-ischemic encephalopathy, persistent fetal circulation, cardiomyopathy, meconium aspiration), and lethal congenital anomalies are the main contributing factors to the high mortality rate for IUGR fetuses and neonates. Most intrauterine fetal deaths occur between 38 and 42 weeks of gestation. Improved survival depends on achieving an optimal balance between the consequences of elective preterm delivery and the risks of continued IUGR.

TABLE 26-11 CLINICAL PROBLEMS OF THE SMALL-FOR-GESTATIONAL-AGE NEONATE

Problem	Pathogenesis/Pathophysiology	Prevention/Treatment

Acute renal failure	Hypoxia/ischemia	Cardiovascular support
Immunodeficiency	Malnutrition Congenital infection	Early, optimal nutrition Specific antibiotic and immune therapy

Asphyxia

Perinatal asphyxia is an uncommon event in SGA infants, but it does occur at increased frequency in SGA infants and can complicate the immediate neonatal course of severe IUGR infants. SGA infants frequently do not tolerate labor and vaginal delivery, and signs of fetal distress are common. In such cases, the already stressed, chronically hypoxic infant is exposed to the acute stress of diminished blood flow during uterine contractions. Cord blood lactate concentrations are often increased despite overall normal cord blood pH. Preterm SGA infants are delivered by cesarean section twice as often as preterm AGA infants (136,139). SGA infants have an increased incidence of low Apgar scores at all gestational ages (136), and these infants frequently need resuscitation.

P.513

The acute fetal hypoxia, acidosis, and cerebral depression may result in fetal death or neonatal asphyxia. Severe IUGR results in a large

proportion of stillborn infants. Myocardial infarction, amniotic fluid and meconium aspiration, and cerebral edema and necrosis often are noted at autopsy in these severely IUGR stillborn infants. An inadequate resuscitation at birth adds double jeopardy to the in utero insults. Sequelae of perinatal asphyxia include multiple organ system dysfunction that, in the more severe cases, includes hypoxic-ischemic encephalopathy, heart failure from hypoxia-ischemia and glycogen depletion, meconium aspiration syndrome, persistent pulmonary hypertension, gastrointestinal hypoperistalsis and ischemia-induced necrosis leading to focal perforation, and acute renal tubular necrosis and renal failure. However, surfactant-deficiency respiratory distress syndrome is not increased in more mature SGA infants closer to term, despite the increased incidence of other forms of respiratory distress. Hypocalcemia may occur following asphyxia in SGA infants, although this is uncommon unless there is excessive phosphate released from damaged cells by acidosis followed by correction with sodium bicarbonate.

Neonatal Metabolism

Hypoglycemia

Hypoglycemia is extremely common in SGA infants, increasing with the severity of IUGR (Fig. 26-16) (140,141,142,143,144,145,146,147,148). The risk of hypoglycemia is greatest during the first 3 days of life, but fasting hypoglycemia, with or without ketonemia, can occur repeatedly up to weeks after birth. Early hypoglycemia usually is as a result of diminished hepatic and skeletal muscle glycogen contents (145,147). Early hypoglycemia is aggravated by diminished alternative energy substrates, including reduced concentrations of fatty acids from the scant adipose tissue and decreased concentrations of lactate from the hypoglycemia. Hyper-insulinemia, increased sensitivity to insulin, or both may contribute to a greater incidence of hypoglycemia, although there are very few, if any, accurate measures of insulin sensitivity at different times and among different conditions in SGA infants to support such assumptions (142). SGA infants also demonstrate decreased gluconeogenesis (149), and resolution of persistent hypoglycemia is coincident with improved capacity for, and rates of, gluconeogenesis.

Deficient counterregulatory hormones also contribute to the pathogenesis of hypoglycemia in SGA infants (150). Catecholamine release is deficient in these neonates during periods of hypoglycemia. Although basal glucagon levels may be elevated, exogenous administration of glucagon fails to enhance glycemia because of the decreased hepatic glycogen stores.

Fasting hypoglycemia is now less common in SGA infants as conventional nutritional treatment now involves earlier enteral and intravenous feeding and a more liberal use of intravenous glucose (139). All SGA infants should have early and frequent measurements of blood or plasma glucose concentrations. Blood glucose concentrations should be kept at greater than 50 mg/dL. Early enteral feeding usually can prevent hypoglycemia. In less mature infants or those who have other clinical problems, intravenous glucose should be started at 4 to 8 mg/min/kg as soon after birth as possible—preferably by 30 minutes of age. This initial infusion rate should be adjusted in response to measurements of blood glucose concentration every 30 to 60 minutes until these values are consistently greater than 50 mg/dL. Less frequently repeated measurements should be continued until the infant is tolerating reasonably full enteral feedings. Infants with severe hypoglycemia (less than 20 mg/dL) that is persistent for more than 10 to 30 minutes, with coma and seizures, should be treated immediately with an intravenous “minibolus” of 10% dextrose in water at 200 mg/kg (2 mL/kg), followed by a glucose infusion of 10% dextrose in water at 4 to 8 mg/min/kg. Glucose concentrations should be measured at least every 30 minutes until concentrations are consistently above 45 mg/dL for blood or above 50 mg/dL plasma (or serum). Infants at greatest risk of having severe hypoglycemia are those who have been asphyxiated and those who are the thinnest according to the Ponderal index, representing those infants with the least amount of body glycogen content. Similarly, breast-fed twins who are not supplemented with a carbohydrate source are at risk, particularly the smaller twin, and they should be monitored carefully.

Figure 26-16 Incidence of hypoglycemia prior to first feeding (blood glucose less than 30 mg/dL) among large-for-gestational-age, average-for-gestational-age, and small-for-gestational-age (SGA) infants, demonstrating the much greater incidence of early hypoglycemia among SGA infants at all gestational ages. From Lubchenco LO, Bard H. Incidence of hypoglycemia in newborn infants classified by birth weight and gestational age. *Pediatrics* 1971;47:831, with permission.

P.514

Hyperglycemia

Very preterm SGA infants have developmentally low insulin secretion rates and plasma insulin concentrations, which may underlie the relatively common problem of hyperglycemia in ELBW SGA infants (151). Unnecessarily high rates of glucose infusion (greater than 14 mg/min/kg) also contribute to this hyperglycemia (152). Higher concentrations of counterregulatory hormones, such as epinephrine, glucagon, and cortisol,

also may contribute, although there is only limited evidence to support this commonly held assumption. In contrast, administration of insulin to even preterm SGA infants usually produces prompt decreases in glucose concentration, indicating at least normal and probably greater than normal insulin sensitivity (153).

Lipid Metabolism

SGA infants also have lower plasma free fatty acid levels than normally grown infants. Fasting blood glucose levels in SGA infants directly correlate with plasma free fatty acid and ketone body levels. Additionally, once fed, SGA infants have a deficient utilization of intravenous triglycerides. After the intravenous administration of triglyceride emulsion, SGA infants have high free fatty acid and triglyceride levels, but ketone body formation is attenuated (154,155). These observations indicate that the utilization and oxidation of free fatty acids and triglycerides are diminished in SGA neonates. Free fatty acid oxidation is important because it spares peripheral tissue use of glucose, whereas the hepatic oxidation of free fatty acids may contribute the reducing equivalents and energy required for hepatic gluconeogenesis. Deficient provision or oxidation of fatty acids may be partly responsible for the development of fasting hypoglycemia in these infants.

Energy Metabolism

When nursed in a neutral thermal environment, SGA infants demonstrate the usual decline of the respiratory quotient after birth, representing a shift toward free fatty acid oxidation. During the first 12 hours after birth, basal oxygen consumption may be diminished in SGA neonates. Similar observations have been recorded in utero among spontaneously SGA fetal lambs, indicating a deficiency of potentially oxidizable substrates in both situations. Supporting this hypothesis is the marked increment of oxygen consumption that occurs in well-fed SGA infants (156), similar to the increase in energy production after nutritional rehabilitation of infants with marasmic kwashiorkor. The increment of oxygen consumption after fetal or infantile malnutrition represents the energy cost of growth. Partly because of enhanced caloric intake, and

because metabolic rate and oxygen consumption are related more to gestational age than birth weight, SGA infants have a higher oxygen consumption rate and a higher rate of total energy expenditure (primarily as a result of increased resting energy expenditure) than less mature neonates (155). This also reflects an increase in cell number relative to total mass and greater heat production in response to increased heat loss. Although some nutritional balance studies of preterm SGA infants have demonstrated an increase of fecal fat and protein loss, more recent studies indicate adequate digestion of nutrients and percent nutrient retention of metabolizable nutrient intake. Thus, these infants can achieve normal, and occasionally faster, rates of growth compared with preterm AGA infants.

Those SGA infants who, because of chromosomal or infectious insults early in gestation, cannot increase their growth rate do not demonstrate increased rates of oxygen consumption after appropriate caloric intake.

Amino Acid and Protein Metabolism

SGA infants are particularly deficient in muscle mass. Improving nutrition of skeletal muscle, and total body protein, is a priority in these infants. There is conflicting information from a limited number of studies, however, about how well SGA infants tolerate aggressive amino acid and protein nutrition. ELBW and VLBW SGA infants have higher rates of protein loss in stools, and of lipids (141), with 11% to 14% lower rates of absorption. This may be partly compensated for by higher intakes, which can normalize metabolizable protein intakes. Further, although growth rate may be increased in SGA infants by increased intake of protein and nonprotein calories, specific evidence for this comes largely from preterm infants, some of whom were AGA and some SGA (157). Also, animal studies show more limited pancreatic development and intestinal size in SGA offspring (158,159), which may limit feeding tolerance, protein digestion, and the production of insulin.

Some studies have shown that amino acid turnover rates are higher in SGA LBW infants (160), but other studies show no difference (161,162). SGA infants may be more energy efficient in protein synthesis (162). This could explain faster rates of growth in SGA vs. AGA infants of the

same gestational age, who are fed the same diet (156,157). Thus, SGA infants possibly may tolerate higher protein intake, but the benefit of increased intake is not clear (157).

Nutritional Problems and Management

In fetal sheep that are acutely glucose deficient, amino acids are used for oxidation and for glucose production (163). With chronic glucose deficiency, protein breakdown remains increased and IUGR develops, but amino acids are not used for glucose production or oxidation more than normally (164). It is not clear if human infants born following similar patterns of IUGR and nutrient deficiency will have similar patterns of metabolism after birth, nor is it known what types and amounts of nutrients are best fed to such infants to restore normal metabolism and to reestablish normal rates of growth as quickly as possible. A rapid rate of glucose supply can lead to marked hyperglycemia,

P.515

especially in the ELBW preterm SGA infant. On the other hand, amino acid intolerance is not exaggerated in SGA infants, despite some earlier evidence that amino acids are not used as readily for gluconeogenesis. If insulin and IGF-I are deficient in these infants, one would also expect lower anabolic rates until glucose and amino acid supplies and concentrations, and production rates of these growth factors, are restored. Similar issues may apply to lipid tolerance. Such considerations have prompted some reluctance to feed the SGA infant as aggressively as their deprived nutritional state would indicate, but large-scale, rigorous trials of different rates and amounts of nutrition to such infants have not been conducted. Such trials are needed to determine whether these infants will tolerate more aggressive feeding and whether this will result, safely, in improved nutritional rehabilitation, growth, and perhaps, neurodevelopmental outcome.

Temperature Regulation

Impaired placental function leading to ineffective heat elimination from the SGA fetus may result in a higher than normal temperature in the infant at birth (150,153). A normal increase in nonshivering

thermogenesis is seen in these infants because brown fat is available (165,166). However, depletion of brown fat may occur more readily if exposure to cold is prolonged (167). In utero stress that depletes catecholamine stores can contribute to a failure of brown fat to produce heat. Compared with term infants, SGA infants have a narrow thermoneutral range. Heat production cannot match the rate of heat loss with continued cold stress. The rapid heat loss as a result of the large head-to-body ratio and increased surface area seen in all infants is exaggerated in the SGA infant. Heat is also lost more quickly through a thin layer of subcutaneous fat insulation (165,167). Because they are gestationally more mature than their preterm peers, SGA infants do have a more generous thermoneutral range for weight and are better able to maintain the increased metabolic rate necessary to increase heat production (168). Also, SGA infants of more than 30 weeks of gestation may have increased skin maturity and less evaporative heat loss than AGA infants of comparable weight (169), indicating that thermal neutral environments should be based on gestational age and not weight alone (170). Heat production may be impaired by concurrent conditions of hypoglycemia and hypoxia seen commonly in these patients. The normal response to cold involves increased muscular activity and catecholamine (norepinephrine) release. Central nervous system depression may prevent this normal response to cold (165).

During the first few hours of life, oxygen consumption and heat production may be less than anticipated as a result of decreased available substrate. Fewer fatty acids are available for oxidation. Later, as nutritional support is provided, the infant may have higher than expected oxygen consumption. Brain oxygen requirements are high, and in the SGA infant brain tissue represents a large proportion of body weight. Limited availability of glucose in utero limits metabolic rate. After delivery, as glucose substrate is provided, the brain increases its metabolic rate and oxygen consumption. Based on brain size, increased rates of oxygen consumption are appropriate in the SGA infant (171). It is critical, therefore, that the SGA infant be resuscitated and nursed in a thermoneutral environment. The newborn should be placed immediately under a radiant warmer and dried well. A prewarmed hat will minimize

excessive heat loss from the head. A flexed posture decreases exposed surface area and may slow heat dissipation.

Current and future studies of the value of selective brain cooling of infants suffering perinatal hypoxic-ischemic encephalopathy may indicate an advantage for this unique approach in SGA infants as well.

Polycythemia-Hyperviscosity Syndrome

SGA infants manifest an increased incidence of polycythemia (172). Increased red blood cell volume is likely related to chronic in utero hypoxia leading to increased erythropoiesis (173,174). Maternal-fetal transfusion may occur chronically with fetal hypoxia or more acutely with episodes of fetal distress. Even when not polycythemic (venous hematocrit greater than 60), SGA infants have higher than normal hematocrit (174). Approximately half of all term SGA infants have a central hematocrit above 60% and about 17% of term SGA infants have a central hematocrit above 65% in contrast to only about 5% in AGA term infants (175,176). The plasma volume of SGA infants immediately after birth averages 52 mL/kg, as opposed to 43 mL/kg in AGA infants. Once equilibrated at 12 hours of life, the plasma volume becomes equivalent in the two groups. In addition to an enhanced plasma space, the circulating red blood cell mass is expanded.

Viscosity is directly related to venous hematocrit, and increased viscosity interferes with normal tissue perfusion. Although the incidence of hyperviscosity is about 5% in the general population, it is seen much more frequently (18%) in SGA infants (175). In these cases, polycythemia is the most likely etiology of hyperviscosity. Most polycythemic infants remain asymptomatic, but SGA infants are at greater risk of symptoms and clinical consequence (176). Interestingly, male SGA infants are at highest risk. Polycythemia contributes to hypoglycemia and hypoxia. Altered viscosity interferes with neonatal hemodynamics and results in abnormal postnatal cardiopulmonary and metabolic adaptation. There is also an increased risk of necrotizing enterocolitis. In addition to correcting hypoxia and hypoglycemia in these infants, partial volume exchange transfusion should be considered

to lower hematocrit and minimize the risks of polycythemia and hyperviscosity.

Immune Function and Infectious Disease Risk

Immunologic function of SGA infants may be depressed at birth and may persist into childhood, as in older infants with postnatal onset of malnutrition (177). Deficiencies

P.516

have been demonstrated in lymphocyte number and function, which include decreased spontaneous mitogenesis and reduced response to phytohemagglutinin. Similarly, these infants tend to have lower immunoglobulin levels during infancy and demonstrate an attenuated antibody response to oral polio vaccine.

Miscellaneous Problems

At birth, cord prealbumin and bone mineral content are low in term SGA infants (178). Calcium and iron stores may be low as a result of chronic decreased placental blood flow and insufficient nutrient supply.

Significant hypocalcemia can occur after stressful birth complicated by acidosis. Thrombocytopenia, neutropenia, prolonged thrombin and partial thromboplastin times, and elevated fibrin degradation products are also problems among SGA infants (179,180,181). Sudden infant death syndrome may be more common after IUGR. Inguinal hernias also disproportionately follow preterm IUGR.

OUTCOMES AND LONG-TERM CONSEQUENCES OF SMALL-FOR-GESTATIONAL-AGE INFANTS

Hospitalization

At term, SGA infants are admitted more frequently to the intensive care unit and have longer hospital stays than their AGA counterparts. Even among term infants well enough to avoid neonatal intensive care unit admission as newborns, the incidence of readmission to hospital during the first year is significantly increased for SGA infants. Neurologic disorders and other morbidities requiring follow-up and hospitalization

are more frequent among IUGR infants, occurring 5 to 10 times more often than among AGA infants. SGA infants also are more likely to be hospitalized for serious respiratory infections, especially if the mother smoked cigarettes at the time of conception and at other times.

Growth and Developmental Outcome

Most studies of normal and restricted fetal growth and development support the concept that critical windows of time are present in human development during which normal growth of certain tissues (e.g., fat, muscle, bone) or organs (pancreas, brain) must occur. Insults at such times limit growth and can program persistent, even lifelong failures in growth and development (182). In rats, for example, undernutrition at a vulnerable period of brain development permanently decreases brain size, brain cell number, normal behavioral development, learning, and memory (183,184). Permanent deficits may result if growth failure occurs during these critical periods (185).

SGA infants are a heterogeneous group of babies with the potential for a variety of outcomes. Some are small from genetic or familial causes and therefore may be expected to achieve their full growth potential and have normal neurodevelopment (186). Others have specific chromosomal errors or injury from infections, which are likely to result in severe and unrecoverable failure of growth and development. Most have a less defined reason for abnormal in utero growth. The infant with symmetric growth restriction may have little chance for postnatal catch-up growth after an early, global disruption of growth. However, a neonate who had normal growth in early gestation, but developed growth restriction from limited nutrient availability in later gestation later, has a reasonable potential for catch-up growth and normal development.

Studies of growth-restricted infants have been plagued by methodologic problems. Many early studies included all small infants without adequate distinction between those born at different gestational ages or those with limited familial or genetic growth potential. Infants with obvious chromosomal abnormalities and evidence of congenital infection also were included. Only relatively recently have studies of outcome of IUGR and SGA infants included in the study design the recognition that the

etiology of small size at birth carries great prognostic value. More recent studies of this subject also have been limited by uncontrolled confounding factors. An infant's perinatal morbidity, including inborn or outborn (requiring transport) status, presence of abnormal umbilical artery waveforms (121), and a variety of neonatal complications, such as asphyxia, hypoglycemia, polycythemia, and cold stress, can impact on ultimate outcome (185,186,187). Multiple gestation and even birth order can influence future growth potential.

Socioeconomic status and environment are among the most important, but difficult to control for, variables affecting the growth and development of SGA infants. Several studies have attempted to differentiate between the influences of biologic and environmental variables (187, 188). There are strong associations between socioeconomic factors and the cognitive development and school performance of growth-restricted children.

Postnatal Physical Growth of Small-for-Gestational-Age Infants

Although measurements of weight, length (or height), and head circumference are standardized and reproducible, many authors have given more attention to one measurement over another or have been more concerned with a specific interrelationship of measurements, such as the Ponderal index (189). In general, SGA infants continue to be smaller and relatively underweight for age as they grow older, even through adolescence and early adulthood (Fig. 26-17). These infants more commonly have short stature as teenagers and young adults, indicating lifelong growth deficit.

Differences in patterns of early growth have been observed in SGA infants. Normal infants experience a period of rapid growth during the first 3 years of life. Adult size correlates with the individual growth curve after this time. Moderately affected SGA infants who had primarily a reduction in weight in the third trimester of gestation

follow the same pattern of normal neonatal and infant growth, but tend to have an accelerated velocity of growth during the first 6 months (189). This catch-up growth occurs primarily from birth to 6 months of age, with some infants continuing an accelerated rate of growth for the first year. A few of these infants will achieve a normal growth percentile and thereafter have a growth rate similar to appropriately grown children (189,190). Head circumference parallels growth in length during catch-up and sustained growth periods. After the first year, no difference in the rate of growth has been noted (189,190).

Figure 26-17 Distribution of height at age 17 years in 30 boys (A) and 34 girls (B) born small for gestational age (solid bars) and their peers who were born appropriate for gestational age (shaded bars). From Paz I, Seidman DS, Danon YL et al. Are children born small for gestational age at increased risk of short stature? *AM J Dis Child* 1993;147:337.

Ultimate weight and height are less in SGA children when compared to their normal siblings (189,190). In one study of 4- to 6-year-old children (189), 45% of siblings were at or above the 50th percentile for weight and height, whereas only 12% of their SGA siblings achieved the 50th percentile. Interestingly, a subgroup of severely growth-restricted infants (less than 40% of expected birth weight) compared to less affected SGA peers showed no difference in weight or height at 6 months of age, adding concern for the growth outcome of even modest degrees of IUGR. Former SGA infants have been shown to have no delay in bone age, puberty, or sexual maturation at adolescence, although they were shorter, lighter, and had smaller heads. Muscle mass between the two groups was similar, but adipose tissue development was less in the SGA group (191).

Because head size correlates with brain size, volume, weight, and cellularity, head growth at the time of birth and the degree of catch-up growth thereafter are prognostic of future neurodevelopment. Deficient fetal head growth recognized by relative microcephaly at birth, whether at term or preterm, is felt to be a poor prognostic indicator, as it reflects the severity and duration of *in utero* growth failure. A lack of head sparing and small occipital-frontal circumference (OFC) is associated with poor neurologic and psychological outcome (192). Head size, if catch-up head growth has not occurred by 8 months of age, is a predictor of lower intelligence test scores at 3 years of age (193). This correlation seems to be independent of environmental or other risks. Decreased head size when compared to siblings carries significant risks of deficient mental and motor function (188).

Postnatal Neurodevelopmental Outcome of Full-Term, Small-for-Gestational-Age Infants

Neurologic disorders and other morbidities are more frequent in SGA infants as a group, occurring 5 to 10 times more often than in AGA infants. However, in full-term, mild-to-moderately SGA infants who have normal brain growth, no hypoxic-ischemic injury, and good environmental support, IUGR may have little impact on behavior or

mental ability in adolescence or adulthood (185,186, 192). There is no increased incidence of major handicap (189,191,193,194) and no increased risk of severe neurologic morbidity (192) in term infants born small for gestational age. Cerebral palsy is infrequent in this group (194). Routine neurologic examination is usually normal (191). Although the absence of gross neurologic outcome in the term SGA infant is reassuring, evidence of minimal brain dysfunction among these children continues to be of concern. Many studies have revealed signs of minor brain damage, including hyperactivity, short attention span, learning problems, poor fine motor coordination, and hyperreflexia. An increased number of diffuse abnormalities are seen on electroencephalogram (194). In one study, 30% of term SGA children at 5 years of age had speech problems, which included a delayed onset of speech, immature vocabulary with persistent infantile articulation, and poor receptive and expressive abilities for age (194). In contrast, only 1.5% of the general population and about 5% of their siblings had speech difficulties. Former term SGA infants more frequently have substandard school performance and display subtle neurologic and

P.518

behavioral problems despite a normal IQ. Sensori-motor abilities are frequently affected. Overall there is no correlation between the severity of growth restriction and learning deficit, although those with poor early brain growth in infancy have more problems (193). Measures of cognition at 4 to 6 years of age correlate well with testing at adolescence. This suggests that cognitive potential is reached early, with little change later. It seems likely that environmental and socioeconomic factors play a significant role in the learning deficiencies seen in these children (188).

TABLE 26-12 FETAL, NEONATAL/INFANCY, AND ADULT DISORDERS THAT MIGHT RESULT FROM FETAL PROGRAMMING AS A CONSEQUENCE OF FETAL UNDERNUTRITION AT DIFFERENT STATES OF GESTATION^{a, b}

	Trimester of Pregnancy		
	First	Second	Third
Consequences	Low growth trajectory	Disturbed fetal-placental	Brain growth sustained, but not relationships body
Fetal adaptation	Down regulation of fetal growth	Insulin resistance	Growth factor(s) resistance/deficiency
Anthropometry	Symmetric	Mixed	Asymmetric
Infant growth	Reduced infant growth	Reduced infant growth	Catch-up growth possible
Adult life	Increased BP	Increased BP, NIDDM,	Increased BP, NIDDM, ischemic heart disease hypercholesterolemia, ischemic heart disease

^a BP, blood pressure; NIDDM, noninsulin-dependent diabetes mellitus.

^b From Barker D. *Mothers, babies, and diseases later in life*. London: BMJ Books, 1994, with permission.

At adolescence, trends toward lower test scores, especially in mathematics, and an increased incidence of learning disabilities have been noted (191,194). There also is a trend toward slower alternating movements on physical examination. Most believe, however, that the cognitive and academic differences in these children are small and do not significantly affect school performance or ultimate intellectual ability.

Postnatal Neurodevelopmental Outcome in Preterm, Small-for-Gestational-Age Infants

The prognosis for preterm SGA infants is less clear and is easily confounded by other problems of preterm birth. In general, subnormal intellectual outcomes are more common among preterm SGA infants than term SGA infants. Some authors have shown that those infants suffering the dual insults of preterm birth and growth restriction are at higher risk of neurodevelopmental deficit (195,196). Among extremely preterm infants, gestational age, and not growth status, has been the most significant predictor of intellectual outcome (197). By 3 years of age, social and environmental factors play an increasing role and may impact on development in either a positive or negative way (197).

Socioeconomic status is independently associated with learning disabilities in these children (187).

When compared with their appropriately grown same-weight counterparts, SGA preterm infants have a lower incidence of major developmental handicaps and cerebral palsy. Specific motor deficits are more common in AGA infants (198,199). Minor neurologic abnormalities are more frequently observed in SGA infants (198). Diffuse cerebral damage as a result of hypoxia and decreased intrauterine blood flow, especially to the brain, probably accounts for the differences in expression of brain damage seen in preterm AGA and SGA children (200). Restricted growth for gestational age is associated with more cognitive disability in infants who were born preterm (199,201). The need for special education is higher and becomes apparent at an earlier age in these preterm SGA infants when they reach school age (200).

Possible Adult Disorders Resulting from Intrauterine Growth Restriction

Recent epidemiologic evidence indicates that obesity, insulin resistance, diabetes, and cardiovascular disease are more common among adults who were smaller than normal at birth and very likely SGA secondary to IUGR, particularly those who had a high placental-to-fetal-weight ratio (202). A variety of animal studies support this concept, including the greater incidence of obesity, glucose intolerance, plasma lipid abnormalities, and hypertension in offspring whose mothers were fed a low-protein diet during pregnancy (203,204,205,206). These examples indicate that certain adult pathologies may be unavoidable consequences of environmentally imposed conditions, such as severe and prolonged fetal undernutrition, which lead to fetal growth restriction to ensure fetal survival. These conditions may represent an example of "programming," in which an insult, when applied at a critical or sensitive stage in development, may result in a lasting, even lifelong, effect on the structure

P.519

or function of the organism (183). IUGR, therefore, is increasingly seen as an adaptive physiologic process, even though it can produce adverse fetal, neonatal, and potentially adult consequences (Table 26-12) (207). Mechanisms responsible for these later-life morbidities in adults, who were growth restricted in utero, are not yet established. There is some evidence of diminished pancreatic growth and development, which might become manifest in later life as pancreatic insufficiency when the adult starts and then continues eating a diet rich in simple carbohydrates and lipids. Peripheral insulin resistance may develop in the same way, and hypertension in adulthood may be the result of altered adrenal development in response to IUGR.

Chapter 27

Multiple Gestations

Mary E. Revenis

Lauren A. Johnson-Robbins

The incidence of twins, triplets, and higher-order multiple gestations now accounts for approximately 3% of all pregnancies in the United States. The products of multiple gestations comprise a disproportionate number of admissions to neonatal intensive care units and suffer greater morbidity than do singletons. In 2002 16% of all preterm deliveries in the United States were due to multifetal gestations (1). In addition to prematurity, the products of multiple gestations are susceptible to unique problems which may intensify as the numbers increase. A review of the major problems can help the clinician to anticipate the medical needs and prepare the parents for what lies ahead. Most of the issues about twins discussed in this chapter apply to all multiple gestations.

EPIDEMIOLOGY

The incidence of multiple gestations in the United States has increased dramatically during the past three decades as a result of the shift in maternal age distribution to older ages, as well as the increased use of fertility enhancement therapy. The number of births from twin deliveries and higher-order multiples rose respectively to 31.1 and 1.84 per 1,000 live births in 2002 (1). The actual rate of twin conceptions is much higher because early fetal loss with a vanishing twin is far more common than clinically recognized (2). In 1,000 pregnancies studied early with ultrasonography, Landy and associates (2) found a twin conception rate of 3.29%, with subsequent reduction to a single fetus in 21.2% of those pregnancies.

The incidence of naturally conceived higher-multiple births is mathematically described by the Hellin-Zeleny law, which states that if twins occur at a frequency of $1/N$, triplets occur at a frequency of $(1/N)^2$, quadruplets at $(1/N)^3$, and so on. Because most epidemiologic studies exclude data on twins with no live-born member, they grossly underestimate the incidence of multiple gestations.

Natural monozygotic twinning occurs at a fairly constant rate of 3.5 per 1,000 live births, with limited variation among populations. The occurrence of monozygosity is not affected by environment, race, physical characteristics, or fertility. The relatively new reproductive technology of zona manipulation enhances artificial reproductive technology success, but is also associated with a remarkable increase in monoamniotic twinning. Following zona manipulation, 17.3% of the resulting

multiple gestations are monoamniotic. The zona may act as a container for the dividing cell mass, disruption of which may allow for monozygotic twinning (3).

In contrast, rates for dizygotic twins vary greatly among populations, from 1.3 per 1,000 live births in Japan to 49 per 1,000 live births in Nigeria (4). Other factors that influence the incidence of dizygotic twinning include a maternally transmitted familial tendency, race, nutrition, parity, advanced maternal age, coital frequency, and seasonality. Twins are found most often in black populations and least often in Asians. Taller, heavier women bear twins at a rate 25% to 30% higher than short, undernourished women (4). Parity is an independent risk factor, with multiparous women having a greater likelihood for multiple gestations (5). Advanced maternal age predisposes to dizygotic twinning, with peak incidence at 37 years of age (5). Coital frequency has a positive affect, with a high rate of twin conceptions within the first 3 months of marriage (6). Another factor is the effect of the climatic seasons. In the Northern hemisphere, most dizygotic births are autumnal, reflecting more multiple ovulations during the winter and spring months. The seasonality of multiple births does not coincide with the peak months of singleton births (7).

High circulating levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) lead to the release of more than one ovum per menstrual cycle, making multizygotic conceptions more likely. Conception stimulants such as clomiphene citrate (Clomid, Serophene), which act by stimulating endogenous secretion of gonadotropins, raise the incidence of multiple gestations by 6.8% to 17%; exogenous gonadotropins such as menotropins (FSH and LH; Pergonal) or human chorionic gonadotropins (APL., Follutein, Pregnyl, Profasi HP) may increase the incidence as much as 18% to 53.5% (8). The women of the Nigerian Yoruba tribe, who have naturally elevated levels of FSH and LH, have a remarkably high rate of spontaneous, dizygotic

P.524

twinning (1 in 20) (9). Martin and associates (10) examined another population and found that women with dizygotic twins have higher levels of FSH and estradiol than women bearing singletons. A phenomenon likely due to increased pituitary gonadotropin release is the twofold higher incidence of twin conceptions in the 2 months after the cessation of oral contraceptives (11). High FSH and LH levels probably account for the seasonal variation in twinning observed in many countries (12,13).

IMPACT OF REPRODUCTIVE TECHNOLOGY

The increasing use of ovulation-inducing drugs and assisted reproductive technology (ART; *in vitro* fertilization, gamete intrafallopian transfer, and zygote intrafallopian transfer) has contributed to the recent 65% increase in multiple-gestation births in the past two decades. In 2000 there were 99,629 ART

procedures in the United States. Of the 35,025 infants born after these procedures, 53% were products of multifetal pregnancies (44% twins and 9% triplets and higher-order multiples) (14). It is estimated that the number of nonART fertility treatments (ovulation induction and intrauterine insemination) are comparable in number to the ART procedures and associated with even more triplet and higher-order multiple gestations. In 2000 only 18% of triplets were naturally conceived, with 40% a result of ART and estimated 40% due to ovulation induction (15). In addition to the expected increase in dizygotic twins following assisted reproduction, monozygotic twinning with its higher incidence of complications is also more frequent in multiple gestations following assisted reproduction with an incidence of 3.2%, eight times higher than for spontaneously conceived pregnancies (16).

The multiple births resulting from ART are the major factor responsible for the increase in preterm delivery to 12.1%, up 29% from 1981. The use of ART accounts for 3.5% of low-birth-weight (LBW) infants and 4.3 % of very-low-birth-weight infants in the United States because of absolute increases in multiple gestations and also because of higher rates of LBW among singleton infants conceived with this technology (17).

The number of embryos transferred during ART procedures is directly related to the risk of multiple gestations. The multiple rate increases from 33.9% with transfer of two embryos to 41.4%, 43.2%, and 46.5% with transfer of three, four, or five or more embryos, respectively. The rate of triplets increases from 0.8% with transfer of two embryos to 7.4%, 8.4%, and 10.7% with transfer of three, four, or five or more embryos (14).

Each cycle of ART is expensive and not often covered by insurance. An attempt to improve pregnancy success has encouraged transfer of multiple embryos during each procedure, especially for older women. As increasing the number of embryos transferred with ART increases the risk of multiple gestations and thus the risk of complications, the live birth rate is not always improved. For women less than age 35, the live birth rate for each embryo transferred is higher when only two embryos are transferred (42%) than when three (39.7%), four (35.4%), or five or more (33%) embryos are transferred (14,18).

The increase in multiple gestations due to ART and nonART fertility procedures are associated with significant expenses due to increased need for perinatal surveillance and intervention, increased neonatal intensive care utilization, and long-term costs of care for chronic disabilities such as cerebral palsy. To reduce health care expenses, several European countries have passed regulations or guidelines addressing the number of embryos permitted to be transferred during ART procedures (19) or have agreed to pay the expense of ART cycles if a reduced number of embryos are transferred. In the United States, the progressively rising higher-order multiple birth rate finally decreased 9% from 193.5 per 100,000 live births in 1998 to 180.5 in 2000 (1), possibly indicating some moderation of the

number of embryos transferred during ART procedures. There is ongoing debate as to whether regulations in the United States would be effective in reducing the numbers of multiple gestations following ART procedures and improving outcome at a lower cost.

ZYGOSITY

Zygoty is determined by the number of ova fertilized. Higher-order pregnancies may be monozygotic, dizygotic, or multizygotic. In 1955 Corner (20) postulated that monozygotic twins develop by splitting of the conceptus at any time from day 2 after conception through days 15 to 17. The timing of division determines whether monozygotic twins are dichorionic, monochorionic, or conjoined. Dizygotic or multizygotic gestations result if more than one ovum has undergone fertilization at the same coitus or even at different times or with different mates.

At birth, zygoty can be determined by gender differences or by direct placental examination. Other techniques include blood typing, dermatoglyphics, and chromosome banding (21,22). The most precise technique is DNA-variant restriction fragment length polymorphisms (23). Because monozygotic twins carry significantly higher risks of morbidity and mortality prenatally and postnatally, establishing the zygoty of all multiple gestations is clinically important. More effort is going into determining zygoty prenatally using ultrasonography or genetic identification techniques.

PLACENTATION

The placenta from a twin gestation can be monochorionic or dichorionic; if dichorionic, it can be fused or separated, making four types of placentation possible:

- Diamniotic, dichorionic separate
- Diamniotic, dichorionic fused
- Diamniotic, monochorionic
- Monoamniotic, monochorionic

TABLE 27-1 ZYGOSITY DETERMINATION

Clinical Finding	Percentage of Total	
	Deliveries	Zygoty
Different genders	35	Dizygotic
Monochorionic placenta	20	Monozygotic
Same gender and dichorionic placenta	45	8% of monozygotic and 37% of placenta dizygotic infants ^a

^a Further differentiation can be obtained by genotyping. From Cameron AH. The Birmingham twin survey. *Proc R Soc Med* 1968;61:229–234, with permission.

All dizygotic twins have a diamniotic, dichorionic placenta; all monochorionic twins are monozygotic. Zygoty should be determined in the case of twins of the same gender if the placenta is not monochorionic, because these siblings may be monozygotic or dizygotic. Fusion of the placenta does not differentiate zygoty. Table 27-1 lists zygoty determination based on placental examination.

Benirschke (24) described how to determine chorionicity of a fused placenta based on examination of the dividing membranes. The amnion contains no blood vessels and is more transparent than the chorion, which contains fetal vessels and remnants of villous tissue. A monochorionic placenta is one in which the septum is composed of a thin, translucent amnion that can be easily separated and lifted from the chorionic plate. In a dichorionic placenta, the septum is thicker and more opaque. It does not separate as easily from the chorionic plate. Ultrasonography of the dividing membranes early in gestation is useful in some cases to determine the chorionicity, but it is not always technically feasible (25).

A monochorionic, monoamniotic placenta is formed by division of the embryonic disc at 7 to 13 days, which is after differentiation of the amnion. Only 1% to 2% of monozygotic twins are monoamniotic; the fetal mortality rate is as high as 50%, primarily due to twisting, knotting, or entanglement of the umbilical cords (26). Conjoined twins with their necessarily monoamniotic placenta result from the latest and incomplete splitting of the embryonic disc at days 13 to 15 of gestation. The monochorionic, diamniotic placenta with a dividing membrane consisting of two layers of amnion without an intervening chorion is formed at approximately 5 days of gestation. Dichorionic, diamniotic placentas are formed the earliest, within the first 3 days after conception.

ANTEPARTUM COMPLICATIONS

Many complications of pregnancy occur more frequently in multiple gestations.

Preterm labor is the most frequent complication, occurring in 20% to 50% of multiple gestations, most likely due to uterine overdistention. Pregnancy-induced hypertension, placenta previa, antenatal and intrapartum hemorrhage, hyperemesis gravidarum, and premature rupture of membranes all occur at a higher rate (27,28). Polyhydramnios, an almost expected complication of multiple gestations, is transient in pregnancies in which there are no other complications. If persistent, the polyhydramnios suggests abnormal fetal conditions, such as twin-to-twin transfusion syndrome (TTTS) or congenital anomalies (29).

ANTENATAL MANAGEMENT

Recommendations for managing multiple gestations are controversial. The only unquestioned aspect of management is the benefit of early diagnosis, facilitating referral to an appropriate facility for high-risk infants. Antenatal management includes the following components:

- Early diagnosis
- Nutritional intervention
- Cervical cerclage
- Prophylactic tocolysis
- Steroid stimulation of fetal lung maturity
- Therapeutic amniocentesis
- Multifetal reduction
- Bed rest

Bed rest beginning before 28 weeks is commonly advised to decrease perinatal mortality (30). The National Institutes of Health (NIH) Collaborative Study showed no significant effect of antenatal betamethasone therapy in inducing fetal lung maturity in twins, but it is important to note that a relatively small number of twins were enrolled in the study (31). The 1994 NIH Consensus Statement on antenatal corticosteroids recommends betamethasone for all fetuses between 24

and 34 weeks of gestation, including multiple gestations (32).

There are several approaches to limiting the complications seen in higher-order multiple gestation. The first is to limit the number of embryos transferred during *in vitro* fertilization to two. This results in a reduction in pre- and postnatal complications in the mother and infants without affecting the pregnancy or take-home baby rates (18). An alternative is the use of multifetal reduction. Reduction, most often to twins, is usually performed at 9 to 12 weeks of gestation via either the transvaginal or transabdominal route (33). Reduction of quadruplets to twins improves overall outcome, but studies on the effect of reduction of triplets to twins have had conflicting results (33). Infants who are the products of reduced twin gestations have an increased incidence of impaired fetal growth and a lower gestational age at delivery when compared with nonreduced twins (17). Selective termination is used during the second trimester in pregnancies in which one twin is discordant for a major genetic disease or anomaly (34).

P.526

LABOR AND DELIVERY

The total duration of labor in a twin gestation is similar to a singleton gestation, with some differences in the lengths of each stage. Friedman and Sachtelben (35) observed a shorter latent phase during twin labor but a longer active phase and second stage, probably due to dysfunctional labor in an overdistended uterus.

There are many potential complications associated with delivery of multiple gestations, including malpresentation, cord prolapse, cord entanglement, vasa previa, locked twins, and fetal distress. Locked twins occur most often if the chins interlock to prevent expulsion or extraction of the first twin. Locking occurs at a rate of 1 per 817 twin gestations, and uterine hypertonicity, monoamniotic twinning, fetal demise, and decreased amniotic fluid are all contributing factors (36).

The best method of delivery depends on the number of fetuses, presentation of the first fetus, and gestational age. Table 27-2 details the frequencies of each variation of presentation. If both twins are vertex, there is no evidence that cesarean section improves outcome (37). In vertex-nonvertex twin gestations longer than 32 weeks, vaginal delivery is recommended (38). Delivery of the nonvertex second twin can be by total breech extraction or external cephalic version under ultrasound guidance and epidural anesthesia (39). If the first twin is nonvertex, delivery is usually by cesarean section.

Mode of delivery of the preterm multiple gestation depends on many factors, only one of which is the fetal presentation. If premature twins present in a vertex-vertex pattern without other complications, vaginal delivery is attempted, whereas a cesarean section is recommended for all other combinations of presentation if

the gestational age is less than 34 weeks (40). When these recommendations are followed, there is no effect of mode of delivery or birth order on the incidence of intracranial hemorrhage in very-low-birth-weight twins (41,42). Extremely low-birth-weight twins (less than 1,000 grams) have been shown to benefit from cesarean section, regardless of their positioning, with a reduction in postnatal mortality (43).

Delayed-interval delivery of multiple gestations is reported (44,45). Management typically involves the placement of a cervical cerclage, tocolysis, and antibiotic therapy following the delivery of the first fetus to delay the delivery of the remaining fetuses as long as fetal distress is not present. The duration of pregnancy extension is highly variable, with one series achieving a mean of prolongation of 49 days (45). Delayed delivery allows for fetal maturation through either antenatal steroid administration or increasing gestational age.

TABLE 27-2 TWIN PRESENTATION

Delivery (A–B)^a	Percentage of Total Deliveries
Vertex-vertex	42.5
Vertex-nonvertex	38.4
Nonvertex	19.1

^a A, first-born twin; B, second-born twin. (From Young BK, Suidan, J, Antoine C, et al. Differences in twins: the importance of birth order. *Am J Obstet Gynecol* 1985;151:915–921, with permission).

MORTALITY

The frequency of single fetal demise in multiple gestation is reported as 0.5% to 6.8%, although early ultrasonography suggests a much higher rate of early loss (2,46,47,48). The causes of antepartum death include cord accidents, vascular anastomoses with overwhelming blood volume shifts, and velamentous insertion of the umbilical cord. Velamentous insertion, which makes the cord more vulnerable to trauma from twisting and compression, is six to nine times more common with twin gestation and increases the risks for fetal distress and for vasa previa with fetal hemorrhage (49). Most intrauterine deaths in twins are associated with monochorionic placentation (46,47,48).

After the demise of a fetal twin, the surviving fetus is at increased risk for distress, abnormal presentation, or dystocia, and the mother is at risk for toxemia, chorioamnionitis, or disseminated intravascular coagulation. In

dichorionic twins, if the cause of death is intrinsic only to that fetus, complications to the surviving co-twin are rare, except from spontaneous premature labor (48). When one twin dies after at least 15 weeks of gestation in diamniotic pregnancies, a fetus papyraceous develops. The fetus loses all water content, becomes compressed, and because of oligohydramnios, may be mistakenly identified on sonography as a stuck twin. A retained twin may be large enough to hinder labor mechanically, necessitating cesarean section (50). Before 15 weeks, the fetus is resorbed; this is called the vanishing twin phenomenon.

For most monochorionic twins, the death of one twin has little adverse effect on the surviving fetus (51). However, if vascular connections are present, the surviving twin is at risk for complications related to interfetal blood exchange, including disseminated intravascular coagulation. After the death of one twin, partial abruptio placentae, which separates further during labor, may cause asphyxia or demise of the other twin (47). Fetal transfusion syndrome may be related to many of the antepartum deaths complicating twin pregnancy (46,47,48,52).

Fetal mortality for twins 20 or more weeks gestation declined from 31.2 to 20.7 twin fetal deaths per 1,000 live twin births from 1981 to 1997 (53,54). This improvement is associated with an increased preterm birth rate and reductions of complications of the placenta, cord, and membranes, intrauterine hypoxia, and birth asphyxia, suggesting intensified obstetric management of prenatal care and earlier obstetric intervention. The mortality of multiple gestations higher than two is greater than for twins because of smaller fetal size and placental or cord compromise from competition for space (55).

P.527

Multiple gestations account for 10% to 12% of perinatal deaths (1). Increased frequencies of prematurity, pre-eclampsia, hydramnios, placenta previa, abruptio placentae, and cord prolapse contribute to increased mortality. The perinatal mortality rate for triplet pregnancies is reported as 7% to 23% and is strongly related to gestational age at delivery (56).

Despite recent increased rates of preterm delivery of twins, infant mortality of twins has improved in the United States and Canada (53,54), with a decrease from 54 per 1,000 live births in 1983-1984, to 30 per 1,000 live births in 1996 (53) compared to a general infant mortality rate of 6.9 per 1,000 live births in 2000 (1).

TWIN-TO-TWIN TRANSFUSION SYNDROME

Interfetal blood exchange occurs almost exclusively in monochorionic twins with circulations shared through vascular anastomoses that are present in most monochorionic placentas. Only 5% to 18% of these communications are

sufficiently imbalanced to produce TTTS, but the actual rate would be higher if all cases of early fetal death of one twin were identified (27,46,57). Placentas from twin pregnancies complicated by TTTS have been shown to have significantly fewer vascular anastomoses, which are more commonly deep than superficial in location, compared to monochorionic placentas in pregnancies not complicated by TTTS (58). Vascular anastomoses and TTTS are rare in fused dichorionic placentas of dizygotic or monozygotic twins (46,49,51,57).

Acute and chronic forms of TTTS have been described (59,60). The onset of symptoms depends on what type of vessels are in communication, with an unbalanced, arteriovenous anastomosis and unidirectional shunt leading to the earliest and most profound symptoms. If anastomoses are balanced (i.e., artery to artery, vein to vein), the onset and severity of symptoms depend on changes in perfusion pressures that may be temporary and vary throughout gestation or become problematic only after delivery or demise of one twin.

Chronic, unidirectional TTTS manifests at any time after 16 weeks and can occur when an arteriovenous anastomosis joins a high-pressure system with a low-pressure system. The donor twin becomes progressively anemic, hypovolemic, and growth retarded, with oligohydramnios, and is at risk for tissue hypoxia and acidosis from reduced perfusion (52,61). The recipient twin becomes polycythemic and hypervolemic, with polyhydramnios developing from increased urine production to relieve the circulatory volume overload. Disparities in the weight of the heart and other viscera and in the size of glomeruli and pulmonary and systemic arterioles have been reported (52). Both twins are at risk for ischemia, thromboembolism, disseminated intravascular coagulation, and death. In the donor twin, there is hypotension and poor tissue perfusion; in the recipient, there also is poor tissue perfusion from hyperviscosity and polycythemia. Although the net transfusion is in the direction of the recipient, thrombi can exchange freely in either direction through vascular anastomoses, resulting in infarcts or the death of either twin.

Manifestations of TTTS range in severity from mild differences in blood hematocrit to the extremes of anemia and polycythemia affecting the pair (62,63). In the most severe cases, the growth-retarded donor twin may die of chronic hypoxia; the recipient develops congestive heart failure and hydrops and may die. Premature rupture of membranes, preterm labor, and delivery of compromised, premature infants are the usual sequelae. The perinatal mortality is 70% or more (64,65). Prognosis is better if symptoms, diagnosis, and delivery occur at a later gestational age or if hydrops does not develop.

In rare cases, after death of one twin with TTTS, the polyhydramnios resolves and a healthy survivor is born at a later time. However, compromising volumes of blood may be lost from the survivor into the dead twin. Other morbidity results from the release of thrombogenic material from degenerating fetal tissues, resulting in disseminated intravascular coagulation, multiple infarcts, and tissue

necrosis in the live twin (46). Possibly related to thromboembolic arterial occlusion, severe defects, such as porencephaly, multicystic encephalomalacia, renal cortical necrosis, infarcts of the spleen, cutis aplasia, small bowel atresia, colonic and appendiceal atresia with horseshoe kidney, hemifacial microsomia, and necrotic limb, have been observed in the survivor of monochorionic twins after one fetal demise (46,48,66,67,68,69). An increased incidence of these defects is not reported in dichorionic twin survivors after the death of a cotwin.

One suggested criterion for diagnosing chronic TTTS is a hemoglobin difference between twins of 5 g/dL or more. In itself, this is not sufficient to establish TTTS because large differences in hemoglobin concentration also can occur in separate, dichorionic placentas (70). Tan and associates (58) diagnosed TTTS if a birth weight difference of 20% and a hemoglobin difference of 5 g/dL or more was found. However, a birth weight difference of more than 20% occurs with similar frequency in monochorionic and dichorionic pregnancies. The smaller twin may have polycythemia, secondary to intrauterine growth retardation (70). Fetal transfusion studies using adult cells as markers indicate significant interfetal blood exchange sufficient to cause discordant growth, and amniotic fluid volumes occur far more often than differences in hemoglobin concentrations suggest (71). Because TTTS in all degrees is limited to monochorionic placentations, differentiating the type of placenta and detecting vascular anastomoses are important. Measurement of the difference in pulsatility index between fetuses by Doppler examination of umbilic arterial blood flow has been shown to be helpful in the diagnosis of TTTS even before the development of fetal hydrops (72).

Acardiac twinning (i.e., reversed arterial perfusion syndrome) is a rare but interesting variation of TTTS, occurring in 1% of monozygotic twins (73). The nonviable acardiac

P.528

twin's survival depends on the existence of artery-to-artery and vein-to-vein anastomoses to the other twin (74). The structurally normal, pump twin provides the circulation for itself and for its abnormal, acardiac twin, permitting slow growth of the abnormal twin. This can be detected by pulsed and color Doppler flow studies demonstrating arterial blood flow perfusing the acardiac twin. The reversed direction of flow in the umbilical arteries of the acardiac twin (75) leads to unusual congenital anomalies. Often assuming an amorphous shape, the cephalic pole is affected most severely, because it is the region most distal to the retrograde perfusion. The closer and better perfused lower part of the body is relatively spared (74). The diagnosis of acardiac twinning can be suspected prenatally by absence or marked undergrowth of the heart, head, and trunk, and by increased body soft tissue (75,76) of the acardiac twin. Frequent complications include congestive heart failure of the pump twin developing between 22 and 30 weeks of gestation, with cardiomegaly, hepatomegaly, hydrops, intrauterine growth failure, maternal hydramnios, preterm delivery, malpresentation, and fetal

distress (74,77). Increased right atrial enlargement, increased reverse flow in the inferior vena cava, reversed flow in the ductus venosus, and pulsatile flow in the umbilical vein are early indications of hemodynamic decompensation in the pump twin (34,64), which can guide timing of intervention. The mortality rate of the pump twin is 50% to 55%, primarily due to prematurity (74,77).

An acute form of TTTS occurs with rapid transfer of blood through large superficial artery-to-artery or vein-to-vein anastomoses during labor and delivery, resulting in a hypovolemic donor and a hypervolemic recipient with similar birth weights (59,60). The transfusion is from the first to the second twin during the delivery of the first twin. However, if the first cord clamping is delayed, blood from the undelivered twin can be transfused into the first infant. The potential for acute volume changes during labor and delivery of monochorionic twins contributes to their vulnerability, need for resuscitation, and volume management.

Antenatal management of the TTTS previously was limited to close observation and bed rest. Acute polyhydramnios, which often complicates TTTS, is managed with serial amniocenteses of enough amniotic fluid to lessen fetal symptoms (78). Digoxin has been used successfully to treat cardiac failure in a recipient twin (79). Endoscopic laser coagulation of connecting vessels is used in treating severe TTTS (64,65). When the death of both twins is anticipated, selective feticide or fetectomy of the donor twin may permit survival of the recipient twin (80). In some instances, decreasing the polyhydramnios seems to stop or ameliorate the interfetal transfusion dramatically. Serial amniocentesis of the recipient twin with polyhydramnios has a 50% to 60% survival rate with 25% neurologic complications, while endoscopic laser photocoagulation of the communicating vessels has a 52% to 70% survival with only 4% neurologic complications (34,64,65).

STUCK TWIN

The stuck twin phenomenon occurs in a diamniotic pregnancy if there is a relatively acute onset of severe disparity in amniotic volumes, with one growth-retarded twin in an oligohydramniotic sac compressed against the uterine wall. If the oligohydramnios is severe enough, this twin may suffer all the complications of prolonged compression, including pulmonary hypoplasia, abnormal facies, and orthopedic deformation. The other twin is in a distended, polyhydramniotic sac, adding to compression of the smaller twin (81).

The stuck twin phenomenon occurs to some degree in as many as 35% of monochorionic diamniotic twin pregnancies, and it can develop in dichorionic pregnancies (82). In monochorionic twins, the phenomenon may be related to TTTS. Other causes, regardless of placentation, include uteroplacental dysfunction, congenital infection, discordant aneuploidy, and structural malformations. Both twins are structurally normal in 95% of cases. Disparity in

volumes of amniotic fluid can occur if one twin has structural anomalies that lead to polyhydramnios (e.g., neural tube defect, upper gastrointestinal obstruction, congenital heart disease) or oligohydramnios (e.g., ruptured amnion, urinary tract anomalies, growth retardation) (83). The onset is usually between 18 and 30 weeks of gestation (82). Premature labor, possibly related to uterine distention from polyhydramnios and to preterm rupture of membranes, develops in most cases. Without intervention to reverse the fetal compression and uterine overdistention, the chance of survival of both twins is less than 20% (84).

ASPHYXIA

Despite the clinical impression that the first-born twin does better than the second-born twin, there is no demonstrable increase in neonatal death in the second-born twin (37,85). Breech presentation is more frequent, and large placental abruptions are more common in second twins (85). Differences in the 1-minute Apgar score, umbilical venous pH, oxygen pressure, and partial carbon dioxide pressure favor the first-born twin, regardless of route of delivery, placentation, interval between twins, or presentation (86). The second-born twin has potentially greater risk for hypoxia and trauma, regardless of the route of delivery, suggesting physiologic changes after the birth of the first twin. Findings in the venous blood gases suggest compromised intervillous placental blood flow after delivery of the first twin as a major factor.

In triplet pregnancies, although preterm labor is the most frequent complication and most important factor in perinatal morbidity and mortality, the mode of delivery is also important. If delivery is by cesarean section, the third-born triplet has a higher 5-minute Apgar score, and the second- and third-born triplets have increased survival compared with triplets of vaginal delivery (87). If triplets are delivered by cesarean section, the three triplets have a

P.529

similar acid-base status despite the finding of lower 1-minute Apgar scores for the third-born triplet (88). The influence of birth order on acid-base status becomes significant during vaginal births if there is a longer time *in utero* after delivery of the first triplet. Triplets of more than 34 weeks of gestation and with birth weights greater than 2,000 g for each fetus tolerate vaginal delivery more successfully than smaller triplets (87).

GROWTH

Examination of fetuses between 8 and 21 weeks of gestation show similar weight-to-length ratios for singleton and twin fetuses (89). Birth weights of live-born twins up to 30 weeks of gestation are slightly smaller but similar to singletons of the same gestational age, indicating that the growth rate is similar in twins and singletons until 30 weeks of gestation (Table 27-3) (90,91,92). After 30 weeks,

the singleton fetus has accelerated, exponential growth, and twin fetuses have a more linear rate of growth (93). Triplet growth previously was reported to decline progressively after 27 weeks of gestation (64). More recent studies indicate that growth of individual triplets and triplet sets remains linear throughout the third trimester (94) (See Appendices E-1 and E-2).

Better growth in the third trimester for multiple gestations reflects the positive impact of more aggressive maternal nutritional and obstetric care management. In a prospective study of nutritional intervention, the incidence of preterm delivery, LBW, and very low birth weight was lowered by 30%, 25%, and 50%, respectively, compared with twin pregnancies without nutritional intervention, but the rates of intrauterine growth retardation were not affected (95). Singletons are more likely to have LBW if there had been more than one fetal heart on early ultrasonography, and twins are more likely to have LBW if there had been more than two fetal hearts (17), indicating a persistent effect of the prior multiple condition.

Multiple gestations account for 17% of intrauterine growth retardation, with higher mortality rates for affected infants, particularly for the growth-retarded twin if only one is affected (90,96). Monochorionic twins show greater degrees of intrapair variation in birth weight than dichorionic twins, and true intrauterine growth retardation occurs more often in monochorionic twins. The individual members of twin pairs frequently are discordant for the rate of growth due to TTTS, placental insufficiency, intrauterine crowding, or an unequal impact of maternal complications that impair growth, such as preeclampsia. Ultimately, the underlying factor in most instances is a limitation of intrauterine nutrition, which may be shared unequally by the fetuses.

TABLE 27-3 BIRTH STATISTICS FOR MULTIPLE GESTATIONS

	Gestational Age (average in weeks)	Birth Weight (average in grams)
Twins ^a	37.1	2,390
Triplets ^b	33.0	1,720
Quadruplets ^c	31.4	1,482

^c From Collins MS, Bleyl JA. Seventy-one quadruplet pregnancies: management and outcome. *Am J Obstet Gynecol* 1990;162:1384–1391, with permission.

The incidence of discordant fetal growth as measured by biparietal diameter increases significantly as gestation advances. It is important to differentiate discordant growth due to TTTS, in which both twins are at increased risk for morbidity and mortality often before the last trimester, from a twin gestation in which only one fetus shows growth retardation, which usually becomes evident during the last trimester. With discordant growth not due to TTTS, the prognosis for the growth-retarded fetus depends on the severity of the growth failure and its cause, and the prognosis for the normally growing fetus may not be compromised. During the postnatal period, the smaller of the discordant twins has an increased incidence of hypoglycemia and is more likely to have retarded growth and development during childhood (97,98).

CONGENITAL ANOMALIES

Monozygotic twins have an increased frequency of congenital anomalies compared with dizygotic twins or singletons (69). Monozygotic twins frequently are discordant for malformations or for the severity of a given malformation. Some structural defects are related to the monozygotic twinning process, such as conjoined twins or some amorphous twins. Early embryonic malformations and malformation complexes such as sirenomelia, holoprosencephaly, and anencephaly are increased in monozygotic twins, suggesting a common cause for monozygotic twinning and early malformation complexes. Structural defects that result from the disruption of previously normal tissues are associated with the exchange of circulation in monochorionic twins with vascular connections. Those defects in which a vascular disruptive cause has been suggested include central nervous system defects (e.g., microcephaly, porencephalic cysts, hydranencephaly), gastrointestinal defects (e.g., intestinal atresia), renal cortical necrosis, hemifacial microsomia, cutis aplasia, and terminal limb defects (67). Deformations due to crowding and constraint molding of the normal fetus *in utero* during late gestation are similar in type and frequency in dizygotic and monozygotic twins and include foot-positioning deformations. The products of multiple gestation resulting from the use of ART and nonART fertility enhancement procedures are not at higher risk for major congenital malformations compared to naturally conceived multiples. However, limited data show a

P.530

slight but significant increase in the rate of spontaneous sex-chromosome anomalies (0.8%) (99) (aneuploidies and structural *de novo* autosomal aberrations) after intracytoplasmic sperm injection (which is used in cases of male infertility), compared to 0.2% in the general population. Most of the abnormalities are paternally transmitted, consistent with the higher incidence of chromosomal abnormalities in the sperm of men with infertility.

Conjoined twins represent a unique structural defect of monozygotic monoamniotic twins. The nonseparated parts of the otherwise normal twins

remain fused throughout the remaining period of development (100). The incidence of conjoined twins is between 1 in 80,000 to 1 in 25,000 births, and 70% to 80% of these cases are female twins (101). Approximately 40% are joined at the chest (thoracopagus), 34% at the anterior abdominal wall (xiphopagus or omphalopagus), 18% at the buttocks (pygopagus), 6% at the ischium (ischiopagus), and 2% at the head (craniopagus). With ultrasonography, the diagnosis of conjoined twins can be established as early as week 12 of gestation (102). Forty percent of conjoined twins are stillborn, and an additional 35% survive only 1 day (103). Long-term survival with or without surgical separation depends on the anatomic site of attachment and the extent of shared organs (104).

NEONATAL DISORDERS

Prematurity

The preterm birth rate of twins in the United States increased from 40.9% of twin gestations in 1981 to 55% in 1997. This increase was related to more aggressive prenatal surveillance, an increase in labor induction, and an increase in first cesarean delivery (53). Canadian data similarly shows an increase in the preterm birth rate of twins, with a decline in stillbirth rates at and near term gestation (54). Despite increased rates of preterm delivery of twins, infant mortality of twins has improved in the United States and Canada (53,54). Ninety percent of triplets are born prematurely. In 2002, 12 % of twins, 36% of triplets, and 60% of quadruplets were born prior to 32 completed weeks of gestation (1).

Hyaline Membrane Disease

Twins are at increased risk of developing hyaline membrane disease due to the increase in preterm delivery. Both twins are usually affected by hyaline membrane disease. However, if only one twin is affected, it is usually the second-born twin, who had a lower Apgar score at 1 minute and a higher birth weight than the first-born twin (105). The greater risk to the second-born twin probably is related to birth asphyxia (105). Monozygotic twins more often are born prematurely and at an earlier gestational age than dizygotic twins, and they are more prone to develop hyaline membrane disease.

Necrotizing Enterocolitis

Unique risk factors for the development of necrotizing enterocolitis have not been identified for twins or higher multiple gestations, but as a group, they are at an increased risk due to the greater likelihood of prematurity and LBW. Comparisons of twins showed that the most significant factor in predicting the occurrence of

necrotizing enterocolitis and need for surgical intervention was a lower 1-minute Apgar score for the affected twins, predominantly the second-born twin, compared with unaffected cotwins (106). Sann and associates (107) found that, in all their case pairs, it was the first-born twin who had developed necrotizing enterocolitis; in no case did only the second twin have necrotizing enterocolitis. In that study, the first-born infants were more stable, were fed sooner, and had feedings advanced more rapidly than the second-born twins, implicating feeding practices in the higher incidence of necrotizing enterocolitis for the first-born twin.

Infection

One early study reported an increased rate of early-onset group B streptococcal disease in LBW twins compared to LBW singletons (108). Subsequent large population-based studies failed to show an increased risk of early-onset group B streptococcal disease in multiple gestations independent of prematurity (109,110). If just one of a pair of twins is infected or colonized with group B *Streptococcus in utero*, it is most likely the twin positioned adjacent to the cervix, with the exposure due to ascending spread of group B *Streptococcus* through the membranes. Spread of infection through the vascular connections between monozygotic twins has not been documented, although it is theoretically possible. However, spread of group B *Streptococcus* from the amniotic fluid of an exposed twin to a co-twin may occur through intact dividing membranes (111).

The risk of neonatal listeriosis infection is increased with multiple gestations, to 2.8 and 21 times the risk for twin and triplet pregnancies, respectively, compared to singleton births (112). The risk is especially increased when maternal age is greater than 35 years. It is possible that the increased production of hormones or other inhibitors due to larger placental mass with multiple gestations versus singletons decreases immunity to *Listeria*. Discordance of infection is 66%, with the first-born twin at greater risk.

One study showed that multiple-birth preterm infants with bronchopulmonary dysplasia are at an increased risk of developing respiratory syncytial virus illness and pneumonia than are singletons matched for gestational age, and that if one member of a multiple gestation developed respiratory syncytial virus disease, usually the other member(s) did also. Other risk factors that contributed to this were the higher density of adults and children in the households of multiple gestations (113).

Sudden Infant Death Syndrome

Monozygotic and dizygotic twins are at some increased risk of sudden infant death syndrome (SIDS) compared with singletons, and this is especially true for LBW

pairs (114). If the birth weights of the twins differ significantly, it is usually the smaller twin who dies of SIDS (114). For twins discordant for size, the risk of SIDS for the smaller of twins is greater than for LBW and premature singletons or other groups of infants at high risk for SIDS (114). It is unusual for the surviving cotwin also to die of SIDS.

POSTNEONATAL CARE AND FOLLOW-UP

In addition to the long-term impact of some of the perinatal conditions previously mentioned, twins and higher multiples continue to be at risk for medical, developmental, and social problems beyond those experienced by singletons born at similar gestational ages. A brief list of factors that should be considered in following these patients is included to assist the clinician in anticipating the problems, many of which can be lessened by preventive measures, such as the following:

- Parental stress of child rearing (115,116)
- Child abuse and neglect (116,117)
- Intratwin favoritism (118)
- Developmental delay (e.g., performance below chronologic age, especially in language and speech) (119)
- Mental retardation (120,121)
- Cerebral palsy (120,122), Growth delay (123,124)
- Glucose intolerance (125)

Chapter 28

Control of Breathing: Development, Apnea of Prematurity, Apparent Life-Threatening Events, Sudden Infant Death Syndrome

Mark W. Thompson

Carl E. Hunt

The fetus makes breathing movements *in utero* and these movements change in character and frequency throughout gestation (1). This "maturation" of breathing control is likely critical to initiation of spontaneous, regular respiratory effort at birth and normal control of postnatal breathing. Studies in animals and preterm infants have explored the complexities of this maturational process, but an exact timeline has yet to be delineated. In this chapter, normal control of breathing will first be reviewed, the "end-state" of this maturational process will be described, genetic influences on control of breathing will be summarized, and then what is known about fetal breathing, the effects of sleep on fetal breathing, and the factors involved with establishing normal patterns of breathing at birth will be reviewed. Finally, we will review apnea of prematurity (AOP), how this disorder may shed light on the normal maturational process of breathing control, how to treat AOP, and the potential adverse clinical consequences.

NORMAL CONTROL OF BREATHING

The control and maintenance of normal breathing largely reside within the respiratory control centers of the bulbopontine region of the brainstem. Neurons within this area of the brain respond to multiple afferent inputs to modulate their own inherent rhythmicity and provide efferent output to the respiratory control muscles. Multiple afferent inputs induce modulation of the central respiratory center efferent outputs to the respiratory and airway muscles and lungs. These afferent inputs are "categorized" by the respiratory control center; some inputs cause an instantaneous response in the control center output, while others only act to "shape" the respiratory response, resulting in small changes in muscular output, tidal volume, and airway tone (2). Among these inputs are signals from central and peripheral chemoreceptors, pulmonary stretch receptors, and cortical and reticuloactivating system neurons. These afferent inputs and resultant efferent outputs of the central respiratory center are summarized in Fig. 28-1. Sleep state can also have a profound effect on respiratory pattern.

In the adult, these multiple afferent inputs act upon the neurons within the respiratory control center and provide a well-integrated response to perturbations in the system and characteristic respiratory patterns. For example, increased respiratory rate and depth will characteristically result from activation of central chemoreceptors in response to hypercarbia. In the newborn infant and especially in the preterm infant, however, these responses are less well-organized and apnea is a common result of a disorganized response to multiple nonintegrated afferent inputs.

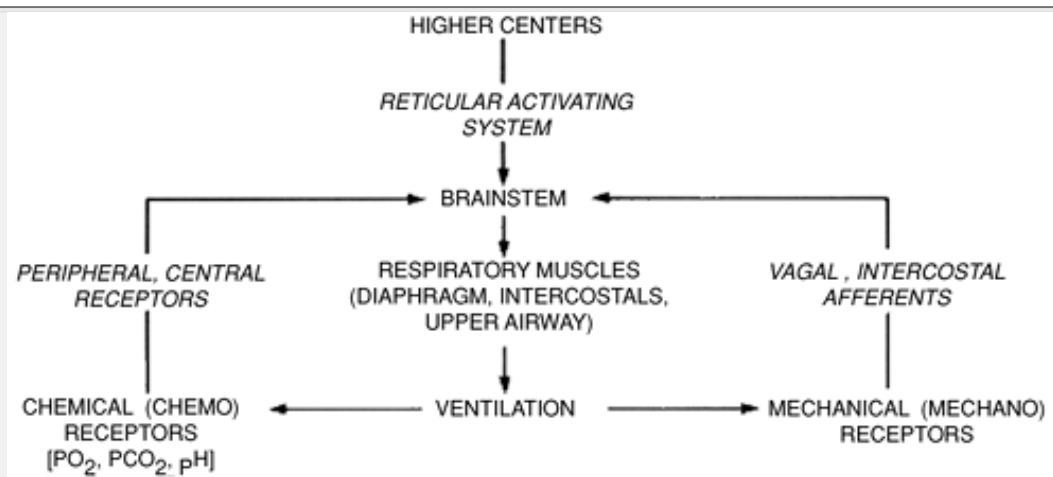

Figure 28-1 Major factors influencing respiratory control. PCO₂, carbon dioxide partial pressure; PO₂, oxygen pressure. (Reprinted from Martin RJ, Miller MJ, Carlo WA. Pathogenesis of apnea in preterm infants. *J Pediatr* 1986;109:733-741, with permission.)

Genetic Influences

Sequencing the approximately 25,000 genes in the human genome has resulted in fundamental changes in our understanding of the role of specific gene products in the pathophysiology of all diseases. Partly related to studies of sudden infant death syndrome (SIDS) pathophysiology, recent genetic studies of cardiorespiratory regulation linking specific genotypes to specific components of brainstem autonomic regulation are also relevant to understanding control of breathing and its developmental regulation in general and to understanding the pathophysiology of AOP and apparent life-threatening events (ALTE) in particular (3).

Neural control of breathing and sleep are closely integrated, and abnormalities in regulation of sleep and circadian rhythmicity can impair cardiorespiratory integration and arousal responsiveness from sleep (4). Circadian rhythmicity has been extensively studied in animals, and homologous counterparts of essential circadian clock genes isolated in *Drosophila* have been identified in mammals (3). Since the sleep-wake cycle is under control of the circadian clock, these circadian master genes, as well as other sleep-related genes, likely influence sleep regulation.

Targeted gene inactivation studies in animals have identified several genes involved with prenatal brainstem development of respiratory control including arousal responsiveness (3). During embryogenesis, the survival of specific cellular populations composing the respiratory neuronal network is regulated by neurotrophins, a multigene family of growth factors and receptors. Brain-derived neurotrophic factor (BDNF) is required for development of normal breathing behavior in mice, and newborn mice lacking functional BDNF exhibit ventilatory depression associated with apparent loss of peripheral chemoafferent input (5). Ventilation is depressed and hypoxic ventilatory drive is deficient or absent.

Krox-20, a homeobox gene important for mouse hindbrain morphogenesis, also appears to be required for normal development of the respiratory central pattern generator (6). *Krox-20*-null mutants exhibit an abnormally slow respiratory rhythm and increased incidence of respiratory pauses, and this respiratory depression can be further modulated by endogenous enkephalins. Inactivation of *Krox-20* may result in the absence of a rhythm-promoting reticular neuron group

localized in the caudal pons and could thus be a cause of life-threatening apnea (3).

Brainstem muscarinic cholinergic pathways are important in ventilatory responsiveness to carbon dioxide (CO₂) (3). The muscarinic system develops from the neural crest, and the *ret* proto-oncogene is important for this development. *Ret* knockout mice have a depressed ventilatory response to hypercarbia, implicating absence of the *ret* gene as a cause of impaired hypercarbic responsiveness. Diminished ventilatory responsiveness to hypercarbia has also been demonstrated in male newborn mice heterozygous for *Mash-1* (7). There is a molecular link between *ret* and *Mash-1*, and the latter is expressed in embryonic neurons in vagal neural crest derivatives and in brainstem locus coeruleus neurons, an area involved with arousal responsiveness.

Serotonergic receptors in the brainstem are critical components of respiratory drive, and abnormalities have been implicated as causal in SIDS (8). Review of the genetics of serotonin metabolism may be very pertinent to understanding important genetic risk factors for SIDS, and serotonin metabolism may be a model for multiple other genetically derived neurotransmitter systems important in maturation and development of control of breathing. Serotonin is a widespread neurotransmitter affecting breathing, cardiovascular control, temperature, and mood (3,9). Serotonin modulates activity of the circadian clock and appears to be the major neurotransmitter of nonrapid eye movement (nonREM), or quiet, sleep. Many genes are involved in the control of serotonin synthesis, storage, membrane uptake, and metabolism. The serotonin transporter gene is located on chromosome 17, and variations in the promoter region of the gene appear to have a role in serotonin membrane uptake and regulation (3,9). Several transporter polymorphisms have been described, including one in the promoter region; the long "L" allele increases effectiveness of the promoter and hence leads to reduced serotonin concentrations at nerve endings compared to the short "S" allele. The L/L genotype is associated with increased serotonin transporters on neuroimaging, and increased postmortem binding. Although no studies have been done in AOP or ALTE subjects, recent data in white, African-American, and Japanese infants indicate that SIDS victims are more likely than controls to have the "L" allele (9,10).

Fetal Breathing

Fetal sheep make regular breathing movements during REM sleep (11). Studies in animal models and human fetuses have demonstrated that there is a maturational progression in fetal breathing movements over gestation and that this respiratory pattern can be altered by a variety of pharmacologic and physiologic inputs.

In the human fetus, ultrasound evidence of fetal breathing movements was first noted with development of high-speed ultrasound in the mid-1970s. These fetal breathing movements have been characterized throughout gestation

P.537

in response to maternal condition and as a potential indicator of overall fetal condition (12). From these studies, several characteristics of fetal breathing are evident. First, regardless of gestation, fetal breathing is not a continuous process. Significant periods of apnea, up to 122 minutes, are seen even in near-term fetuses (13). These periods of apnea are generally more frequent and of longer duration in younger gestational age fetuses (14), but significant respiratory pauses are still seen in presumed healthy near-term fetuses. Second, during periods of frequent respiratory motion, there are patterns of both regular and irregular breathing documented by chest/abdominal wall movements and by Doppler sonography assessing tracheal fluid flow (15). Third, there does appear to be a circadian rhythmicity to fetal breathing movements, with well-documented increases during certain periods of the day as compared to others (13). Fourth, maternal condition, particularly maternal glucose status, can have significant effects on fetal

breathing frequency, with well-documented increases in fetal breathing frequency after maternal glucose loading following maternal fasting. This response to maternal glucose loading is not as pronounced when the mother is not fasting but rather ingesting normal meals during continuous 24-hour ultrasound monitoring (16). Fifth, fetal breathing does appear to be a potential measure of fetal well-being when used in conjunction with other ultrasound parameters. Several studies have documented diminished fetal breathing activity in association with poor fetal health, and this decreased activity, along with other measures of fetal well-being, can be helpful in guiding obstetric actions in terms of need for urgent delivery (17,18).

The fetal breathing pattern responds to a variety of pharmacologic and physiologic manipulations. Fetal breathing has been noted to increase three-fold if the mother inhales 5% CO₂ for 15 minutes (19). Maternal hyperoxia does not alter fetal breathing movements or pattern in near-term normally grown fetuses (20), but growth-restricted fetuses do exhibit an increase in respiratory rate with maternal hyperoxia (21). Tocolytics, indomethacin, and terbutaline increase fetal breathing movements almost two-fold when administered to women in preterm labor between 26 and 32 weeks of gestation (22). Despite the increased sensitivity of ultrasound to detect and characterize fetal breathing movements, almost all of the studies described have been observational in nature and have lacked characterization of several other very important fetal physiologic correlates, such as diaphragmatic electrical activity and sleep state. These human ultrasound studies have also not addressed the effects of pharmacologic and physiologic manipulation on fetal breathing in a controlled fashion. Animal studies, however, do augment the human ultrasound data and provide a clearer picture of the maturational development of breathing control.

Fetal breathing activity in sheep starts early in gestation, arises from centrally mediated stimuli, and occurs primarily during periods of low-voltage electrocortical activity (REM sleep) (11). REM sleep comprises about 40% of fetal life during the last trimester in sheep. Breathing does occur during periods of high-voltage electrocortical activity (quiet sleep), but there is no significant pattern to this breathing—it is only episodic in nature and generally occurs after tonic muscular discharges, i.e., body movements (23).

Additional insights have been obtained using chronically instrumented fetal lambs with direct visualization of fetal breathing and state at baseline and after physiologic manipulations (23). Fetal sheep do not show any periods of wakefulness as indicated by eye opening and purposeful movement of the head. The fetus alternates between REM sleep (low-voltage electrocortical activity) and quiet sleep (high-voltage electrocortical activity). Breathing movements, swallowing, licking, and other body movements occur almost exclusively during REM sleep. The fetus responds to an increase in arterial carbon dioxide pressure (PaCO₂) with an increase in breathing as determined by increases in tracheal pressure, breathing frequency, and integrated diaphragmatic activity, suggesting that both breathing rate and “tidal volume” increase in response to increasing hypercapnia (24,25,26). This breathing activity only occurs in REM sleep and during transitions to quiet sleep. Hypoxic levels of maternal oxygen abolish fetal breathing movements (27). These observations suggest that the relative low oxygen levels in the fetus at baseline contribute to the relative “lack” of fetal breathing movements throughout gestation and that the several-fold rise in oxygen partial pressure at birth is a contributing factor to the initiation of a regular respiratory pattern.

The use of pharmacologic agents in the fetal sheep model has also enhanced our understanding of fetal breathing. Indomethacin, pilocarpine, 5-hydroxytryptophan, and morphine all cause continuous breathing in both REM and quiet sleep. After these “breakthroughs” of breathing activity into quiet sleep, the intensity eventually diminished even when the fetus transitions back to REM sleep in association with decreasing drug levels (1,28).

In summary, animal experiments confirm that fetal breathing does occur. Under baseline conditions and nonpharmacologic manipulation (i.e., hypercarbia, hypoxia, hyperoxia), it occurs primarily during REM sleep (low-voltage electrocortical activity). The fetus does respond to central chemoreceptor input as evidenced by its response to hypercapnia. The fetal response to hypoxia appears to be centrally mediated and results in diminished normal neuronal activity and diminished or absent fetal breathing movements. The peripheral chemoreceptors may also be immature in the fetus and hence further contribute to absence of the "adult" response to hypoxia of an increase in respiratory rate and tidal volume.

Initiation of Breathing at Birth

Despite the enhanced understanding of fetal maturation of breathing control, the understanding remains incomplete regarding factors responsible for initiating and maintaining a regular pattern at birth. The traditional view is that mild fetal asphyxia during labor stimulates peripheral chemoreceptors leading to the first breath, and breathing is

P.538

then maintained via input of other sensory stimuli, e.g., cold and touch. However, this view has been challenged by animal experiments showing that denervation of the carotid and aortic chemoreceptors does not alter fetal breathing or the initiation/continuation of breathing at birth (29). A stable respiratory pattern can also be initiated *in utero* with cord occlusion and hyperoxia, independent of PaCO₂. Postdelivery studies have also documented the importance of cooling in establishing a regular respiratory pattern and of CO₂ in maintaining that pattern (30). There are some data to suggest that a placentally derived factor inhibits fetal breathing and removal of this factor at birth then permits initiation of a regular respiratory pattern (1). This placental inhibitor "theory" is intriguing, but it does not explain the totality of response needed to initiate and maintain a normal respiratory pattern at birth; also, no candidate inhibitor has been suggested. Development and maintenance of respiration in the newborn is more likely due to a complex interaction of sensory stimuli and both central and peripheral chemoreceptor inputs (Fig. 28-1). The degree of maturation in the central respiratory centers also appears to be important since the responses to these stimuli in the term infant are more developed than in the preterm infant.

The Preterm Infant

The respiratory responses to hypercarbia are diminished in preterm infants less than 33 weeks' postconceptional age (PCA) (31), unrelated to any mechanical limitations in achieving adequate tidal volumes. The slope of the CO₂ response curve (Fig. 28-2) increases significantly between 29 to 32 and 33 to 36 weeks of gestation. The cause of this decreased sensitivity of central respiratory centers to CO₂ in preterm infants is related to central nervous system immaturity as indicated by decreased synaptic connections and incomplete dendritic arborization.

Preterm infants and full-term infants up to approximately 3 weeks postnatal age have a characteristic response to hypoxia that is quite different than in older infants. In contrast to the sustained hyperventilation in older infants, preterm infants have only a transient hyperventilation lasting 30 seconds to a minute. Subsequently, minute ventilation returns to baseline over several minutes and then progresses to ventilatory depression despite continued low inspired oxygen concentrations (1). The initial hyperventilatory response may be completely blunted in extremely premature infants (32). It is thought that this transient hyperventilation is in response to peripheral chemoreceptor input that is subsequently overridden by depression of central respiratory centers by hypoxia, and the hypoxic ventilatory depression is secondary to descending inhibition from the upper brainstem, midbrain, or higher structures (33,34).

Figure 28-2 CO_2 response curves for preterm infants with and without apnea of prematurity. $P_a\text{CO}_2$, arterial carbon dioxide pressure. (Reprinted from Gerhardt T, Bancalari E. Apnea of prematurity: I. Lung function and regulation of breathing. *Pediatrics* 1984; 74:58-62, with permission.)

Upper airway reflexes also may play a role in inhibiting respiration, particularly in preterm infants. Multiple sensory afferent fibers exist within the upper airways, and stimulation of these fibers by various mechanisms can result in abnormal respiratory responses. Responses to upper airway afferent fiber stimulation can change markedly with maturation. Newborn rabbits, for example, can exhibit irreversible, fatal apnea with stimulation of the nares. This response does not occur in mature animals (34). Negative pressure in the upper airways in human infants results in depressed ventilation, and isolated application of negative pressure to the upper airway in a rabbit model can result in diaphragmatic inhibition (35). This inhibition may contribute to the centrally mediated apnea (central apnea) occurring in mixed apneas initiated by obstructed breaths. As upper airway obstruction occurs, the infant makes respiratory efforts against this obstruction and the resulting increased negative pressure in the upper airway may result in reflex inhibition of diaphragmatic contraction. Due to a blunted response to hypercarbia and hypoxic ventilatory depression, less mature preterm infants with apnea may be less able to recover spontaneously and hence more likely to require active intervention by health care providers.

Laryngeal reflexes can also have significant effects on control of breathing. Apnea has been associated with overt regurgitation of gastric contents into the upper airway (36). Either regurgitation or reflux of the acidic contents of the stomach into the area of the larynx appears to stimulate chemoreceptors in the receptor-rich area of the larynx. This leads to an inhibitory afferent signal to the central respiratory centers. Animal studies have demonstrated that the area of the larynx is rich in chemoreceptors connecting with afferent fibers leading back to the brainstem. Stimulation of these chemoreceptors results in apnea in a lamb model (37,38).

Periodic Breathing

Periodic breathing is defined as a pattern of breathing alternating with respiratory pauses lasting through three cycles of breathing, with the pauses or apneic periods lasting at least 3 seconds (1,39). Periodic breathing is frequently seen in preterm infants and also in term neonates and young infants.

Periodic breathing appears to occur predominantly during REM sleep, but it also occurs during quiet sleep (32,40). During quiet sleep, periodic breathing is "regular" with consistent durations

while during REM sleep periodic breathing tends to be irregular with inconsistent durations of cycles of periodic breathing. These episodes of periodic breathing are reflective of immaturity of the respiratory control system. While initially thought to be a "benign" respiratory pattern, increasing evidence has indicated that periodic breathing can have pathologic consequences. Particularly in more immature preterm infants, minute ventilation can diminish significantly during episodes of periodic breathing, and oxygen saturations can decrease to hypoxemic levels in association with longer apnea durations and increased time spent in periodic breathing. Since more immature infants generally spend more time in sleep and more of this sleep time is characterized by periodic breathing, these infants can spend a significant amount of time with low oxygen saturations. These extreme degrees of periodic breathing likely reflect a greater general immaturity of the central respiratory control centers; the more "severe" the periodic breathing, the more likely an infant is to demonstrate overt clinical symptoms related to AOP.

It is very likely that both periodic breathing and AOP arise from the same pathophysiology, i.e., inability of the central respiratory control centers to adequately modulate multiple afferent inputs and resulting inhibitory outputs to the muscles of respiratory control. AOP may simply reflect a more severe variant of this dysmodulation. Not all studies have linked periodic breathing with more prolonged apneas (41), but preterm infants that demonstrate frequent intervals of periodic breathing also demonstrate an increased incidence of AOP and hence a general immaturity of the respiratory control system. While periodic breathing can thus be a normal respiratory pattern in both term and preterm infants, the higher the percent sleep time spent in periodic breathing and the greater the length of apnea during apneic periods, the more likely it is that these intervals represent a clinically significant immaturity of the central respiratory system associated with "pathologic" disturbances in central respiratory control.

The prevalence of periodic breathing is not precisely known since most studies have been based on convenience samples not necessarily representative of asymptomatic as well as symptomatic infants. Differing definitions for periodic breathing are an additional concern. In preterm infants less than 1,000 grams, many authors have reported the prevalence to be 100% (1,41). In term infants, the prevalence has been reported to be lower, but still as high as 80% (42,43). The high initial prevalence in both term and preterm neonates diminishes over time, most significantly in the first 6 to 8 weeks of life.

CLINICAL DISORDERS IN CONTROL OF BREATHING

Apnea

Apnea is defined as the cessation of breathing for longer than 20 seconds, or a shorter duration in the presence of pallor, cyanosis (See Color Plate), or bradycardia (44). There are multiple possible etiologic factors leading to symptomatic apnea in the preterm and full-term infant (Tables 28-1 and 28-2). The occurrence of apneic episodes thus requires clinical and laboratory assessments to rule out conditions requiring definitive treatment. There are no systematic prevalence data for symptomatic apnea in full-term infants, but most occurrences will have an identifiable medical cause (Table 28-2). In preterm infants less than 1,500 grams at birth, approximately 70% will have at least one clinically observed episode of symptomatic apnea while in the neonatal intensive care unit (NICU), and about 20% of these infants will have a specific medical cause (Table 28-1). The other 80% of preterm infants with symptomatic apnea do not have a specific medical cause and by exclusion are then diagnosed as having AOP, the most important and prevalent "disorder" of respiratory control occurring in preterm infants.

TABLE 28-1 ETIOLOGY OF APNEA IN PRETERM INFANTS

Cause	Comment
Idiopathic	Apnea of prematurity with immaturity of respiratory centers; modified by sleep state
Central Nervous System	Intracranial hemorrhage, seizures, depressant drugs, hypoxemia, hypothermia, hyperthermia
Respiratory	Pneumonia, obstructive airway lesions, Respiratory Distress Syndrome, laryngeal reflex, phrenic or vocal cord paralysis, pneumothorax, hypoxemia, hypercarbia, nasal occlusion caused by phototherapy eye patches, tracheal occlusion caused by neck flexion
Cardiovascular	Heart failure, hypotension, hypertension, hypovolemia, increased vagal tone
Gastrointestinal	Gastroesophageal reflux, abdominal distension, peritonitis
Infection	Pneumonia, sepsis, meningitis
Metabolic	Acidosis, hypoglycemia, hypocalcemia, hyponatremia, hypernatremia
Hematological	Anemia

Apnea of Prematurity

Pathophysiology

The maturation of cardiorespiratory control and the clinical course of premature infants with AOP parallel each other and are consistent with the data reported in fetal animal studies. AOP is a direct consequence of immaturity of brainstem respiratory control centers. Both the presence

P.540

and severity progressively increase the lower the gestational age. This autonomic immaturity is not unique to respiratory control centers, however. Although there is no objective way to clinically quantify degree of immaturity for other brainstem autonomic control systems, brainstem auditory maturation can be quantified by serial measurements of brainstem conduction time from the auditory-evoked response (wave VI interval) (45). Both improved synaptic efficiency and myelination appear to be responsible for shortening of brainstem auditory conduction times with advancing gestational age. The brainstem auditory nuclei are located in close proximity to the cardiorespiratory centers, and there is a strong association between long brainstem conduction times for the auditory-evoked responses and clinical episodes of AOP. Since not all very-low-birth-weight preterm infants develop AOP and the severity varies even among affected infants of the same gestational age, other genetic and/or environmental risk factors are also likely to be important. Although no genetic, neurotransmitter, or neuropathologic studies have been performed in preterm infants with AOP, performance of such studies may be as informative in AOP as they appear to be in other control-of-breathing disorders.

TABLE 28-2 ETIOLOGY OF APNEA AT BIRTH IN FULL TERM INFANTS

Cause	Comment
Intrapartum asphyxia	Hypoxemia, acidosis, brain stem depression
Placental transfer of CNS-depressant	Narcotics, magnesium sulfate, general anesthetics
Airway obstruction	Choanal atresia, macroglossia-mandibular hypoplasia (Pierre-Robin Sequence), tracheal web or stenosis, airway mass lesions
Neuromuscular disorders	Absent or uncoordinated sucking/swallowing, uncoordinated sucking and breathing, congenital myopathies or neuropathies
Trauma	Intracranial hemorrhage, spinal cord transection, phrenic nerve palsy
Infection	Pneumonia, sepsis, meningitis
Central nervous system	Seizures, congenital central hypoventilation syndrome, Arnold-Chiari malformation, Dandy-Walker malformation

Adapted from Hunt, CE. Apnea and sudden infant death syndrome in strategies in pediatric diagnosis and therapy. Editors: RM Kliegman. W.B. Saunders Co. Philadelphia, PA 1996.

Apneic episodes in AOP are subclassified as central, obstructive, or mixed (34,46). Figure 28-3 demonstrates the respiratory patterns during these events. Central apneas result from lack of respiratory effort. Obstructive apneas (obstructed breaths) are also central in origin but are related to absence of neuromuscular control of upper airway patency rather than absence of inspiratory diaphragmatic stimulation. Hence, obstructive apneas are characterized

P.541

by cessation of inspiratory air flow into the lungs despite persisting respiratory effort. Mixed apneas represent a combination of missed breaths (central apnea) and obstructed breaths. Mixed episodes of AOP can begin either with obstructed breaths or with central apnea, and there can be multiple alternations between obstructed breaths and central apnea within any single episode. In terms of relative frequency of each type, mixed apnea generally accounts for 53% to 71% of events, with obstructive apnea 12% to 20% and central apnea 10% to 25% (34). Preterm infants with AOP have significantly lower ventilatory responses to CO₂ than preterm infants matched for gestational age without AOP (31) (Fig. 28-2).

Incidence and Diagnosis

Threshold criteria for diagnosis have not been objectively defined and there is no established diagnostic test. Reported incidence data are therefore not based on any standardized criteria for diagnosis, but range from a low of less than 10% in preterm infants born at 34 weeks of gestation or more to approximately 60% at birth weights less than 1,500 grams and to a high of greater than 85% among infants born at less than 28 weeks of gestation (44,47,48). The first episodes can manifest themselves within the first 24 hours of life in spontaneously breathing infants without respiratory distress but are typically delayed in infants still receiving mechanical ventilatory support (49).

The identification of individual episodes of AOP is routinely based on detection of: a) central apnea lasting at least 20 seconds using standard impedance-based cardiorespiratory monitoring, b) bradycardia of less than 80 to 100 beats per minute (bpm) depending on gestational age, or c) arterial oxygen desaturation using a pulse oximeter (SpO₂). These symptoms are typically associated with clinically observed cyanosis. To be certain that monitor alarms are clinically significant, episodes initially detected by a monitor alarm need to be confirmed by visual observation (34,50). Since impedance-based cardiorespiratory monitors cannot detect obstructive apneas unless and until associated with bradycardia, however, episodes of AOP will not be detected by the monitor until central apnea has persisted long enough to trigger a monitor alarm or until the bradycardia threshold has been reached. Isolated respiratory pauses of less than 20 seconds without associated bradycardia or desaturation may not be of clinical significance and are not sufficient to justify a diagnosis of AOP. Periodic breathing is typically prominent in infants with AOP but is not sufficient for diagnosis in the absence of associated bradycardia and/or desaturation.

In infants with AOP, the periodic respiratory pauses associated with periodic breathing may be longer than in infants without AOP, and the total time spent in periodic breathing may be longer. Both of these factors contribute to the occurrence and severity of associated bradycardia and/or desaturation (39). Visually confirmed episodes of apnea with associated heart rate decelerations and desaturation are classified as symptomatic episodes. There is no consensus-based threshold number of clinical episodes required for a "diagnosis" of AOP, but the minimum is at least one visually confirmed symptomatic episode unrelated to another medical cause (Table 28-1). The severity of AOP in individual patients and the threshold for initiating treatment are determined by the frequency and severity of subsequent clinically observed episodes. Although a multihour and multichannel recording that includes monitoring for both central and obstructive apneas, bradycardia, and desaturation might provide more objective threshold criteria for diagnosis and treatment, such recordings are not part of routine clinical care and no criteria have been established.

Treatment

Once other medical causes of apnea have been excluded (Table 28-1) and a diagnosis of AOP

established, multiple treatment strategies are available. The first step is to ensure that borderline levels of baseline hypoxemia, anemia, hypocalcemia, and hypoglycemia have been corrected. Infants with intermittent hypoxemia due to episodes of AOP will be at increased risk for reduced tissue oxygen delivery (if they are also anemic) and for further exacerbation of AOP symptoms. Blood transfusions can be effective in reducing the severity of episodes (52,53), but some studies have not shown any correlation between degree of hypoxemia and degree of anemia (54,55 and 56). Some studies suggest that transfusion may be helpful in ameliorating symptoms of AOP only if the baseline hematocrit is less than 25 %. Clinicians should address the following questions when considering transfusion to improve symptoms related to AOP (57):

Are the symptoms related to AOP new in origin?

Has the severity of AOP increased as anemia has worsened?

Is the child receiving oxygen or other ventilatory support?

Has the heart rate increased?

Are other respiratory rhythm changes, such as periodic breathing, more prominent?

Affirmative answers to these questions increase the likelihood that a transfusion may improve clinical symptoms attributed to AOP.

The criteria for pharmacologic or ventilatory support vary among neonatologists, and there are no established clinical guidelines. Treatment is indicated, however, whenever clinical episodes are recurring, do not resolve spontaneously or in response to minimal stimulation, and are associated with bradycardia and intermittent hypoxemia. The first line of therapy is generally a methylxanthine, either caffeine or aminophylline.

Methylxanthines

Methylxanthines are central respiratory stimulants that increase CO₂ sensitivity and hence lead to improved tidal

P.542

and minute volumes and blood gas values. Methylxanthines also increase diaphragmatic function, decrease muscle fatigue, and increase metabolic rate and catecholamine activity. These medications can be given by either oral or intravenous route. Both aminophylline and caffeine have been studied in placebo-controlled trials, and both have been shown to reduce the incidence of apnea (44,58,59 and 60). Table 28-3 reviews the recommended starting doses and dosing intervals for caffeine and aminophylline. The recommended therapeutic blood levels are 5 to 10 µg/mL for aminophylline and 8 to 20 µg/mL for caffeine. Methylxanthine side effects are secondary to catecholamine stimulation and include tachycardia, jitteriness, and irritability. Caffeine has a wider therapeutic index and side effects are uncommon at the recommended blood levels. There is consequently less need to check frequent blood levels. Direct comparisons of aminophylline and caffeine indicate similar efficacy at equivalent levels of central ventilatory stimulation. At equivalent degrees of central chemostimulation, however, side effects are less with caffeine than with aminophylline (61,62,63). Many neonatologists thus recommend caffeine as the preferred methylxanthine for treatment of AOP.

TABLE 28-3 DOSING REGIMENS FOR INITIATING METHYDXANTHINE THERAPY (IV/po) FOR TREATMENT OF SYMPTOMATIC EPISODES IN PRETERM INFANTS WITH APNEA OF PREMATURITY

Drug	Loading	Maintenance
Aminophylline ^a	4 to 6 mg/kg	1 to 3 mg/kg every 8 to 12 hours
Caffeine ^b	10 to 20 mg/kg	2.5 to 4.0 mg/kg per day (base)
Caffeine Citrate ^c	20 to 40 mg/kg	5.0 to 8.0 mg/kg per day

^a Start maintenance dose 8 to 12 hours after loading dose. If changing from IV to po aminophylline, increase dose by 20%. If changing to po theophylline, no change in dose is required.

^b Start maintenance dose 24 hours after loading dose. Caffeine citrate may be given IV or po.

IV, intravenous; po, oral.

Regardless of which methylxanthine is chosen, most infants will have a significant reduction in central apnea events and hence in the severity of episodes. While individual studies measure efficacy in different ways, the number of clinical episodes was generally reduced by 50% to 90% (58,59 and 60,64,65,66 and 67). A Cochrane collaborative review found that both caffeine and aminophylline reduce the number of episodes of apnea and decrease the need for intermittent positive pressure ventilation (68).

The necessary duration of treatment with a methylxanthine is highly variable. AOP improves as brainstem respiratory control centers progressively mature, but there is considerable individual variation in the PCA at which maturation is sufficient to eliminate clinically documented episodes. By 32 to 36 weeks' PCA, most infants with AOP can be weaned from treatment. Since there is no objective threshold to define resolution of AOP, neonatologists will usually use a combination of PCA, length of time since the last documented episode, and general clinical status to decide when to stop treatment. Once therapy is stopped, most physicians will continue to monitor an infant for a variable period of time (3 to 8 days) during drug "washout" before concluding that the infant is ready for discharge. Infants with recurrent clinical symptoms of bradycardia or cyanosis related to AOP will require reinstitution of medical treatment.

Continuous Positive Airway Pressure

Continuous positive airway pressure (CPAP), usually administered using nasal prongs (NCPAP), is also an effective treatment for AOP and is typically used when clinically significant episodes persist despite optimal methylxanthine therapy. At CPAP levels of 2- to 5-cm water, infants with AOP will have fewer episodes (69). This reduction is primarily related to significant reductions in episodes of obstructive and mixed apneas (Fig. 28-4) and has been attributed to splinting open of the upper airways by the positive airway pressure. CPAP levels of 2- to 5-cm water are generally sufficient to reduce upper airway resistance in sleeping premature infants and eliminate clinical symptoms of AOP related to mixed and obstructive apneas.

If NCPAP, in conjunction with a methylxanthine, is not sufficient to prevent recurring episodes associated with bradycardia and intermittent hypoxemia, some investigators have suggested using nasal intermittent positive pressure ventilation (70,71,72). Combined NCPAP and intermittent positive pressure ventilation may most likely be needed when episodes are related predominately to central apneas that are not being effectively eliminated by the NCPAP.

Figure 28-4 Effect of continuous positive airway pressure (CPAP) on a number of apneic episodes 10 seconds or longer in 10 infants with apnea of prematurity. Mixed and obstructive apnea decreased significantly during both periods of CPAP, with no evident effect on central apneas. (Reprinted from Miller MJ, Carlo WA, Martin RJ. Continuous positive airway pressure selectively reduces obstructive apnea in preterm infants. *J Pediatr* 1985;106: 91-94, with permission.)

Doxapram

Doxapram is an intravenous analeptic agent used in central hypoventilation syndrome and acute respiratory failure, and as a postoperative respiratory stimulant (44,73). Treatment with doxapram should be considered whenever methylxanthine therapy and NCPAP have been optimized but significant bradycardia and/or hypoxemia episodes persist. Its mechanism of action appears to be related to stimulation of carotid chemoreceptors at lower doses and to direct stimulation of central respiratory control neurons at higher doses. It is effective in diminishing the number of clinical episodes in small clinical trials and may be most effective when used in low doses in combination with low-dose methylxanthine treatment (74,75). The intravenous loading dose for doxapram is 2.5 to 3.0 mg/kg over 15 minutes followed by a continuous infusion of 1.0 mg/kg titrated to the lowest responsive dose (maximum dose 2.5 mg/kg/hour). At these low doses of doxapram used in AOP, significant side effects are uncommon but increased blood pressure and other side effects of catecholamine stimulation can occur, including lowering seizure threshold.

Intubation and Assisted Ventilation

If an infant is still having clinically significant episodes of bradycardia and/or cyanosis (See Color Plate) secondary to AOP despite optimal pharmacologic and noninvasive positive airway pressure, then endotracheal intubation and positive pressure ventilation is the treatment of last resort. It is infrequent that such invasive treatment is necessary, but no data as to frequency of need are available. Since intubation for treatment of AOP is uncommon, infants with AOP requiring intubation also need to be evaluated for intercurrent illnesses such as sepsis/meningitis and seizures.

Gastroesophageal Reflux

Significant controversy exists as to whether gastroesophageal reflux (GER) makes a significant contribution to episodes of AOP. Multiple studies indicate that stimulation of upper airway and especially laryngeal receptors leads to inhibitory influences on central respiratory centers and subsequent apnea. However, the preponderance of data from human studies indicates no causal link between GER and AOP (76,77 and 78). Some studies using intraluminal impedance techniques have shown a positive correlation between GER and AOP (79), but other studies using the same technique have not shown this correlation (78). GER and AOP may thus coexist in preterm infants and both may require treatment; however, in the absence of specific symptoms of GER, there is no evidence that treatment for GER will ameliorate symptoms of AOP.

Feeding-Related Symptoms

Both the establishment of adequate oral intake and resolution of any apneic or hypoxemic episodes related to persisting AOP are developmentally regulated. Just as resolution of AOP can be tracked by measuring maturation of brainstem auditory conduction using brainstem auditory-evoked responses, so can the attainment of coordinated oral feeding (45). Many infants will resolve their AOP and begin successful oral feeding at approximately the same time developmentally, but it is also possible that oral feedings may further aggravate episodes of AOP if the brainstem areas related to ventilatory control and oropharyngeal coordination are not sufficiently mature.

Feeding is a complex motor task that involves three coordinated steps: sucking, swallowing, and breathing. While full-term infants will breathe while sucking, the preterm infant has greater difficulty with this motor task. In addition, the preterm infant is very likely at the beginning of a feeding session to spend an exaggerated period of time in the initial sucking stage and not breathe at all while in this stage. The full-term infant with no lung disease and a mature suck/swallow mechanism may have a brief period of mild desaturation during oral feeding, but rarely does this lead to bradycardia and apnea. The preterm infant with borderline respiratory status and an immature suck/swallow response, however, is more likely to hypoventilate while feeding due to immature suck/ swallow pattern and response (80,81). If a preterm infant with AOP is demonstrating desaturations with feeding that are leading to bradycardia or apnea, decreased oral intake may be necessary pending further maturational development in oropharyngeal and ventilatory control as related to AOP. In addition to continuing methylxanthine treatment, additional therapeutic intervention may be as simple as providing oxygen immediately prior to and during the feeding (80).

Natural History: Implications for Discharge Planning and Home Care

Most preterm infants with AOP progressively improve with increasing PCA and are clinically normal without treatment by 34 to 36 weeks' PCA. Even after apparent resolution of AOP symptoms, however, symptoms can recur under well-defined conditions. Infection with respiratory syncytial virus (RSV) places infants at risk for apneic episodes, and apnea can be the presenting sign of an RSV infection (82,83). It is unclear why RSV places premature infants at risk for recurrent episodes of apnea, but RSV may alter laryngeal chemoreceptor sensitivity. With recovery from the RSV infection, the apnea episodes also resolve.

Exposure to general anesthesia also places premature infants at risk for recurrent apneic events (84). This is particularly true when inhalational anesthetic agents are used. Apnea-related symptoms can be related to anemia, especially at hematocrit levels below 30% (85). Unrelated

to anemia, the incidence of apnea-related symptoms after discharge from the recovery room may be as high as 5% at 48 to 50 weeks' PCA and does not decrease to less than 1% until 54 to 56 weeks' PCA (84). Most clinically significant episodes, however, occur at less than 44 weeks' PCA, which is very consistent with Collaborative Home Infant Monitoring Evaluation (CHIME) data (46).
Premature

P.544

infants below these PCA limits, especially at lower hematocrit levels, thus need to receive adequate monitoring postoperatively to prevent life-threatening events.

Persisting or recurring symptoms at home associated with a prior history of AOP in former premature infants has become an issue of increasing clinical importance. At least in part related to discharge at younger PCAs, a significant minority of AOP patients have persisting symptomatic episodes related to apnea, bradycardia, cyanosis, or a combination thereof, when otherwise ready for discharge. In the CHIME study, for example, 17% of 443 infants less than 1,750 grams and 34 weeks or less of gestational age at birth were still symptomatic at the time of discharge home and 29% of these 443 infants were discharged with a methylxanthine (46).

Numerous studies have attempted to establish the minimum number of symptom-free hospital days without treatment required to ensure that symptoms would not recur after discharge home. Based on retrospective chart reviews in otherwise healthy preterm infants 1,500 grams or less and 32 weeks or less at birth and noting frequency of clinical episodes of apnea, bradycardia, and/or color change related to AOP, infants may be symptom-free for up to 8 days and still have another event (86). These investigators thus concluded that 8 symptom-free days were required to ensure resolution of AOP. In a different study based on monitor alarms, preterm infants with bedside monitor alarms had very infrequent apnea 20 seconds or more in duration when approaching discharge but had a higher frequency of desaturation and bradycardia with short apneas compared to preterm infants free of monitor alarms for at least 2 days (87). Among preterm infants with birth weights less than 1,250 grams, not having any clinically apparent episodes, and otherwise ready for discharge, 24-hour recordings of oxygen saturation, heart rate, respiratory impedance, and end-tidal CO₂ partial pressure revealed significant apnea in 91%, the majority of which were obstructive (88). Significant apnea was defined as apnea of longer than 12 seconds in association with a heart rate decrease of at least 10% or a decrease of at least 10 percentage points in oxygen saturation. Since there was no apparent correlation between severity of these pre-discharge recorded events and apparent life-threatening events or sudden unexpected death in the first 6 months of age, however, these data do not clarify whether one should delay discharge or prescribe home-based intervention for events detected only by overnight recording and not evident by bedside observation. In the absence of a clear standard of care in this regard, individual practice is highly variable. Some centers discharge preterm infants after as few as 3 days or as long as 5 to 7 days or more without a clinical event. There are no data to suggest that the relative risk of having an ALTE or dying of SIDS is any greater in infants discharged after just 3 days versus 5 to 7 or more days or that the relative risk is greater in infants in whom the event-free period is determined only by clinical observation versus overnight recordings.

The CHIME provides new insights regarding how long AOP-related events can persist after discharge home and the potential value of home-based memory monitor recordings in assessing risk for subsequent life-threatening or fatal events (46). The CHIME study was performed with a specially designed memory monitor utilizing respiratory inductance plethysmography to detect obstructed breaths as well as central apneas. Healthy full-term infants, premature infants, subsequent siblings of prior SIDS victims, and infants with a prior idiopathic ALTE were monitored until 6 months' postnatal age. The events stored for analysis included events exceeding conventional alarm thresholds (apnea of at least 20 seconds or heart rate less than 60 to 80 bpm

for at least 5 seconds, depending on PCA) and extreme events (apnea of at least 30 seconds or heart rate less than 50 to 60 bpm for at least 5 seconds, depending on PCA).

Conventional events were common in all groups and at least one occurred in 41% of infants. Of those conventional events with apnea of at least 20 seconds, 50% included three or more obstructed breaths. Extreme events occurred in 10% of all infants. Among extreme events with apnea of at least 30 seconds, 70% included three or more obstructed breaths. In general, the degree of hypoxemia increased with increasing duration of apnea or bradycardia, and 25% of extreme events were associated with a decrease in oxygen saturation (SpO₂) of at least 10%.

Compared to healthy term infants, preterm infants were more likely to have at least one extreme event, especially preterm infants younger than 34 weeks of gestation and with birth weights of less than 1,750 grams. Among these preterm groups, the relative risk of at least one extreme event was 18.0 in those who had persisting symptoms related to AOP within the last 5 days prior to NICU discharge and was 10.1 in those who had no clinical AOP-related events for at least 5 days before discharge. In these two groups, the risk of at least one extreme event and at least one conventional event remained higher than in the healthy term infants until approximately 43 weeks' PCA.

The CHIME study does not establish whether it is clinically important to detect conventional or extreme cardiorespiratory events by home memory monitoring. It is not known, for example, whether infants with a prior history of AOP are at greater risk for SIDS than gestational age-matched preterm infants without such a history, and the CHIME study was not designed to determine to what extent the presence and severity of extreme events in preterm infants after discharge home may be contributing to the greater prevalence of SIDS in preterm infants.

Neurodevelopmental Outcome

Most reports have found little evidence of any neurodevelopmental risk directly attributed to a history of AOP or ALTE (39,89). All of these AOP studies are limited due to nonstandardized criteria for diagnosis and for quantifying severity of apnea-related events in the NICU, and due to variable treatment strategies (89,90). Precisely measured predischarge apnea related to AOP, however, has been

P.545

reported to be predictive of lower developmental indices at two years of age (91).

No outcome studies in preterm infants with AOP have considered the potential impact of cardiorespiratory events occurring at home during early infancy even though persistence beyond term gestation appears to be common, especially at lower birth weights (46,92). Using treatment with doxapram as a surrogate for severe AOP in preterm infants with birth weights of less than 1,250 grams, the duration of doxapram treatment and total dose received are significantly greater in children with isolated mental delay at 18 months compared to matched controls not receiving doxapram (93).

The CHIME study also provides some insights regarding risk for neurodevelopmental sequelae in infants with events documented using home memory monitoring (94). Among 256 infants (46% preterm) who used the home monitor and returned at 92 weeks' PCA for performance of the Bayley Scales of Infant Development-Revised (BSID-II), there was an inverse relationship between number of conventional events detected by home cardiorespiratory monitoring and neurodevelopmental outcome. This decrease in neurodevelopmental performance was observed both in full-term and preterm infants but was limited to the Mental Development Index (MDI). The adjusted difference in mean MDI scores with at least five events compared to no events was 5.6 points lower in full-term infants and 4.9 points lower in preterm infants. There was a trend

toward a lower adjusted difference in mean Psychomotor Development Index scores with at least five events compared to no events in full-term infants ($P = 0.07$) but not in preterm infants. A dose effect is suggested by the tendency for mean BSID-II values with 1 to 4 events to be intermediate between 0 and at least 5 events. These findings are consistent with recent studies of sleep-disordered breathing in children showing diminished school performance several years later and in adults showing neuropsychologic deficits and gray matter loss by high-resolution magnetic resonance imaging in multiple sites (95,96 and 97). These CHIME data do not clarify, however, whether lower developmental performance at 1 year of age in preterm infants is caused by the events documented at home or whether the events and developmental delay are both the consequence of antecedent events in the NICU or antenatally. Since the findings in preterm infants are similar to those observed in full-term infants, however, the developmental outcomes appear at least in part attributable to the home-based events. It is unknown to what extent these developmental delays in preterm infants can be reduced or eliminated by improvements in hospital-based treatment of AOP or in home-based treatment of persisting events.

IDIOPATHIC APPARENT LIFE-THREATENING EVENTS

An ALTE is defined as a sudden, unexpected change in an infant that is frightening to the caregiver but does not lead to death or persistent collapse (98). Most patients are younger than 12 months and generally younger than 6 months of age. Episodes are characterized by some combination of apnea, color change, change in muscle tone, choking, and gagging (39). Approximately 40% to 50% of ALTE cannot be explained by the history and clinical evaluation and are hence classified as idiopathic. The percent of idiopathic cases is likely higher when symptoms are sleep related. Incidence rates for an ALTE vary from 0.5 to 10.0 per 1,000 live births; this 20-fold difference is likely related to different case definitions and methods of ascertainment. Most studies of ALTE do not include information about birth weight and gestational age, but the incidence in preterm infants has been estimated to be in the range of 8% to 10% (88). In the CHIME study, 30% of 152 infants with an idiopathic ALTE were 37 weeks of gestation or less at birth. Preterm infants thus are at increased risk for an idiopathic ALTE, but it is unknown to what extent this might be related to a prior history of AOP or to persisting symptoms of AOP.

Infants with an idiopathic ALTE are at increased risk for SIDS, but there is no consensus as to the magnitude of this risk or the extent to which prematurity or AOP might be a related factor. History of an idiopathic ALTE has been reported in 5% to 9% of SIDS victims (98,99). The risk of SIDS appears to increase with two or more idiopathic events, but no definitive incidence rates are available. In the CHIME study, the relative risk of having at least one extreme event was increased in preterm infants with a history of an idiopathic ALTE, but only until about 43 weeks' PCA (46).

Infants experiencing an idiopathic ALTE are candidates for home memory monitoring. In such patients, memory monitors can be useful in determining risk for, and timely identification of, recurrent life-threatening episodes, and perhaps useful in reducing the risk for neurodevelopmental sequelae from subsequent events (94). There are no data to indicate, however, that the risk for SIDS can be reduced by using a home monitor (100).

SUDDEN INFANT DEATH SYNDROME

SIDS is defined as the sudden death of an infant that is unexpected by history and unexplained by a thorough postmortem examination, which includes a complete autopsy, investigation of the scene of death, and review of the medical history (101). An autopsy is essential in all sudden and unexpected infant deaths because the history and scene investigation do not exclude all causes,

including unsuspected congenital abnormalities and fatal child abuse. Comprising more than 7% of all infant mortality in the United States, SIDS was the third leading cause of infant mortality in 2000, ranked below congenital anomalies (21%) and disorders relating to short gestation/low birth weight (15%). About 2,650 infants died of SIDS in the United States in 1999, a rate of 0.67 in 1,000 live births; preliminary data suggest a lower rate for 2000 (102).

P.546

SIDS is the most common cause of postneonatal infant mortality in developed countries, generally accounting for 40% to 50% of infant deaths between 1 month and 1 year of age and about 20% of all deaths in infants discharged from a NICU. In full term infants, SIDS is rare before 1 month of age; the peak incidence occurs at 2 to 4 months of age, and 95% of all cases have occurred by 6 months of age. Compared to full-term infants, SIDS in preterm infants occurs at a younger PCA but older postnatal age (103).

Pathology

There is no autopsy finding pathognomonic of SIDS and no finding required for the diagnosis. There are, however, some common pathologic observations (104). Petechial hemorrhages are found in more than 90% of cases and may be more extensive than in other causes of infant mortality. Pulmonary edema is often present and may be substantial. Autopsy studies demonstrate structural evidence (tissue markers) indicative of preexisting, chronic low-grade asphyxia in nearly two-thirds of SIDS subjects (105). These tissue markers include persistence of adrenal brown fat, hepatic erythropoiesis, brainstem gliosis, and increased substance P. SIDS infants as a group have both prenatal and postnatal growth retardation, again consistent with prenatal and postnatal low-grade asphyxia. Vascular endo-thelial growth factor, which is upregulated by hypoxia, is elevated in cerebrospinal fluid of SIDS victims compared to control cases, confirming that SIDS is preceded by hypoxia and suggesting that it is prolonged hypoxia (106). The elevated levels of hypoxanthine in vitreous humor observed in SIDS infants further indicate a relatively long period of tissue hypoxia preceding death (105,107). Since adenosine, a precursor of hypoxanthine, is a respiratory inhibitor, these observations suggest that asphyxia from any cause could cause a secondary acceleration of adenosine monophosphate catabolism and adenosine accumulation and hence a vicious cycle leading to progressive hypoventilation and worsening asphyxia.

Brainstem structure and function have been a major focus of postmortem studies in SIDS victims. In addition to gliosis, findings include a persistent increase of dendritic spines and delayed maturation of synapses in the medullary respiratory centers, decrease of tyrosine hydroxylase immunoreactivity, and decreased catecholaminergic neurons in the brainstem (108). Significant decreases in serotonin receptor immunoreactivity in vagal medullary centers important in control of breathing have also been observed (109). Collectively, these results suggest that a maturational delay or malfunction related to cardiorespiratory autonomic regulation is one mechanism leading to SIDS.

The arcuate nucleus in the ventral medulla has been a particular focus for studies in SIDS victims. It is an integrative site for vital autonomic functions, including breathing and arousal, and is integrated with other regions that regulate arousal and autonomic chemosensory function. Quantitative three-dimensional anatomic studies indicate that a small subset of SIDS victims have hypoplasia of the arcuate nucleus, and histopathologic studies have observed bilateral, partial, and monolateral hypoplasia in as many as 57% of SIDS victims (110,111). Neurotransmitter studies of the arcuate nucleus have also identified receptor abnormalities in some SIDS victims that involve several receptor types relevant to autonomic control overall and to ventilatory and arousal responsiveness in particular. These deficits include significant

decreases in binding to kainate, muscarinic cholinergic, and serotonergic receptors (8). Protein kinase C (PKC) and neuronal nitric oxide synthase (NOS) in the brainstem are critical components of respiratory drive, and abnormalities have been implicated as causal in SIDS (112). Prenatal cigarette smoke exposure is an important risk factor for SIDS, and decreased immunoreactivity to selected PKC and NOS isoforms have been observed in rats exposed prenatally to cigarette smoke.

Environmental Risk Factors

Numerous maternal and infant risk factors for SIDS have been identified (Table 28-4). Some of these risk factors may be surrogates for more fundamental factors (99). Some risk factors that are modifiable have been the successful focus of risk-reduction campaigns, resulting in

P.547

decreased SIDS rates (100). Preterm infants are approximately 3 to 6 times more likely to die of SIDS than full-term infants (100,103,113,114). The environmental risk factors associated with SIDS in preterm infants are not substantially different than those observed in full-term infants (Table 28-5), and there is an inverse relationship between risk for SIDS and birth weight/gestational age. The postnatal age of preterm infants dying of SIDS is 5 to 7 weeks later than that of full-term infants, and the PCA is 4 to 6 weeks earlier than that for full-term infants (Table 28-6).

TABLE 28-4 ENVIRONMENTAL FACTORS ASSOCIATED WITH INCREASED RISK FOR SIDS

Maternal and antenatal risk factors

Smoking

Drug exposure (e.g., cocaine, heroin)

Nutritional deficiency

Inadequate prenatal care

Low socioeconomic status

Decreased age, education

Single marital status

Increased parity

Shorter interpregnancy interval

Intrauterine hypoxia

Fetal growth retardation

Infant risk factors

Age (peak 2-4 months)

Male gender

Race/ethnicity (e.g., African American and American Indian)

Growth failure

No pacifier (dummy)

Prematurity

Prone (and side) sleep position

Recent (febrile) illness

Smoking exposure (prenatal and postnatal)

Soft sleeping surface, soft bedding

Thermal stress/overheating

Colder season, noncentral heating

SIDS, sudden infant death syndrome. Adapted from Malloy MH, Freeman DH Jr. Birth weight- and gestational age-specific sudden infant death syndrome mortality: United States, 1991 versus 1995. *Pediatrics* 2000;105:1227-1231, with permission.

In response to international back-to-sleep campaigns introduced in numerous countries in the 1990s, SIDS rates have declined by 50% or more as the prevalence of placing infants prone for sleep has decreased dramatically. These dramatic decreases in SIDS rates have generally not

been associated with significant decreases in other risk behaviors. The 40% reduction in SIDS rates in the United States in 1992-1998 as prone prevalence decreased by approximately 50%, however, was associated with a 25% decrease in maternal reporting of smoking during pregnancy.

The odds ratio for SIDS in prone-sleeping infants in a meta-analysis of case-control studies was 2.8 (95% confidence intervals [CI] 2.1-3.6) (99). The highest risk for SIDS may occur in infants usually placed nonprone but placed prone for last sleep ("unaccustomed prone") or found prone ("secondary prone"). Unaccustomed prone is more likely to occur in day care or other settings outside the home and highlights the importance of educating all infant caretakers about appropriate sleep positioning. As prone sleeping rates have declined following SIDS risk-reduction campaigns, side sleeping has also emerged as an independent risk factor for SIDS, with a relative risk of 2.0 compared to supine sleeping. The American Academy of Pediatrics has recommended since 1996 that supine sleeping be the preferred sleeping position for all infants (100), but they did not explicitly include preterm infants in this recommendation. As prone- and side-sleeping prevalence have decreased, unsafe sleeping practices, including soft sleep surfaces and soft bedding, have emerged as significant risk factors (99). Bed sharing has been implicated as another risk factor for SIDS, but studies have not classified risk for SIDS according to reason for bed sharing and have only partially adjusted for other pertinent risk factors such as breastfeeding.

Despite initial concern that supine sleeping would increase the risk for adverse events such as aspiration, vomiting, and trouble sleeping, studies have not identified any adverse consequences of supine sleeping compared to prone sleeping (115). No symptom or illness was increased among nonprone sleepers during the first 6 months of age, and some illnesses were less common, especially ear infections. Aspiration has not been observed to occur more frequently in infants sleeping supine, and infants sleeping supine do not appear to be at increased risk for episodes of apnea or cyanosis (See Color Plate).

Preterm infants were initially excluded from "back-to-sleep" campaigns. This exclusion was based on data from the NICU that ventilation and oxygenation, especially with persisting respiratory symptoms, were better when positioned prone compared to supine. When preterm infants are sufficiently mature and healthy to be discharged home without supplemental oxygen, however,

there is no clinically significant impairment in respiratory status when sleeping supine compared to prone. The American Academy of Pediatrics has therefore recommended since 2000 that all infants should sleep supine at home regardless of gestational age at birth (100), but adherence with this recommendation remains limited. Infants with birth weights of less than 1,500 grams

are more likely to be placed to sleep in the prone position at home than infants with a birth weight of 1,500 to 2,499 grams (26% versus 14%) even though risk for SIDS is greater at birth weights less than 1,500 grams compared to greater than 1,500 grams (113). Strategies are needed to reassure health care providers that the supine position for sleeping is as safe and effective in preterm as in full-term infants and to model safe sleeping practices in the NICU as the discharge planning process begins.

Maternal smoking during pregnancy has consistently been associated with increased risk of SIDS (99). The relative risk is in the range of 4.7 and represents one of the most significant modifiable risk factors following declines in prone sleeping. There appears to be a small independent effect of paternal smoking during pregnancy, but studies examining the influence of other household members have been inconsistent. Infants dying from SIDS tend to have higher concentrations of nicotine in their lungs than control infants, regardless of reported smoking exposure (116). Elimination of prenatal exposure to cigarette smoke could theoretically reduce the risk of SIDS by approximately 30% to 40% (117). It is difficult to assess the independent effect of postnatal exposure to cigarette smoke because smoking exposure during and after pregnancy are highly correlated, but studies do suggest that eliminating postnatal exposure to environmental cigarette smoke might further reduce risk for SIDS. In some studies of bed sharing as a risk factor for SIDS, this association has been linked with postnatal maternal smoking.

There are several potential mechanisms to explain why cigarette smoke exposure is a risk factor for SIDS. Maternal smoking can potentiate hyperplasia of pulmonary neuroendocrine cells, and dysfunction of these cells may contribute to the pathophysiology of SIDS (3). Both animal and clinical studies indicate decreased ventilatory and arousal responsiveness to hypoxia following fetal exposure to nicotine (118). The age-specific attenuation of hypoxic defenses following nicotine exposure suggests impaired brain catecholamine metabolism. *In vitro* studies suggest that smoking increases risk for SIDS due to greater susceptibility to viral and bacterial infections and enhanced bacterial binding after passive coating of mucosal surfaces with smoke components (119).

Most studies have not identified an association between SIDS and maternal alcohol use during or following pregnancy after adjusting for cigarette smoke exposure (99). A recent study, however, identified an increased frequency of binge drinking during pregnancy of 73% in mothers of SIDS victims compared to 45% in control mothers (120).

Maternal drug use during pregnancy is a risk factor for SIDS, with a two-fold increased risk of SIDS observed in the National Institute of Child Health and Human Development Cooperative Epidemiological Study after adjusting for birth weight, race, and age (121). Another study identified a seven-fold increased risk for SIDS among infants of substance-abusing mothers compared with drug-free mothers (122). Relative risks vary from 3.1 (CI 0.43-21.74) for phencyclidine and 6.9 (4.04-11.68) for cocaine to 15.1 (6.30-36.20) for opiates. The variable and sometimes conflicting results appear related at least in part to failure to control for confounding variables and sometimes to inadequate sample size.

No clear association has been identified between SIDS and specific viral or bacterial pathogens (99). It has been suggested that upper respiratory infections or other minor illnesses in conjunction with other factors, such as prone sleeping, may play a role in the pathogenesis of SIDS. Deficient inflammatory responsiveness to infection has also been hypothesized to be a mechanism for SIDS (3,119,123). Partial deletions in the *C4* gene may contribute to this apparent link between upper respiratory infection and SIDS. Mast cell degranulation has been reported in SIDS victims; this is consistent with an anaphylactic reaction to a bacterial toxin, and some family members of SIDS victims also have mast cell hyperreleasability and degranulation, suggesting a genetic component to risk for an anaphylactic reaction (124).

Gene-Environment Interactions

The actual risk for SIDS in individual infants is determined by complex interactions between genetic and environmental risk factors (3). There appears, for example, to be an interaction between prone/side sleep position and impaired ventilatory and arousal responsiveness. Face-down or nearly face-down sleeping does occasionally occur in prone-sleeping infants and can result in episodes of airway obstruction and asphyxia in healthy full-term infants (125). Healthy infants will arouse before such episodes become life threatening, but infants with insufficient arousal responsiveness to asphyxia would be at risk for sudden death. There may also be links between modifiable risk factors such as soft bedding, prone-sleep position, and thermal stress, and links between genetic risk factors such as ventilatory and arousal abnormalities and temperature or metabolic regulation deficits. The increased risk for SIDS associated with fetal and postnatal exposure to cigarette smoke also appears at least in part to depend on genetic risk factors (3).

There are substantial data indicating that both genetic and environmental factors contribute to an increased risk for death from most natural causes in siblings. The next-born siblings of first-born infants dying of any noninfectious cause, for example, are at significantly increased risk for infant death from the same cause, including complications of prematurity and SIDS (3). The relative risk is 9.1 for concordance of cause of recurrent death versus 1.6 for a discordant cause of death, and the relative risk for recurrence of each cause of infant death is similar for SIDS (5.4-5.8) and for each of the other causes (range 4.6-12.5). The risk

P.549

for recurrent infant mortality in subsequent siblings from the same cause as in the index sibling thus appears to be increased to a similar degree for both explained causes and for SIDS. These increased risks in SIDS families are consistent with genetic risk factors associated with brainstem abnormalities in autonomic control interacting with environmental risk factors.

Physiologic Studies

Physiologic studies have been performed in healthy infants during early infancy, a few of whom

later died of SIDS (99). Physiologic studies have also been performed in infant groups at increased risk for SIDS, especially in infants having experienced an unexplained ALTE and in subsequent siblings of SIDS victims (Table 28-7). In the aggregate, these physiologic studies are indicative of a brainstem abnormality related to neuroregulation of cardiorespiratory control and other autonomic functions and are consistent with the autopsy findings in SIDS victims. The observed physiologic abnormalities include respiratory pattern, chemoreceptor sensitivity, control of heart and respiratory rate or variability, and asphyxic arousal responsiveness. A deficit in arousal responsiveness may be a necessary prerequisite for SIDS to occur but may be insufficient to cause SIDS in the absence of other genetic or environmental risk factors. Autoresuscitation (gaspings) is a critical component of the asphyxic arousal response, and a failure of autoresuscitation in victims of SIDS may be the final and most devastating physiologic failure (126). Most full-term infants less than 9 weeks of age arouse in response to mild hypoxia, but only 10% to 15% of normal infants older than 9 weeks of age arouse (127). These data thus suggest that as full-term infants mature, their ability to arouse to mild/moderate hypoxic stimuli diminishes as they reach the age range of greatest risk for SIDS.

The ability to shorten Q-T interval as heart rate increases appears to be impaired in some SIDS victims, suggesting that such infants may be predisposed to ventricular arrhythmia (100). Infants studied physiologically and later dying of SIDS have higher heart rates in all sleep-waking states, diminished heart rate variability during wakefulness, and significantly lower heart rate variability at the respiratory frequency across all sleep-waking cycles. Even in early infancy, therefore, future SIDS victims differ in the extent to which cardiac and respiratory activity are coupled. No heart rate variability data are available in preterm infants with AOP compared to gestational age-matched infants without AOP or to full-term infants.

Part of the decreased heart rate variability and increased heart rate observed in infants who later die of SIDS may be related to decreased vagal tone. This decreased tone appears at least in part to be related to vagal neuropathy or to brainstem damage in areas responsible for parasympathetic cardiac control. Comparing heart rate power spectra before and after obstructive apneas in infants, future SIDS victims do not have the decreases in low-frequency to high-frequency power ratios observed in control infants (128). Some future SIDS victims thus have different autonomic responsiveness to obstructive apnea, perhaps indicating impaired autonomic nervous system control associated with higher vulnerability to external or endogenous stress factors and hence to reduced electrical stability of the heart.

Home cardiorespiratory monitors with memory capability have recorded the terminal events in some SIDS victims (129). These recordings, however, have not included SpO₂ and do not permit identification of obstructed breaths due to reliance on transthoracic impedance for breath detection. In most instances, there has been sudden and rapid progression of severe bradycardia that is either unassociated with central apnea or appears to occur too soon to be explained by the central apnea. These observations are consistent with an abnormality in autonomic control of heart rate variability, or with obstructed breaths and associated bradycardia or hypoxemia.

Reducing Risk for Sudden Infant Death Syndrome

The international back-to-sleep campaigns have significantly reduced environmental risks for SIDS and have been associated with reductions in SIDS rates of 50% or more since the early 1990s. Despite the successes with risk reduction, however, there is no intervention that can be guaranteed to prevent SIDS in individual infants. Home electronic surveillance for apnea and bradycardia has been utilized for more than two decades, but no suitably designed prospective studies have been performed and hence no data exist to support a role for home cardiorespiratory monitors in preventing SIDS (130).

use in preterm and full-term SIDS victims and live controls (132). The prevalence estimates for monitor use for birth weights of 500 to 1,499, 1,500 to 2,499, and 2,500 grams or more were 20%, 3%, and 1% in African-American infants versus 44%, 9%, and 1% for other infants. In no instance was there a significant difference in prevalence of home monitor use in SIDS versus case controls, and in African-American infants with birth weights of 500 to 1,499 grams, the adjusted odds ratio for SIDS was significantly higher (3.9) with a home monitor. This higher odds ratio likely reflects a higher risk for SIDS in those infants monitored in this retrospective nonrandomized observational study.

Preventing extreme events such as observed in the CHIME study may be necessary if home monitors are to have any potential for reducing risk for SIDS (47). Even if prolonged apnea including obstructed breaths were not a primary autonomic abnormality contributing to risk for SIDS, home monitoring could still be potentially helpful if apnea of any type causing bradycardia or hypoxemia as part of the terminal event could be reliably detected sufficiently early to be amenable to intervention before the onset of life-threatening hypoxemia. However, this hypothesis remains untested and neither home electronic surveillance using current technology nor any other intervention can be recommended as a strategy to prevent SIDS. Despite absence of any proven prospective intervention to prevent SIDS, dramatic decreases in population-based risk can be achieved by eliminating modifiable risk factors associated with SIDS.

Chapter 29

Acute Respiratory Disorders

Jeffrey A. Whitsett

Ward R. Rice

Barbara B. Warner

Susan E. Wert

Gloria S. Pryhuber

Successful adaptation to air breathing at the time of birth is the culmination of an orderly process of growth and differentiation of pulmonary cells, leading to alveolar and capillary surfaces capable of providing oxygen and eliminating carbon dioxide. Failure to achieve adequate gas exchange at birth represents a major cause of perinatal morbidity and mortality. This chapter reviews the common disorders of neonatal respiratory adaptation, including respiratory distress syndrome (RDS), pulmonary meconium aspiration syndrome (MAS), pulmonary hypertension, pneumonia, air leak, pulmonary hemorrhage, transient tachypnea of the newborn (TTN), and other causes of acute respiratory dysfunction in the perinatal period. The clinical manifestations and therapy of these disorders are discussed in the context of the morphologic, biochemical, and physiologic factors critical to normal pulmonary growth, maturation, and function in the newborn.

HUMAN LUNG DEVELOPMENT

Human lung development is normally divided into five distinct stages of organogenesis, which describe the histologic changes that the lung undergoes during morphogenesis and maturation of its structural elements (1,2). These five stages include the embryonic, pseudoglandular, canalicular, sacular, and alveolar stages of lung development. Human lung development is initiated during the early embryonic period of gestation (3-7 weeks postcoitum) as a small sacular outgrowth of the ventral foregut called the respiratory diverticulum. During the subsequent pseudoglandular stage of lung development (5-17 weeks postcoitum), formation of the conducting airways, i.e., the tracheobronchial tree, occurs by elongation and repetitive branching of the primitive bronchial tubules. Vascularization of the surrounding mesenchyme with formation of the air-blood barrier, i.e., the alveolar-capillary membrane, occurs during the canalicular stage of lung development (16-26 weeks postcoitum). Cytodifferentiation of bronchiolar and alveolar epithelial cells is also initiated during this stage. Enlargement and expansion of the peripheral air spaces occurs during the sacular stage of lung development (24-38 weeks postcoitum), resulting in the formation of primitive sac-like alveoli and thick interalveolar septa. Formation of thin secondary alveolar septa and remodeling of the capillary bed occurs during the alveolar stage of lung development (36 weeks postcoitum to 8 years of age), giving rise to the mature alveolar organization of the adult lung (Fig. 29-1).

The human lung is a derivative of the primitive foregut endoderm and the surrounding splanchnic mesoderm. The primitive respiratory diverticulum appears at 3 weeks of gestation as an enlargement of the caudal end of the laryngotracheal sulcus located in the median pharyngeal groove, which is an outgrowth of the ventral wall of the primitive esophagus. During the fourth week of gestation, the respiratory diverticulum enlarges and subdivides into the left and right primary bronchi (see Fig. 29-1A,B). The primitive lung grows caudally, expanding into the mesenchyme surrounding the primitive foregut, although the trachea becomes separated from the esophagus by a band of mesenchymal tissue called the tracheoesophageal septum. Between 4 and 5 weeks of gestation, the left and right primary bronchi subdivide to produce secondary, or lobar, bronchi (see Fig. 29-1C,D). Further subdivision of lobar bronchi into tertiary or segmental bronchi occurs during the sixth week of gestation, with the lung taking on a lobulated appearance as the segmental buds are formed (see Fig. 29-1E,F). The developing respiratory tract is lined by endodermally derived epithelium that forms the conducting airways and alveoli. The surrounding mesoderm is composed of mesenchymal cells that will differentiate into connective tissue components,

P.554

P.555

including blood vessels, fibroblasts, smooth muscle cells, and cartilage.

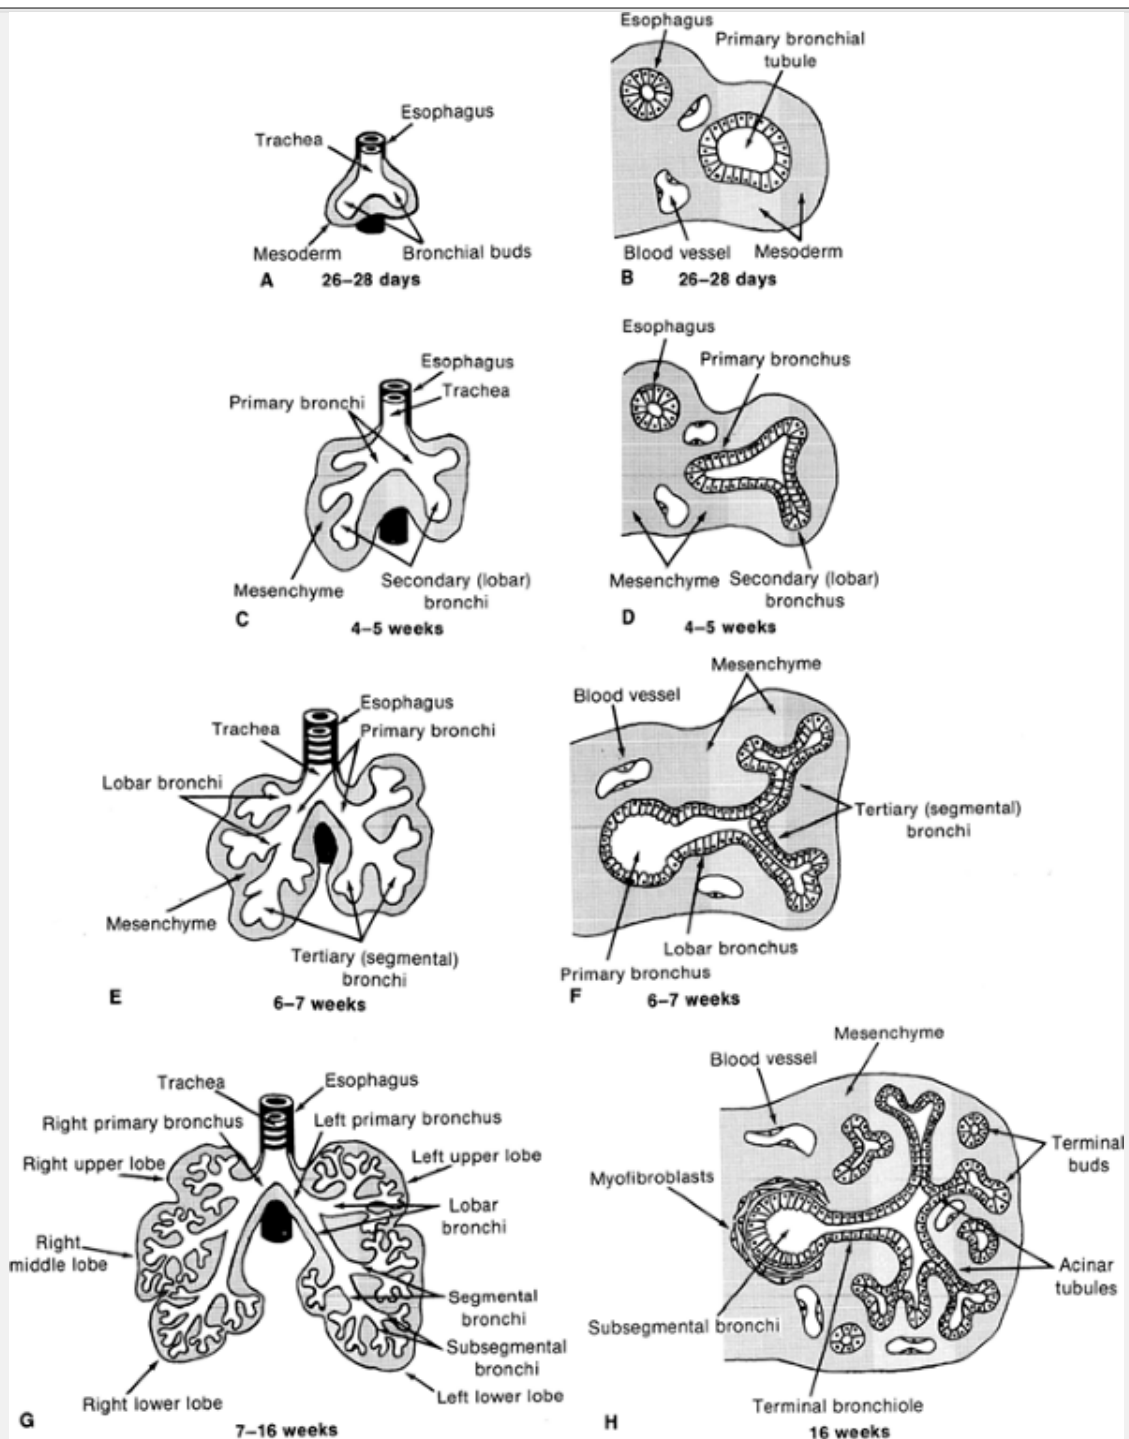

Figure 29-1 Lung development during the embryonic (A-F) and pseudoglandular (G, H) stages of organogenesis. The overall branching pattern of the primitive lung (left panels) results in the development of the bronchial tree. The histologic organization of the fetal lung becomes more complex as branching morphogenesis progresses through these stages (right panels).

Preacinar blood vessels first appear at the end of week 4. Pulmonary arteries arise from the sixth pair of aortic arches and grow into the mesenchyme, in which they accompany the developing airways, segmenting with each bronchial subdivision. Pulmonary veins develop as outgrowths of the left atrium of the heart and subdivide several times before connecting to the pulmonary vascular bed. Intraacinar vessels develop later, in parallel with alveolar formation.

The pseudoglandular stage of fetal lung development extends from about 5 to 17 weeks of gestation and is marked by the formation of the bronchial portion of the lung. This occurs through a process known as branching morphogenesis, during which the segmental tubules of the developing lung undergo repetitive lateral and terminal dichotomous branching to form the primitive bronchial tree (see Fig. 29-1G,H). By week 17 of gestation, the segmental bronchi have subdivided to produce approximately 23 generations of bronchial tubules ending in the terminal bronchioles. These bronchial tubules are lined initially by a pseudostratified columnar epithelium containing large pools of glycogen. A prominent basement membrane underlies the epithelium, and

mesenchymal cells adjacent to these tubules differentiate into fibroblasts, which become organized in a circumferential orientation, perpendicular to the long axis of the tubules. As branching progresses, pseudostratified columnar epithelium is reduced to a tall columnar epithelium, especially in distal regions of the bronchial tree. During this period, cytodifferentiation of the airway epithelium occurs in a centrifugal direction with ciliated, nonciliated, goblet, neuroendocrine, and basal cells appearing first in the more proximal airways. Cartilage, smooth muscle cells, and mucous glands are also found in the trachea during the pseudoglandular stage of development and extend as far as the segmental bronchi.

The canalicular stage of fetal lung development extends from week 16 to 26 of gestation. By the end of week 16, the terminal bronchioles have divided into two or more respiratory bronchioles that have subdivided into small clusters of short acinar tubules and buds lined by cuboidal epithelium. These structures undergo further differentiation and maturation to become the adult respiratory unit, or pulmonary acinus, consisting of the alveolated respiratory bronchiole, alveolar ducts, and alveoli. Clusters of acinar tubules and buds continue to grow by lengthening, subdividing, and widening at the expense of the surrounding mesenchyme (Fig. 29-2A). This peripheral growth is accompanied by the formation of intraacinar capillaries, which align themselves around the air spaces, establishing contact with the overlying cuboidal epithelium. During this stage of lung development, type II epithelial cell differentiation occurs in acinar tubules with formation of intracellular multivesicular bodies and multilamellar bodies, the storage form of pulmonary surfactant phospholipids. Type I epithelial cell differentiation occurs in conjunction with development of the air-blood barrier, wherever endothelial cells of the developing capillary system come into contact with the overlying epithelial cells.

During the saccular stage of fetal lung development, which extends from week 24 to 38 of gestation, the terminal clusters of acinar tubules and buds begin to dilate and expand into thin, smooth-walled, transitory ducts and saccules that later become the true alveolar ducts and alveoli of the adult (Fig. 29-2B). During this stage, there is a marked reduction in the amount of interstitial tissue. Intersaccular and interductal septa develop, which contain a delicate network of collagen fibers and the intraacinar capillary bed. Near the end of this stage, elastin is deposited in regions in which future interalveolar septa will form. Increasing amounts of tubular myelin, the secretory form of pulmonary surfactant, are seen in the air spaces.

The alveolar stage, which extends from 36 weeks of gestation to between 2 and 8 years of age, is the last stage of lung development and is marked by the formation of secondary alveolar septa, which partition the transitory ducts and saccules into true alveolar ducts and alveoli (Fig. 29-2C,D). This process of alveolarization greatly increases the surface area of the lung available for gas exchange. At the beginning of this period, the secondary interalveolar septa consist of short buds or projections of connective tissue that contain a double capillary network and interstitial cells that are actively synthesizing collagen and elastic fibers. By 5 months of age, these secondary interalveolar septa have lengthened and thinned, and now contain only a single capillary network. Although definitive alveoli can be found in the human lung by 36 weeks of gestation, 85 to 90% of all alveoli are formed within the first 6 months of life. Overall the number of alveoli increases by about six-fold between birth and adulthood, i.e., from an average of 50 million alveoli in the term lung to 300 million in the adult human lung. After the first 6 months of life, alveolar formation occurs at a slower pace until about 2 to 8 years of age, when further growth of the lung becomes proportional to growth of the body. The surface area available for gas exchange, and its diffusion capacity, increases linearly with body weight up to about 18 years of age. The conducting airways also increase in length and diameter, although airspace and capillary volume increase coordinately at the expense of interstitial volume.

DEVELOPMENTAL ANOMALIES

Each of these stages of lung development includes distinct changes in tissue organization and cellular differentiation that are important for subsequent growth and maturation of the lung. Structural and functional defects in lung development at birth can often be traced to arrested or aberrant development during one of these periods of organogenesis, often as a result of mutations in genes critical for patterning and growth of the lung, such as the *GLI* gene (Pallister Hall Syndrome), which is a component of the

P.556

Sonic Hedgehog signaling pathway, and the fibroblast growth factor receptor, *FGFR2*, gene (Pfeiffer's, Apert's, and Crouzon's syndromes). Developmental anomalies of the lung occur through defective division and differentiation of the lung bud, of the left or right bronchial bud or of the trachea and esophagus. Pulmonary agenesis, tracheal and bronchial malformations, tracheoesophageal fistulas, ectopic lobes, and bronchogenic and pulmonary cysts arise during the embryonic and pseudoglandular stages of lung development. Clinical disorders related to pulmonary hypoplasia, acinar dysplasia, alveolar capillary dysplasia, and respiratory insufficiency are

associated with later periods of development. Pulmonary hypoplasia can be caused by a reduction of space within the pleural cavity, usually as a consequence of another primary developmental defect, such as congenital diaphragmatic hernia, or by a reduction in the amount of amniotic fluid following premature rupture of membranes or in association with renal dysgenesis Potter's syndrome. Respiratory distress syndrome and bronchopulmonary dysplasia are associated with premature birth at a time when biochemical functions (e.g., surfactant production) and structural functions (e.g., elasticity) of the lung are still underdeveloped.

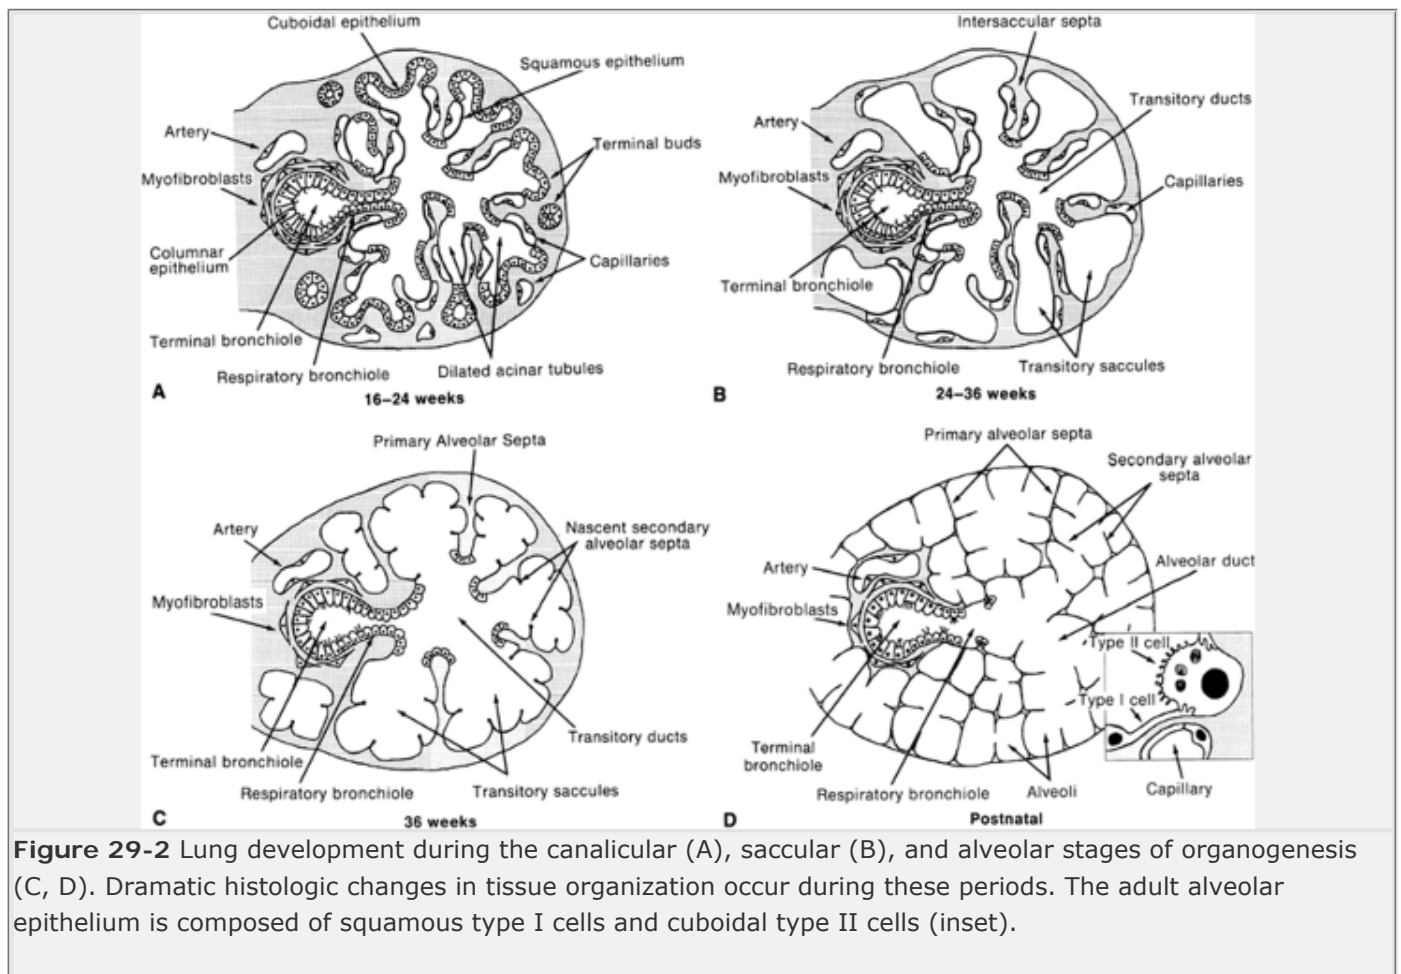

Figure 29-2 Lung development during the canalicular (A), sacular (B), and alveolar stages of organogenesis (C, D). Dramatic histologic changes in tissue organization occur during these periods. The adult alveolar epithelium is composed of squamous type I cells and cuboidal type II cells (inset).

Hereditary-Genetic Causes of Acute Respiratory Failure in the Newborn

Mutations in the surfactant protein B and C genes are rare causes of acute respiratory failure in neonates (3,4). Hereditary SP-B deficiency causes respiratory distress, generally in full-term infants, within the first day of life. Respiratory failure progresses despite ventilatory support, surfactant replacement or ECMO, generally causing death from respiratory failure in the first months of life. Mutations in the SP-B gene are inherited as autosomal recessive traits, resulting in the lack of SP-B in the airways and severe surfactant dysfunction. Hereditary SP-B deficiency is a lethal disease, although some infants have been successfully treated with lung transplantation. The definitive diagnosis is made by genotyping. Mutations in the SP-C gene are generally inherited as autosomal-dominant, and cause both acute and chronic interstitial lung disease in

P.557

newborns, infants, and adults. This disorder is associated with the lack of SP-C protein in alveolar lavage and with mutations in the proSP-C protein. The diagnosis of SP-C deficiency is made by genotyping. Mutations in a transport protein, ABCA3, also cause neonatal respiratory failure. Like hereditary SP-B deficiency, ABCA3 defects are inherited as autosomal recessive genes and cause respiratory failure that is refractory to ventilation and surfactant therapy (5).

THE SURFACTANT SYSTEM

The unique physical-chemical boundary between the alveolar gases and the highly solvated molecules at the apical surface of the respiratory epithelium generates a region of high surface tension produced by the unequal

distribution of molecular forces among water molecules at an air-liquid interface. Surface-active material at this interface in the alveoli provides surface-tension-lowering activity that contributes to the remarkable pressure-volume associations characteristic of the lung. This surface-active material, called surfactant, has been subject to intense study in recent decades (6,7 and 8).

Deficiency or dysfunction of pulmonary surfactant plays a critical role in the pathogenesis of respiratory diseases in the newborn period. Pulmonary surfactant exists in a variety of physical forms when isolated from the alveolar wash of the lung. These physical forms include lamellated and vesicular forms and highly organized tubular myelin. Tubular myelin is highly surface active and, although composed predominately of phospholipids, its unique structure depends on Ca^{2+} and lung surfactant proteins A (SP-A), B (SP-B), and D (SP-D). Tubular myelin represents the major extracellular pool of surfactant from which a lipid monolayered/multilayered film is generated to produce an interface between the hydrated cellular surfaces and alveolar gas (Fig. 29-3). Lamellated and vesicular forms of surfactant represent nascent or catabolic forms of surfactant material respectively; the latter is taken up by type II epithelial cells and recycled. Surfactant proteins A, B, C, and D play important roles in the organization and function of the surfactant complex regulating surfactant homeostasis. Alveolar surfactant concentrations are tightly controlled by a variety of mechanisms that modulate lipid and protein synthesis, storage, secretion, and recycling.

Figure 29-3 Surfactant phospholipids are synthesized in the endoplasmic reticulum, transported through the Golgi apparatus to multivesicular bodies, and ultimately packaged in lamellar bodies before secretion. After exocytosis of the lamellar bodies, surfactant phospholipids are organized into a complex lattice called tubular myelin phospholipid that provides material for a monolayer-multilayer at the air-fluid interface in the alveolus. Surfactant phospholipids and proteins are taken up by type II cells, probably transported by endosomal multivesicular bodies, and then catabolized or transported to lamellar bodies for recycling. A fraction of surfactant proteins and lipids are also catabolized by alveolar macrophages. Surfactant proteins are synthesized in polyribosomes and extensively modified in the endoplasmic reticulum, Golgi apparatus, and multivesicular bodies. Surfactant proteins are detected within lamellar bodies or in secretory vesicles closely associated with lamellar bodies before secretion into the alveolus.

Composition of Surfactant

Pulmonary surfactant is composed primarily of the phospholipids phosphatidylcholine and phosphatidylglycerol (Fig. 29-4). These lipid molecules are enriched in dipalmitoyl acyl groups attached to a glycerol backbone that pack tightly and generate low surface pressures (Fig. 29-5). Rapid spreading and stability of pulmonary surfactant are achieved by the interactions of surfactant proteins and phospholipids. Surfactant is synthesized and secreted by

P.558

type II epithelial cells in the alveolus. Synthesis of phosphatidylcholine, surfactant proteins, and lamellar bodies, an intracellular storage form of pulmonary surfactant, increases with advancing gestation. Lamellar bodies are secreted into the lung liquid that contributes to the amniotic fluid. The measurement of amniotic fluid phosphatidylcholine, disaturated phosphatidylcholine, phosphatidylglycerol, or the surfactant proteins has provided useful biochemical markers that predict lung maturation and the adequacy of lung function at birth (e. g., lecithin-sphingomyelin [L-S] ratio and phosphatidylglycerol values). Surfactant function can be assessed by a variety of physical and physiologic tests that measure its ability to reduce surface tension at an air-liquid interface and to spread rapidly during dynamic compression and expansion. The Wilhelmy balance, Langmuir trough, pulsating bubble meter, and a variety of animal models have been used to assess the efficacy of surfactant and surfactant replacements.

Figure 29-4 Pulmonary surfactant components are expressed as a percentage of the total weight. Chol, cholesterol; DG, diacylglycerol; DPPC, dipalmitoylphosphatidylcholine; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; SM, sphingomyelin. Adapted from Possmayer F. Pulmonary surfactant. *Can J Biochem Cell Biol* 1984; 62:1121, with permission.

Control of Surfactant Synthesis and Secretion

Synthesis of pulmonary surfactant is closely linked to the morphologic and biochemical differentiation of alveolar type II cells in the peripheral respiratory epithelium. Interactions between mesenchymal and epithelial cells, mediated by direct cell-cell contact or by paracrine factors, contribute to the differentiation process. Endocrine factors also modulate the differentiation of type II epithelial cells and the synthesis of surfactant components. In vivo and in vitro evidence supports the role of glucocorticoids in the modulation of morphologic differentiation and production of phospholipids and surfactant proteins by the lung.

Phospholipid Synthesis

Phosphatidylcholine is produced by type II epithelial cells using extracellular substrate and the glycogen stores that accumulate in the pretype II cells of the fetal lung. Metabolic pathways producing phosphatidylcholine depend on the production of phosphatidic acid and a glycerophosphate backbone (see Fig. 29-5); the latter is produced as an intermediate of the glycolytic pathway (9). The synthesis of phosphatidylcholine involves the deacylation of phosphatidic acid and its reaction with cytidine diphosphocholine (CDP-choline).

Figure 29-5 Dipalmitoylphosphatidylcholine (DPPC) is the most abundant phospholipid in pulmonary surfactant. The acyl chains of DPPC pack tightly to form the surfactant monolayer, reducing surface tension in the alveolus.

Disaturated forms of phosphatidylcholine may be formed *de novo*, using disaturated acyl precursors or by remodeling, i.e., salvage pathway, of phospholipids by deacylation and reacylation reactions. Production of CDP-choline is critical to phosphatidylcholine synthesis and is achieved by phosphorylation of choline and transfer to cytidine triphosphate in a reaction dependent on choline kinase and choline phosphate cytidylyltransferase. The activities of many of the enzymes in the synthetic pathway for phosphatidylcholine increase with advancing gestation in the lung, generally increasing in the last third of gestation (9,10).

Glucocorticoid Enhancement of Pulmonary Maturation

A variety of hormonal factors influence the rate of production of the enzymes controlling phosphatidylcholine synthesis in the developing lung (9,10). Glucocorticoids are the most clinically relevant and useful of these agents. Studies in fetal lambs and humans demonstrated that administration of glucocorticoid to the dam or mother resulted in precocious respiratory function in prematurely

P.559

born offspring. The initial clinical studies of Liggins and Howie demonstrated that maternal administration of glucocorticoid decreased the incidence of respiratory distress in premature infants (11). Although the precise mechanisms by which glucocorticoids induce pulmonary maturation and lung function in premature infants have not been discerned, increased phosphatidylcholine synthesis and morphologic remodeling of the alveolar architecture, including the thinning of interstitial components of the fetal lung, are observed after glucocorticoid treatment. Glucocorticoids regulate several genes that are associated with the differentiation of the fetal lung, including the genes encoding enzymes involved in the synthesis of phosphatidylcholine and the surfactant proteins. The effects of glucocorticoid on lung cell differentiation are mediated in part by glucocorticoid receptors, which, when occupied by hormones, influence gene transcription and mRNA stability, altering the abundance of the proteins synthesized by pulmonary cells. Prenatal glucocorticoid therapy is useful in prevention of RDS in preterm infants.

Other Hormonal Influences

Thyroid hormones i.e., T₃, T₄, thyrotropin-releasing hormone (TRH), estrogens, prolactin, epidermal growth factor, β -adrenergic agents, and other agents that enhance cellular cAMP levels influence pulmonary maturation or biochemical indices of pulmonary maturation. Both T₃ and T₄ increase the synthesis of phospholipids in mammalian lung but do not readily cross the placenta.

Surfactant Secretion

Surfactant is stored within type II cells in large lipid-rich organelles called lamellar bodies. Secretion of lamellar bodies occurs by a process of exocytosis that is regulated by a number of physical and hormonal factors. Stretch, the mode of ventilation, and the labor process enhance surfactant secretion and extracellular surfactant pool sizes at birth. Catecholamines, purinoceptor agonists (e.g., adenosine triphosphate) that activate protein kinases, and Ca^{2+} ionophores enhance phospholipid secretion by type II cells *in vitro* (9). Hyperglycemia and hyperinsulinemia inhibit surfactant phospholipid secretion. Newly secreted surfactant enters the extracellular space and undergoes dramatic structural reorganization to form tubular myelin, a process dependent on SP-A, Ca^{2+} , phospholipids, and SP-B. Phospholipids must move from tubular myelin to form monolayers and multilayers at the air-liquid interface, thereby reducing collapsing forces in the alveoli.

Surfactant Recycling and Catabolism

The process of inflation and deflation produces spent forms of surfactant phospholipids that are taken up by type II cells and reused or catabolized. Surfactant proteins B and C enhance the reuptake of phospholipids *in vitro*. Surfactant phospholipid is recycled. In the adult rabbit lung, the half-life of surfactant phospholipids is approximately 8 hours, and in newborn animals, the half-life is 3.5 days. The intracellular and extracellular pools of surfactant are generally larger in the newborn animal than in adults. A relatively small fraction of the alveolar surfactant pool is cleared by catabolism and alveolar macrophages, with most of the surfactant phospholipid recycled or catabolized by type II epithelial cells. Recent studies support an important role for granulocyte/macrophage-stimulating factors and their receptors in the mediation of surfactant clearance, acting primarily on the alveolar macrophage. Defects in granulocyte-macrophage cerebrospinal fluid (GM-CSF) signaling, caused by autoantibodies to GM-CSF or mutations in its receptor, cause alveolar macrophage dysfunction leading to marked lipid accumulation in the postnatal lung, in turn, causing the syndrome of pulmonary alveolar proteinosis. Exogenously administered surfactant is reused efficiently by adult and newborn lungs (12). The effects of surfactant replacement therapy are therefore related both to the direct surface-tension-lowering properties of surfactant introduced into the airway and to the recycling of the exogenously delivered phospholipids by type II cells.

The Role of Surfactant in Lung Disease

Quantitative and qualitative abnormalities of pulmonary surfactant contribute to the pathogenesis of lung disease in the newborn infant. In premature infants, deficiencies in surfactant production and secretion decrease intracellular and extracellular pools of surfactant, leading to alveolar surfactant insufficiency and atelectasis. Qualitative abnormalities of surfactant are also associated with many types of lung injury. Alveolar-capillary leak, hemorrhage, pulmonary edema, and alveolar cell injury fill the alveolus with proteinaceous material that inactivates surfactant. Serum and nonserum proteins, including albumin, fibrinogen, hemoglobin, and meconium, are potent inactivators of pulmonary surfactant *in vivo* and *in vitro*; SP-A, SP-B, and SP-C act synergistically to stabilize the surface properties of phospholipids in the presence of these inactivating proteins. Inhibitory factors associated with surfactant dysfunction in acute lung injury can be overcome by the administration of exogenous surfactants that contain the surfactant proteins.

Surfactant Replacement

The first successful surfactant replacement therapy in humans was reported by Fujiwara and colleagues in 1980 (13). Natural synthetic and semisynthetic surfactants have been successfully administered into the lungs of premature infants for treatment of RDS, for the treatment of meconium aspiration, and are being tested for therapy of other lung diseases. Surfactant replacement has become standard for prevention and treatment of RDS. Animal surfactant preparations containing phospholipids, SP-B, and SP-C (e.g., Survanta, Curosurf, Infasurf) and synthetic preparations

composed primarily of phospholipids mixed with spreading agents (e.g., Exosurf) are in clinical use (7,8), although the animal based preparations are most widely used. The surfactant preparations containing surfactant proteins provide highly surface active material to the alveolus. Surfactant replacement also contributes to the pool size of surfactant phospholipids, providing substrate for surfactant synthesis by means of the recycling pathways.

RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome, previously called hyaline membrane disease, is a common cause of morbidity and mortality associated with premature delivery. Respiratory distress syndrome is a developmental disorder rather than a disease process per se, and it is usually associated with premature birth. The incidence and severity of RDS generally increase with decreasing gestational age at birth and are usually worse in male infants. Infants of diabetic mothers with poor metabolic control and infants born after fetal asphyxia, maternofetal hemorrhage, or after pregnancies complicated by multiple births are at higher risk for RDS. Respiratory distress syndrome affects approximately 20,000 to 30,000 infants each year in the United States and complicates about 1% of pregnancies. Approximately 50% of the infants born between 26 and 28 weeks of gestation develop RDS, whereas fewer than 20% to 30% of premature infants at 30 to 31 weeks have the disorder.

Clinical Presentation

Infants with RDS present at birth or within several hours after birth with clinical signs of respiratory distress that include tachypnea, grunting, retractions, and cyanosis (See Color Plate) accompanied by increasing oxygen requirements. Physical findings include rales, poor air exchange, use of accessory muscles of breathing, nasal flaring, and abnormal patterns of respiration that may be complicated by apnea. Chest radiographs are characterized by atelectasis, air bronchograms, and diffuse reticular-granular infiltrates, often progressing to severe bilateral opacity characterized by the term "white-out" (Fig. 29-6). Radiographic patterns in RDS are variable and may not reflect the degree of respiratory compromise.

The infant attempts to maintain alveolar volume by prolonging and increasing expiratory pressures by breathing against a partially closed glottis, causing the grunting noise characteristic of RDS, but often seen in other respiratory disorders as well. Increasing oxygen requirements and the need for ventilatory support often occur rapidly in the first 24 hours of life and continue for several days thereafter. The clinical course depends on the severity of RDS and the size and maturity of the infant at birth. In uncomplicated RDS, typically seen in more mature infants, recovery occurs over several days, and infants generally no longer require oxygen or ventilatory support after the first week of life. The most premature infants are at greatest risk for severe RDS and frequently develop complications, including central nervous system (CNS) hemorrhage, patent ductus arteriosus (PDA), air leak, and infection, which contribute to prolonged requirements for oxygen and ventilatory support.

Figure 29-6 This premature infant presented with grunting, retractions, and cyanosis after delivery. The diffuse reticular-granular opacification, air bronchograms, and decreased lung volumes in the chest radiograph film indicate respiratory distress syndrome.

Pathology

Pathologic findings early in the course of RDS include atelectasis, pulmonary edema, pulmonary vascular congestion, pulmonary hemorrhage, and evidence of direct injury to the respiratory epithelium (Fig. 29-7). Epithelial cell injury is especially evident in the bronchiolar region of the lung. Histologic findings include the

presence of hyaline membranes, the characteristic eosinophilic material derived from bronchial and bronchiolar injury to epithelial cells. Alveolar spaces are generally not inflated, and at autopsy, the lungs of infants with RDS are often airless on passive deflation. Leukocytic infiltration is not observed early in the course of RDS unless complicated by infection. Pulmonary edema, hemorrhage, and hemorrhagic edema are common pathologic features in RDS, especially if the clinical course is further complicated by PDA and congestive heart failure.

Pathophysiology

Avery and Mead first demonstrated the paucity of alveolar surfactant in the lungs of infants dying of RDS (14). Quantitative and qualitative abnormalities of the pulmonary surfactant system are critical to the pathogenesis of RDS in premature infants. Lack of pulmonary surfactant leads to progressive atelectasis, loss of functional residual

P.561

capacity, alterations in ventilation-perfusion ratio, and uneven distribution of ventilation. The RDS is further complicated by the relatively weak respiratory muscles and the compliant chest wall of the premature infant, which impair alveolar ventilation. Diminished oxygenation, cyanosis (See Color Plate), and respiratory and metabolic acidosis contribute to increased pulmonary vascular resistance (PVR). Right-to-left shunting through the ductus arteriosus, foramen ovale, and intrapulmonary ventilation-perfusion mismatch further exacerbate hypoxemia.

Figure 29-7 Dilated air spaces, hyaline membranes, and extensive atelectasis are seen throughout the lung of an infant born at 28 weeks of gestation with severe respiratory distress syndrome (Hematoxylin and eosin stain; original magnification $\times 250$). (Courtesy of Edgar Ballard, Cincinnati Children's Hospital, Cincinnati, OH.)

Prevention

Although the incidence of premature birth in the United States (approximately 7%) has not changed significantly in recent decades, the incidence of severe RDS has decreased at each gestational age as advances in maternal care and strict attention to avoidance of asphyxia and infection at birth have become standard treatment. Careful fetal monitoring, treatment of underlying maternal disorders, determination of amniotic fluid lamellar body number or other biochemical indicators of fetal lung maturity, and administration of tocolytics and maternal glucocorticoids have decreased the incidence of RDS. Although a single course of antenatal steroids improves lung function and reduces the risk of newborn death, current evidence from animal and clinical studies suggests that additional courses of steroids do not further improve lung function and are associated with risks of

adverse consequences (15). Surfactant replacement can further decrease the incidence and severity of RDS. Rapid restoration of blood volume after hemorrhage and correction and avoidance of anemia, acidosis, and hypothermia improve the clinical outcomes in RDS as well. Positive-pressure ventilation and continuous positive airway pressure (CPAP) improve the course of severe RDS, but do not prevent the disease itself.

Treatment

Postnatal therapy of RDS begins with careful assessment and resuscitation. Adequate ventilation, oxygenation, circulation, and temperature must be assured before the infant is transferred from the delivery room to the appropriate site of care. Surfactant replacement therapy may be initiated at birth in infants at risk for RDS or thereafter, as symptoms of RDS are established and the diagnosis of RDS is confirmed. Ventilatory management of neonatal respiratory disorders has been reviewed and is detailed in Chapter 30 (16).

Adequacy of ventilation and oxygenation must be established as soon as possible to avoid pulmonary vasoconstriction, further ventilation-perfusion abnormalities, and atelectasis. Positive-pressure ventilation, CPAP, and oxygen therapy may be required at any time during the course of RDS and must be readily available to the infant. Close monitoring of pH, oxygen saturation, partial pressure of CO₂ (PCO₂), and partial pressure of oxygen (PO₂) by transcutaneous monitors and by arterial catheterization or sampling of arterialized capillary blood is critical in guiding mechanical ventilation and ambient oxygen requirements. Surfactant replacement therapy is provided through the endotracheal tube and is often used several times during the early course of RDS to maintain pulmonary function. Exogenous surfactants are given by intratracheal instillation of doses of approximately 100 to 150 mg of phospholipid per 1 kg of body weight. Animal-derived surfactants cause a more rapid improvement in oxygenation and lung compliance when compared to currently available synthetic surfactants (17).

Mild or moderate RDS can be managed by CPAP applied by mask, nasal cannula, nasal prongs, or endotracheal or nasopharyngeal tubes. In general, 3 to 6 cm of water (H₂O) pressure is applied to the infant's airway.

Oxygenation and effort of breathing are usually rapidly improved by CPAP. Rapid fluctuations in blood gases may occur, requiring careful monitoring of PCO₂ and PO₂. As forced inspiratory oxygen requirements decrease during recovery, airway pressure is decreased, and the infant is weaned to head hood or nasal cannula oxygen. Apnea, inadequacy of ventilation, atelectasis, mucous plugging, hyperaeration, or air leak may complicate the care of infants with RDS.

P.562

Careful attention to the mechanical details of the application of CPAP or mechanical respirators is required. Mandatory ventilation should be instituted well in advance of respiratory failure and severe respiratory acidosis to avoid severe hypoxemia and atelectasis. Ventilation is maintained through an endotracheal tube, which can be placed nasally or orally, for delivery of oxygen and positive pressure. Pressure-cycled ventilators are most frequently used in the neonatal intensive care unit (NICU) and are controlled by setting positive inspiratory pressure, rate, inspiratory-expiratory times, and positive end-expiratory pressures (PEEP). Volume-cycled ventilators, in which fixed volumes are delivered to define the respiratory cycle, are used less frequently in the newborn. As in all respiratory therapy, critical attention to adequacy of ventilation, as assessed by PO₂, PCO₂, pH, and transcutaneous oxygen saturation, is required on an almost continual basis to adjust to the rapid changes in respiratory status occurring in these critically ill infants. Barotrauma and oxygen toxicity to the lung represent significant pulmonary complications in the therapy of RDS. Excesses in ventilation, peak or mean airway pressure, and oxygen therapy should be avoided. Because hyperoxia is associated with retrolental fibroplasia, a major cause of blindness in premature infants, arterial PO₂ must be carefully monitored, generally maintaining PO₂ between 50 to 80 mm Hg. Other forms of ventilation such as high-frequency or jet ventilators are often used in combination with exogenous surfactant for the treatment of RDS. These therapies are often considered for treatment of severely affected infants whose ventilation has not been adequately supported by conventional mandatory ventilation and surfactant therapy. Although some controlled trials indicate high frequency ventilation may reduce the risk of chronic lung disease in preterm infants, this mode of therapy may increase the usual adverse neurologic outcomes and should therefore be utilized with caution (18). Nitric oxide (NO) has also been used successfully in the treatment of respiratory failure in term infants. However, for premature infants, there has been no clear demonstration of improvement in any clinically relevant outcome in the randomized trials conducted to date (19).

Complications

CNS hemorrhage, intraventricular hemorrhage (IVH), and PDA represent significant clinical problems affecting the care of infants with RDS. Patent ductus arteriosus and subsequent congestive heart failure and pulmonary edema further compromise respiratory function, decreasing pulmonary compliance and perhaps inactivating pulmonary surfactant. Prompt diagnosis and medical or surgical treatment of PDA are indicated during the treatment of RDS. Acute CNS hemorrhage is often associated with shock, pulmonary compromise, and pulmonary hemorrhage. Fluctuations in respiratory status may contribute to IVH and can be minimized by careful attention to respiratory care and by judicious use of sedation. Intravenous fluids and administration of oral feedings must be adjusted carefully during acute and convalescent care of infants with RDS. Excessive fluid administration impairs pulmonary function and increases the risk of PDA.

MECONIUM ASPIRATION SYNDROME

Meconium-stained amniotic fluid (MSAF) occurs in approximately 12% of live births. The cause, pathophysiology, and treatment of MSAF and MAS have been recently reviewed (20).

Meconium first appears in the fetal ileum between 10 and 16 weeks of gestation as a viscous, green liquid composed of gastrointestinal secretions, cellular debris, bile and pancreatic juice, mucus, blood, lanugo, vernix and approximately 72% to 80% water. The dry weight composition consists primarily of mucopolysaccharides, with less protein and lipid. Although meconium appears in the intestine very early in gestation, MSAF rarely occurs before 38 weeks of gestation. Incidence of MSAF increases thereafter, and approximately 30% of newborns have MSAF if born after 42 weeks of gestation. The increased incidence of MSAF with advancing gestational age probably reflects the maturation of peristalsis in the fetal intestine. Motilin, an intestinal peptide that stimulates contraction of the intestinal muscle, is in lower concentrations in the intestine of premature vs. postterm infants. Umbilical cord motilin concentration is higher in infants who have passed meconium than in infants with clear amniotic fluid. Intestinal parasympathetic innervation and myelination also increase throughout gestation and may play a role in the increased incidence of passage of meconium in late gestation.

In utero passage of meconium is also associated with fetal asphyxia and decreased umbilical venous blood PO_2 (Fig. 29-8). Experimentally, intestinal ischemia produces a transient period of hyperperistalsis and relaxation of anal sphincter tone, leading to the passage of meconium. The fetal diving reflex, which shunts blood preferentially to the brain and heart and away from the visceral organs during hypoxia may enhance intestinal ischemia. The gasping respiratory efforts that accompany fetal asphyxia contribute to the actual entry of meconium into the respiratory tract, resulting in MAS.

Meconium in amniotic fluid is a hallmark of fetal compromise and demands critical evaluation of fetal well-being. However, most infants with MSAF do not have lower Activity, Pulse, Grimace, Appearance, and Respiration (APGAR) scores, more acidosis, or clinical illness than infants born with clear amniotic fluid. Fetal heart rate patterns do predict those infants at greatest risk of significant meconium aspiration syndrome and poor outcome. When normal fetal heart rate patterns are observed in cases of MSAF, the neonatal outcome is generally comparable to deliveries with clear amniotic fluid. In contrast, perinatal morbidity is increased in newborns with abnormal fetal heart rates and MSAF. Neonatal outcomes of

P.563

deliveries complicated by MSAF associated with fetal tachycardia or decreased fetal heart rate variability are similar to those of nonmeconium-stained infants with similar abnormalities of fetal heart rate. Those babies with abnormal fetal tracings are at greatest risk for the meconium aspiration syndrome. However, in infants with a normal fetal heart rate pattern, MSAF generally carries a low risk for perinatal morbidity.

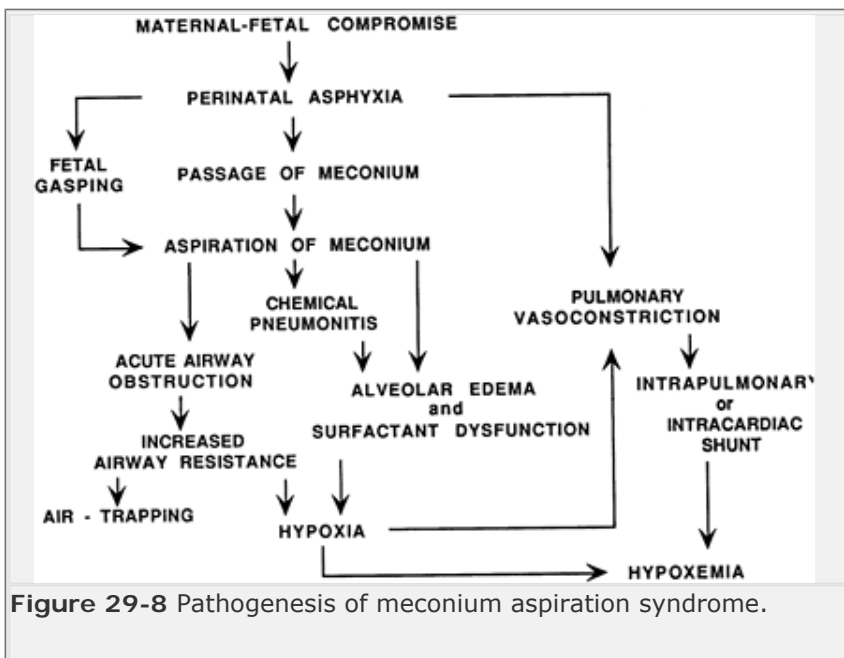

Figure 29-8 Pathogenesis of meconium aspiration syndrome.

Clinical Presentation

Meconium found below the vocal cords defines MAS. MAS occurs in approximately 35% of live births with MSAF or in approximately 4% of all live births. Meconium aspiration syndrome describes a wide spectrum of respiratory disease, ranging from mild respiratory distress to severe disease and death despite mechanical ventilation. MAS typically presents as respiratory distress, tachypnea, prolonged expiratory phase and hypoxemia soon after birth in an infant heavily stained on the nails, hair, and umbilical cord with meconium or born through thick meconium. Infants with severe MAS often have an increased anterior-posterior dimension of the thorax, a "barrel" chest, secondary to obstructive airway disease. Persistent pulmonary hypertension is also frequently observed in infants with severe MAS. Less severe meconium aspiration, typically of nonparticulate meconium, may present with the appearance of a pneumonitis with mild increased work of breathing or peaceful tachypnea reaching a peak at one to three days and resolving slowly over the first week of life.

The chest radiographs of infants with MAS, especially when associated with thick particulate meconium, are heterogeneous and demonstrate coarse infiltrates, with widespread consolidation and areas of hyperaeration (Fig. 29-9). Pleural effusions are detected in approximately 30% of infants with MAS. There is an increased risk of pneumothorax or pneumomediastinum, which occur in approximately 25% of severely affected infants. Chest radiographs are abnormal in more than one-half of infants with meconium detected below the vocal cords, although fewer than 50% of the infants with abnormal radiographs have significant respiratory distress. The severity of chest radiographic abnormalities may not correlate well with the severity of clinical disease.

Figure 29-9 This full-term infant was born with fetal bradycardia and thick meconium in the amniotic fluid. Cyanosis and respiratory distress were evident within minutes of delivery. The chest radiograph film demonstrates coarse, irregular infiltrates, hyperinflation (left and right diaphragms at ribs 10 to 11) and right pleural effusion indicative of meconium aspiration syndrome. Endotracheal and nasogastric tubes are in position.

Pathology

Postmortem examination of lungs from infants with severe MAS reveals meconium, vernix, fetal squamous cells and cellular debris in the air spaces from the airways to the alveoli. An inflammatory response with polymorphonuclear leukocytes, macrophages, and alveolar edema may be observed, but large quantities of meconium may be present without histologic signs of inflammation. Hyaline membrane formation, pulmonary hemorrhage, and necrosis of pulmonary microvasculature and parenchyma can occur. Platelet-rich microthrombi in small arterioles and increased muscularization of distal arterioles have been described in some infants dying of MAS.

Pathophysiology

The pulmonary abnormalities in MAS are related primarily to acute airway obstruction, decreased lung tissue compliance, and parenchymal lung damage (see Fig. 29-8). Instillation of meconium into adult rabbit and newborn dog tracheas causes acute mechanical obstruction of proximal and distal airways (21). A ball-valve mechanism producing partial airway obstruction contributes to air trapping, which results in increased anterior-posterior chest diameter, increased expiratory lung resistance, and increased functional residual capacity. Complete obstruction of small airways may result in regional atelectasis and

P.564

ventilation-perfusion inequalities. Disruption of surfactant function by serum and nonserum proteins and fatty acids contributes to atelectasis, decreased compliance, and resulting hypoxia. Additionally, meconium may be toxic to pulmonary epithelial cells and may itself contain, and stimulate, the production of pro-inflammatory cytokines including IL-8 and TNF- α .

In more than one-half of the infants with severe MAS, pulmonary hypertension with right-to-left shunting contributes to the characteristically severe and sometimes refractory hypoxemia. Such clinical pulmonary hypertension correlates with increased muscularization of distal pulmonary vessels pathologically and, experimentally, with chronic intrauterine hypoxia. Perinatal asphyxia is a critical underlying factor in the pathogenesis of MAS, increasing the risks for pulmonary hypertension and meconium aspiration.

Prevention

Before the late 1970s, it was thought that aspiration of amniotic fluid and meconium occurred during the first few breaths after delivery. Therapy was aimed at preventing MAS at the time of delivery by DeLee suctioning of the nasopharynx before delivery of the shoulders and before the first breath and, after delivery, immediate intubation and suctioning of the trachea to limit aspiration of meconium from the oropharynx and trachea into the distal lung. Mortality from MAS was decreased when the trachea was suctioned immediately after birth (22). DeLee suctioning of the nasopharynx while the infant was at the perineum also decreased morbidity and mortality from MAS. However, meconium aspiration syndrome continues to occur in infants who are adequately suctioned in the delivery room. Aspiration of meconium or amniotic fluid in utero probably occurs in some infants with MAS, particularly in those with perinatal asphyxia. Generally, fetal lung fluid flows outward from the lungs into the amniotic sac. However, studies with radiopaque contrast and ^{51}Cr -labeled erythrocytes injected into the amniotic sac demonstrated that some amniotic fluid enters the fetal lung even in the nonasphyxiated human fetus. Gasping associated with inhalation of amniotic fluid or meconium occurs in fetal lambs, rhesus monkeys, and humans in response to fetal asphyxia induced by compression of the umbilical cord or maternal aorta. Fetal gasping may be a critical factor in entry of meconium into the lung before birth. Antenatal diagnosis and treatment of fetal asphyxia is therefore critical for prevention of MAS. Amnioinfusion, the infusion of saline into the amniotic sac, decreases cord compression and dilutes meconium, potentially minimizing its toxicity after aspiration (23). Despite clinical studies supporting the use of intrapartum amnioinfusion to decrease the rate of emergency cesarean section and to decrease morbidity related to MAS, data regarding its efficacy have not supported its widespread use in MSAF.

Based on the findings that meconium aspiration may occur in utero, is occasionally accompanied by asphyxia, and that the benefit of immediate intubation in the delivery room of infants with MSAF may be out-weighted by the risks of trauma to the airway, a more selective approach to intubation of neonates exposed to meconium in utero is now recommended (24). The oropharynx and naso-pharynx of all meconium-exposed neonates should be cleared on delivery of the head by a wall-mounted DeLee suction device. Immediate tracheal intubation and suctioning is recommended only if the infant is depressed. The utilization of this type of protocol has decreased

the need for emergent intubation by up to 40% without an increase in incidence or severity of meconium aspiration syndrome. Clearing the airway and establishing respiration and oxygenation remain however basic to the resuscitation of all infants.

Treatment

Postnatal therapy for MAS begins with continuous observation and monitoring of infants at risk. Vigorous treatment of nonrespiratory sequelae of neonatal asphyxia, including temperature instability, hypoglycemia, hypocalcemia, hypotension, and decreased cardiac function are critical to promoting the fetal-to-newborn physiologic transition. Attention also needs to be given to the potential effects of multi-organ hypoxemia and ischemia, including reduced renal function, reduced liver production of clotting factors, hypoalbuminemia, cerebral edema, and seizures. Pulmonary vasoconstriction is associated with MAS, and correction of hypoxemia and acidosis is indicated. Chest physiotherapy and suctioning of particulate meconium may be useful if there is airway obstruction and the infant maintains adequate oxygenation during such therapy. Exogenous surfactant has been used successfully for the treatment of meconium aspiration, decreasing air leak and the need for extracorporeal membrane oxygenation. Continuous monitoring of oxygenation by transcutaneous oxygen monitoring or pulse oximetry and assessment of PaO₂, PaCO₂, and pH should be used to guide the application of oxygen therapy and mechanical ventilation. The presence and severity of pulmonary hypertension should be evaluated by echocardiography in the hypoxemic infant with meconium aspiration syndrome. Broad-spectrum antibiotics are routinely used in the therapy of MAS in infants with abnormal radiographic findings and respiratory distress, although their efficacy in MAS is unproven. Treatment of acute MAS with glucocorticoids has not been beneficial.

Surfactant Treatment

Recent research suggests beneficial effects of surfactant replacement therapy, inhaled NO, and high-frequency oscillatory ventilation for MAS. Meconium instilled into canine or piglet lungs or mixed with surfactant in vitro inactivates surfactant function, decreasing lung compliance, lung volumes, and oxygenation. Surfactant inactivation

P.565

can be overcome by addition of exogenous surfactant. Several studies suggest that surfactant therapy may decrease respiratory failure associated with MAS (25). Findlay and associates (26) determined that surfactant replacement (6 mL/kg, Survanta) improved oxygenation and reduced the incidence of air leaks and the severity of pulmonary morbidity when begun within 6 hours after birth. Response to the first dose was moderate. However, after the second and third doses, given 6 hours apart, improvements were documented in mean arterial-to-alveolar PO₂ ratio and in oxygenation index. Optimal dose, method, and timing of instillation of surfactant in MAS remain to be determined.

Ventilatory Support

Mechanical ventilation is required in up to 30% of infants with severe MAS and must be managed carefully. Although improvement in oxygenation was observed in patients with MAS treated with 4 to 7 cm H₂O PEEP, further studies to confirm the safety and efficacy of positive end-expiratory pressure in MAS are needed. Continuous positive airway pressure or PEEP may aggravate hyperinflation associated with MAS and should be used with caution. Pneumothorax or pneumomediastinum occur frequently during the course of MAS because of the ball-valve effect of meconium and may occur before the application of positive-pressure ventilation. Lengthening the expiratory time of the ventilatory cycle may minimize hyperinflation. Oscillation and high-frequency jet ventilation have been used in the treatment of MAS, but reports of their safety and efficacy in MAS are conflicting.

High-frequency oscillatory ventilation (HFOV) has been studied alone and in combination with INO as treatment for MAS. Kinsella and associates (27) found that the response rate of infants with MAS to HFOV plus INO was greater than the response rate to either HFOV or INO with conventional ventilation alone. Extracorporeal membrane oxygenation (ECMO) has been used successfully in rescue treatment of severe MAS refractory to conventional ventilatory therapy. As of June 2003, more than 6,300 neonates with MAS were registered as receiving ECMO in the Extracorporeal Life Support Organization (ELSO) database, with a 94% survival rate (28). Surfactant therapy during ECMO reduced the perfusion time required and the overall rate of complications after

PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

Gersony and colleagues (29) described hypoxemia in two infants with "persistent physiologic characteristics of the fetal circulation (PFC) in the absence of recognizable cardiac, pulmonary, hematologic, or central nervous system disease." Because the placenta is no longer present and the ductus arteriosus may or may not be patent, the term persistent pulmonary hypertension of the newborn (PPHN) is now used to describe this disorder. The pathophysiology of PPHN is related to a failure to make the transition from high pulmonary vascular resistance (PVR) and low pulmonary blood flow, characteristic of the fetus, to the relatively low PVR and high pulmonary blood flow of the postnatal infant. The clinical syndrome of PPHN has been recently reviewed (30).

Pathophysiology

The pathophysiology of PPHN is best understood within the framework of the current knowledge of the transitional circulation. Normal transition occurs in four phases: the *in utero* phase, the immediate phase occurring in the first minutes after birth, the fast phase developing in the first 12 to 24 hours, and the final phase, which requires days or months to complete.

In Utero Circulation

The *in utero* phase is characterized by PVR that exceeds systemic vascular resistance, resulting in right atrial and ventricular pressures exceeding left atrial and ventricular pressures. As a result of this pressure differential, more than one-third of the oxygenated blood returning from the placenta through the inferior vena cava streams across the patent foramen ovale (PFO), is ejected from the left ventricle, and perfuses the head and neck vessels and the lower body. Venous blood returning through the superior vena cava preferentially flows into the right ventricle and main pulmonary artery. A small amount of this deoxygenated blood, comprising approximately 8% of the cardiac output and with a PO_2 less than 20 mm Hg, does perfuse the lungs, but because of elevated PVR, most is shunted across the PDA to mix with the blood in the aorta distal to the cervical and subclavian arteries. The lower body is therefore perfused with relatively less well oxygenated blood than the head and neck. Because of the large right-to-left shunt at the PFO and the PDA, blood bypasses the lungs *in utero*. Persistence of the elevated PVR after birth, without the benefit of placental oxygenation, results in the profound hypoxemia characteristic of PPHN. The mechanisms that maintain the fetal state of high PVR are under study. Pulmonary vasoconstriction induced by hypoxia, alterations in NO and arachidonic acid metabolism, and systemic acidosis probably contribute to physiologic abnormalities in PPHN.

Immediate Phase

The second stage of normal transition, the immediate phase, is accomplished in the first minute after birth when the fluid-filled fetal lungs are distended with air during the first breath. A rapid decrease in PVR occurs with the mechanical distention of the pulmonary vascular bed, allowing more oxygenated blood to perfuse the lungs. The entry of air into the alveoli improves the oxygenation of the pulmonary vascular bed, further decreasing PVR.

P.566

Fast Phase

The fast phase of the transitional circulation occurs for 12 to 24 hours after birth and accounts for the greatest reduction in PVR. The drop in PVR has been associated with the production of vasodilators, such as prostacyclin and endothelial-derived relaxing factor *i.e.*, NO. Prostacyclin is produced in the neonatal lung in response to rhythmic distension of the lungs. Pretreatment of the fetal lamb with cyclooxygenase inhibitor decreased prostacyclin production and prevented the late fall in PVR. The role of cyclooxygenase and prostacyclin in the transitional circulation may have clinical implications. Persistent pulmonary hypertension of the newborn has been observed in infants of mothers receiving aspirin or nonsteroidal antiinflammatory agents that inhibit cyclooxygenase activity. However, prostacyclin induction at birth is transient, and it does not account for pulmonary vasodilation occurring in response to increasing oxygen tension. Likewise, indomethacin did not reverse decreased PVR caused by hyperbaric oxygen. The role of pulmonary production of potent vasodilatory leukotrienes, which also occurs during the initiation of ventilation, is unclear.

The pulmonary vasodilation and increase in pulmonary blood flow occurring in response to oxygenation can be virtually masked by inhibitors of the endothelial-derived relaxing factor, NO. NO is induced by oxygen, adenosine triphosphate (ATP), and shear stress and is elevated in 1-day-old lamb pulmonary arteries and pulmonary veins in comparison to near-term fetuses and few-week-old lambs. NO causes vasodilation by inducing the guanylate cyclase enzyme. The resultant increase in cGMP in turn activates a kinase that decreases intracellular calcium, allowing smooth muscle cell relaxation. The vascular effects of NO are specific and localized because of its great affinity for hemoglobin, especially deoxyhemoglobin. Thus, NO can cause pulmonary vasodilation without systemic hypotension. Prostaglandin, PGI₂ in particular, and NO are believed to be the principal agents responsible for the decrease in pulmonary vascular resistance in the fast phase of transition to air breathing.

Final Phase

The final phase of the neonatal pulmonary vascular transition involves remodeling of the pulmonary vascular musculature (31). In the normal fetal and term lung, fully muscularized, thick-walled preacinar arteries extend to the level of the terminal bronchioles. Intraacinar and alveolar wall arteries are not muscularized. Within days after delivery, medial wall thickness of preacinar vessels smaller than 250 μ m in diameter decreases, and within months, medial wall thickness of vessels larger than 250 and smaller than 500 μ m also decreases. Hypoxia at birth prevents the remodeling and regression of the smooth muscle of the preacinar bronchiolar arteries. In utero, or after birth, high-flow states and chronic hypoxia stimulate cells of the intraacinar and alveolar arteries to differentiate into smooth muscle and connective tissue, resulting in abnormally thickened and reactive arteriolar musculature. Distal extension of smooth muscle with increased numbers of adventitial fibroblasts and extracellular matrix has been described in pulmonary arteries of infants dying of severe MAS with PPHN.

Etiology

Persistent pulmonary hypertension of the newborn has a variety of causes that can be classified by the predominant abnormality involved (Table 29-1). Identification of the cause and subclass of PPHN is helpful in predicting severity and reversibility of PPHN in the neonate. Assessment of the clinical severity of PPHN helps determine the need for referral to nurseries with ECMO and NO capability.

Clinical Presentation

Clinically, PPHN presents as labile hypoxemia that is often disproportionate to the extent of pulmonary parenchymal disease. Infants with PPHN are commonly appropriate for gestational age and near term. The perinatal history frequently includes factors associated with perinatal asphyxia. Clinical symptoms include tachypnea, respiratory distress, and often rapidly progressive cyanosis (See Color Plate), particularly in response to stimulation of the infant. The cardiovascular examination may be normal or may reveal a right ventricular heave, closely split or single loud S₂, and low-pitched systolic murmur of tricuspid regurgitation suggesting that pulmonary arterial pressure is equal to or greater than systemic arterial pressure. A gradient of 10 mm Hg between right arm and lower extremity oxygen pressures suggests right-to-left shunting at the ductus arteriosus and is consistent with, although not required for, the diagnosis of PPHN. PPHN may occur without differential oxygen saturations if the ductus arteriosus is closed and mixing of cyanotic and oxygenated blood is occurring within the lungs or at other intracardiac sites. Differential diagnosis of PPHN includes severe pulmonary parenchymal disease, such as severe MAS, RDS, pneumonia, or pulmonary hemorrhage, and congenital heart disease, such as transposition of the great arteries. Critical pulmonic stenosis, hypoplastic left ventricle, or severe coarctation should be considered in the differential diagnosis. Methods used to differentiate PPHN from pulmonary parenchymal disease or cardiac disease are outlined in Table 29-2.

The oxygenation of infants with severe pulmonary parenchymal disease without PPHN generally improves after treatment with oxygen or mechanical ventilation. Infants with PPHN often have little or no parenchymal lung disease. They are easily ventilated but remain hypoxic despite high fraction of inspiratory oxygen (FiO₂).

Oxygenation will frequently improve markedly with improved ventilation and/or correction of metabolic acidosis in infants with PPHN. Cyanotic congenital heart disease (CCHD) is usually associated with fixed, structural mixing of venous and arterial blood. In infants with CCHD,

hypoxemia is generally unresponsive to increased exogenous oxygen, mechanical ventilation, hyperventilation, or alkalinization. Diagnosis of PPHN can be complicated by the coexistence of pulmonary hypertension, parenchymal lung disease, or CCHD. Echocardiography is useful in the diagnosis of structural heart disease and

assessment of pulmonary hypertension in this clinical setting.

Pathology	Associated Diseases	Proposed Mechanism	Prognosis
Functional vasoconstriction; normal pulmonary vascular development	Acute perinatal hypoxia Acute meconium aspiration Sepsis or pneumonia (especially group B streptococci) Respiratory distress syndrome Hypoventilation CNS depression ^a Hypothermia Hypoglycemia	Response to acute hypoxia, particularly in the presence of acidemia	Good; reversible
Fixed decreased diameter; abnormal extension and hypertrophy of distal pulmonary vascular smooth muscle	Placental insufficiency Prolonged gestation <i>In utero</i> closure of ductus arteriosus Aspirin Nonsteroidal antiinflammatory agents Single ventricle without pulmonic stenosis Chronic pulmonary venous hypertension TAPVR ^a Obstructive left-sided heart lesions Idiopathic diseases	Response to chronic hypoxia Excessive pulmonary blood flow <i>in utero</i> Elevated pulmonary venous pressure	Poor; fixed structural lesion
Decreased cross-sectional area of the pulmonary vascular bed	Space-occupying lesions Diaphragmatic hernia Lung dysgenesis Pleural effusions Congenital lung hypoplasia Potter syndrome Thoracic dystrophies	Hypoplasia of alveoli and associated vessels	Poor; fixed structural lesion
Functional obstruction to pulmonary blood flow	Polycythemia Hyperfibrinogenemia	Increased blood viscosity	Good, unless chronic

^a CNS, central nervous system; TAPVR, total anomalous pulmonary venous return.

Therapy

Supportive medical management includes correction of underlying abnormalities that may include shock, polycythemia, hypoglycemia, hypothermia, diaphragmatic hernia, or CCHD. Metabolic acidosis and hypotension should be corrected.

Specific therapy for PPHN is aimed at increasing pulmonary blood flow, decreasing right-to-left shunting and reducing ventilation/perfusion (V/Q) mismatch. High ambient oxygen and mechanical ventilation are the pulmonary therapeutic interventions for treatment of PPHN. Ligation of the PDA is not useful, and it may be detrimental. Cardiac failure may occur after PDA ligation as the right ventricle fails in the face of high pulmonary resistance without the safety valve of the patent ductus. Shunting between the pulmonary and systemic circulations, such as through the ductus arteriosus or patent foramen ovale, depends on the relative pressures of each system. Therefore, optimal therapy decreases pulmonary artery pressure although increasing or not changing systemic arterial pressure and cardiac output.

Infants with severe PPHN are often sensitive to activity and agitation. Stimulation should be minimized during

the care of these infants. Transcutaneous and intravascular monitoring equipment and temporal clustering of interventions reduce agitation. Muscle relaxants (e.g., pancuronium) and sedatives are frequently beneficial but should be used with caution. Paralysis may further compromise ventilation and may mask clinical signs of respiratory insufficiency. Sedatives should be chosen to minimize cardiovascular side effects such as systemic hypotension. Infants with PPHN, especially if asphyxiated or septic, frequently develop systemic hypotension and signs of cardiac failure. The hematocrit should be maintained at or above 45%, and volume expansion may be used to support the circulation. Elevated right heart pressure with increased PVR, poor venous return secondary to high intrathoracic pressures during mechanical ventilation, and predisposing asphyxia may contribute to myocardial dysfunction that may be responsive to dobutamine. Adrenergic pressors are commonly used for refractory hypotension but should be

P.568

used with caution, as they may contribute to pulmonary vasoconstriction. There is anecdotal evidence supporting efficacy of hydrocortisone, 10 mg/kg/dose, for the treatment of refractory hypotension in the newborn with PPHN and right-to-left intravascular shunt.

TABLE 29-2 DIAGNOSTIC EVALUATION OF SEVERE NEONATAL HYPOXEMIA

Test	Method	Result ^a	Suggested Diagnosis
Hyperoxia	Expose to 100% FiO ₂ for 5-10 min	PaO ₂ increases to >100 mm Hg PaO ₂ increases to <20 mm Hg	Pulmonary parenchymal disease Persistent pulmonary hypertension or cyanotic congenital heart disease
Hyperventilation-hyperoxia	Mechanical ventilation with 100% FiO ₂ and respiratory rate 100-150 breaths/min	PaO ₂ increases to >100 mm Hg without hyperventilation PaO ₂ increases at a critical PCO ₂ , often to <25 mm Hg No increase in PaO ₂ despite hyperventilation	Pulmonary parenchymal disease Persistent pulmonary hypertension Cyanotic congenital heart disease or severe, fixed pulmonary hypertension
Simultaneous-preductal-postductal PO ₂	Compare PO ₂ of right arm or shoulder to that of lower abdomen or extremities	Preductal PO ₂ ≥ 15 + postductal PO ₂	Patent ductus arteriosus with right-to-left shunt
Echocardiography	M-mode Venous contrast injection Two-dimensional echocardiography Doppler	Increased RVPEP and RVET Simultaneously appears in PA and LA Deviation of intraatrial septum to left; rule out congenital heart defect Failure of acceleration of systolic blood flow between large main pulmonary artery and small peripheral pulmonary artery	Right ventricular systolic time interval ratio (RVSTI = RVPEP/RVET > 0.5) predicts PPHN Patent foramen ovale Increased pulmonary arterial pressure Suggests right-to-left PDA or intracardiac shunt

^a LA, left atrium; PA, pulmonary artery; PDA, patent ductus arteriosus; PPHN, persistent pulmonary hypertension of the newborn; RVET, right ventricular ejection time; RVPEP, right ventricular ejection period.

Respiratory and Metabolic Alkalosis

The often dramatic response of infants with PPHN to respiratory or metabolic alkalosis has led to their use in the care of infants with severe PPHN, however the sometimes transient benefit of alkalosis must be balanced against the risk of secondary lung injury, neurologic compromise from hypocapnic alkalosis and cellular effects of infusion of hypertonic solutions. The degree of pulmonary parenchymal disease and risk of barotrauma may affect the clinical choice of inducing respiratory or metabolic alkalosis. Although it may be necessary to transiently raise arterial pH with increased ventilation and base to reverse severe pulmonary vasoconstriction, because of pulmonary and neurologic concerns, sustained hypocapnia and metabolic acidosis are not advocated. INO and normalization of acid-base and ventilatory status are preferred. Excessive mechanical ventilation with overdistension of the lung may increase right-to-left shunting. Pulmonary barotrauma associated with aggressive ventilation should be avoided. Hypocarbic alkalosis, by shifting the hemoglobin-oxygen dissociation curve, may also compromise the release of oxygen at the tissue level. Hyperoxia and hypocarbia may adversely affect cerebral blood flow. When used, weaning from ventilation NO and oxygen must proceed with caution, because dramatic liability of PO₂ is often observed in infants with PPHN.

Nitric Oxide and High-Frequency Oscillatory Ventilation

Pharmacotherapy of PPHN was recently reviewed (32). Various vasodilators such as tolazoline and prostaglandins D2 and E1 have been studied for treatment of PPHN (32). At doses required to decrease PVR, these agents often cause undesirable systemic vasodilation and hypotension. Tolazoline was previously used for therapy for PPHN but has not been shown to improve outcome.

At low pharmacologic doses, <40 parts per million, INO specifically dilates the pulmonary vasculature. Avid binding to hemoglobin prevents INO from dilating systemic blood vessels. Additionally, INO preferentially vasodilates vessels of alveoli that are patent, thus improving V/Q matching. Other less specific vasodilators may

P.569

increase blood flow to atelectatic alveoli, increasing V/Q mismatch. Inhaled NO combined with conventional ventilation increased oxygenation and decreased the oxygen index of approximately 30% of infants with PPHN. The likelihood of response to INO appeared inversely related to the severity of parenchymal disease (27). In patients with moderate PPHN, (alveolar-arterial oxygenation gradient, A-aDO₂ = 500-599), 15% of those treated with INO, vs. 58% of controls, progressed to severe PPHN (33). Approximately 25% of PPHN infants failing to respond to INO responded to INO combined with HFOV, suggesting improved response to INO if ventilation strategies are optimized to recruit atelectatic alveoli. The combined use of exogenous surfactant, HFOV and INO to coordinately enhance alveolar recruitment and perfusion appears to provide at least additive if not synergistic effects, especially in RDS and meconium aspiration cases. A systematic review of twelve randomized controlled trials in term or near-full term infants with hypoxic respiratory failure, concluded that INO reduced the need for ECMO. Approximately 50% of infants demonstrated improved oxygenation with INO treatment, those with diaphragmatic hernia were least likely to respond (34). No adverse effects of INO were reported.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation has been useful for the treatment of severe PPHN refractory to medical management. The first newborn survivor of ECMO therapy was reported by Bartlett and colleagues in 1975 (35). In 1999, the National Registry of Neonatal ECMO, and in 2003, the International Summary data of the ELSO Registry reported an 80% survival rate for the infants with the primary diagnosis of PPHN who were treated with ECMO (28,36). Most of these infants met criteria for greater than 80% risk of mortality with conventional medical management. However, criteria used to determine risk of mortality vary from institution to institution and frequently are based on retrospective chart reviews, reflecting older methods of medical management. It is impossible to determine how these infants would have done with modern conventional therapy.

Long-Term Outcome

Most infants treated for PPHN have few residual respiratory symptoms, neurologic or developmental sequelae by 1 year of age (37). Of infants with more severe parenchymal disease, qualifying for INO or ECMO, approximately 25% have persistent BPD or recurrent reactive airway disease at 1 and 2 years of age. Of 133 children with moderately severe persistent PPHN, with oxygenation index of 24 ± 9 at study entry, randomized to receive INO

or placebo, approximately 13% had major neurologic abnormalities, 30% had cognitive delays, and 19% had hearing loss (38). There was no difference between INO treated and control infants. Particularly, infants with severe MAS or congenital diaphragmatic hernia and PPHN have an increased risk for chronic pulmonary sequelae (39). Continued oxygen therapy, bronchodilators, diuretics, and enhanced nutrition may be necessary to treat residual disease and establish adequate growth. Hearing, vision, and neurologic development should be followed closely in infants treated for PPHN, especially if severely asphyxiated. Approximately 25% of infants treated with INO or ECMO for PPHN remain below 5% for weight at 1 to 2 years of age. Approximately 10% to 12% are diagnosed with severe neurodevelopmental disability. The risk of neurologic, growth, and pulmonary sequelae is greatest in infants with PPHN secondary to congenital diaphragmatic hernia (39).

Pneumonia

Pneumonia remains a significant cause of morbidity and mortality for preterm and term infants. The incidence of pneumonia in NICU patients exceeds 10% (40), with mortality of perinatally acquired pneumonia varying between 4% and 20% (40,41). Pneumonia may be acquired transplacentally, during the birth process, or postnatally, and it is caused by a variety of pathogens, including viruses, bacteria, and fungi (Table 29-3). Unique environmental and host factors predispose the neonate to pulmonary infections. The increased susceptibility of neonates for pneumonia may be related to immaturity of mucociliary clearance, small size of the conducting airways, and lowered host defenses. Invasive procedures, such as tracheal intubation, barotrauma, and hyperoxic damage to the respiratory tract may further impair resistance to pneumonia. The nosocomial flora of the hospital nursery, whether derived from nursery equipment or the unwashed hands of caregivers, are important vectors of pathogenic organisms.

Transplacental Viral Pneumonias

Pneumonia acquired through the transplacental route is most commonly of viral origin. Rubella, varicella-zoster, cytomegalovirus (CMV), herpes simplex virus (HSV), and human immunodeficiency virus (HIV) are acquired by this route. Transplacentally acquired pneumonitis is also associated with adenoviral, enteroviral, and influenza viral infections. Viral pneumonia is usually part of a systemic illness, reflecting hematogenous spread from the mother. Severity and onset of respiratory symptoms varies from respiratory failure at delivery to chronic pneumonia evolving months after birth.

Fetal infection may result from a primary maternal infection acquired during pregnancy or from reactivation of a latent infection. *In utero* transmission of rubella occurs as a result of primary infection acquired during pregnancy. Transmission of varicella-zoster, HSV, and CMV occurs as a result of primary or recurrent maternal infection. The timing of maternal infection in relation to birth is often a critical factor in outcome. Congenital varicella typically develops when primary maternal chickenpox

P.570

occurs within the 21 days preceding parturition. If maternal varicella occurs less than 5 days before birth, antepartum transfer of maternal antibody to the fetus is minimal, increasing the risk of systemic varicella infection in the neonate. Varicella pneumonia usually presents 2 to 4 days after the onset of the exanthem. Although varicella pneumonia is often self-limited, it can cause significant mortality and morbidity. Treatment with varicella-zoster immune globulin within 72 hours of birth improves clinical outcome in neonates exposed to varicella. Pneumonitis is not a common presentation in congenital CMV or herpes, but it is more common in perinatally acquired CMV and HSV. Pulmonary disease caused by transplacental transfer of the HIV virus generally presents after the neonatal period.

TABLE 29-3 PRIMARY PATHOGENS OF NEONATAL PNEUMONIA

TABLE 29-3 PRIMARY PATHOGENS OF NEONATAL PNEUMONIA

Vector	Viruses ^a	Bacteria	Other Agents
Transplacental	Rubella	<i>L. monocytogenes</i>	
	Varicella-zoster	<i>M. tuberculosis</i>	
	HIV	<i>T. pallidum</i>	
	CMV		
	HSV		
Perinatal	HSV	Group B streptococci	<i>C. trachomatis</i>
	CMV	Gram-negative enteric (i.e., <i>E. coli</i> , <i>U. urealyticum</i> , <i>Klebsiella</i>)	
Postnatal	CMV	<i>S. aureus</i>	<i>C. albicans</i>
	HSV	<i>P. aeruginosa</i>	
	Community based (i.e., RSV, influenza, parainfluenza)	<i>Flavobacterium</i>	
		<i>S. marcescens</i>	

^a HIV, human immunodeficiency virus; CMV, cytomegalovirus; HSV, herpes simplex virus; RSV, respiratory syncytial virus.

Transplacental Bacterial Pneumonias

Transplacental bacterial infections are less common causes of pneumonia. *Listeria monocytogenes*, *Mycobacterium tuberculosis*, and *Treponema palladium* are the most common organisms. Maternal listeriosis classically presents with a flu-like syndrome, with fever and chills occurring up to 2 weeks before delivery. Preterm labor and meconium staining of amniotic fluid, even in preterm infants, are common. Early onset listeriosis generally presents soon after birth with respiratory distress and pneumonia. Radiographic findings are nonspecific, consisting of peribronchial or widespread infiltrates. Congenital tuberculosis occurs most commonly in infants born to women with primary infections. Respiratory symptoms in neonatal tuberculosis typically present at 2 to 4 weeks of age. Transplacental transfer of *T. palladium* occurs most commonly during primary or secondary maternal infection, usually after 20 weeks of gestation. *Pneumonia alba* is relatively uncommon in congenital syphilis and refers to the pale, firm, and enlarged lungs seen at autopsy. Although the rate of congenital syphilis has declined from its peak in 1991, clinicians must remain aware of all manifestations of congenital syphilis.

Pneumonia Acquired in the Perinatal Period

Neonatal pneumonia is most commonly acquired during the process of labor and delivery. Infection occurs from organisms ascending from the genital tract after rupture of fetal membranes or acquired during passage of the infant through the birth canal. Respiratory symptoms are often present at delivery or have their onset in the first few days of life. Despite the abundance and heterogeneity of organisms in the genital tract, only a few commonly cause pneumonia. These organisms parallel pathogens causing early onset of sepsis.

In U.S. nurseries, group B Streptococcus (GBS) remains the most frequently identified organism causing neonatal pneumonia and sepsis (42). The second most common group of organisms to produce early onset sepsis or pneumonia are the gram-negative enteric bacilli: *Escherichia coli*, *Klebsiella*, *Enterobacter*, and *Proteus* species. For term infants, as the rate of GBS disease has declined with the introduction of intrapartum antibiotic prophylaxis, the rate of disease caused by other organisms has been relatively stable (42). In very low birth weight (VLBW) infants, as the rate of Group B streptococcal disease has declined, there has been an increase in *E. coli*, the majority of which is ampicillin resistant (42,43 and 44). Herpes simplex and CMV are the most common viral agents causing early onset pneumonia. Pneumonia caused by *Chlamydia trachomatis* usually begins at 2 to 8 weeks of age with upper respiratory tract symptoms, a staccato cough, and apnea. Antecedent conjunctival infection is common but not always observed. Interstitial pneumonitis and hyperinflation are associated with chlamydial pneumonia. *U. urealyticum* is a common inhabitant of the lower genital tract of women and is frequently associated with histologic evidence of chorioamnionitis. *U. urealyticum* is a cause of acute congenital

pneumonia and has also been associated with chronic lung disease in infants.

Pneumonia Acquired in the Postnatal Period

Newborns exposed to respiratory equipment or humidified incubators are at risk for respiratory infection by *Pseudomonas* species, *Flavobacterium*, *Klebsiella*, or *Serratia marcescens*. Direct contamination by the hands of caretakers as a result of inadequate hand washing is associated with outbreaks of *Staphylococcus aureus* and gram-negative enteric organisms. Cytomegalovirus that is acquired postnatally through blood products or breast milk commonly presents as a pneumonitis. With advances in transfusion technology, acquisition through blood products is rare. Cytomegalovirus is shed intermittently in human milk, and can be transmitted to the infant. In term infants there is typically no resulting clinical illness. In preterm infants clinical symptoms have been reported, including development of systemic disease (45).

Neonatal HSV infection is most often associated with HSV type II. However, data from the National Institute of Allergy and Infectious Disease indicate that 27% of symptomatic neonatal HSV infections were caused by HSV type I (46). Postnatal infection from HSV generally occurs from orolabial, oropharyngeal, or breast lesions. Community-based respiratory pathogens, including respiratory syncytial virus, influenza, parainfluenza, and enteroviruses, occur in the nursery. Pneumonia resulting from epidemic outbreaks of various enteroviral agents, including echovirus 22 and coxsackievirus type B, is often associated with other clinical manifestation of enteroviral disease. Risk factors for nosocomial fungal infections include VLBW, prolonged antibiotic therapy, intubation, central line catheter placement, intravenous alimentation, and corticosteroids. Pneumonia caused by *Candida albicans* usually presents in the context of disseminated disease. *Mycoplasma* species may also cause pneumonia in the postnatal period.

Figure 29-10 Acute neutrophilic response with atelectasis and hyaline membranes (arrows) are seen in lung tissue from a full-term infant who died at 2 days of age of group B streptococcal pneumonia. Pathologic Findings

Three common histopathologic patterns have been associated with neonatal pneumonia: hyaline membrane formation, suppurative inflammation, and interstitial pneumonitis. Hyaline membrane formation is a nonspecific response seen in lung injury associated with surfactant deficiency, pneumonia, and oxygen therapy. Damage to the alveolar epithelium results in cell necrosis and leakage of cell and serum proteins into the alveolar space. Hyaline membranes in neonatal pneumonia are often observed after GBS infection, but they are also associated with fatal pneumonia caused by *H. influenzae*, gram-negative enteric organisms, and viral agents. Bacteria are commonly seen within the hyaline membranes (Fig. 29-10). Disruption of alveolar capillary permeability and cell injury results in leakage of proteins into the alveolus that further inactivate pulmonary surfactant, leading to atelectasis. The decreased compliance, atelectasis, and hypoxemia seen in pneumonia are often indistinguishable from findings in surfactant-deficient lungs in premature infants. The chest radiographic findings in RDS and neonatal pneumonia may be identical, although bronchopneumonia and pleural effusions are more common in GBS and other bacterial causes of neonatal pneumonia than in RDS.

Suppurative Pneumonia

Staphylococcus aureus, enteric bacilli such as *Klebsiella pneumoniae*, *E. coli*, and *Pseudomonas* species, and fungi can cause

P.572

suppurative pneumonia. An intense inflammatory response often occurs in the lungs during these bacterial infections. Necrosis of lung parenchyma, microabscess formation, and partial obstruction of terminal bronchioles results in thin-walled, air-filled pneumatoceles. Spontaneous rupture of these structures can produce pneumothorax. Microabscesses may consolidate into larger cavities or rupture to the pleural space, causing emphysema. Pneumonia may be focal or may consolidate to produce large confluent abscesses. Perfusion of consolidated lung tissue causes venous admixture and hypoxemia.

Interstitial Pneumonitis

Interstitial pneumonitis is typically caused by a virus and characterized by interstitial inflammation, edema, mononuclear infiltration, and septal hyperplasia. Alveolar spaces may remain uninvolved, but in severe cases, a serous exudate containing desquamated pneumocytes and macrophages may be associated with hyaline membrane formation. Septal wall necrosis may occur, adding a component of hemorrhage to the inflammatory exudate. Alveolar capillary block associated with the inflammation may impair respiratory function. CMV, HSV, varicella-zoster, rubella, HIV, enteroviruses, and the community-based pathogens, such as respiratory syncytial, influenza and parainfluenza viruses, are commonly associated with interstitial pneumonitis.

Group B Streptococcal Pneumonia

During the 1970s, GBS emerged as the predominant pathogen causing neonatal sepsis and pneumonia. Colonization rates in pregnant women, because that time, have remained relatively stable at 10% to 30% (41,47). Infants become infected by aspiration of contaminated amniotic fluid or acquisition during passage through the birth canal. Vertical transmission rates for untreated GBS is approximately 50% (46). Invasive disease is much less common, developing in 1% to 3% of colonized infants. Factors increasing the risk for infection include maternal group B streptococcal bacteria, prolonged rupture of membranes (>18 hours), maternal intrapartum temperature (>100.4), chorioamnionitis, and prematurity (41). Mortality from invasive disease has declined from 50% to approximately 4% secondary to advances in neonatal care in the 1990s (48).

Intrapartum chemoprophylaxis has been shown to be effective in preventing early onset of GBS disease. With the introduction of intrapartum antibiotic prophylaxis, the incidence of early onset disease has decreased by 70% from 18 cases per 1,000 live births to 0.5 cases per 1,000 live births (41,49). In 2002, the Center for Disease Control and Prevention recommended universal screening of all pregnant women at 35 to 37 weeks' gestation, and intrapartum antibiotics for all GBS colonized women (41).

Figure 29-11 A full-term infant of an uncomplicated pregnancy developed respiratory distress, cyanosis, and periods of apnea within 6 hours of life. The blood culture and urine latex particle agglutination assay were positive for group B streptococci. Diffuse reticulogranular pattern, air bronchograms, and right pleural effusion without significant volume loss are consistent with common radiologic features of group B streptococcal pneumonia.

Early onset GBS disease presents within the first week of life. Septicemia (30%-40%), meningitis (20%-30%), and pneumonia (30%-40%) are the most common presentations. Exposure to intrapartum antibiotics has not changed the clinical presentation of illness with up to 95% of infants presenting within 24 hours and 90% of affected infants present with respiratory distress (49). Radiographic features of GBS infection may be indistinguishable from RDS, although pleural effusions may help differentiate GBS from RDS (Fig. 29-11). In two-thirds of affected infants, increased vascular markings or patchy infiltrates are observed on the initial chest radiographs. Respiratory distress in the absence of radiographic abnormalities may be associated with pulmonary vascular hypertension and hypoxemia. Late-onset GBS usually presents from 1 to 6 weeks after birth and is commonly associated with meningitis.

Respiratory failure in GBS pneumonia results from hyaline membrane formation, atelectasis, and pulmonary hypertension. Pulmonary hypertension is proposed to be mediated by high-molecular-weight polysaccharide exotoxin. In animals, infusion of GBS exotoxin results in an initial increase in pulmonary vascular pressures and fever, followed by a second phase characterized by granulocytopenia, granulocyte trapping in the lung, and increased pulmonary vascular permeability (50).

Isolation of GBS from cultures of blood, cerebrospinal fluid, or suppurative foci is diagnostic of GBS infection. Surface cultures of skin or mucous membranes are not useful because of the large number of infants colonized but not infected. Antimicrobial therapy is usually instituted before an organism is identified and consists of a penicillin and an aminoglycoside. After the organism is identified and meningitis is excluded, therapy can continue with penicillin alone at 200,000 U/kg/day, usually

P.573

for 10 to 14 days. Extensive supportive care, including oxygen, mechanical ventilation, and cardiovascular support, may also be required in treating an overwhelming infection.

Herpes Simplex Pneumonia

The incidence of neonatal HSV is increasing in the United States, affecting 1,500 to 2,200 infants per year. Classification of HSV infection is based on the site and extent of involvement; HSV may be classified as a cutaneous infection; as encephalitic, with or without cutaneous infection; and as a disseminated infection. Mortality is highest among infants with disseminated disease. The mortality rate of infants with HSV pneumonitis is approximately 79% (46,51). Transmission of HSV infection to the neonate is most frequently related to direct contact with virus at delivery. Most women delivering infants with symptomatic HSV disease shed virus asymptotically at delivery, and fewer than 20% of these women reported a history of previous infection (51). Whether the maternal infection is primary or recurrent is important in the pathogenesis of neonatal HSV infection. Infants of women with serologic evidence of a recent primary infection are more likely to develop disease than infants of women with recurrent herpes. Primary infections are associated with higher titers of viral shedding and with low levels of protective antibodies, placing the neonate at higher risk. Rupture of the amniotic sac for longer than 6 hours is associated with increased risk of neonatal HSV infection, although infection after cesarean section with intact membranes has also been reported.

Herpes simplex virus pneumonitis usually presents as part of a disseminated HSV infection. Many severely involved infants have no skin lesions. Infants typically develop signs of infection at 4 to 5 days of life. Fever, tachypnea, jaundice, and irritability, progressing to respiratory failure, shock, and disseminated intravascular coagulation are commonly seen. Diffuse interstitial pneumonitis and hemorrhagic pneumonitis are characteristic of HSV infection of the lung.

Diagnosis of HSV may be made by identification of HSV DNA through PCR or viral isolation by culture. Viral cultures should be obtained from skin lesions, cerebrospinal fluid, stool, urine, throat, nasopharynx, and conjunctiva. HSV deoxyribonucleic acid (DNA) may be identified in cerebrospinal fluid (CSF), aspirated skin vesicles, or blood. Hepatic dysfunction, neutropenia, bleeding diathesis, and interstitial pneumonitis are commonly associated with HSV but are not diagnostic. Serologic assays are not of clinical value, because they do not differentiate between antibodies to HSV types 1 and 2 or between maternal IgG and endogenously produced antibodies. Intranuclear inclusions and multinucleated giant cells observed in scrapings from cutaneous lesions are supportive but not diagnostic of HSV infection.

Early antiviral therapy decreases the progression from localized, cutaneous HSV infection to disseminated disease, and decreases the mortality from HSV infection. High-dose parental acyclovir is now widely used in treatment of HSV infection in the neonate and is currently considered the treatment of choice (52).

Transient Tachypnea of the Newborn

TTN was first described in 1966 by Avery and colleagues in a group of eight patients, seven of whom were delivered vaginally at or near term (53). All of the infants presented at or shortly after birth with grunting, retractions, and an increased respiratory rate. Respiratory rates of the original infants ranged from 80 to 140 breaths/min, and the symptoms persisted for 2 to 5 days. These infants could be differentiated from infants with other acute lung diseases by their clinical course and radiographic findings. Although the precise cause of TTN remains unknown, it was originally postulated that infants with TTN had reduced lung compliance because of delayed resorption of lung fluid at the time of birth. Many clinicians support the original proposal of Avery and colleagues that TTN results from distention of interstitial spaces by fluid, leading to alveolar air trapping and decreased lung compliance. Because the original description, others have postulated that TTN may result from mild immaturity of the surfactant system. Lack of phosphatidylglycerol in amniotic fluid samples obtained from infants with TTN supports the latter concept.

The incidence of TTN is approximately 11 per 1,000 live births. The risk factors for TTN include prematurity, maternal sedation, maternal fluid administration, maternal asthma, exposure to b-mimetic agents, and fetal asphyxia. Delivery by cesarean section also predisposes the term infant to TTN (54). Children with TTN as neonates are also more likely to develop asthma during ages zero to 4 (55).

Infants with TTN initially present with grunting, retractions, and increased respiratory rate. The symptoms of tachypnea may persist for several days, and most infants require less than 40% oxygen to maintain adequate systemic oxygenation. The radiographic findings in this disorder are ill defined but include increased central vascular markings, hyperaeration, evidence of interstitial and pleural fluid, prominent interlobar fissures, and cardiomegaly (Fig. 29-12). Furosemide has been utilized to treat TTN, but a recent meta-analysis failed to demonstrate any benefit of this therapy (56). Because TTN is self-limited, no specific therapy is indicated, although adequate ventilation and oxygenation must be maintained. Because the symptoms of TTN are nonspecific and consistent with neonatal sepsis or pneumonia, most infants with TTN are evaluated for infection and are treated with broad-spectrum antibiotics pending a definitive diagnosis.

Pulmonary Hemorrhage

Pulmonary hemorrhage in the newborn may vary from a focal, self-limited disorder to massive, lethal hemorrhage.

P.574

The incidence of pulmonary hemorrhage in the neonatal period ranges from 0.8 to 1.2 per 1,000 live births, although the incidence was 74% of all liveborn infants in one autopsy series of 70 newborns and is as high as 10% in babies less than 30 weeks gestation (57). Asphyxia, prematurity, intrauterine growth retardation, infection, hypothermia, oxygen therapy, severe Rh hemolytic disease, and coagulopathy are associated risk factors. In some studies, surfactant therapy has been associated with an increased incidence of pulmonary hemorrhage, although this remains controversial. Although disseminated intravascular coagulation may precede pulmonary hemorrhage, most infants with pulmonary hemorrhage do not have a coagulopathy. Pulmonary hemorrhage generally presents within the first week of life, and the mortality rate after pulmonary hemorrhage is estimated to be 75% to 90%. Although most infants who develop pulmonary hemorrhage have the predisposing factors of extreme prematurity and underlying asphyxia and stress, there are a few case reports describing previously healthy, term infants with pulmonary hemorrhage associated with an inborn error of the urea cycle and elevated blood ammonia.

Figure 29-12 This full-term infant was born by cesarean section and developed tachypnea and grunting that resolved 48 hours after birth. Perihilar vascular densities, streaky opacities of interstitial edema, fluid in the interlobar fissures, small pleural effusions, and cardiomegaly are observed on the radiograph. These features are indicative of transient tachypnea of the newborn.

Clinical Findings

The observation that the hematocrit of lung effluent in pulmonary hemorrhage is lower than the hematocrit of blood supports the concept that most of these infants have hemorrhagic pulmonary edema. Neonatal pulmonary hemorrhage is therefore thought to result from shock, hypoxia, and acidosis, which lead to left ventricular failure and increased pulmonary capillary pressure with subsequent hemorrhagic pulmonary edema. Chest radiographic findings in pulmonary hemorrhage depend on whether the hemorrhage is focal or massive. Because blood or hemorrhagic edema fluid has tissue density, hemorrhagic tissue appears opacified. It is often difficult to differentiate focal hemorrhage from atelectasis or pneumonia by chest radiographs. In the case of massive pulmonary hemorrhage, the lungs can be atelectatic and opacified. The clinical course of massive pulmonary hemorrhage usually involves rapid deterioration of ventilatory function. Affected infants develop progressive hypoxia and hypercarbia with resultant respiratory acidosis and may rapidly succumb to this disorder.

Treatment

Early detection and aggressive intervention improve the outcome of massive pulmonary hemorrhage, an otherwise lethal syndrome. Positive-pressure ventilation and oxygen are critical components of therapy. Blood volume and hematocrit should be vigorously restored and maintained with erythrocyte transfusions. Careful correction of hypotension, hypoxemia, and acidosis is also indicated. Coagulation abnormalities should be assessed and may be corrected with fresh-frozen plasma or appropriate clotting factors. Pressors and diuretics are indicated if congestive heart failure develops. Surfactant therapy has also been suggested as a useful adjunct in neonates with a clinically significant pulmonary hemorrhage.

AIR LEAKS

Air leaks include pneumothorax, pneumomediastinum, pneumopericardium, and pulmonary interstitial emphysema (PIE).

Pathophysiology

Pulmonary interstitial emphysema, pneumomediastinum, pneumothorax, and pneumopericardium are closely related clinical entities. Air leak begins with formation of PIE in which alveoli rupture into the perivascular and peribronchial spaces. Air may be trapped in the interstitium of the lung, leading to PIE, but it may also dissect into the mediastinum along the perivascular and peribronchial spaces, producing pneumomediastinum. Mediastinal air ruptures into the pleural space, producing pneumothorax, or into the pericardial space, producing pneumopericardium. In some instances, air can form blebs on the surface of the lung that rupture to produce pneumothorax. Rupture of the lung directly into the pleural space is thought to occur rarely.

Risk Factors

Air leaks occur in 1% to 2% of all newborn infants, but they are thought to cause symptoms in only 0.05% to 0.07%. Mechanical ventilation and CPAP are important risk factors contributing to air leak in infants with lung disease. Cystic adenomatoid malformation also predisposes infants to spontaneous pneumothorax. Summarizing data

P.575

from 11 studies, Madansky found that air leak occurred in 12% of infants with RDS who were not on assisted ventilation, 11% of infants on CPAP, and 26% of infants on mechanical ventilation (58). The incidence of air leak in infants admitted to the NICU is approximately 2% to 8%, but it is higher if only low-birth-weight infants are considered. As of 1986, of infants weighing 500 to 999 g at birth who developed air leak, 35% had PIE, 20% had pneumothorax, 3% had pneumomediastinum, and 2% had pneumopericardium (58). Infants developing air

leak are at higher risk of death, but the risk changes with postnatal age at the time of the air leak. Aspiration syndromes, including MAS, are frequently complicated by air leak.

Radiographic Evaluation

The chest radiographs of infants with PIE have been described as demonstrating a salt-and-pepper pattern in which the radiolucent interstitial air is juxtaposed to lung parenchyma (Fig. 29-13). Radiolucent air is present in the pleural space in a pneumothorax. Because chest radiographs of neonates are usually performed in the supine position, pleural air of a pneumothorax may accumulate in the anterior chest and may be visible only on a cross-table lateral or decubitus radiograph. In a tension pneumothorax, the lung and mediastinal organs may be displaced away from the side of the pneumothorax (Fig. 29-14). The thymus may be outlined in pneumomediastinum, seen on radiographs. Pneumopericardium results in a characteristic outline of the heart by radiolucent air.

Figure 29-13 Chest x-ray film of pulmonary interstitial emphysema (PIE). A premature infant with severe respiratory distress syndrome requiring mechanical ventilation developed worsening respiratory acidosis and hypoxia refractory to increased ventilatory support. An anteroposterior chest x-ray film demonstrates a salt-and-pepper pattern resulting from radiolucent interstitial air surrounding compressed lung tissue. A left chest tube was placed to treat pneumothorax, a common complication of pulmonary interstitial emphysema.

Figure 29-14 A full-term infant born by a difficult breech delivery presented shortly after birth with crepitus in the neck area, tachypnea, grunting, and retractions. An anteroposterior chest x-ray film demonstrates bilateral pneumothorax under tension on the left. The heart and mediastinum are compressed and shifted to the right. The left pleural air herniates across the midline. The left diaphragm is depressed and inverted. Subcutaneous emphysema is seen in the soft tissues of the neck.

Pulmonary Interstitial Emphysema

Pulmonary interstitial emphysema occurs most frequently in smaller infants being treated by mechanical ventilation for primary lung disease. In this clinical setting, PIE is associated with a mortality rate of more than 50%. Unilateral PIE can be managed by placing the infant with the affected side down for 24 to 48 hours. Selective bronchial intubation and high-frequency or jet ventilation have been used to treat unilateral PIE. Careful attention to peak and mean inspiratory pressures may be beneficial in preventing and treating PIE. High-frequency ventilation may be helpful. Bronchopulmonary dysplasia is a frequent sequel in infants surviving PIE.

Pneumothorax, Pneumomediastinum, and Pneumopericardium

Infants with pneumothorax often present with grunting, tachypnea, cyanosis (See Color Plate), and retractions. Accumulated air may collapse the lung or shift the mediastinum to the side opposite the air leak. A shift of the trachea or point of maximal impulse and decreased breath sounds on the affected side may be found on clinical examination. Pneumothoraces fall into two major groups: spontaneous pneumothorax in otherwise healthy, full-term infants, which most often occurs within minutes of birth, and pneumothorax in infants with significant pulmonary disease, which frequently occurs several days after birth, during therapy for pulmonary disease.

P.576

Prompt recognition of air leak is essential for effective therapy. Unexpected changes in ventilatory requirements or status and abrupt fall in blood pressure, heart rate, respiratory rate, and PO₂ may indicate an air leak. Transillumination of the thorax can be useful in the diagnosis of pneumothorax and the response to therapy. Treatment of tension pneumothorax requires immediate surgical drainage and placement of a chest tube. For treatment of pneumothorax that does not involve tension or cardiovascular compromise, inhalation of 100% oxygen, usually for 4 to 6 hours, can be used as a nitrogen washout method in term infants. Premature infants should not be treated with hyperoxia because they are at risk for retrolental fibroplasia. Pneumomediastinum and pneumopericardium that does not unduly stress the infant can also be managed with 100% oxygen therapy. Tension pneumopericardium is life threatening, must be drained surgically, and is associated with a high incidence of morbidity and mortality.

Chapter 30

Bronchopulmonary Dysplasia

Jonathan M. Davis

Warren N. Rosenfeld

Bronchopulmonary dysplasia (BPD) is a chronic lung disease that develops in newborn infants treated with oxygen and positive-pressure mechanical ventilation for a primary lung disorder. The introduction of new treatment modalities (e.g., surfactant replacement therapy, high-frequency ventilation, extracorporeal membrane oxygenation, inhaled nitric oxide [INO]) has significantly improved the outcome for many critically ill premature and term infants. As a result, more infants are surviving the newborn period and developing BPD. Approximately 10,000 new cases of BPD occur each year in the United States and there is significant associated morbidity and mortality. There has been significant debate about the exact definition of BPD, further complicated because the specific nature of the disease has changed with the widespread use of surfactant and other therapeutic interventions. Although the current form of BPD appears to be much less severe than in the past, BPD is still an extremely important complication of neonatal intensive care (NICU) and the most common form of chronic lung disease in infants.

The modern history of BPD began with Northway's observations in 1967 (1). This study documented the clinical course, radiographic findings, and histopathologic lung changes in a group of infants who had received oxygen and ventilatory support for treatment of respiratory distress syndrome (RDS) and established the term BPD. Although Northway originally postulated that oxygen toxicity caused BPD, the exact mechanisms causing the lung injury are complex and are currently the subject of intense investigation. Treatment with positive-pressure ventilation appears to be a critical factor in the development of BPD, although factors such as oxygen toxicity, prematurity, genetic predisposition, infection and inflammation may also play important roles. Therapies for infants with BPD are directed toward improving the pathophysiologic abnormalities after they occur and include oxygen, mechanical ventilation, fluid restriction, and a variety of medications. Many different therapies can be used in these infants, often concurrently. The optimal treatment and prevention strategies have not been definitively established.

This chapter reviews the definition and incidence of BPD (also known as chronic lung disease in newborns), its pathogenesis, pathophysiologic changes, treatment strategies, and long-term outcome. Newly developed approaches for the prevention of BPD in high-risk infants are presented.

DEFINITION AND INCIDENCE

In the original description of BPD, Northway defined chronic lung changes in a group of premature neonates who survived mechanical ventilation for treatment of RDS (1). Northway's definition of BPD included radiologic, pathologic, and clinical criteria. BPD was divided into four developmental stages. The acute stages, I and II were indistinguishable from RDS and were seen in the first 10 days of life. Stages III and IV marked the transition to the chronic stages of this disease, with stage IV forming the basis for the definition of BPD. This stage described abnormalities that persisted beyond 1 month of age in patients who continued to require respiratory support (i.e., ventilation or oxygen supplementation). Chest radiographs demonstrated cyst formation and hyperexpansion alternating with areas of atelectasis.

As the care of neonates has become more sophisticated and smaller, sicker infants survived, the clinical and radiographic findings that define BPD have changed. Northway's original criteria depended heavily on a progression of radiographic changes, and clinical criteria were considered secondary. Further refinement was offered by Bancalari, whose criteria included ventilation for at least the first 3 days of life and respiratory symptoms (e.g., tachypnea, auscultatory rales, retractions) at 28 days of life, a need for supplemental oxygen to maintain a partial pressure (PaO_2) greater than 50 mm Hg and an abnormal chest radiograph at 28 days of life (2).

TABLE 30-1 DEFINITION OF BRONCHOPULMONARY DYSPLASIA: DIAGNOSTIC CRITERIA^a

Gestational Age	<32 Wkr	≥32 Wk
Time point of assessment	36 wk PMA or discharge to home, whichever comes first	>28 d but <56 d postnatal age or discharge home, whichever comes first
Treatment with oxygen >21% for at least 28 d plus		
Mild BPD	Breathing room air at 36 wk PMA or discharge, whichever comes first	56 d postnatal age or discharge, whichever comes first
Moderate BPD	Need for <30% oxygen at 36 wk PMA or discharge, whichever comes first	Need for <30% oxygen at 56 d postnatal age or discharge, whichever comes first
Severe BPD	Need for >30% oxygen and/or positive pressure, (PPV or NCPAP) at 36 wk PMA or discharge, whichever comes first	Need for >30% oxygen and/or positive pressure (PPV or NCPAP) at 56 d postnatal age or discharge, whichever comes first
Definition of abbreviations: BPD = bronchopulmonary dysplasia; NCPAP = nasal continuous positive airway pressure; PMA = postmenstrual age; PPV = positive-pressure ventilation.

P.579

Many infants who eventually develop chronic lung disease do not require prolonged mechanical ventilation, nor have significant radiographic abnormalities. Several studies have used less stringent criteria to define BPD such as simply the requirement for oxygen supplementation at 28 days of life (3,4). Shennan and associates questioned the large number of normal neonates who would be included by this criterion and suggested that the need for supplemental oxygen at 36 weeks postconceptual gestational age may be a more accurate predictor of ultimate pulmonary outcome (5). Other investigators have found that the most reliable method to definitively establish the diagnosis of BPD is the presence of chronic respiratory symptoms (e.g., asthma, repeated pulmonary infections) requiring treatment with bronchodilators or corticosteroids in the first year or two of life (6,7). Recently, a consensus conference convened by the National Institutes of Health suggested a new definition of BPD that incorporates many elements of previous definitions and attempts to categorize the severity of BPD (Table 30-1) (7). Ultimately, the definition of BPD will need to be validated with clinically important long-term endpoints in a prospective fashion.

The incidence of BPD depends on the definition used and the patient population studied. Several surfactant replacement trials have reported the incidence of BPD, defined as oxygen dependency at 28 days with appropriate radiographic findings, to be in the range of 11% to 63% and varying significantly by center (8,9,10,11). It appeared from these studies that the incidence of BPD decreased only slightly after surfactant therapy. However, the prevalence, or total number of infants with BPD, increased because of improved survival. Fenton and associates subsequently reported that exogenous surfactant had significantly improved the survival of many low-birth-weight infants in their geographically defined population and was actually associated with a marked increase in the incidence of BPD (12). BPD will continue to be an important problem for the neonatologist and pediatric pulmonologist in the future. Further study of the mechanisms involved in the lung injury process and the development of possible prevention strategies are urgently needed.

PATHOGENESIS

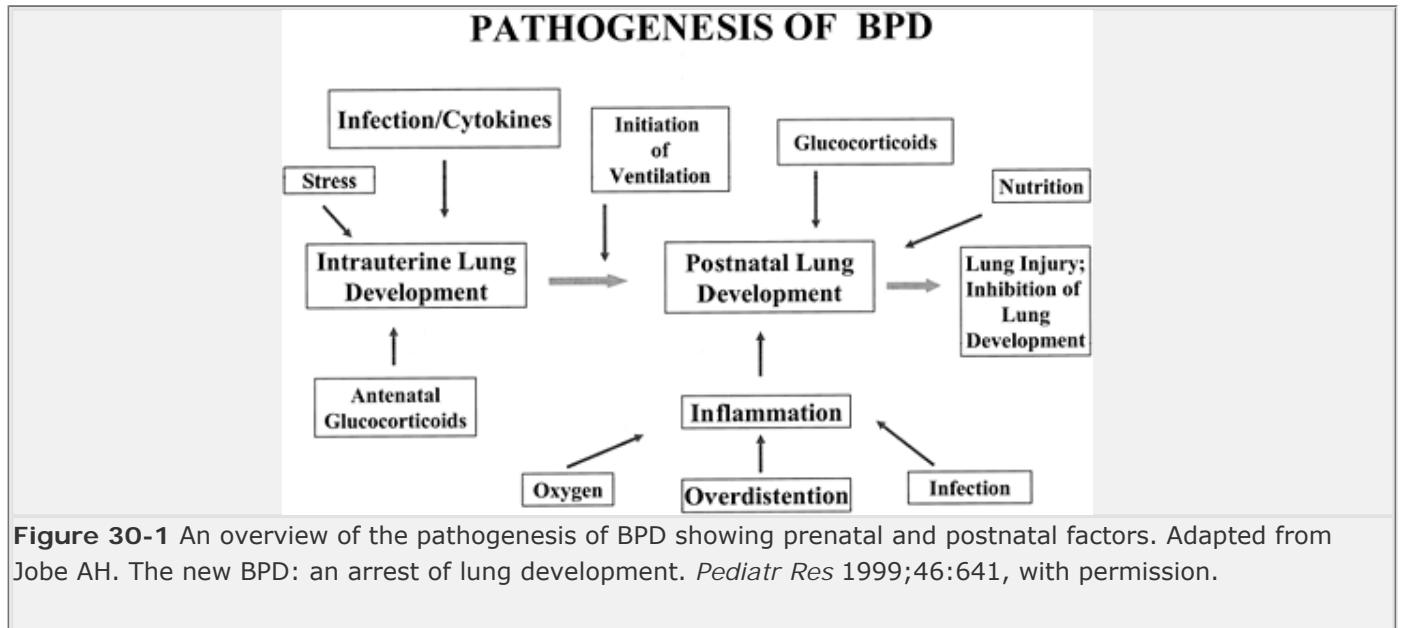

No single factor has been identified as the cause of BPD. Its origin is multifactorial and may depend on the nature of the injury, mechanisms of response, or the infant's inability to respond appropriately to the injury process (Fig. 30-1). Although Northway attributed the occurrence of BPD primarily to prolonged hyperoxia in infants with RDS, numerous other causes have been proposed.

Barotrauma/Volutrauma

Although the initial phases of lung injury in BPD are the result of the primary disease process (e.g., RDS), superimposed positive-pressure mechanical ventilation appears to

P.580

add to the lung injury and provoke a complex inflammatory cascade that ultimately leads to chronic lung disease. Barotrauma is the term generally used to describe the lung injury that occurs secondary to positive-pressure mechanical ventilation, although volutrauma from excessive tidal volume ventilation may be a more appropriate term to describe this lung injury process.

The role of barotrauma in BPD depends on several factors, including the structure of the tracheobronchial tree and the physiologic effects of surfactant deficiency. With surfactant deficiency, surface tension forces are elevated, aeration is unequal, and most terminal alveoli are largely collapsed. The pressure needed to distend these poorly compliant sacculi is high and is transmitted to the terminal bronchioles and alveolar ducts. In the premature infant, these airways are highly compliant and subject to rupture. Gas then dissects into the interstitium and pleural space, resulting in the development of pulmonary interstitial emphysema (PIE) and pneumothorax. These complications are strongly associated with the development of BPD, suggesting that ventilator-induced lung injury is important in the pathogenesis (13,14).

Nilsson and colleagues have shown that even brief periods of positive-pressure ventilation cause bronchiolar epithelial damage in the lung, with the severity of the injury correlating with the amount of peak pressure used (15). Even with normal tidal volumes, ventilation of the immature or injured newborn lung results in nonuniform inflation and relative overdistension of ventilated segments, especially in the presence of low functional residual capacity (FRC) as a result of surfactant deficiency. Stretching of capillary endothelium and distal lung epithelium increases permeability to serum proteins that may further inhibit surfactant function, creating a vicious cycle that promotes lung injury.

The adverse effects of tidal volume breaths in lungs with low FRC can be ameliorated with better lung recruitment by application of higher positive end-expiratory pressure (PEEP). Experimental studies have shown that overdistension of the lung (not increased pressure) is responsible for lung injury in the surfactant-deficient lung (14). For example, strapping the chest wall to restrict overexpansion increases lung pressure but limits lung stretch, and ameliorates lung injury in animal models (16). Tremblay and associates have observed that mechanical ventilation with high tidal volumes and low PEEP markedly increases edema and cytokine production in the lung of rats (17). In this same model, lung injury increased cytokine release from the lungs into the systemic circulation, suggesting a potential mechanism linking multi-organ dysfunction and sepsis syndrome with lung injury. Improved survival of adults with acute respiratory distress syndrome (ARDS) has been found when employing a ventilator strategy that used low tidal volumes with high PEEP to recruit atelectatic lung regions and improve FRC (18).

Strategies to prevent lung injury have included changes in methods of ventilation. Even brief exposure to large tidal volume breaths during resuscitation shortly after birth can initiate early lung injury, which decreases the subsequent response to surfactant therapy (19). With the increased use of nasal continuous positive airway pressure (NCPAP), many preterm infants may be able to be managed without the need for endotracheal intubation and mechanical ventilation, which may lessen the risk for lung injury. Synchronized intermittent mechanical ventilation (SIMV) and high-frequency devices have also been extensively studied. Bernstein and associates reported that infants (<1,000 g) treated with SIMV developed less BPD than those receiving conventional ventilation (20). Several multicenter trials have demonstrated that high-frequency oscillatory

ventilation (HFOV) or high frequency jet ventilation (HFJV) using high volume, alveolar recruitment strategies in conjunction with surfactant replacement therapy reduced complications of mechanical ventilation (PIE, pneumothorax) and lowered the incidence of BPD compared to conventional ventilation (21,22). However, these findings have not been consistently found in other trials. Regardless of the type of ventilation strategy used, it is important to avoid even brief periods of overdistension, because high tidal volumes and hypocarbia are associated with a greater risk for developing both BPD and neurologic injury (23,24). A retrospective study of 1,105 newborns born with birth weights about 2,000 g between 1984 to 1987 demonstrated a strong relationship between prolonged hypocapnia ($\text{PaCO}_2 < 35$ torr) and the development of cerebral palsy (CP) (24).

The use of surfactant replacement therapy has reduced some complications of mechanical ventilation. Surfactant permits more equal distribution of pressures and ventilation to all alveoli, prevents overdistension of distal air spaces and bronchioles, and stabilizes lung volume. A major benefit of surfactant therapy has been the ability to reduce airway pressures and the incidence of air leak, while maintaining a greater uniformity of lung recruitment. However, BPD continues to be an important problem despite the widespread use of exogenous surfactant and strategies to minimize lung injury from mechanical ventilation (e.g., permissive hypercapnia). Van Marter and associates recently studied 452 premature infants weighing 500 to 1,500 g at birth who were born at specific neonatal centers in either Boston or New York. They found that the incidence of BPD was significantly higher in Boston (22%) compared to New York (4%), even after adjusting for baseline risk factors, such as severity of prematurity (25). Using multivariate analyses to examine differences in specific respiratory care practices during the first week of life, most of the increased risk of BPD was associated with the early initiation of mechanical ventilation. Interestingly, the use of both exogenous surfactant and indomethacin increased the risk for BPD. This suggests that attempts to minimize the use of mechanical ventilation using nasal continuous positive airway pressure (NCPAP) (with or without exogenous surfactant) may actually lower the incidence and severity of BPD in high-risk infants. Ongoing multicenter trials of early NCPAP in premature infants are currently underway. BPD continues to be a serious problem, suggesting that

P.581

barotrauma is only one of many factors involved in the pathogenesis of BPD.

Oxygen and Antioxidants

Under normal conditions, a delicate balance exists between the production of oxygen free radicals (also called reactive oxygen species) and the antioxidant defenses that protect cells in vivo. Free radicals are molecules with extra electrons in their outer ring and they are toxic to living tissues (Table 30-2). Oxygen has a unique molecular structure and is abundant within cells. It readily accepts free electrons generated by oxidative metabolism within the cell, producing free radicals. Increased free-radical production can occur under conditions of hyperoxia, reperfusion, or inflammation. Alternatively, free radicals can increase because of an inability to quench production because of inadequate antioxidant defenses. Damage caused by oxygen free radicals includes lipid peroxidation, mitochondrial injury, protein nitration and unraveling of nucleic acids.

The premature neonate may be more susceptible to free-radical damage because adequate concentrations of antioxidants may be absent at birth. Frank and associates documented the development of the antioxidant enzymes superoxide dismutase (SOD), catalase, and glutathione peroxidase in the lungs of rabbits during late gestation (Fig. 30-2) (26). The 150% increase in these enzymes during the last 15% of gestation parallels the maturation pattern of pulmonary surfactant. These developmental changes in the fetal lung allow proper ventilation by reducing surface tension and provide for the transition from the relative hypoxia of intrauterine development to the oxygen-rich extrauterine environment. Premature birth can occur before the normal upregulation of these antioxidant systems and other free radical scavengers (e.g. vitamin E, ascorbic acid, glutathione, and ceruloplasmin) and may result in an imbalance between oxidants and antioxidants and an increased risk for the development of BPD. Experimental animal models have shown that exposure to chronic hyperoxia can induce inflammation and lung injury that has many features seen in infants developing BPD. Both epithelial and endothelial cells are extremely susceptible to oxidant injury, leading to increased permeability edema and cell dysfunction. Hyperoxia also impairs mucociliary function, promotes inflammation and inactivates antiproteases, further complicating clinical outcome.

TABLE 30-2 FREE RADICALS

Radical	Symbol ^a	Antioxidant
Superoxide anion	O ₂ ⁻	Superoxide dismutase, uric acid, vitamin E
Singlet oxygen	¹ O ₂	β-carotene, uric acid, vitamin E
Hydrogen peroxide	H ₂ O ₂	Catalase, glutathione peroxidase, glutathione
Hydroxyl radical	OH•	Vitamins C and E
Peroxide radical	LOO•	Vitamins C and E
Hydroperoxyl radical	LOOH	Glutathione transferase, glutathione peroxidase

^aL, lipid.

Figure 30-2 Developmental changes in antioxidant levels and activity during gestation. The increases in superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GP) late in gestation are similar to those seen for pulmonary surfactant (dark, thick line). From Frank L, Groseclose EE. Preparation for birth into an O₂-rich environment: the antioxidant enzymes in the developing rabbit lung. *Pediatr Res* 1984;18:240, with permission.

Clinical studies suggest that free radicals are involved in the pathogenesis of BPD. Plasma concentrations of allantoin, an oxidation byproduct of uric acid, has been shown to be significantly elevated in the first 48 hours of life in infants developing BPD compared to controls (27). Expired pentane and ethane have also been measured as indirect evidence of free radical-induced lipid peroxidation in the first week of life and found to be significantly elevated in neonates subsequently developing BPD (28). Varsila and colleagues analyzed proteins in tracheal aspirates in the first week of life and found evidence of protein oxidation (carbonyl formation) in infants developing BPD (29). Banks and associates found a fourfold increase in plasma 3-nitrotyrosine concentration in infants developing BPD compared to controls, indicating increased evidence of reactive nitrogen species (endogenous nitric oxide [NO] reacting with superoxide) modifying serum proteins (30). Of note, the multicenter STOP-retinopathy of prematurity (ROP) trial examined whether exposing premature infants to higher inspired oxygen concentrations would prevent the development of severe ROP. Although the effects of the increased oxygen were minimal on the eyes, exposed infants had a marked increase (55%) in the incidence of BPD and pulmonary infections (31).

Further evidence for the role of oxygen free radicals in lung injury comes from animal studies, which have shown that antioxidant supplementation with SOD and catalase reduces cell damage, increases survival, and prevents lung

injury from prolonged hyperoxia and mechanical ventilation (32,33). Genetically engineered mice overexpressing SOD survive longer, whereas mice with disrupted SOD genes die more quickly in a hyperoxic

environment compared to normal diploid controls (34,35). These studies all demonstrate that oxygen free radicals are intimately involved in the development of acute lung and chronic lung disease in newborn infants.

Inflammation

Marked inflammation in the lung appears to begin a cascade of destruction and abnormal repair that develops into BPD. The initial stimuli activating the inflammatory process in the lung may be oxygen free radicals, pulmonary barotrauma, infectious agents, or other stimuli that result in the attraction and activation of leukocytes. Inflammation appears to play an important role in the pathogenesis of BPD and allows many factors to be unified into a single cause of this disease. Inflammatory mediators and cellular responses have been found to be prominent in animal models of lung injury and in infants who develop BPD.

A sustained increase in the number of neutrophils that generate excessive oxygen free radicals in tracheal fluid samples distinguishes infants who develop BPD from those who recover spontaneously (36,37). Additionally, the presence of activated macrophages, high concentrations of lipid products, inactivated α -1-antitrypsin activity, and other markers of active inflammation are strongly linked with the development of BPD (38). Release of early response cytokines, such as tumor necrosis factor- α (TNF- α), interleukin-1 β (IL-1 β), interleukin-8 (IL-8), and transforming growth factor (TGF)- β by macrophages and the presence of soluble adhesion molecules (e.g., selectins) may impact other cells to release chemoattractants and recruit neutrophils which further amplify the inflammatory response (38,39,40,41,42). Elevated concentrations of pro-inflammatory cytokines (IL-6, IL-8) in conjunction with reduced antiinflammatory products, (IL-10) usually appear in tracheal aspirates within a few hours of life in infants subsequently developing BPD (40,41,42). All these agents recruit and activate leukocytes resulting in significant pulmonary damage, including breakdown of capillary endothelial integrity and leakage of macromolecules (e.g., albumin) into alveolar spaces. Albumin leakage and pulmonary edema are known to inhibit surfactant function and have been postulated to be important factors in the development of BPD (43).

The release of elastase and collagenase from activated neutrophils directly destroys the elastin and collagen framework of the lung. The breakdown products of collagen (hydroxyproline) and elastin (desmosine) have been recovered in the urine of infants who develop BPD (44). The major defense against the action of elastase activity is α 1-proteinase inhibitor, which may be inactivated by oxygen radicals. Increased elastase activity accompanied by compromised antiproteinase function may enhance lung injury. This combination has been demonstrated in tracheal aspirates and serum of neonates who develop BPD (45,46,47).

As the acute cycle of injury continues with further production and accumulation of inflammatory mediators, significant injury to the lung can occur during a particularly critical period of rapid growth; six divisions from 24 to 40 weeks of gestation. It appears likely that this abnormal inflammatory process is primarily responsible for the acute and the chronic changes that occur in the lungs of infants with BPD. Watterberg and associates have demonstrated that extremely premature infants have evidence of adrenal insufficiency at birth with the lowest serum cortisol concentrations during the first week of life correlating with increased lung inflammation and adverse respiratory outcome (48). Pilot studies examining early treatment with low-dose hydrocortisone in extremely low birth weight (LBW) infants increased the likelihood of survival without BPD, a benefit that was particularly apparent in infants born to mothers with chorioamnionitis (49). The mechanisms of action may include suppression of lung inflammation with less inhibition of lung growth observed with higher doses of steroids or even beneficial effects of low dose hydrocortisone on lung development. These studies all clearly support the notion that this abnormal inflammatory process is primarily responsible for the acute and the chronic changes that occur in the lungs of infants with BPD.

Infection

Subclinical intrauterine infection and the ensuing inflammatory response have been clearly implicated in the etiology of preterm labor and premature rupture of membranes (50). Growing evidence indicates that prenatal infection and inflammation are major risk factors for the subsequent development of BPD. Although several investigators have found a lower incidence of RDS in preterm infants born to mothers with chorioamnionitis and funisitis (possibly as a result of an adaptive response to in utero stress), they also observed a significantly higher incidence of BPD in these same infants (51). This suggests that although intrauterine infection may accelerate lung maturation, the ensuing inflammatory response may also "prime the lung," causing lung injury, progressive inflammation and subsequent inhibition of lung growth. Subsequent exposure to hyperoxia and mechanical ventilation may further exacerbate the injury process in an already infected and/or inflamed lung.

Ureaplasma urealyticum has been recovered from cervical cultures of pregnant women and implicated as a

possible cause of chorioamnionitis, prematurity, and BPD (52). Cassell and colleagues cultured tracheal aspirates and blood and found that BPD developed in 82% of infants (<1,000 g) colonized with *Ureaplasma*, compared with 41% of those with negative cultures (52). In contrast, other studies have found that although *Ureaplasma* was frequently detected (by culture or polymerase chain reaction) in many LBW infants, its presence was not associated

with the development of BPD (53,54). It is possible that infection simply acts as a stimulus for the inflammatory response, with recruitment of leukocytes and the production of cytokines and oxygen free radicals, ultimately leading to the development of BPD. Normal defense mechanisms against infection can be compromised in the lungs of these chronically ventilated, premature infants. This makes them more susceptible to colonization and subsequent infection with a variety of infectious agents (e.g., virus, bacteria, fungi) that may affect the severity of BPD (55). Several large clinical studies have found a strong correlation between the presence of BPD and the development of late-onset sepsis, usually with organisms such as *staphylococcus epidermidis* (56,57). These infections are associated with increased morbidity, mortality, and length of hospital stay and appear to contribute to the severity of BPD.

Nutrition

The nutritional status of the critically ill premature infant may also be important in the development of BPD. Adequate calories and essential nutrients for growth may be lacking during a period of stress and growth; vital components for immunologic and antioxidant defenses may be inadequate; and the nutritional supplements provided may actually contribute to ongoing damage.

Premature infants have increased nutritional requirements because of increased metabolic needs and rapid growth requirements. If these increased energy needs are not met, the infant will develop a catabolic state, which most likely contributes to the pathogenesis of BPD. Inadequate nutrition could interfere with normal growth and maturation of the lung and may potentiate the deleterious effects of oxygen and barotrauma. Newborn rats with inadequate caloric intake have decreased lung weights, protein levels, and DNA content (58). These abnormalities were even greater in pups that were nutritionally deprived at birth and exposed to hyperoxia.

Antioxidant enzymes may play a vital role in the protection of the lung and the prevention of BPD. Many of these enzymes have trace elements (e.g., copper, zinc, selenium) that are an integral part of their structure. Deficiencies in these elements may compromise the premature infant's defenses and predispose the lung to further injury. The repair of elastin and collagen is limited in animals that are undernourished, and copper and zinc may be necessary for this repair (59). Although supplementation with these elements may provide protection to the lung and prevent hyperoxic lung injury, clinical trials using limited dosing strategies have not been able to demonstrate a beneficial effect in preventing BPD (60). Vitamin deficiency has been postulated to be important in the development of BPD. Although current nursery feeding and hyperalimentation regimens appear to provide adequate amounts of vitamin E for preterm infants, a relative decrease in the concentrations of other vitamins may be important in the pathogenesis of BPD. For example, Vyas and colleagues reported significant decreases in levels of ascorbate (which can function as an antioxidant) in tracheal aspirate fluid from infants developing BPD compared to control infants, suggesting that supplementation with vitamin C might be beneficial (61). However, early supplementation with high dose "antioxidant" vitamins has been studied in preterm baboons and was not efficacious in preventing lung damage from prolonged hyperoxia (62).

Concentrations of vitamin A (retinol) may also be deficient in very LBW infants (63,64,65). This vitamin appears to be important in maintaining cell integrity and in tissue repair. Its deficiency has been associated with changes in the ciliated epithelium of the tracheobronchial tree (66). Husted and associates demonstrated lower serum retinol levels in cord blood and at day 21 of life in infants who developed BPD (65). Similarly, Shenai and colleagues demonstrated lower plasma retinol concentrations in the first month of life in infants who subsequently developed BPD (67). Despite adequate supplementation, some infants remain vitamin A deficient, presumably from increased absorption of parenteral vitamin A into the tubing of the intravenous administration set or from higher nutritional requirements (68). A multicenter trial of vitamin A supplementation in premature infants at risk for developing BPD recently demonstrated that large doses of intramuscular vitamin A given three times per week was associated with a small (7%), but significant reduction in the incidence of BPD, suggesting that vitamin A deficiency is an important contributor to lung injury (69).

Large volumes of intravenous fluids are often administered to premature infants to provide adequate fluid requirements (from increased insensible water losses) and sufficient calories. Excessive fluid administration can

be associated with the development of a patent ductus arteriosus and pulmonary edema, which can lead to an increase in oxygen and ventilator requirements and the subsequent risk of BPD (55,70). Early closure of the ductus, using indomethacin or surgical ligation, has been associated with improvements in pulmonary function, but these approaches have not affected the incidence of BPD (71).

Genetics

Numerous investigators have observed that neonates were more likely to develop BPD if there was a strong family history of atopy and asthma. Nickerson and Taussig found a positive family history of asthma in 77% of infants with RDS who subsequently developed BPD, compared with only 33% who did not (72). Bertrand evaluated the relationship of prematurity, RDS, and need for mechanical ventilation to a family history of airway hyperactivity (73). The severity of lung disease was directly related to the degree of prematurity and the duration of oxygen exposure. However, siblings and mothers of infants with the most significant lung disease had evidence of airway reactivity, suggesting that all three factors are involved in

P.584

determining long-term outcome. When histocompatibility loci (HLA) were examined, Clark and associates found that only infants with HLA-A2 developed BPD, again suggesting that other underlying factors that are poorly understood may be important in the pathogenesis of BPD (74). More recently, Hagan reported that a family history of asthma is associated with an increase in the overall severity of BPD in premature infants but does not appear to be a causative factor (75).

PATHOPHYSIOLOGIC CHANGES

Infants with BPD demonstrate abnormal findings on clinical examination, chest radiograph, pulmonary function testing, echocardiogram, and morphologic examination of the lung. The severity of BPD is directly proportional to the degree of the pathophysiologic insult and can be assessed through all of these techniques. Determining the severity of BPD is complex and has been the subject of several workshops sponsored by the National Institutes of Health and many publications. Several scoring systems have been developed to address this important issue.

Clinical Assessment

A clinical scoring system to help evaluate the severity of BPD was developed by Toce and colleagues (76). Infants with BPD are tachypneic and may have intercostal and subcostal retractions. Accessory muscles may be used to assist with respiration. Infants can be hypoxic and hypercarbic and may grow poorly despite adequate caloric intake. The Toce system attempts to standardize clinical assessment, and a severity score can be assigned to each infant at 28 days of postnatal age and at 36 weeks postconceptual age. The clinical assessment should be adjusted if infants are receiving multiple medications for their BPD (e.g., diuretics, methylxanthines), NCPAP, or positive-pressure mechanical ventilation.

Radiographic Abnormalities

Northway and associates first described radiographic abnormalities characteristic of BPD in 1967 (1). A staging system was employed that documented the progression of the disease process through four distinct stages. The first stage was similar to uncomplicated RDS and occurred in the first few days of life. The BPD often progressed to pulmonary parenchymal opacities (stage II), a bubbly appearance (stage III), and then to an inhomogeneous appearance with marked hyperinflation, bleb formation, irregular fibrous streaks, and cardiomegaly (stage IV).

The radiographic progression of BPD is now seldom categorized by these four stages, so Edwards and colleagues redefined the radiologic changes (77). Their system is based on the four most prominent radiographic findings in BPD, including lung expansion, emphysema (including bleb formation), interstitial densities, and cardiovascular (CV) abnormalities (Table 30-3). More severe changes are associated with higher scores (maximum of 10). The occurrence of hyperinflation or interstitial abnormalities on chest radiograph appears to correlate with the development of airway obstruction later in life (78). Because the severity of BPD has continued to change so significantly over the past decade, Weinstein developed a new scoring system incorporating some of the more subtle radiographic signs that are often seen today in infants with BPD (Fig. 30-3) (79). The utility of these scoring systems remains to be demonstrated.

Computed tomography (CT) and magnetic resonance imaging (MRI) of the lung may provide more details of the structural disease in BPD, and can reveal significant abnormalities that are not readily apparent on chest radiographs (Fig. 30-4) (80). These findings can be important in determining ultimate pulmonary morbidity. CT scans often show regional heterogeneity, with regions of hyperinflation or "emphysema" and sparse arterial density alternating with relatively normal appearing regions. MRI of ventilated premature newborns may demonstrate striking regional variations in lung disease, with marked gravity-dependent

atelectasis and edema. More studies of the role of CT and MRI in BPD are needed to correlate structural and functional changes.

TABLE 30-3 ROENTGENOGRAPHIC SCORING SYSTEM FOR SEVERITY OF BRONCHOPULMONARY DYSPLASIA ^b			
Variable	0	1	Score ^a
Cardiovascular abnormalities	None	Cardiomegaly	Gross cardiomegaly or RVH or enlarged MPA
Hyperexpansion (anterior plus ≤14 posterior rib count)		14.5-16	≤16.5, or flattened hemidiaphragms
Emphysema	No focal areas	Scattered, small, abnormal lucencies	At least one large bleb or bulla
Fibrosis or interstitial abnormalities	None	Interstitial prominence; few abnormal, streaky densities	Dense fibrotic bands, many abnormal strands
Subjective	Mild	Moderate	Severe

^a Rib counts intersecting level of the dome of the right hemidiaphragm. MPA, main pulmonary artery; RVH, right ventricular hypertrophy.

Figure 30-3 Typical chest radiograph of a 1-month-old infant with evolving bronchopulmonary dysplasia. The bilateral hazy appearance represents inflammatory exudate, edema, and atelectasis.

Cardiovascular Changes

In addition to adverse effects on airways and alveoli, acute lung injury also impairs growth, structure and function of the developing pulmonary circulation after premature birth (81). Endothelial cells have been shown to be particularly susceptible to oxidant injury and the media of small pulmonary arteries may also undergo smooth muscle cell proliferation (82). Structural changes in the lung vasculature contribute to high pulmonary vascular resistance (PVR) as a result of narrowing of the vessel diameter and decreased angiogenesis. In addition to these structural changes, the pulmonary circulation is further characterized by abnormal vasoreactivity, which also increases PVR (83). Overall, injury to the pulmonary circulation can lead to the

development of pulmonary hypertension and cor pulmonale, which contributes significantly to the morbidity and mortality of severe BPD (84). Echocardiographic assessment is an extremely valuable tool in confirming these diagnoses.

In addition to pulmonary vascular disease and right ventricular hypertrophy, other CV abnormalities that are associated with BPD include left ventricular hypertrophy (LVH) and systemic hypertension. Steroid therapy can cause LVH, which tends to be transient and resolves when the drug is stopped. A high incidence of systemic hypertension can be seen in BPD, but its etiology remains obscure (85). Systemic hypertension may be mild, transient or severe and usually responds to pharmacologic therapy. On occasion, further evaluation of such infants may reveal significant renal vascular or urinary tract disease. Whether the high incidence of systemic hypertension in BPD reflects altered neurohumoral regulation, or increased catecholamines, angiotensin or antidiuretic hormone levels are still unknown.

Changes in Pulmonary Mechanics

The development of computerized pulmonary function systems has enabled more accurate measurements of pulmonary mechanics in newborn infants with BPD. Increased respiratory system resistance and bronchial hyperactivity can be demonstrated even during the first week of life in preterm neonates who subsequently develop BPD (86). These abnormalities are common in older infants with BPD and can cause dynamic airway collapse and expiratory flow limitation (Fig. 30-5) (87). Other abnormalities of lung function include increased dead

P.586

space ventilation, decreased lung compliance, maldistribution of ventilation and abnormal ventilation-perfusion matching (88). Functional residual capacity (FRC) is often reduced early in the course as a result of atelectasis, but increases during the later stages of BPD as a result of gas trapping and hyperinflation. Increased respiratory rate with shallow breathing increases dead space ventilation that results from marked regional variability and decreased lung surface area. Nonuniform damage to the airways and distal lungs results in variable time constants for different areas of the lungs, altering the distribution of inspired gas to relatively poorly perfused lung segments and worsening ventilation-perfusion matching.

Figure 30-4 A: Chest radiograph of a 2-month-old infant with bronchopulmonary dysplasia, showing right-sided atelectasis and a shift of the mediastinum. The lung fields have a hazy appearance. B: Computed tomography scan on the same infant. The major bronchi and areas of atelectasis are apparent. Fibrotic changes and a bleb are seen on the left (arrow).

Figure 30-5 A: Normal flow-volume loop. B: Expiratory flow limitation as a result of dynamic collapse of small airways during expiration. INSP, inspiration; EXP, expiration.

Two methods used to measure lung compliance include dynamic measurement and passive expiratory techniques after airway occlusion (89). Both methods show a reduction of lung compliance in infants with BPD. The decrease in lung compliance appears to correlate well with morphologic changes in the lung (e.g., atelectasis, edema, fibrosis). Compliance can be reduced because of increased resistance, with frequency dependence of compliance, when infants are breathing rapidly (90). The use of pulmonary function testing to follow the progression of BPD and the response of the lung to various therapeutic interventions has become widespread, but care must be used in the interpretation of results because of inherent variability in the measurement and possible error from excessive chest wall distortion (91,92).

Pathologic Changes

Detailed morphometric studies have extensively characterized the lung pathology of infants dying with BPD (7,93-95). The pathology of BPD provides insights into the effects of acute lung injury and repair processes in the developing lung, and the impact of the timing of this injury. Pathologically, the original reports of BPD described a continuous process through distinct stages of the disease, originating with an acute exudative phase and progressing to a chronic proliferative phase of the disease (93). Older reports describe a gross cobblestone appearance of the lungs, representing alternating areas of atelectasis, marked scarring and regional hyperinflation. Typical histologic features of this BPD include marked airway changes, such as squamous metaplasia of large and small airways, increased peribronchial smooth muscle and fibrosis, chronic inflammation and airway edema, and hyperplasia of submucosal glands. Parenchymal disease is characterized by volume loss from atelectasis and alveolar septal fibrosis alternating with overdistension or emphysematous regions (Fig. 30-6). Mesenchymal thickening with increased cellularity and destruction of alveolar septae with alveolar hypoplasia is present, suggesting a marked reduction in surface area available for gas exchange. Growth of capillary beds is reduced and small pulmonary arteries have hypertensive structural

P.587

remodeling, which includes smooth muscle hyperplasia and distal extension of smooth muscle growth into vessels that are normally nonmuscular.

Figure 30-6 Light micrograph from a 1-year-old infant with bronchopulmonary dysplasia shows areas of atelectasis alternating with areas of hyperinflation (Original magnification times 4.).

Figure 30-7 Lung histology from an infant dying in the postsurfactant era with the typical changes of the "new BPD," showing alveolar simplification and reduced septation (original magnification times four; provided by Dr. Steven Abman).

Although reductions in alveolar number were described in older infants dying with BPD, a pattern of "alveolar simplification" has become the most striking pathologic feature of the "new BPD" (Fig. 30-7) (7,94). In contrast with past reports, recent studies of infants dying with BPD describe fewer signs of airway injury and interstitial fibrosis, but emphasize persistent reductions of distal airspace and vascular growth (95). Decreased alveolarization and impaired growth of small pulmonary arteries results in decreased lung surface area for gas exchange, which has important functional implications regarding late cardiopulmonary sequelae (see above). In addition to changes in the distal lung, the pathology of BPD is further characterized by abnormal airway structure. The trachea and main bronchi of infants with BPD often reveal significant lesions, depending on the frequency and duration of endotracheal intubation. Grossly, mucosal edema or necrosis can be focal or diffuse. The earliest histologic changes include patchy loss of cilia from columnar epithelial cells, which can then become dysplastic or necrotic, resulting in breakdown of the epithelial lining and decreased pulmonary clearance of mucous and other material. Ulcerated areas may involve the mucosa or extend into the submucosa. Infiltration of inflammatory cells (neutrophils and lymphocytes) into these areas may be prominent. Goblet cells appear hyperplastic, suggesting greater capacity for increased mucous production that can mix with cellular debris. Granulation tissue often develops in the subglottis as a result of damage from the endotracheal tube or more distally throughout the airway as a result of trauma from repeated suctioning. Significant narrowing of the trachea and main bronchi secondary to injury can lead to subglottic stenosis, tracheal cysts and polyps, and related lesions. Tracheomalacia may often complicate the course of severe BPD and can appear as marked redundancy of the posterior wall of the trachea, as a result of chronic ventilation of the compliant premature

airway.

MANAGEMENT

The current approach to infants with BPD is multidisciplinary and directed toward improving the complex pathophysiologic abnormalities that have been previously described. In addition to chronic respiratory disease, infants with BPD have significant growth, nutritional, neurodevelopmental, and CV problems. The severity of respiratory disease varies widely among infants with BPD. In its most severe presentation, children with BPD may require chronic ventilation or prolonged home oxygen therapy. Even infants who have successfully weaned off supplemental oxygen therapy have recurrent hospitalizations for lower respiratory exacerbations as a result of viral infections (respiratory syncytial virus and influenza), reactive airways disease, pulmonary hypertension or congestive heart failure. Additionally, persistent or recurrent respiratory exacerbations may also be as the result of structural lesions (e.g., tracheomalacia, subglottic stenosis, bronchomalacia), chronic aspiration (gastroesophageal reflux or swallowing dysfunction), or others. In addition to supplemental oxygen therapy, chronic treatment with bronchodilators, diuretics, corticosteroids, and nutritional supplements are commonly used as supportive therapy. Often, many of these therapies are used concurrently with the potential for significant side effects.

P.588

The major treatment approaches are described in the following sections.

Mechanical Ventilation

With established disease, patients with BPD who require prolonged ventilatory assistance generally require larger tidal volume breaths and a slower rate to enhance the distribution of gas as a result of heterogeneity of lung units. Ventilation of infants with severe BPD with fast rates and smaller tidal volumes increases dead space ventilation and may worsen gas exchange and increase gas trapping. Arterial blood gases should be optimally maintained with a pH of 7.25 to 7.40, PCO_2 of 45 to 55 mm Hg, and PO_2 of 55 to 70 mm Hg. The best method of assessing adequate oxygenation and ventilation is an arterial blood gas obtained from an indwelling arterial catheter when the infant is quiet. Intermittent arterial puncture may be accurate if obtained quickly or if local anesthesia is used, but may not be representative if the infant is awake and agitated. Capillary blood gases should not be used to make significant therapeutic decisions because of wide variability and poor correlation with arterial blood gases (especially in older infants who have already had multiple heel sticks for phlebotomy) (96). However, if samples are obtained properly (i.e., after adequate warming and without squeezing the heel or finger), the pH and PCO_2 may correlate with arterial values. The use of pulse oximetry can assist in ventilatory management and may reflect arterial values. End-tidal CO_2 measurements may not correlate well with arterial values in infants with significant ventilation-perfusion mismatch and chronic lung disease. As mentioned previously, hypocarbia and hyperventilation may increase the risk for BPD and should definitely be avoided (23,24).

Because oxygen appears to cause more significant lung damage than mechanical ventilation in animal models, sufficient mean airway pressure should be used to avoid atelectasis and maintain the fraction of inspired oxygen (FiO_2) at less than 0.5 (97). Inspired gas temperature should be maintained from 36.5°C to 37.5°C to ensure adequate humidity and minimize core temperature fluctuations and the progression of chronic lung disease (98). Weaning infants with BPD from mechanical ventilation is often difficult and should be done slowly. When peak inspiratory pressures have been reduced to approximately 15 to 20 cm H_2O and FiO_2 to less than 0.4 with acceptable blood gases, the ventilator rate (if using a conventional, time cycled ventilator) should be reduced slowly to allow the infant to gradually breathe more independently. This is essential because prolonged ventilation may be associated with atrophy of the muscle fibers of the diaphragm and increased diaphragmatic fatigue (99). When infants have been weaned to a ventilator rate of 10 to 20 breaths/min, elective extubation should be attempted. With synchronized mechanical ventilation, the infant is allowed to set his/her own inspiratory time and respiratory rate. Weaning infants from this type of ventilation involves reducing the inspiratory pressure as previously described. Analysis of pulmonary mechanics before extubation may not be useful in determining optimal time of extubation because multiple factors (e.g., central inspiratory drive, diaphragmatic endurance, chest wall stability) may be important (100). Infants should not be weaned to continuous endotracheal tube positive airway pressure (CPAP) because increased airway resistance and work of breathing can cause fatigue, apnea, and carbon dioxide (CO_2) retention (101). The use of methylxanthines

before extubation or NCPAP just after extubation may facilitate successful extubation (102,103). Higgins and colleagues demonstrated that infants weighing less than 1,000 g were almost four times as likely to be successfully extubated on the first attempt when NCPAP was used compared with an oxyhood (76% vs. 21%) (103). Chest physiotherapy and suctioning should be performed frequently to maintain a patent airway and prevent atelectasis.

Prolonged intubation and ventilation may be associated with the development of airway abnormalities (e.g., subglottic stenosis, tracheomalacia) (104). These should be considered in infants who rapidly and repeatedly fail attempts at extubation. A bronchoscopic evaluation should be performed in these infants or in any infant intubated for more than 2 to 3 months who continues to require prolonged ventilation. Surgical intervention (e.g., cricoid split, tracheostomy) should be performed if necessary.

Oxygen

In infants with BPD, chronic hypoxia results in pulmonary vasoconstriction, pulmonary hypertension, and the development of cor pulmonale. This contributes significantly to the morbidity and mortality of BPD. Elevated pulmonary artery pressures and pulmonary vascular resistance have been described in infants with BPD undergoing cardiac catheterization (83-85,105). Significant reductions in pulmonary pressures were found when oxygen was administered. Oxygen is now known to act as a pulmonary vasodilator by stimulating the production of endogenous NO (106). The NO diffuses into the vascular smooth muscle and stimulates the production of cyclic GMP (cGMP), which causes vasodilation by sequestering calcium. Ideally, PaO₂ should be maintained between 55 and 70 mm Hg in infants with BPD.

Pulse oximetry has become the most popular noninvasive method of neonatal oxygen monitoring. Pulse oximeters are most accurate when operating along the steep portion of the oxygen-hemoglobin dissociation curve and may be more reliable than measuring PaO₂ (107). Keeping the oxygen saturation (SaO₂) generally between 90% to 95% should exclude values of PaO₂ that are less than 45 mm Hg or greater than 100 mm Hg. Careful monitoring of oxygen status is essential because hypoxia can cause pulmonary hypertension, increased airway constriction, and growth failure. Repeated episodes of oxygen desaturation often develop in premature neonates with BPD during mechanical ventilation (108). This appears to be related to

P.589

a decrease in central respiratory drive and alterations in pulmonary mechanics. Prone positioning (with careful monitoring) may increase SaO₂ and decrease the frequency of hypoxemic episodes (109).

Hyperoxia may worsen BPD or increase the risk of retinopathy of prematurity (110). The STOP-ROP trial examined the role of oxygen therapy in retinopathy of prematurity, and suggested that infants who were treated with supplemental oxygen to maintain oxygen saturations more than 95% had a higher risk for BPD than infants treated with supplemental oxygen that targeted lower saturations (31). However, interpretation of these data in the setting of preventing or treating infants with pulmonary hypertension are limited, because the targeted ranges for the low and high oxygen saturation groups fell between typical recommendations for oxygen therapy. Current recommendations for treatment of patients with BPD and pulmonary hypertension are to maintain oxygen saturations at 92% to 96%. Whether higher oxygen saturations increase lung injury remains unproven, but the adverse effects of hypoxemia are clear.

Oxygen can be administered through an endotracheal tube, hood, tent, or nasal cannula. Increased FiO₂ may be needed during periods of increased stress (e.g., during feedings). Oxygen should be withdrawn gradually and may be required for months. If oxygen-dependent infants can maintain an SaO₂ of more than or equal to 90% for at least 40 minutes in room air, then it appears that they can be successfully weaned from supplemental oxygen (111). Infants with BPD can be discharged from the neonatal intensive care unit and receive oxygen at home. The use of booster transfusions to increase oxygen-carrying capacity in oxygen-dependent infants with BPD is controversial. Alverson and associates demonstrated significant increases in oxygen content and systemic oxygen transport and decreases in oxygen consumption and oxygen use in infants with BPD after booster blood transfusion (112). However, hemoglobin levels did not appear to correlate well with systemic oxygen transport and did not predict which infants would benefit physiologically from transfusion. The need for multiple transfusions has been significantly reduced by minimizing phlebotomy and by using human recombinant erythropoietin therapy (113).

Nutrition

Because infants with BPD have increased metabolic demands, calories must be maximized to support tissue repair and growth. Enteral feedings with fortified breast milk or with premature formulas provide the best source of calories. Feedings should be given by intermittent or continuous gavage until the infant can be fed orally. Feedings can be concentrated to increase caloric density, or glucose polymers (e.g., polyose), protein supplements (ProMod) and medium-chain triglycerides (MCT) can be added to provide optimal calories although minimizing fluid intake. Infants may require 120 to 140 calories/kg of body weight each day to gain weight (10 to 30 g/day). If fluid restriction interferes with the administration of adequate calories, a diuretic can be used to prevent fluid overload.

Intravenous nutrition should be started early (day 1-2 of life) to provide adequate sources of protein, fat, and carbohydrates. This may affect the ultimate outcome and severity of BPD, especially in the very-low-birth-weight infant. The early use of percutaneous silastic central catheters has greatly enhanced the ability to provide more optimal calories to LBW infants (114). Progressive increases in intravenous amino acid concentrations should optimally provide up to 3.5 g of protein per kilogram each day. The acid-base status of the infant should be monitored because acid loads may not be well tolerated. Intravenous lipids (20% suspension) should be administered as a continuous infusion over 20 to 24 hours. Up to 3 g of lipids per kilogram each day can be safely infused if serum triglyceride levels are closely followed. However, early administration of lipids may be associated with more severe BPD (115,116). Intravenous glucose is a good source of calories, but excessive loads (<4 mg/kg/min) may result in increased oxygen consumption, CO₂ production, and resting energy expenditures in infants with BPD (117). Adequate calcium and phosphorus intake is necessary, especially in infants receiving furosemide, to promote bone mineralization and prevent secondary hyperparathyroidism and rickets. Vitamins and trace metals should also be supplemented. Many premature infants are deficient in vitamin A, and adequate supplementation may promote tissue regeneration and growth in the lung and decrease the incidence and severity of BPD (66). Trace metals such as copper, zinc, and selenium are essential for the structure and function of antioxidant enzymes and should be provided.

Medications

Many different types of drug therapies are used, often concurrently, to improve the clinical status of infants with BPD. The exact dosages, efficacy, mechanisms of action, pharmacokinetics, and side effects have not been well established. National Institutes of Health (NIH)/FDA consensus panels are currently working to establish optimal treatment regimens for infants with BPD.

Diuretics

Furosemide (Lasix) is the treatment of choice for fluid overload in infants with BPD. It acts on the ascending loop of Henle and blocks chloride transport. Furosemide increases plasma oncotic pressure and lymphatic flow and decreases interstitial edema and pulmonary vascular resistance (118,119). Several studies have demonstrated that daily, alternate-day or even aerosolized furosemide improves clinical respiratory status and pulmonary mechanics and facilitates weaning from mechanical ventilation in infants with BPD (120,121,122). Side effects of furosemide are numerous and include volume depletion, contraction alkalosis, hyponatremia, hypokalemia,

P.590

chloride depletion, renal calculi secondary to hypercalcinuria, nephrocalcinosis, cholelithiasis, osteopenia, and ototoxicity (118). Supplemental potassium chloride is usually needed to prevent electrolyte depletion and alkalosis, but sodium chloride supplements should be avoided if possible.

The thiazides affect renal tubular excretion of electrolytes, but they are less potent than furosemide (123). Potassium and bicarbonate excretion accompany the sodium and chloride excretion produced by the thiazides. For this reason, the thiazides are usually given in conjunction with spironolactone (Aldactone), which is a competitive inhibitor of aldosterone. Spironolactone is a relatively weak diuretic that causes increased sodium, chloride, and water excretion although sparing potassium. Although a few controlled trials examining the use of a thiazide diuretic and spironolactone in infants with moderate BPD demonstrated increased urine output and improvements in pulmonary mechanics, others could find no effect on gas exchange or pulmonary mechanics (124,125,126). Side effects of the combination of a thiazide with spironolactone include azotemia, hyperuricemia, hyponatremia, hyperkalemia or hypokalemia, hyperglycemia, hypercalcinuria, and hypomagnesemia (118). Overall, although it appears that short-term administration of diuretics may improve pulmonary mechanics in premature infants, there is limited data regarding the long-term benefits of these

agents in reducing the need for ventilatory support, reducing the length of hospitalization or improving long-term clinical outcome (127). Longer-term studies establishing optimal treatment regimens in infants with evolving or established BPD are definitely needed. Diuretic dosing is shown in Table 30-4.

Bronchodilators

Albuterol is a specific β_2 -agonist that has become the inhaled agent of choice in the treatment of reversible bronchospasm in infants with BPD. Albuterol aerosolization has been associated with acute improvements in pulmonary resistance and lung compliance secondary to bronchial smooth muscle relaxation (128). These changes in pulmonary mechanics returned to baseline by 4 hours after administration. Side effects are infrequent but can include tachycardia and hypertension. Tolerance may develop with prolonged usage.

Atropine is a competitive inhibitor of acetylcholine. In the lung, atropine decreases mucus secretion and transport in large airways and causes significant bronchial smooth muscle relaxation (129). Ipratropium bromide is a related muscarinic antagonist that is a much more potent bronchodilator than atropine and has significantly fewer side effects. In infants with BPD, ipratropium causes a significant improvement in pulmonary mechanics that is similar to that seen after treatment with albuterol (130). The combination of ipratropium and albuterol may be more effective than either agent alone (129,130). A selective β_2 agent should initially be used in older infants with BPD; ipratropium can be added if clinical improvement is not seen. Ipratropium can be used alone if significant side effects from albuterol occur.

The methylxanthines (e.g., caffeine, theophylline) are routinely used to increase respiratory drive and reduce the frequency of apnea in infants with apnea of prematurity (99). They are also used in the treatment of infants with BPD. Measurements of pulmonary mechanics in infants with BPD have shown that caffeine and theophylline can reduce pulmonary resistance and increase lung compliance, presumably through a direct bronchodilator action (131,132). These agents act as mild diuretics and improve skeletal muscle and diaphragmatic contractility. This is particularly important in chronically ventilated infants who may develop diaphragmatic atrophy and fatigue. Improved skeletal muscle contractility may stabilize the chest wall and improve functional residual capacity (133). These actions may facilitate successful weaning from mechanical ventilation. There may be a synergistic effect if theophylline and a diuretic are used concurrently (124).

TABLE 30-4 COMMONLY USED MEDICATIONS FOR BRONCHOPULMONARY DYSPLASIA

Medication	Dosage ^a
Diuretics	
Furosemide	0.5-2.0 mg/kg/dose i.v. or p.o. bid (qd in infants <31 weeks postconceptual age)
Chlorthiazide	5-20 mg/kg/dose i.v. or p.o. bid
Hydrochlorthiazide	1-2 mg/kg/dose p.o. bid
Spironolactone	1.5 mg/kg/dose p.o. bid
Inhaled agents	
Albuterol	0.02-0.04 mL/kg/dose of a 0.5% solution diluted to 1-2 mL with half-normal or normal saline q4-6h
Ipratropium bromide	0.025-0.08 mg/kg diluted to 1.5-2.5 mL in half-normal or normal saline q6h; doses up to 0.176 mg may be used
Systemic agents	
Aminophylline (i.v.), theophylline (p.o.)	LD 5 mg/kg; MD 2 mg/kg/dose q8-12h; serum levels of 5-15 mg/L
Caffeine citrate	LD 20 mg/kg; MD 5 mg/kg i.v. or p.o. q24h
Dexamethasone	0.1-0.2 mg/kg/day i.v. or p.o. divided q12h for 2-3 days, decrease by 50% for 2-3 days, then taper another 50% for 2-3 days and discontinue
^a LD, loading dose; MD, maintenance dose.	

The half-life of theophylline is 30 to 40 hours in newborns, and theophylline is metabolized primarily to caffeine in the liver and excreted in the urine. Adverse reactions include gastrointestinal (GI) (e.g., gastroesophageal

reflux, diarrhea), central nervous system (e.g., agitation, seizures), CV (e.g., tachycardia, hypertension), and endocrine (e.g., hyperglycemia) disturbances (118). The half-life of caffeine may be as long as 100 hours. It is excreted unchanged in the urine. Side effects of caffeine are similar to those of theophylline, but are rarely encountered. Caffeine is a safer drug with a wider therapeutic index and fewer side effects than theophylline and may be a more appropriate adjunct in the treatment of apnea and BPD in preterm infants. Although all of these agents appear to improve lung mechanics in infants with BPD short-term, it is unclear whether prolonged therapy causes sustained clinical benefits. Older patients with BPD often have asthma, characterized by intermittent and reversible airways obstruction during acute respiratory exacerbations, and seem to be highly responsive to bronchodilator therapy.

Corticosteroids

Corticosteroids are synthesized by the adrenal cortex and are composed of mineralocorticoids, which affect fluid and electrolyte balance, and glucocorticoids, which affect the metabolism of many tissues and possess potent antiinflammatory properties (134). Dexamethasone is a synthetic corticosteroid that has been used in the prevention and treatment of BPD. Dexamethasone has multiple pharmacologic effects, although the down-regulation of the inflammatory cascade is thought to be primarily responsible for the improvements in pulmonary function in infants with severe BPD. Clinical studies have consistently shown that steroids acutely improve lung mechanics, gas exchange and reduce inflammatory cells and their products in tracheal samples of patients with BPD (135,136,137). Despite these studies, there have been multiple experimental and clinical studies that have raised concerns that excessive doses and prolonged use of corticosteroids can impair head growth, neurodevelopmental outcome, lung structure and long-term survival (138,139). Additionally, a recent multicenter study was halted prior to completion as a result of a high incidence of GI perforation (140). Steroids (e.g., dexamethasone) should be selectively used at lower doses and tapered appropriately over shorter durations (5-7 days) in ventilator dependent infants with severe, persistent lung disease. Discussions with the family regarding potential risks and benefits should occur prior to the initiation of treatment (139). The use of steroids should be delayed if possible until approximately one month of age. Other side effects include systemic hypertension, hyperglycemia, cardiac hypertrophy, poor somatic growth, sepsis, intestinal bleeding, and myocardial hypertrophy (141,142). Inhaled steroids have been studied, but the major effect was to decrease the perceived need for the use of systemic steroids (143). Recognition that some premature newborns may have adrenal insufficiency that could increase the risk for BPD prompted interest in the use of low dose cortisol replacement therapy (48). A randomized multicenter study was initiated to examine this question, but even this trial was recently halted as a result of excessive side effects in infants receiving low-dose hydrocortisone supplementation.

Physical Therapy

Physical therapy may help overcome various types of motor deficits (144). Infants with RDS and BPD are at increased risk for subsequent gross motor, fine motor, or cognitive developmental delays. To optimize ventilation, these infants use neck extension and accessory muscles. This produces abnormal posture of the neck, scapula, shoulder, and trunk. Efforts to reduce this abnormal posture and normalize tone should be provided in conjunction with a physical therapist. Infants are first positioned in a more neutral alignment. Strengthening of neck and trunk muscles follows this, although independent movements and exploration of the environment through infant stimulation techniques can be performed. A pacifier is used to facilitate and strengthen the suck reflex, especially when the infant is able to tolerate gavage feedings. When infants are fed orally, coordination of breathing, sucking, and swallowing may be difficult. Positioning the infants in natural flexion and using mandibular compression and cheek and upper palate stimulation may be helpful. Nasal oxygen is often necessary to assist the infant in feeding without tiring.

At the time of discharge, a comprehensive home therapy program is implemented. Nursing needs and home physical and occupational or speech therapy are ordered as necessary. Reevaluation at appropriate intervals is scheduled in a neonatal high-risk follow-up program, with emphasis on the possible need for an early intervention program. These treatment programs emphasize teaching parents specific handling, positioning, and stimulation techniques. Normalizing muscle tone and posture and stimulating desired patterns of movements are the goals of these therapies.

OUTCOME

Most neonates who develop BPD ultimately achieve normal lung function and thrive. However, this group of

and developing significant long-term complications. During infancy, continued normal lung growth should result in slow improvement of pulmonary function and weaning from oxygen therapy. Later in childhood, other respiratory problems (e.g., reactive airway disease) and abnormal neurologic development are additional complications that may occur and require careful follow-up. Interpreting outcome studies has become more difficult as a result of the frequent introduction of new treatment modalities such as exogenous surfactant which has significantly influenced neonatal outcome.

Mortality

In Northway's original group of 32 infants, only 13 survived the first month of life (1). Nine (69%) of these survivors developed BPD and five died within the first year of life primarily of pulmonary hypertension and cor pulmonale. The remaining four infants with BPD had persistent respiratory abnormalities that resolved slowly over time. In sharp contrast to this 66% mortality rate, more recent studies have shown a significant improvement in mortality which has continued to fall with the changing epidemiology of BPD. Several surfactant replacement studies have demonstrated significantly improved survival, even in infants who develop BPD. Although Phibbs found a 32% incidence of BPD in his surfactant treatment and control groups, there were no deaths from BPD in the surfactant-treated group and only three deaths in the control group (145). Palta followed a cohort of 533 infants weighing less than 1500 grams who were born between 1988 and 1990 and survived until discharge (6). The incidence of BPD was 25% in this group. Only 9 patients (1.7%) died following hospital discharge, but it is unclear whether these deaths were related to the development of BPD. Twenty-one percent of all infants in this cohort had respiratory problems at 2 years corrected age, which correlated only weakly with a diagnosis of BPD at 36 weeks postconceptual age. In a more recent study from Finland, 211 survivors from the NICU weighing less than 1,000 grams were followed (146). Although 39% of neonates met criteria for a diagnosis of BPD, only one patient died as a result of causes associated with BPD (mortality 1.2%) and none died of sudden infant death syndrome (SIDS). More recent studies from the postsurfactant era suggest that BPD has generally become less severe than seen in the past and is associated with a better outcome if it does develop.

Cardiopulmonary Function

Although pulmonary function in most survivors with BPD improves over time with continued lung growth and permits normal activity, abnormalities detected by pulmonary function testing may remain. Follow-up studies of children with BPD have shown increased airway resistance and reactivity, decreased lung compliance, ventilation-perfusion mismatch, and blood gas abnormalities (e.g., increased PCO_2) that may continue into later years (147,148). These abnormalities appear to correlate extremely well with the presence of clinical respiratory symptoms such as wheezing. Although some authors have suggested that the pulmonary dysfunction is directly related to the development of BPD, others have demonstrated that many mechanically ventilated premature babies (with/without BPD) can have abnormal pulmonary function in later life. Blayney investigated patients with BPD at 7 and 10 years of age and found that although lung growth had occurred normally, residual volumes were increased and forced expiratory volumes and flow rates were reduced (149). Fifty percent of these children had a history of wheezing, suggesting airway hyperactivity. Significant improvement in pulmonary function occurred from years 7 through 10, indicating that pulmonary abnormalities from BPD persist well into childhood and continue to improve slowly over time. Filippone and colleagues reported similar results from a cohort of patients (<1250 grams at birth) with BPD who were followed up to 8-9 years of age (150). At 2 years of age, 66% had abnormalities on pulmonary function testing (diminished maximal flow at FRC). At school age only 16% reported any clinical difficulties, but abnormalities of pulmonary mechanics persisted with forced expiratory volume (FEV1) reduced to 76% of predicted and forced mid-expiratory flow (FEF) (25-75) to 63%. Hakulinen also found lower airway conductance and increased residual volumes in children who had BPD (151). The most significant abnormalities were found in children who had clinical respiratory symptoms, especially early in their childhood (<2 years of age). Although there was an increased need for hospitalization because of pulmonary problems for the first 2 years of life in children with BPD, by 6 to 9 years of age, none had evidence of wheezing or respiratory distress.

As the overall severity of BPD has decreased in recent years, so have the long-term clinical and cardiopulmonary sequelae. Baraldi and colleagues demonstrated progressive improvements in pulmonary function tests over the first 2 years of life, although evidence of airway dysfunction persisted (152). Mitchell and Teague studied

premature infants with and without BPD at 6 to 9 years of age (153). They found reduced soluble gas transfer at rest and with exercise in children with BPD, explained by abnormal pulmonary architecture and/or right ventricular dysfunction affecting cardiac output. It appears that abnormal cardiopulmonary function is greatest in the first 2 years of life in infants with BPD. Survival beyond that age permits children to function at near normal capacity, although persistent abnormalities can be detected into adolescence.

Infection

Increased susceptibility to infection has been documented in infants with BPD. Respiratory syncytial virus (RSV) is a major pathogen that causes illness and the need for rehospitalization and mechanical ventilation in children with BPD. Infants are more susceptible to RSV infection because of impaired lung defenses secondary to damaged lung tissue (154,155). Monthly intramuscular injections of

P.593

monoclonal antibodies (palivizumab) have been shown to decrease the incidence and severity of RSV infection in high-risk premature infants by 55% (156). Indications for use include significantly premature infants who are home and less than 6 months of age during RSV season (November-December to March-April), infants under 2 years of age with BPD, or any preterm infant with BPD who has received supplemental oxygen in the previous 6 months. Other viruses such as rhinovirus and influenza, although not as common as RSV, may also be an important cause of lower respiratory tract disease in infants with BPD (157).

Growth and Neurologic Development

It is not surprising that the most critically ill and premature infants who develop BPD have an increased risk for growth failure and abnormal neurodevelopmental outcome. Infants with BPD have increased metabolic demands and caloric requirements and may grow poorly during infancy and childhood (158,159,160). Markestad observed that children with improving respiratory function exhibited faster catch-up growth, and those with continued respiratory problems failed to do so (161). Other studies have shown that a significant proportion of infants with BPD are consistently in the lower percentiles for height, weight, and head circumference (162). This is frequently found during the first 2 years of life, when respiratory symptoms and illness may be prominent (151). Huysman found that although infants with BPD increased in length, total body fat and free fat mass, growth was significantly less than term controls (163). Gregoire compared growth rates in extremely premature infants with and without BPD and found that significant differences existed at birth, but had resolved by 18 months corrected age (164).

Giacchia studied a group of preterm infants with BPD over the first 2 years of life and compared them to a group of age-matched premature infants and term controls (165). Both groups of premature infants had comparable growth rates and average mean standard scores for Wechsler IQ. However, all of the premature infants were significantly smaller than the term controls and had lower scores for performance and full-scale IQ. Singer found no difference in intelligence between infants with BPD and age-matched premature controls at 3 years of life, but motor function was significantly impaired (166). Hack and associates also followed a group of extremely premature infants who received exogenous surfactant at birth and found that BPD was among the most significant predictors of an abnormal motor developmental index (MDI) (odds ratio (OR) 2.18) and neurologic abnormalities (OR 2.46) (167). Several more recent follow-up studies have confirmed that a diagnosis of BPD continues to be associated with a higher risk for abnormal neurodevelopmental outcome in premature infants (168,169). The relative contribution of BPD to poor outcome continues to be defined. However, infants developing BPD are often the smallest, sickest patients in the neonatal intensive care unit and consequently can develop other conditions such as periventricular leukomalacia, intraventricular hemorrhage, retinopathy of prematurity and sepsis which also appear to be important variables in determining developmental outcome (168).

The introduction of surfactant replacement therapy has resulted in significantly improved survival and the development of less severe BPD. It is reassuring that follow-up studies have found that the number of children with significant neurodevelopmental handicaps has not increased despite the survival of an increased number of smaller, sicker infants who frequently develop BPD.

PREVENTION STRATEGIES

A multidisciplinary approach to the prevention of BPD in infants is needed. The use of antenatal steroids in mothers at high risk of delivering a premature infant may reduce the severity and incidence of BPD (170). The

early use of NCPAP (with or without prior surfactant treatment) may eliminate the need for mechanical ventilation in some premature infants or facilitate successful extubation in others (103). Aggressive treatment of symptomatic patent ductus arteriosus with fluid restriction, diuretics, indomethacin (or possibly ibuprofen), or surgical closure may reduce the severity of BPD. Tidal volumes and inspired oxygen concentrations should be reduced as low as necessary to reduce hypocarbia, volutrauma, and oxygen toxicity. Using more aggressive lung recruitment strategies, such as more liberal PEEP, HFV or perhaps, prone positioning may also be beneficial. The early use of synchronized mechanical ventilation or high frequency ventilation (HFV) in newborn infants with significant RDS may reduce the severity and incidence of BPD (20,21,22). The combined use of HFV and surfactant replacement may prevent significant lung damage in premature and term infants with significant lung disease unresponsive to surfactant replacement and conventional mechanical ventilation (171,172). Further conclusive evidence of the beneficial effects of both synchronized ventilation and HFV in premature infants is needed.

Aggressive nutritional support is critical in helping to promote normal lung growth, maturation, and repair. It also protects the lung from the damaging effects of hyperoxia, infection, and barotraumas (173). Systemic supplementation with vitamin A in sufficient quantities to establish normal serum retinol concentrations has been reported to reduce the incidence of BPD, although the need to administer repeated doses through the intramuscular route over a prolonged period of time has limited the widespread use of this therapy.

Numerous studies have demonstrated that the early use of dexamethasone may reduce the incidence of BPD, presumably by treating cortisol deficiency and minimizing inflammation (138). However, early dexamethasone should not be used to prevent BPD because of significant concerns regarding increased mortality, side effects (e. g., GI perforation) and long-term sequelae (CP) (139,140). A

P.594

promising method for preventing the development of BPD appears to be prophylactic supplementation of human recombinant antioxidant enzymes. This seems to be a logical strategy in preventing BPD, because oxygen free radicals appear to play a major role in the pathogenesis of lung injury and premature infants are known to be relatively deficient in these enzymes at birth. Several animal studies have shown that prolonged exposure to high oxygen concentrations can cause severe lung damage and death, and administration of antioxidants can prevent many of these complications (174,175,176,177,178,179,180,181). Recombinant human CuZnSOD (rhSOD) has been administered prophylactically to the lung of premature infants at high risk for developing BPD. In preliminary studies in premature infants, the prophylactic use of both single and multiple intratracheal doses of rhSOD appeared to mitigate inflammatory changes and severe lung injury from oxygen and mechanical ventilation with no apparent associated toxicity (179,180). In animal studies, the rhSOD appeared to localize both in intracellular and extracellular compartments following intratracheal instillation with significant quantities of active protein present 48 hours after the dose is given (182). Multicenter trials using prophylactic, intratracheal rhSOD in premature infants at high-risk for developing BPD have recently been completed (181). Premature infants (birth weight 600-1,200 g) receiving intratracheal instillation of rhSOD at birth had significantly (44%) less episodes of respiratory illness (wheezing, asthma, pulmonary infections) severe enough to require treatment with bronchodilators or corticosteroids at a median of one year corrected age compared to placebo controls (Fig. 30-8). The largest effects were seen in infants less than 27 weeks gestation, with decreased episodes of respiratory illness accompanied by significant reductions (<50%) in emergency room visits and hospital readmissions (Fig. 30-9). This suggests that rhSOD did prevent long-term pulmonary injury from RDS in high-risk premature infants. Further therapeutic intervention trials are needed to ultimately develop a therapy that can prevent

P.595

or significantly ameliorate this important chronic lung disease.

Asthma Medications

Figure 30-8 The use of asthma medications to treat significant respiratory illness in infants at 1-2 years of age from the multicenter trial of rhSOD in preterm infants. The entire group is presented and a subset of infants <27 weeks gestation at birth. The open bars represent the percent of treated infants in the placebo group and the shaded bars the r-h CuZnSOD group (* $p = 0.05$; ** $p < 0.01$). From Davis JM, Parad RB, Michele T, et al. Pulmonary outcome at 1 year corrected age in premature infants treated at birth with recombinant human CuZn superoxide dismutase. *Pediatrics* 2003;111: 469, with permission.

Figure 30-9 The number of emergency room visits and hospital admissions (all causes) in a subset of infants <27 weeks gestation at birth who had received placebo (open bars) or rhSOD (shaded bars) (* $p = 0.05$; ** $p < 0.01$). From Davis JM, Parad RB, Michele T, et al. Pulmonary outcome at 1 year corrected age in premature infants treated at birth with recombinant human CuZn superoxide dismutase. *Pediatrics* 2003;111:469, with permission.

Another area that is currently being investigated involves protecting the pulmonary vasculature from injury with inhaled NO (INO). INO may not only lower PVR and improve gas exchange, but may also enhance distal lung growth and improve long-term outcome. Extensive laboratory and clinical studies suggest that INO lowers PVR and improves oxygenation in patients with pulmonary hypertension, including premature infants with severe RDS and BPD (183,184). However, there are persistent concerns about potential toxicity and adverse effects of INO therapy in premature infants (185). Experimental data have suggested that INO therapy may be "lung protective" in several animal models, including premature lambs with RDS (186). Whether INO therapy has a potential role in the prevention of pulmonary vascular injury in premature newborns at risk for BPD is unknown. A multicenter clinical trial of low-dose INO therapy (5 ppm) was recently performed in severely ill premature newborns with RDS who had marked hypoxemia despite surfactant therapy (183). In this study, INO acutely improved PaO₂, but did not improve survival. Notably, there was no increase in the frequency or severity of intracranial hemorrhage or BPD, and the duration of mechanical ventilation was reduced. Based on these

findings, a multicenter trial is now underway to determine whether early treatment with low dose INO therapy will prevent the early inflammatory changes that contribute to BPD, and protect the pulmonary circulation from injury during this critical time period.

Chapter 31

Principles of Management of Respiratory Problems

William E. Truog

Sergio G. Golombek

Although the principles of management of respiratory disorders are constant, the techniques of treatment have become more complex recently because of increasing and increasingly sophisticated technology. This complexity results from the incorporation into routine care of highly technical equipment and the necessity for skilled personnel—dedicated to the smooth functioning of life-sustaining devices. Knowledge of the pathophysiology of lung disorders and the maturational status of the lung is essential to applying the imperfect evidence derived from clinical trials and from experience to everyday use of assisted ventilation.

The goal of respiratory treatment is to provide tissue oxygenation and carbon dioxide (CO₂) removal in a safe and effective manner. Excessive oxygen delivered to the airways or to organs can be harmful. Excessive lung distention can result in stretching and tearing of the lung. Excessive alveolar ventilation with resultant respiratory alkalosis and hypocarbia can in a detrimental manner alter blood flow distribution and oxygen unloading. In contrast, respiratory and/or metabolic acidosis may constrict pulmonary blood vessels, thus affecting pulmonary blood flow and oxygen uptake. Attention to organ system dysfunction other than the lung must occur in parallel with respiratory management or the efforts directed to optimizing delivery of assisted ventilation will be useless. One of the most challenging aspects of ventilatory treatment is the dynamic way in which the ventilatory needs can change because of either the treatment applied or the progression of the underlying disease. This chapter reviews the indications, methods, and complications of respiratory management and available methods of assessment.

OXYGEN THERAPY

Optimal Level Of Oxygenation

Considerable debate has occurred about what constitutes an acceptable level of oxygen tension or hemoglobin saturation, especially in extremely preterm infants (1). The debate has focused on the contribution of excessive or of insufficient supplemental oxygen levels and hence levels of arterial pO₂ in the etiology of multiple disorders of prematurity. These disorders include central nervous system injuries, especially leukomalacia or hemorrhagic infarction; development or progression of retinopathy of prematurity (ROP); chronic lung disease of prematurity; and perhaps other disorders associated with excess level of reactive oxygen species (ROS).

Because of the direct relationship between elevated fraction of inspired oxygen (FiO₂) and arterial oxygen partial pressure (PaO₂) and the generation of ROS, it is reasonable that the arterial partial pressure of oxygen (PO₂) and/or oxyhemoglobin saturation be minimized to a level sufficient to allow adequate oxygen tissue delivery with satisfactory reserves. There are several practical limitations to this seemingly innocent idea. Cardiopulmonary status of extremely preterm babies is inherently unstable. There is intrinsic cyclicality to such physiologic events as cardiac output and to spontaneous respiration rate and depth, and the variable contribution of spontaneously generated respirations in addition to those associated with assisted respiration.

Hemoglobin concentration is subject to significant changes and the relative quantity of the various forms of hemoglobin can change rapidly over the first days and weeks (e.g., decreasing fetal hemoglobin and increasing adult hemoglobin). As this occurs, the relationship between partial pressure of oxygen tension and oxygen saturation can change in somewhat unpredictable ways in short periods of time. Relying on only one measurement exclusively (e.g., PaO₂ or pulse oximeter saturation [SpO₂]) either may mask or may exaggerate changes in the tissue oxygen delivery. Hemoglobin concentration is measured per mL or 100 mL of blood, but the actual blood volume, and hence total body hemoglobin concentration, can vary in sometimes unpredictable ways also.

The overall limitation in assessing tissue gas exchange is that all the elements of tissue oxygen delivery are not routinely assessed at bedside. For example, arterial blood pressure measurements, either by sphygmometry or by direct arterial measurement, do not measure cardiac output or oxygen tissue delivery. Clinicians have available only summary information, at best, of total body oxygen delivery and consumption. In fact the body might be considered as interdependent organs with individualized oxygen consumption. Satisfactory levels of oxygen delivery in one or most of these may not be satisfactory for a particularly high-consuming area, and interorgan changes and distribution of blood flow can have a marked impact on local oxygen tissue delivery and consumption and hence on the risk of organ-specific ischemic injury.

For babies treated with assisted ventilation, it is possible to manipulate arterial oxygen tension, perhaps at the cost of other kinds of injury, especially to the lung. The tradeoff between mean airway pressure and FiO_2 in the treatment of conditions associated with low end expiratory volume (e.g., respiratory distress syndrome or RDS) is one example of a difficult balancing act in clinical medicine. Central venous sampling or selective sampling of organ specific venous drainage would be crucial to optimizing the pressure FiO_2 -dichotomy, but obtaining that information is impractical.

Two randomized studies (2,3) and one case series (4) demonstrated that maintaining pulse Doppler oximetry levels in a higher end of normal range in a group of babies with progressive ROP did not result in reduced progression of ROP, but was associated with borderline statistically and clinically significant increases in pulmonary problems. However, Schultz and associates (5) demonstrated that with oxygen saturation and FiO_2 maintained in a lower range of "normal," there appeared to be an elevated pulmonary vascular resistance (PVR) and subsequent VA/Q mismatch (Fig. 31-1). Should episodes of lower SpO_2 and higher PVR be exacerbated, then altered gas exchange with acute elevations in CO_2 and subsequent ill effects on cerebral circulation could develop. The interdependency of these variables has meant that at present it is difficult to recommend, based on clinically relevant outcomes, a proper oxygen level.

Figure 31-1 Relationship between venous admixture and PaO_2 . From Schulze A, Whyte RK, Way RC, Sinclair JC. Effect of the arterial oxygenation level on cardiac output, oxygen extraction, and oxygen consumption in low birth weight infants receiving mechanical ventilation. *J Pediatr* 1995;126 (5):777, with permission.

An arterial PaO_2 of 45 mm Hg results in a saturation of fetal hemoglobin (HbF) of approximately 90%. Maintaining the PaO_2 above 50 mm Hg should be sufficient for tissue oxygen needs but excessive levels are quickly achieved. Mitochondrial PO_2 is about 2 mm Hg.

The gap between the alveolar partial pressure of oxygen (PaO_2) and the PaO_2 indicates the magnitude of the arterial O_2 gradient across the lungs and provides an indication of the magnitude of right-to-left shunting of blood. A simplification of the alveolar air equation provides an estimate of PaO_2 i.e., $PaO_2 = PiO_2 - PaCO_2$.

Because at sea level the barometric pressure, minus water vapor pressure, is approximately 700 mm Hg, the percent of inspired oxygen multiplied by 7 equals PiO_2 in mm Hg (e.g., 21% [approximate, equals] 147 mm Hg,

50% [approximate, equals] 350 mm Hg). Because PaCO₂ approximates PACO₂ because of a usually small arterial-alveolar CO₂ gradient (aADCO₂), PaCO₂ can be substituted for PACO₂, and PAO₂ can be derived. For example, if an infant is breathing gas with FIO₂ of 0.6, with the measured PaO₂ of 70 mm Hg and the PaCO₂ of 40 mm Hg, the PAO₂ = 420 - 40 = 380 mm Hg, and the alveolar-arterial gradient for O₂ (AaDO₂) approximates 310 mm Hg. In an infant without either lung disease or a significant right-to-left cardiac shunt, the AaDO₂ should not exceed 25 mm Hg while breathing ambient air. Infants with severe RDS may have an AaDO₂ in excess of 500 mm Hg while breathing 100% oxygen.

Oxygen Delivery

Each gram of HbF binds 1.37 dL of oxygen. The full-term newborn with a hemoglobin (Hb) of 17 g/dL binds and transports 23 dL of oxygen per 100 dL of blood. Less than 2% of transported O₂ is carried as oxygen dissolved in plasma. Normal tissue oxygen consumption extracts 4 mL O₂/100 mL if oxygen consumption and cardiac output are normal. HbF binds oxygen with a greater affinity than adult HbA. The oxyhemoglobin saturation curve is nonlinear, and the P₅₀, the PaO₂ at which Hb is 50% saturated, increases with gestational age (Fig. 31-2). The higher the P₅₀, the greater the driving pressure for oxygen unloading. The curve gradually shifts to the right as hemoglobin A increases after birth. Several factors can adversely affect tissue oxygen delivery, including decreased cardiac output, maldistribution of cardiac output, arterial vasoconstriction, and shifts in the O₂ dissociation curve. Oxygen unloading in the tissues is increased with a shift to the right of the O₂ dissociation curve (i.e., decreased O₂ affinity of Hb) facilitated by a local decrease in pH, increase in PaCO₂, and increase in temperature. A shift to the right of the O₂ dissociation curve can result from transfusion of adult red blood cells. Oxygen uptake depends on adequate

P.602

alveolar ventilation (V_A), an appropriate ventilation-perfusion match in the lungs, and absence of right-to-left shunting. Oxygen uptake or increased O₂ affinity of Hb (associated with a shift of the curve to the left) is enhanced by alkalosis, decreased temperature, decreased 2,3-diphosphoglycerate, and increased HbF.

Figure 31-2 Oxygen equilibrium curves of hemoglobin at birth, 2 months of age, and adulthood. Note the increase in P₅₀ with age.

Oxygen Administration

There are two methods by which to deliver supplemental oxygen to neonates: an oxygen hood with sufficient

gas flow to prevent CO₂ retention and a nasal cannula or prongs. The concentration and the rate of flow are varied, and the precise amount of oxygen delivered to the lungs by nasal prongs is difficult to determine. This is because there may be dilution of inspired air through ill-fitting prongs or through an open mouth. Estimates of the effective FiO₂ have been based on patient's weight, gas flow rate, and concentration of oxygen blended in the blender (6). The O₂-air mixture should be warmed to the same temperature as the incubator air, which should be in the range of thermal neutrality (see Chapter 24).

ASSESSMENT OF GAS EXCHANGE

Clinical Assessment

The infant with respiratory problems may present with a wide spectrum of clinical findings. The infant's response depends on the degree of prematurity, lung and chest wall development, and maturation of respiratory control. The full-term infant may be able to increase the work of breathing to accomplish adequate gas exchange without treatment, including oxygen administration. The extremely premature infant will have a much weaker respiratory drive and inadequate muscular development and, thus, is less able to compensate for lung abnormalities. The classic clinical signs of respiratory distress are helpful in the assessment of the mature newborn infant. Nasal flaring, grunting respirations, and tachypnea are almost always present. With progression of lung disease and decreased lung compliance, chest wall retractions become more marked. With increased work of breathing, retractions progress from sternal to subcostal, to intercostal, and then to a seesaw pattern of chest and abdominal wall movement. The full-term infant may increase respiratory rate above 100 per minute, with shallow respirations. This pattern is the most efficient way to increase gas exchange, with the least costly work of breathing. Expiratory grunting represents an effort to retard expiratory flow to increase end-expiratory pressure and maintain alveolar patency. It is unsafe to rely on color changes as an indication of oxygenation, as abnormalities in peripheral perfusion as a result of poor cardiac output, hypotension, or hypovolemia may be misleading. Similarly, infants with recurrent apnea will have intermittent deficiency in gas exchange. Auscultation assists in determining the quality of air entry in various parts of the lung and the presence of airway secretions or obstructions.

Measurement and Techniques

The measurement of blood gases and pH helps to confirm clinical impressions, and verifies the values obtained by pulse oximetry, transcutaneous electrodes, and end-tidal CO₂ monitoring. Most importantly, it helps to minimize the risks of hypoxia, hyperoxia, hypocapnia, hypercapnia, and metabolic acidosis.

Blood Gas Tension Measurements

Blood may be obtained by puncture of a peripheral artery, cannulation of a peripheral or umbilical artery, venous blood sampling, or capillary puncture. Venous and/or capillary blood values provide an approximation of arterial partial pressure of CO₂ (PCO₂) and pH but limited information about arterial oxygenation. The PCO₂ in venous blood is approximately 6 mm Hg higher and the pH is 0.03 lower than in arterial blood.

Peripheral arterial blood most often is sampled from the radial or posterior tibial arteries using a 23- or 25-gauge needle. Peripheral puncture is indicated when the anticipated number of samples will be small, or if arterial cannulation is unsuccessful. The painful nature of the procedure may result in altered breathing and a spurious result.

Cannulation

The choice of peripheral artery or umbilical artery catheterization usually is determined by the size of the infant, and the anticipated duration of the cannulation. The major advantage of a peripheral arterial catheter is the avoidance of umbilical cannulation and risk of thrombosis. A right radial arterial catheter has the unique advantage

of sampling preductal PaO₂, which more accurately reflects retinal artery PO₂.

The need to insert a catheter into the umbilical artery should be based on the infant's maturation, postnatal age, and the type, severity, and expected duration of the illness. The high incidence of thrombus formation on the catheter tip, with its attendant risk of mural thrombus or emboli, must be weighed against the potential benefits to the infant. The tip of the umbilical catheter should rest in a low or high position to avoid the risk of occlusion, thrombosis, or direct infusion into a major branching artery. The distance to various levels within the aorta is estimated from the infant's shoulder to umbilicus distance and the chart of Dunn (Fig. 31-3) (7). The high location range is below the ductus arteriosus and above the takeoff of the celiac artery, with the tip resting between T5 and T10. At the lower site, the tip should be above the bifurcation of the aorta (L3 to L5) and below the takeoff of the renal and inferior mesenteric arteries. There appears to be a higher complication rate with catheters in the low position. The higher position allows greater leeway for catheter migration, although there is a greater risk of downstream embolization. A thoracoabdominal radiograph should be obtained immediately after catheter placement and before medications are infused. Once the catheter is in place, there is a risk of intraluminal clotting. Therefore, a continuous infusion is required, as is flushing of the line following blood sampling. Heparinization of fluid infusions is performed in many special care nurseries routinely. The umbilical arterial catheter fluids serve as a site of low grade hemolysis. Amino acid containing fluids can reduce this risk and supply some necessary protein constituents (8). A pressure strain gauge should be connected to the catheter, with alarm limits to indicate changes in blood pressure. Dampening of the pressure waveform indicates intraluminal or catheter tip narrowing or obstruction. The catheter should be removed once the infant has improved, the frequency of blood gas determinations has decreased to once or twice per day, and systemic arterial pressure monitoring no longer is essential.

The complications of umbilical artery catheterization are listed in (Table 31-1). The most frequent problem is peripheral vasospasm associated with blanching or patchy cyanosis (See Color Plate) of the distal leg, foot, or toes. If this does not improve with reflex vasodilation by warming of the contralateral leg, or worsens over the next 15 to 20 minutes, the catheter should be removed. Some thrombosis at the catheter tip is inevitable. Fortunately, the rate of complications from thrombus formation is relatively low.

Transcutaneous PO₂ and PCO₂

Transcutaneous PO₂ monitoring can be used selectively in conjunction with pulse oximetry. Most devices contain oxygen (O₂) and CO₂ electrodes. Noninvasive PO₂ measurements continue to be helpful in certain situations, particularly if transcutaneous PCO₂ also is obtained. Calibration before use and correlation with an arterial sample are necessary, but the need for subsequent blood samples should be reduced.

Figure 31-3 Relation between the shoulder-to-umbilicus measurement and the length of umbilical artery catheter needed to reach the aortic bifurcation, diaphragm, and aortic valve. From Dunn PM. Localization of the umbilical catheter by post-mortem measurement. Arch Dis Child 1966;41:69, with permission.

Arterial PO₂ and transcutaneous PO₂ are not identical. Differences can arise from local O₂ consumption by the skin or by the electrode itself, heating of the skin, O₂ diffusion time, and response time of the electrode (9). Skin blood flow may be affected by vasopressor medications, hypotension, and shock (10). Use of transcutaneous PO₂ can reduce the number of blood sampling procedures, particularly during a period when rapid changes in O₂ administration or mechanical ventilatory settings are taking place. Continuous monitoring for several hours also allows assessment of changes as a result of position, handling, suctioning, and feeding and for comparison with arterial oxygen saturation (SaO₂) monitoring. The risk of partial thickness burns precludes its use for longer than 5 hours at a single site on the body.

TABLE 31-1 COMPLICATIONS OF UMBILICAL CATHETERIZATION

Complication	Incidence	Comment
Limb ischemia	<20%	Assess Doppler arterial and venous flow from femoral region to dorsalis pedis; if reflex and unilateral, apply warmth to contralateral extremity; if persistent (>15 min), remove catheter
Thrombosis	<90%	Assess by aortic ultrasonography
Infection		Remove in presence of gram-positive blood culture if catheter was inserted more than 24 h previously; no relation to duration of catheter
Colonization	57%	
Sepsis	5%	
Blood loss	Rare	Connection to blood pressure transducer with alarm should prevent significant loss
Vascular perforation	Extremely rare	On removal, clamp for 5-10 min

Pulse Oximetry

Pulse oximetry provides a safe, accurate, and noninvasive adjunct to the assessment of tissue oxygenation (11,12). Oxygen saturation is determined by infrared spectrometry, utilizing two electrodes and a small cuff that can be placed around a hand, foot, or toe without requiring heating or calibration. One electrode contains two diodes that emit light at two wavelengths: red at 660 nm and infrared at 940 nm. The other electrode senses the light from both of these diodes that has not been absorbed by blood or tissue. The relative concentration of hemoglobin-oxygen (HbO₂) and deoxyhemoglobin determines the amount of transmitted light, because different forms of Hb have markedly different absorption characteristics. The ratio of the amount of light absorbed at each wavelength is used to calculate a SaO₂ value. The pulsed element of the apparatus allows the instrument to differentiate added arterial blood oxygenation and absorption from tissue, and it subtracts the amount contributed by nonpulsatile venous blood flow. With PO₂ values greater than 40 mm Hg, the saturation accurately reflects measurements of PO₂ obtained by catheter sample or by transcutaneous PO₂ (12).

A PaO₂ of 60 to 90 mm Hg results in a saturation value of 94% to 98% (see Fig. 31-2), and changes of 1% to 2% usually reflect a PaO₂ change of 6 to 12 mm Hg. The point of inflection at which the HbO₂ dissociation curve

grows steep has considerable variability and depends on proportions of hemoglobin A, HbF, PCO_2 , pH, and temperature. Generally, these variables are not so critical to the interpretation of the percent SaO_2 in arterial blood as they are to PaO_2 . Below 40 mm Hg, the SaO_2 falls below 90%. Poor correlation with PaO_2 exists when the SaO_2 is above 96%, in which case the PaO_2 may be well above 100 mm Hg. In very low birth weight (VLBW) infants who require chronic oxygen administration and who are at risk for developing ROP, the upper limit of saturation should be reduced to 95% or less depending on local nursery policies. Inaccuracies may reflect improper placement, movement, or peripheral ischemia. Motion artifacts also produce invalid readings. However, these problems are less significant with newer pulse-Doppler devices.

Near-Infrared Spectroscopy

Utilization of the unique light-absorbing properties of Hb and HbO_2 , as used in pulsed oximetry, has led to a sophisticated method of appraising tissue oxygenation by means of near-infrared spectroscopy. Near-infrared light penetrates the skin, bone, and various tissues and can be detected by electrodes placed on opposite sides of an infant's skull. This permits assessment of cerebral tissue O_2 and alterations in cerebral blood volume. Hb and cytochrome a and a_3 (cyt a, a_3) change their absorption characteristics according to the degree of oxygenation. The wavelength at which maximal absorption occurs is different for HbO_2 , deoxygenated Hb, total Hb, and reduced and oxygenated cyt a, a_3 . The small cranial size of the infant weighing less than 1500 g makes cross-temple spectroscopy feasible. However, the technique has not gained widespread use in clinical neonatology.

End-Tidal CO_2 Monitoring

The concentration of CO_2 at the mouth or nose rises to reach a plateau at the end of each breath. This plateau reflects the alveolar CO_2 concentration under normal conditions, but may be inaccurate if there is marked ventilation-perfusion inequality or inhomogeneity of lung disease. Recent refinements to end-tidal CO_2 detection equipment permit in-line or "mainstream" infrared monitoring just proximal to the endotracheal tube (capnography), with a continuous display of the PCO_2 waveform. There is minimal dead space of the apparatus, and sampling accuracy has improved to compensate for the low expiratory flow rates characteristic of small premature infants. End-tidal CO_2 is less reliable in extremely small premature infants. Capnography is as accurate as capillary PCO_2 but is less precise than transcutaneous monitoring (13,14,15).

Hazards of High or Low Arterial CO_2

Identifying a safe range of PCO_2 has proven as difficult as for PaO_2 . There are substantial risks to hypocarbia (Fig. 31-4)

P.605

(16) (Table 31-2). Limiting the exposure time to hypocarbia may be important in preventing the development of cystic periventricular leukomalacia or decreasing the risk of CLD (17,18 and 19). There has been an increase in use of permissive hypercarbia, by which PaCO_2 levels of 50 to 60 mm Hg are sought and maintained. The rationale is to avoid high peak inspiratory pressure or to delay the onset of or to avoid assisted ventilation (20,21).

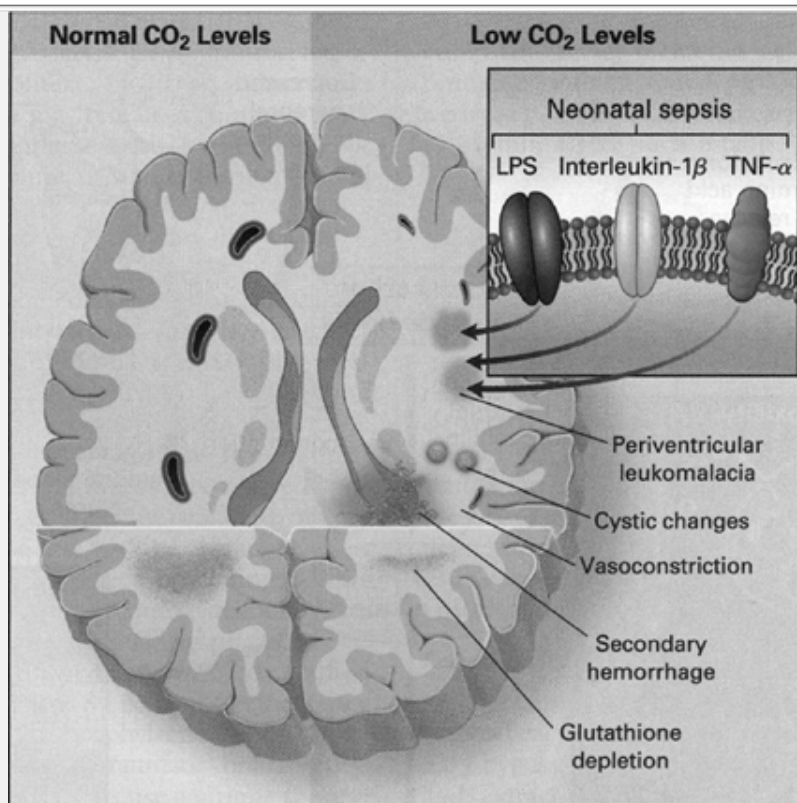

Figure 31-4 Effects of Hypocapnia on the Brain in Premature Infants. Hypocapnia has been implicated in the pathogenesis of neonatal white-matter injuries, including periventricular leukomalacia, resulting in intraventricular hemorrhage. At normal carbon dioxide levels (left-hand side of figure), cerebral blood flow is determined by local metabolic demand. Prolonged or severe hypocapnia includes severe cerebral vasoconstriction, resulting in brain ischemia, particularly in poorly perfused areas of the brain such as watershed areas (right-hand side of figure). This ischemia may initiate white-matter destruction in the brain of premature infants. Additionally, antioxidant depletion (caused by excitatory amino acids), lipopolysaccharide (LPS), and cytokines produced in response to sepsis, such as interleukin-1 β and tumor necrosis factor α (TNF- α), potentiate the process. Finally, restoration of the normal partial pressure of arterial carbon dioxide can result in cerebral vasodilation, which may precipitate or contribute to intraventricular hemorrhage. From Laffey JG, Kavanagh BP. Hypocapnia. *N Engl J Med* 2002;347 (1):43, with permission.

STRATEGIES FOR RESPIRATORY SUPPORT

Continuous Positive Airway Pressure

The application of end-expiratory pressure is intended to prevent alveoli and/or terminal airways from collapsing to airlessness. Continuous positive airway pressure (CPAP) may be applied during spontaneous breathing or as positive end-expiratory pressure (PEEP) during mechanical ventilation. This usually requires pressures between 4 to 6 cm H₂O for CPAP and 3 to 8 cm H₂O for PEEP.

TABLE 31-2 RISKS OF HYPOCARBIA AND HYPERCARBIA

Hypocarbica

- Overventilation increases risk for pulmonary injury
- Decreases cerebral perfusion, associated with ischemic whitematter injury
- Increase in pH, interfering with tissue O₂ unloading

Hypercarbica

- Underventilation may increase areas of lung collapse and increase VA/Q mismatching necessitating higher F_IO₂
- May decrease pH elevating pulmonary vascular resistance and increase VA/Q mismatching

- Increases cerebral perfusion with associated risk of hemorrhagic infarctions

The physiologic effects of CPAP/PEEP may vary depending on the underlying pulmonary pathology, although the primary goal is to prevent alveolar collapse. Grunting respirations in infants with respiratory distress suggest laryngeal narrowing and increased resistance to expiratory flow to increase end-expiratory alveolar pressure. In the surfactant-deficient state, alveoli will collapse at end-expiration unless a minimum distending pressure is maintained. CPAP of 3 to 4 cm H₂O will prevent alveolar collapse but will not recruit atelectatic alveoli. Opening pressures of 12 to 15 cm H₂O are required to inflate collapsed alveoli. The infant will need to create a large distending airway pressure in the absence of CPAP. The shear forces from opening and closing of small airways may contribute to alveolar epithelial damage. Additionally, resultant abnormal distending forces on terminal or respiratory bronchioles will contribute to small airway injury. CPAP above physiologic levels of 3 to 4 cm H₂O may cause overinflation of some alveoli. Therefore, inflation and deflation may occur on the flatter portion of the pressure-volume curve and increase the work of breathing. CPAP theoretically could stimulate surfactant secretion. Maintenance of alveolar volume will reduce right-to-left shunting of blood through atelectatic alveoli, hence reducing oxygen needs.

Indications

The clinical indications for CPAP are varied. Initial use was directed at infants with RDS with the goal of avoiding or at least delaying intubation and mechanical ventilation. The gestational age, birth weight, and stage and severity of respiratory disease should be factored into the decision to initiate CPAP. If infants have severe lung disease, e.g., meconium aspiration, severe respiratory distress syndrome with FiO₂ needs <6, or idiopathic pulmonary hypertension, more appropriate therapy would include assisted ventilation.

Infants <1,000 g birth weight are at considerable risk for developing chronic lung disease (CLD) and recurrent apneic episodes; therefore, they commonly are intubated and supported with mechanical ventilation as a result of

P.606

their inability to sustain an adequate respiratory effort. They often develop an increasing oxygen need during the second week of life, associated with radiographic signs of CLD and attributed, in part, to assisted ventilation. CPAP may be beneficial in maintaining patency of extremely small terminal airways and prealveolar gas exchange units in these very immature infants. CPAP appears to be well tolerated by such infants over a period of many days. The increased enthusiasm for the use of CPAP is stimulated by the desire to minimize or prevent CLD. Because assisted ventilation is one putative factor in the etiology of CLD, the use of CPAP shortly after birth to avoid or minimize barotrauma has much appeal. Avoidance of endotracheal intubation should decrease the chances for tracheal injury, airway infection, abnormal mucociliary function, and over-inflation from excess ventilator pressure or volume.

Brief intubation and the administration of a single dose of surfactant followed by nasal CPAP has been advocated as another method of reducing the need for mechanical ventilation in infants with moderate RDS (22). Improvement in gas exchange has been demonstrated; however, more evidence of its efficacy in reducing the incidence or severity of CLD is required.

Recurrent Apnea

CPAP helps some infants with recurrent apnea of prematurity to sustain a more regular respiratory rate. The mechanism of its action is not well understood, although an increase in functional residual capacity (FRC) may alter the Hering-Breuer reflex or stabilize the thoracic cage, minimizing chest wall distortion and possibly altering inhibitory spinal cord reflexes (23). CPAP also helps to overcome obstructive apnea and decreases total respiratory system resistance (24,25).

Earlier methods of applying CPAP utilized an enclosed head box, face masks, and nasopharyngeal tubes. More recently, nasal prongs have been adapted to fit most infants. One device (the ALADDIN Infant Flow System, Hamilton Medical Inc., Reno, NV) appears to be well tolerated by both large and small infants. This apparatus maintains a constant flow of air by incorporating a double fluidic jet system within the apparatus. During inspiration, one jet maintains the flow to match the infant's inspiratory effort; during expiration, gas flow is reversed by a second jet to assist outflow while maintaining a constant minimum pressure. This system

presumably does not add to the work of breathing and reduces the need to use high flow rates to compensate for air leak around the nasal prongs. A second system utilizes a variable depth water seal for the expiratory circuit to sustain continuous airway pressure (26). CPAP can also be applied utilizing constant flow ventilators.

Complications

CPAP may have adverse effects. Overinflation can result in increased work of breathing and decreased efficiency of gas exchange. Pneumothorax and pneumomediastinum may result from lung overdistension. Carbon dioxide retention may occur as a result of either increased dead space or ineffective ventilation of some alveoli. If the mean thoracic pressure is elevated with high levels of PEEP or CPAP, e.g., above 7 to 8 cm H₂O in the absence of lung disease, cardiac output may be decreased because of impaired systemic and pulmonary venous return. The nasal prongs may cause irritation if the fit is not appropriate or the infant is active. Gastric distention may occur, making gastric feedings difficult, and often an indwelling or gastric tube is required for decompression.

Effectiveness

Does the use of CPAP decrease the need for assisted ventilation and does it prevent or ameliorate CLD in VLBW infants? Clinical trials conducted before the era of routine surfactant use and contemporary neonatal ventilation devices are now of limited relevance. Recent studies comparing the efficacy of conventional mechanical ventilation (CMV) to CPAP following the administration of surfactant found some differences in need for ventilation as an outcome although the number of infants studied was small (22,28).

CPAP is used to facilitate weaning from mechanical ventilation. Some infants, experiencing recurrent apneic episodes, appear to benefit (29), whereas infants evaluated in other studies have shown no benefit (30). Additional information is needed to confirm whether CPAP is an effective adjunct to successful extubation. The technique of nasal intermittent positive pressure ventilation (NIPPV) may gain widespread use if it can be shown to improve long-term outcome (31).

Assisted Mechanical Ventilation

Treatment with assisted ventilation is applied commonly to newborns across the neonatal birth weight spectrum (Fig. 31-5) (32). Illustrated is the rate of use of assisted ventilation, adjusted by birth weight, and the percent of all infants treated for more than or equal to 24 hours. Thirty-eight percent of treated infants were over 2,500 g birth weight in this survey, covering all California and New York State births for 1994-1995. Neonatologists must be expert in providing assisted ventilation across a 10-fold range of patient weight (0.5 kg-5.0 kg) and providing safe and effective assisted ventilation across a range of lung development from premature airways with preacinar gas exchange spaces to a virtually completely alveolarized organ. Thus, both size (patient and lung volume) and range of development are immense.

The Immature Lung

The immature lung presents a special hazard for the application of assisted ventilation. The application of positive pressure for the purpose of increasing ventilation and optimizing ventilation-perfusion (V/Q) matching may injure

P.607

epithelial and endothelial tissues. In the incompletely developed lungs, structures are less elastic and more vulnerable to barotrauma. Injury to the mesenchymal and epithelial tissues that later give rise to alveolar septation and vascular formation may be irreversible. Studies in adult animals have demonstrated that otherwise healthy lungs can suffer injury, which is reflected by increased airway fluid and deterioration of gas exchange, if inappropriate distending lung pressures are applied (33). The particular problems of providing assisted ventilation are illustrated in Fig. 31-6 (34). Relative immaturity of distal bronchioles and respiratory ducts, coupled with fluid-filled and collapsed alveoli, create a set of conditions leading to overdistention of some areas and underventilation of other areas, with resultant ineffective gas exchange. This uneven ventilation, coupled with injury produced by reactive oxygen species, contributes to the common problem of chronic lung disease of prematurity. The risk of its development is inversely correlated with birth weight.

Figure 31-5 Distribution of total births and neonatal mechanical ventilation by birth weight. The primary y axis is the mechanical ventilation rate per 1000 live births within a given weight category. The secondary y axis is the percentage of all births and of all mechanical ventilation hospitalizations. Data are from New York and California for 1994. Higher mechanical ventilation rates are seen in smaller babies. However, because most babies are >2500 g, a large proportion of ventilated babies are of normal weight. From Angus DC, Linde-Zwirble WT, Clermont G, Griffin MF, Clark RH. Epidemiology of neonatal respiratory failure in the United States. Projections from California and New York. *Am J Respir Crit Care Med* 2001;164:1154, with permission.

Great strides have been made in understanding how the immature lung differs from a mature lung in phospholipid and surfactant-associated protein biosynthesis. However, there are factors other than surfactant biosynthesis that are unique to the immature lung and that increase the susceptibility to injury. These factors include, but are not limited to, incomplete development of the supportive net of collagen and elastin (35,36), incomplete development of the capillary bed in the gas exchange areas (37), relative instability of the chest wall with reduced capacity to maintain expiratory lung volume at FRC, immaturity of the neural control producing sustained spontaneous respiratory effort, and probable immaturity of the metabolic functions of the pulmonary endothelium.

Respiratory failure ensues when spontaneous breathing efforts fail to produce adequate alveolar ventilation. In newborn infants, this may occur because of failure of adequate output from central nervous system respiratory centers, an overly compliant chest wall that increases the work of breathing, metabolic problems as a result of limited energy stores, or profoundly noncompliant lungs requiring more work and depleting available energy stores. Each of these may be an indication for assisted ventilation. In most neonatal respiratory disorders, these problems occur in combination, and the diagnosis of respiratory failure cannot be ascribed to any single cause.

Establishment of an Artificial Airway

PHYSIOLOGIC AND ANATOMIC AIRWAY PECULIARITIES

The newborn infant has distinct anatomic and physiologic characteristics of the airways and a strong preference for nasal breathing for the first few months of life (38). Nasal or nasopharyngeal obstruction because of secretions, mucosal

injury, or congenital abnormalities may produce respiratory distress. Approximately one-half of the infant's airway resistance occurs in the nose, although the narrowness of the lower respiratory tract results in a total

airway resistance approximately 15 times greater than that of an adult (39). Edema and inflammation can produce extremely high resistance to air flow in these narrow airways. During expiration, the airways become narrower, and resistance increases.

Figure 31-6 A: A mature alveolar duct and alveoli. Dotted line, surfactant; P_{ALV} , alveolar pressure; P_{AW} , airway pressure; P_{PL} , pleural pressure; F_i , tissue force (stretched springs) acting inward; F_o , tissue force directed outward; T_w , wall tension or recoil pressure. B: The end-expiratory airway pressure (P_{AW}) equals zero in an immature distal airway (left). The saccules (SAC) and airways contain fluid (shaded area). The axial airway is concave at the air-liquid interface as a result of the surface tension forces. The peripheral SACs are collapsed or fluid filled. The lax tissues are represented by relaxed springs. The inspiratory airway pressure (P_{AW}) is equal to 26 cm H₂O (right). The distended distal airway has a high wall tension (T_w). The liquid front has been pushed peripherally, but the SACs are still not inflated. From Thibeault DW, Lang MJ. Mechanisms and pathobiologic effects of barotrauma. In: Merritt TA, Northway WH Jr, Boynton BR, eds. *Bronchopulmonary dysplasia. Contemporary issues in fetal neonatal medicine*. Boston: Blackwell Scientific Publishers, 1988:82, with permission.

Endotracheal Intubation

Route

Orotracheal and nasotracheal intubation may be used for prolonged mechanical ventilation of term and premature infants. The principal advantage of the nasal route is the stabilization of the tube afforded by the close fit within the naris, but the nasal passages may limit the size of tube that can be used. Necrosis of the nasal septum or the alae nasi can occur if circulation is impaired because the tube is too large. Orotracheal intubation is more easily and quickly accomplished and is indicated for delivery room and emergency situations. It is the preferred route for prolonged mechanical ventilation.

The endotracheal tube should allow a small air leak between the tube and the glottis. A tube that fits too snugly within the trachea is likely to cause pressure necrosis of the mucosa. If too large a leak is allowed, it may be difficult to achieve sufficient pressure for ventilation of noncompliant lungs. A tube with a 2.5-mm inner diameter usually fits infants weighing less than 1,000 g; a 3-mm tube fits those from 1,000 to 2,000 g; a 3.5-mm tube fits those from 2,000 to 3,000 g; and 3.5- to 4.0-mm tube fits larger infants.

Technique

Orotracheal intubation is a simple procedure that can be accomplished atraumatically within a few seconds. The necessary equipment consists of a straight-bladed laryngoscope, a suction catheter connected to a suction apparatus, an endotracheal tube of the appropriate size with an adapter for the bag or respirator, and an optical flexible Teflon introducer, bent to prevent its tip from protruding beyond the end of the endotracheal tube. The infant is ventilated with 100% oxygen by mask for a few breaths. A catheter to deliver oxygen can be taped to the laryngoscope blade to enhance oxygen delivery during intubation (40). The infant's neck is straightened

without hyperextension by placing a small towel under the shoulders, and the head is steadied by an assistant. The laryngoscope is

held in the left hand between the thumb and first two fingers. The heel of the hand is placed against the infant's left cheek to provide stability. The blade is introduced into the right side of the mouth, and the tongue is deflected to the left as the blade is advanced into the vallecula, anterior to the epiglottis. The laryngoscope is lifted rather than rotated so that the larynx is elevated and the glottis is brought into view (Fig. 31-7). The pharynx is suctioned if necessary. The endotracheal tube is introduced into the mouth to the right of the laryngoscope and gently guided into the glottis under direct vision.

Figure 31-7 Laryngoscopy for endotracheal intubation.

The nasotracheal tube is inserted without an introducer through the naris and gently guided along the floor of the nose. The laryngoscope is placed in the mouth to the right of the orotracheal tube, and the tip of the nasotracheal tube is seen in the posterior pharynx. A Magill forceps is held in the right hand and introduced to the right of the laryngoscope. The nasotracheal tube is grasped a few millimeters back from its tip with the forceps, and the tip of the tube is elevated until it is almost at the glottis. It is helpful to have an assistant grasp the exterior end of the nasotracheal tube to assist in advancing it. The orotracheal tube is left in place until just before insertion of the nasotracheal tube in the glottis.

Pretreatment with pancuronium bromide and atropine may minimize heart rate and intracranial pressure changes associated with endotracheal intubation (41,42). Morphine and/or midazolam are commonly provided prior to intubation attempts to reduce agitation. Size and stability of the patient dictate the exact choice of adjunctive medication use.

Positioning

The length of the trachea from the vocal cords to the carina varies from about 3.6 cm in the smallest premature infants to 6 cm in large, term infants. Optimal positioning for the tip of an endotracheal tube is in the middle of the trachea, in which it is least subject to dislodgment into the pharynx or displacement into a bronchus. The proper depth of insertion of an endotracheal tube, as determined by postmortem and radiographic measurements, is related to body weight (43). Suggested depths of insertion for orotracheal intubation are given in (Table 31-3) (43,44).

TABLE 31-3 DEPTH OF INSERTION OF AN OROTRACHEAL TUBE FROM THE LIPS OF A PREMATURE INFANT

Infant Weight (kg)	Depth of Insertion (cm)
1.0	7
2.0	8
3.0	9
4.0	10

Immediately after intubation, the position of the tube should be confirmed by inspection and auscultation. Identification of humidity in the tube or of CO₂—by a sensitive color detector—helps confirm endotracheal tube placement. Two common errors of tube placement are intubation of the esophagus and intubation of the right main-stem bronchus. The former should be suspected if insufflation through the tube produces abdominal distention with little chest expansion and if air movement is heard better over the stomach than over the chest. Breath sounds that are louder over the right chest than the left suggest that the tube is in the right main-stem bronchus. Auscultation, although helpful, is not reliable because breath sounds are well transmitted in a small chest. A chest radiograph should be obtained to confirm tube placement.

Care of Endotracheal Tubes

A tube in the trachea interferes with the physiologic mechanisms for clearance of respiratory secretions and may itself stimulate secretions. Meticulous care is needed to prevent accumulation and inspissation of secretions which can obstruct the tube. Routine changing of the tube is unnecessary and subjects the infant to the repeated risk of trauma to the larynx and interruption of ventilation. However, the most common reason for sudden deterioration of an otherwise stable ventilated infant is dislodgment or blockage of the tracheal tube. The volume and quality of secretions vary with the type of pulmonary disease and with the individual patient. Suction frequency may vary from once each hour to fewer than two or three times per day. Both “in-line” techniques and discontinuation of positive-pressure ventilation are used for suctioning of airway secretions. “In-line” techniques offer the advantage of no loss of distending pressure during the suctioning process. However, no formal comparisons of the safety of the two techniques have been conducted.

Another important aspect of the care of artificial airways is the provision of adequate humidification. The endotracheal tube bypasses the nasal and pharyngeal mucosa, which normally warms and humidifies inspired gases. If heat and humidity are not provided from an external

P.610

source, drying of the lower airway mucosa, thickened secretions, and hypothermia may result. Inspired gases should be passed through a heated nebulizer with a constant readout temperature probe so that they are delivered to the airway already warmed to a range of 34°C to 36°C, and saturated. Inadequate humidification can contribute to airway injury (45).

Indications for Assisted Ventilation

The decision for initiation of assisted ventilation should be individualized for each baby. Factors to consider include underlying disease and its expected natural history, birth weight, gestational age, postnatal age, chest radiographic appearance, progression of clinical signs, serial arterial blood gas tension measurements, and pH measurements. The criteria indicating a need for mechanical ventilation are difficult to define, and there is lack of unanimity about a particular threshold for PaO₂, partial pressure of CO₂ (PaCO₂), or FiO₂. In general, the PaO₂ should be maintained at or above 50 mm Hg because of reasonable oxyhemoglobin saturation at this level, but the maximal level of inspired O₂ dictating intubation and application of assisted ventilation remains controversial. A trend of rising PaCO₂ with concomitant decrease in pH or onset of apnea indicates a need for mechanical assistance. After assisted ventilation is initiated, the generally accepted goals are to maintain the PaO₂ between 45 and 70 mm Hg, PaCO₂ at 45 and 60 mm Hg or less, and pH at 7.25 or more although

minimizing PIP and FiO_2 , and optimizing mean airway pressure (PAW[gas]) and PEEP. These general guidelines must be interpreted and often must be modified to provide optimal support for the individual patient.

Because acute lung disease is usually more severe and protracted in more immature infants, criteria for intervention for infants weighing less than 1,000 g differ from those for larger or older infants. For example, a 750 g infant with RDS has a high probability of developing apnea, fatigue, or both, and most of these infants require assisted ventilation even if the FiO_2 need is less than 40%. A 2,500 g, 36-week-old infant with RDS has greater muscular and caloric reserve and is able to sustain rapid ventilatory rates and higher respiratory work for several days without assistance. With a normal PaCO_2 , inspired O_2 may be increased to between 80% and 90% before intubation in some infants. Infants of gestational age 35 to 39 weeks and older than 24 hours who develop respiratory failure with RDS may benefit from surfactant treatment (46).

Physiologic Considerations

An understanding of the effects of mechanical ventilation on the lungs requires knowledge of the interplay among thoracic mechanics, including pulmonary compliance and airway resistance, lung volumes, respiratory control mechanisms, and alveolar gas exchange.

Lung compliance change in lung volume per unit pressure change, in units of $\text{mL/cm H}_2\text{O}$ depends on the elastic properties of the tissue, which are influenced by the lung volume and abnormalities such as tissue inflammation and edema. Compliance is low if there is alveolar collapse or overdistention. Expansion from alveolar collapse requires inflation pressures of 12 to 20 $\text{cm H}_2\text{O}$ in preterm infants with RDS to achieve tidal volumes of 3 to 5 ml/kg . The lungs of infants with RDS have areas of collapse and overexpansion, and there is nonuniformity of compliance. Other conditions, such as pneumothorax, lobar atelectasis or consolidation, and pulmonary edema, decrease compliance. The most relevant measure of compliance, specific compliance, is calculated by normalizing compliance by end-expiratory volume (EEV), the functional equivalent of FRC measured during positive pressure ventilation. Very low or high values for EEV will reduce compliance. Changes in compliance, EEV, and gas exchange are not concordant, at least not during RDS. This has limited the value of bedside measurements of compliance, particularly without concomitant measurements in EEV. Chest wall compliance usually is high and does not present a problem to mechanical ventilation.

Airway resistance ($\text{cm H}_2\text{O/L/s}$) is inversely related to the fourth power of the radius during laminar air flow.

Airway resistance is high in infants, increasing with low lung volumes and with obstruction of the airway. High rates of air flow increase resistance by producing turbulence in the airways.

The rate at which lung areas inflate and deflate is determined by resistance and compliance. An increase in airway resistance increases the time required for air to reach the alveoli; a decrease in compliance results in less time required to reach equilibrium. The product of resistance and compliance is the pulmonary time constant. Changes in resistance or compliance can alter the pattern or distribution of ventilation, and recognition of the variations in the time constant (e.g., short with poor compliance, prolonged with increased airway resistance) helps determine respirator settings. Unfortunately, a single time constant does not exist for all lung areas during complex pulmonary disorders. Thus, all conventional positive-pressure ventilators produce areas of overinflation and underinflation of gas exchanging areas, each contributing to suboptimal gas exchange.

Because RDS should result in a short time constant, rapid inspiratory and expiratory respirator times are permissible, and mean airway pressure should be increased to improve oxygenation. With meconium aspiration or airway edema, the time constant is slower, and sufficient time for expiration is important to avoid gas trapping, overdistention of the lungs, and possible air leak. If the expiratory time (T_E) is shorter than the time constant of the lung for expiration, overdistention results. If the overall time constant for the lung is longer than the imposed ventilator inspiratory time (T_I), inadequate ventilation could result. Unequal time constants coexisting in different parts of the lung are most likely to occur if pulmonary abnormalities are unevenly distributed, as in pneumonia, meconium aspiration, pulmonary interstitial emphysema, pneumothorax, or CLD, in which case the optimal T_I or T_E becomes difficult to determine.

The circulatory effects of mechanically applied pressure to the alveoli are important. Normal breathing results in

negative intrapleural pressure that enhances venous return and cardiac output. Positive-pressure breathing can impede venous return and may diminish cardiac output. Pressure during inspiration decreases the pulmonary

capillary circulation as long as alveolar pressure exceeds capillary pressure and can affect total pulmonary blood flow and hence gas exchange.

Lung Volume Measurements During Mechanical Ventilation

Application of hot wire anemometry or pneumotachography to time-cycled pressure-limited ventilation systems allows measurement of inspiratory and expiratory tidal volumes, minute ventilation (V_E), and air leak, the difference between tidal volumes measured during inspiration and expiration at any combination of ventilator settings. Tidal volume can be correlated with peak inspiratory pressure (PIP), inspiratory gas flow rate, T_I and PEEP. Knowledge of tidal volume from bedside measurements helps allow determination of the optimal PIP to achieve optimal tidal volume. For many clinical situations, this value is between 3 and 5 ml/kg. This knowledge allows minimizing PIP, which, if excessive, otherwise may induce or exacerbate the small airway injury of CLD. However, knowledge of tidal volume and V_E does not provide knowledge of distribution of inspired ventilation and of \dot{V}_A/\dot{Q} matching. Distribution of tidal volume may vary with the associated PIP; low PIP can result in tidal volume distribution only to already overinflated lung regions, resulting in worsened \dot{V}_A/\dot{Q} matching, development or exacerbation of high \dot{V}_A/\dot{Q} areas, and worsening of CO₂ retention, despite normal or elevated \dot{V}_E .

Many ventilators now have pulmonary graphic systems to monitor breath-by-breath pressure-volume and flow-volume loops. These graphics can be helpful in evaluating the extent of airway instability during inspiration and especially expiration. Pressure-volume curves may be helpful in detecting overdistention and/or air trapping or small airway obstruction. One limitation in the use of pulmonary graphics is the considerable breath-to-breath variability in the pattern exhibited, probably more than exists with assisted ventilation of adults. There is as yet no strong evidence suggesting that a clinically important outcome can be modified in neonates with reliance on interpretation of these patterns of airflow and pressure.

Automated bedside EEV measurements are now available. The devices utilize helium dilution methodology and early trials demonstrated safe use and reproducible measurements. Their use may allow a more individualized approach to application of PEEP in infants.

Investigation of New Forms of Assisted Ventilation

The gold standard approach to the introduction of new therapies in medicine is the performance of prospective, definitive, randomized clinical trials (RCT) with predetermined clinically relevant primary outcomes. This approach has been followed belatedly but now enthusiastically in Neonatology. Part of the acceptance of the results of RCTs devolves from effective blinding of the treatment group assignment, and the widespread agreement that the control group received the best available therapy known at the time. When these principles are applied to trials testing new approaches in assisted ventilation, there are several obvious limitations.

It is difficult to conduct a blinded clinical study of two different types of assisted ventilation, especially if different ventilators are used. It is difficult to agree on what constitutes optimal standard of care to be used for the control group. This applies not only to the minutia of management of the ventilation device itself, but also to the ancillary supportive care. Even if agreement about standards of care is achieved, it is difficult to sustain adherence to these standards of care.

Contemporary ventilators designed for application to neonates are very complex devices. This complexity mandates a balance in the performance of clinical trials between the rigid prescriptions of ventilator management vs. the "field level" studies with greater tolerance for physician specific practices. The latter study design may have perhaps more applicability to broad populations, but runs the risk that center-to-center variance in approach and in outcome may be greater, potentially diluting the signal of interest. Although these issues are inherent in all prospective definitive trials, they are particularly acute when applied to testing modes of assisted ventilation in neonates.

Identifying a clinically relevant outcome can be difficult. Death is the obvious outcome of interest, but for most populations of neonates treated with assisted ventilation, it may be an insensitive marker and not informative for other important outcomes. Utilizing a surrogate marker for death (e.g., need for ECMO) has worked well for clinical trials of near term infants, but will not work well for babies ineligible for ECMO, (those less than 34 to 35

weeks gestation). For preterm infants, evidence of pulmonary injury (i.e., CLD) in combination with death is commonly used. However, even these outcomes pose problems because of the poorly understood pathogenesis of CLD and the role of factors other than assisted ventilation that contributes to its development and severity. Combined outcomes melded into one also have the problem that reduction in one part of the primary outcome (death) may increase the incidence of the adverse-associated outcome. Some studies testing different forms of assisted ventilation were plagued by the problem that to qualify for the study, infants first were treated with one form of assisted ventilation for a variable period before the application of different patterns of ventilation could be undertaken. More recent trials, especially those testing HFV (47,48,49), have largely avoided this problem. Some studies, even those purporting to show a benefit from an experimental form of ventilation, may demonstrate the benefit because the control patients demonstrated a

higher than expected rate of adverse outcomes. Successful recruitment of sufficiently large populations in sufficiently short time and the ability to stratify them in a meaningful way can also prove to be difficult. This is increasingly true, given the role of economics in the decision regarding whether eligible patients for definitive clinical trials are moved from one center to another to participate in those trials (50).

Despite these limitations and others, advances have occurred in the application of assisted ventilation using randomized clinical trials. RCTs will remain valuable to better understand the limitations and strengths of the many different patterns of assisted ventilation.

Conventional Ventilation

Available Modes and Details of Use

Several manipulations of applied pressure allow for an increase in PaO₂. The physician decides whether to increase FiO₂ or P_{AW}[gas] by considering the prior settings and balancing the possible harmful effects of increasing PAW[gas] against those of increasing FiO₂, recognizing that threshold limits are arbitrary. If the FiO₂ is approaching 1.0, and SpO₂ or PaO₂ are unacceptably low, then other options must be invoked. During time-cycled, pressure-limited ventilation, if PEEP is already 5 to 6 cm H₂O, the PIP or the T_I is increased. The use of PEEP helps to maintain patent small airways and prevent collapse to airlessness of those alveoli already open. Inspiratory pressures of <15 cm H₂O usually are required to open collapsed or fluid-filled acinar areas. A combination of an increase in the TI with 6 cm H₂O PEEP may be helpful during the initial phase of assisted ventilation for RDS. With subsequent opening of air spaces, the optimal TI may need to be decreased. The use of an end-inspiratory pause or plateau should improve the distribution of inspired gas if there are regional differences in airway resistance. However, if the alveolar pressure exceeds capillary pressure, there will be tamponade of the pulmonary circulation and development of high [V with dot above]_A[Q with dot above] areas.

Hypoxemia may persist during all combinations of ventilator settings in some conditions, and other underlying abnormalities should be suspected. The clinician should always consider the degree of air leak around the endotracheal tube when adjusting pressure and flow rates. Echo-cardiographic evaluation of the infant for coexisting pulmonary vascular hypertension or structural or functional heart disease is then indicated. Other management considerations are listed in Table 31-4.

If there is airway obstruction, as may occur with CLD or meconium aspiration, optimal ventilator settings may differ from those used for RDS. Because there is a relatively long time constant, the gas flow rate should not be too rapid, and there should be adequate time for expiration. One of the multiple available newer modes of assisted ventilation may then be useful.

TABLE 31-4 MANAGEMENT CONSIDERATIONS

TABLE 31-4 MANAGEMENT CONSIDERATIONS

- Utilize alternative mode of ventilation (e.g., HFV, SIMV, A/C, PRVC)
- Raise the hematocrit to 45-50% with packed erythrocyte transfusions
- Reposition baby into prone position if supine or into left or right lateral positions
- Use of sedation with or without paralysis; if infant is paralyzed, discontinue its use
- Change to a larger size endotracheal tube to diminish air leak
- Consider repeated doses of exogenous surfactant beyond 24 h of age
- Administer diuretics to change pulmonary fluid concentration
- Increase cardiac output and/or systemic blood pressure with agents
- Undertake trial of NO
- Consider use of corticosteroids

A/C, assist/control; HFV, high-frequency ventilation; IMV, intermittent mandatory ventilation; SIMV, synchronous intermittent mandatory ventilation; PRVC = pressure regulated volume control.

Patient-Triggered Ventilation

The goal of patient-triggered ventilation is to maximize the efficiency of spontaneous breathing efforts although minimizing the risk of insufficient ventilation or trauma to airways (51). All patterns of patient-triggered ventilation require a rapidly responding sensor and transducer that can detect the onset of spontaneous inspiratory effort and provide the mechanical initiation of machine-assisted ventilation during the early phase of the infant's inspiration. Currently used methods to signal the initiation of inspiratory effort are listed in Table 31-5. The current methodology allows transduction to be accomplished in as short a time as 30 to 50 ms, approximately one-tenth the duration of the inspiratory phase of a spontaneous respiratory cycle (Fig. 31-8) (52). The means by which this signal is provided and the addition of other subtle but potentially important changes in the capabilities of particular ventilators differentiate one type of conventional neonatal ventilator from another (53). A list of available modes and their theoretical advantages is found (Table 31-6).

Although it is not clear that modern means of patient-triggered ventilation have achieved their optimum, these methods have already gained widespread acceptance for three reasons. These include the clinical impression that infants are more comfortable and less distressed although being ventilated with patient-triggered ventilation; there may be at least modest improvements in pulmonary gas exchange (53) during patient-triggered ventilation; and there appears to be decreased need for sedation and muscle relaxation. Even with patient-triggered ventilation, it is important to recognize the pitfalls that may occur when the synchronized intermittent mandatory ventilation (SIMV) rates are too high or when the patient is allowed to breathe in the assist/control mode (Fig. 31-9) (53). With assist/control, hyperventilation may occur, especially if the sensor

P.613

for initiation of respiration is inappropriately sensitive and triggers ventilator breaths that are not associated with patient inspiratory effort. If the goal is to avoid breaths triggered late in inspiration or during expiration, then flow-triggering systems are less prone to auto triggering and have a shorter and more consistent response time than impedance-triggered systems (54). The "Pressure-Regulated Volume Control" mode available with the Siemens Series 300 ventilator has proven useful in correcting gas exchange problems in larger preterm infants or term infants. However, the set tidal volume is arbitrary because of loss of volume to the compliant breathing circuit leading to inaccuracy of its measurement (55). If end tidal CO₂ is measured with the ventilator, then a second measure of tidal volume (V_T) is made at the breathing tube, which may be more reflective of actual V_T.

No definitive clinical trial of this variable flow mode of ventilation compared to conventional patterns of ventilation in the treatment of low-birth-weight (LBW) infants has been reported.

Modes	Theoretical Advantages
IMV	Pressure and time limited breaths
SIMV	Fresh gas flow allowing efforts at spontaneous breathing
A/C	Synchronized, controllable number of assisted breaths
PAV	Every spontaneous breath assisted with a monomorphic wave form
PSV	Respiratory pressure is servo- controlled and is proportional to endogenous volume and flow
PSV + VG	Inspiratory time and flow are variable but PIP is still fixed
	Time variable inspiration
	Constant flow
	Automatic attempt to deliver same tidal volume

IMV = Intermittent mandatory ventilation, SIMV = Synchronized intermittent mandatory ventilation, A/C = Assist/Control, PAV = Proportional assist ventilation, PSV = Pressure support ventilation, VG = Volume guarantee

Figure 31-9 Tidal volume tracings (inspiration = upward) demonstrating three patterns of ventilator interaction with spontaneous breathing. In this illustration, tidal volume of spontaneous breaths is less than that of ventilator breaths. A: Asynchronous intermittent mandatory ventilation (IMV) with ventilator breaths delivered during spontaneous expiration. During IMV, ventilator breaths occur at a constant rate, with random timing with respect to spontaneous breaths. B: Synchronous intermittent mandatory ventilation (SIMV) with ventilator breaths delivered early in selected spontaneous inspirations. During SIMV, ventilator breaths occur more irregularly, but the ventilator delivers the set rate synchronously with spontaneous breaths. C: Assist/control mode, with ventilatory breaths delivered early in all spontaneous inspirations. The assist/control mode delivers ventilatory breaths synchronously with all spontaneous breaths and may lead to increased ventilation. From: Cleary JP, Bernstein G, Mannino FL, Heldt GP. Improved oxygenation during synchronized intermittent mandatory ventilation in neonates with respiratory distress syndrome: a randomized, crossover study. *J Pediatr* 1995;126:407, with permission.

No studies have been reported to date which measured a clinically important outcome after a significant duration of exposure to a patient interactive device compared to another similar device. One study did examine in a crossover design in infants with respiratory distress syndrome the effect of pressure-support ventilation plus volume guarantee, a volume targeted form of ventilation. Results of measurements of end expiratory volume and of minute ventilation are shown Figs. 31-10 and 31-11 (57). No obvious improvement could be detected in VE, a/A, or EEV when PCO₂ was controlled.

The ability to reduce assisted ventilatory support in a controlled manner with patient-interaction devices is improved compared to that with ventilator models available previously. Decremental changes in back-up rate,

PIP and FiO_2 can be accomplished smoothly and cumulatively reduce the reliance on the “trial-and-error” approach to reduction in ventilatory support necessary with older generation devices. One established adjunctive therapy for VLBW infants is the use of methylxanthine therapy with discontinuation of assisted ventilation. Routine use of this medical therapy reduces the need for reintubation and reintroduction of assisted ventilation (58).

Figure 31-10 The relationship between the VE and the mode of ventilation (SIMV or PSV + VG). The difference between the two modes is significant ($*p = 0.012$). From Olsen SL, Thibeault DW, Truog WE. Crossover trial comparing pressure support with synchronized intermittent mandatory ventilation. *J Perinatol* 2002;22: 461, with permission.

Pressure-Regulation vs. Volume Guidance

It is helpful to think of current modes of conventional rate assisted ventilation as either pressure-controlled or volume targeted (59). The reintroduction of volume-controlled ventilation after unsuccessful use of this modality in the 1970s allows more choices after decades of pressure- and time-controlled neonatal ventilation. Some adjunctive features of volume-control ventilation include variable and limited T_i , decelerating inspiratory flow rates and patient-ventilator interaction. They can provide variable pressure support to maintain relatively constant minute ventilation. During pressure-controlled assisted breathing, there can also be pressure-support breaths—pressure once generated is constant during T_i but flow is decelerating. In summary, availability of many choices within the realm of conventional rate assisted ventilation allows greater individualization of assistance between patients and in the same patient during different stages of pulmonary insufficiency. However, definitive evidence of improvement in mortality or of decrease in clinically important morbidity with these new tools, compared to older modes of assisted ventilation, is lacking.

Figure 31-11 The relationship between the EEV and the model of ventilation (SIMV or PSV + VG). The difference between the two modes is significant ($*P = 0.011$). High-Frequency Ventilation

Principles of Use

High-frequency ventilation (HFV) is defined as the use of small tidal volumes at supraphysiologic rates to provide oxygenation and ventilation. It generally refers to the use of rates above 150 breaths per minute. In some cases, V_T is less than the dead space. Thus, the mechanisms of high-frequency ventilation differ from the conventional combination of convection and diffusion. This mode can still achieve adequate gas exchange. Many theoretical and experimental studies have demonstrated that a number of convective and diffuse mechanisms act in concert to affect gas transport during high-frequency ventilation (Fig. 31-12) (60). There is augmented mixing of gas in the airways, through increased energy of the gas molecules at high ventilator frequencies and high flows. The end result is that fresh gas reaches the alveoli. Various patterns of high-frequency ventilation are illustrated in Fig. 31-13 (61).

The major advantage of high-frequency ventilation seems to be its potential to prevent some deleterious consequences of mechanical ventilation. When used in animal models with a strategy of optimizing lung inflation. High-frequency oscillatory ventilation (HFOV) improved gas exchange and lung mechanics, promoted uniform inflation, reduced air leak, and decreased the concentration of inflammatory mediators in the lung, as compared with conventional mechanical ventilation (62,63). Attempts have been made to differentiate high-frequency ventilators based on several ventilator-specific factors (Table 31-7) (61). The distinction among the types of high-frequency ventilators may be relevant to the appropriate matching of any one type of high-frequency ventilator to a particular part of the natural history of a neonatal pulmonary disorder.

Figure 31-12 Gas-Transport Mechanisms During High-Frequency Ventilation. The major gas-transport mechanisms that are operative under physiologic conditions in each region (convection, convection and diffusion, and diffusion alone) are shown. There are seven potential mechanisms that can enhance gas transport during high-frequency ventilation: turbulence in the large airways, causing enhanced mixing; direct ventilation of close alveoli; turbulent flow with lateral convective mixing; pendelluft (asynchronous flow among alveoli as a result of asymmetries in airflow impedance); gas mixing as a result of velocity profiles that are highly asymmetric (leading to the streaming of "fresh" gas toward the alveoli along the inner wall of the airway and the streaming of "alveolar" gas away from the alveoli along the outer wall); laminar flow with lateral transport by diffusion (Taylor dispersion); and collateral ventilation through nonairway connections between neighboring alveoli. From Slutsky AS, Drazen JM. Perspective. Ventilation with small tidal volumes. *N Engl J Med* 2002;347 (9):630, with permission.

P.616

Ventilation Devices and Their Indications

Three main types of high-frequency ventilators are used to treat neonates: high-frequency jet ventilators (HFJV), high-frequency flow interrupters (HFFI), and HFOV. These devices differ both in the way they generate HFV breaths and in the parameters that can be adjusted to control ventilation and oxygenation (Table 31-7).

High-Frequency Jet Ventilation

High-frequency jet ventilators are designed for the delivery of high-flow, short-duration pulses of pressurized gas directly into the upper airway through a specifically designed endotracheal tube lumen. These systems operate at rates of 150 to 600 breaths/min. Exhalation is passive. Effective tidal volumes are greater than the anatomic dead space. The ventilator is servocontrolled and operates to maintain a constant pressure at the endotracheal tube tip. The technique of high-frequency jet ventilation has been investigated to determine its efficacy in the management of VLBW infants to reduce mortality or the development of chronic lung disease in this population (64,65). Using chronic lung disease as an outcome variable is difficult in any study because of the multiple confounding factors that may develop (66).

The current status of jet ventilation as a primary mode of support for low-birth-weight infants is unclear. Keszler and associates (65) conducted a multicenter study in which 130 patients were enrolled. Half were treated with HFJV and half were treated with a continuation of conventional mechanical ventilation (nonsynchronized intermittent ventilation). Virtually all the infants had been treated with exogenous surfactant. Mortality and need for ventilatory support at 28 days of life were the same in the two groups, but there was a reduction from 40% to 20% for continuing respiratory support at 36 weeks postconceptional age among infants treated with high-frequency ventilation. This study also showed the HFJV was superior to tidal ventilation for preventing pulmonary interstitial emphysema. It is interesting to note that the 28-day BPD rate and the survival rate were comparable to that found 10 years earlier in a study comparing HFOV with conventional ventilation in infants without prior delivery of surfactant (67). These encouraging results are contrasted with another prospective randomized study in a comparable but smaller population of VLBW infants (68). In that study with HFJV there was an increased risk of adverse outcomes, defined as large intraventricular hemorrhage, periventricular leukomalacia, or

P.617

death. No difference in incidence of chronic lung disease was noted. The finding of leukomalacia had been previously associated with hypocarbia produced by treatment with HFJV during the first 3 days of life (68),

although no cause-and-effect relationship could be established.

TABLE 31-7 HIGH-FREQUENCY VENTILATORS				
	Flow Interruption	Jet Ventilator	Oscillatory Ventilators	
Commercially available device	Infant Star (Infrasonics, San Diego, CA)	Bunnell Life Pulse (Bunnell, Salt Lake City, UT)	Sensormedics (Sensormedics, Anaheim, CA)	Draeger Babylog 8000 plus (Draeger Medical Inc, Telford, PA)
Indications	Failure of conventional ventilation in VLBW infants; PIE	PIE; intractable air leak; failure of conventional ventilation	Primary or rescue treatment of respiratory failure; prevention of ECMO	
Variables	Rate of conventional breaths; frequency of high-frequency	Variable inspiratory "on-time" rate of 240-600 beats/min	Rate; mean airway pressure; I—E ratio	Can be used as continuous flow, cycled ventilator or as HFOV*, with flow and volume monitoring
Use with conventional ventilation	Yes	Yes	No	
Expiratory phase	Passive(?)	Passive	Active	Passive (conventional vent.)/active (HFOV)
Special precautions	>2 kg; no published trials	Sudden decrease in PCO ₂ ; respiratory alkalosis	Sudden decrease in PCO ₂ ; respiratory alkalosis	

* HFOV is not available in the USA.

Hybrid Patterns of Ventilation

A hybrid device combining elements of jet and flow interruption to generate high-frequency ventilation, coupled with low-rate conventional ventilation, is available (Infrasonics, San Diego, CA). This device is operated at 10 to 15 Hz, with pauses in the high-frequency ventilator operation during the conventional breath inspiratory phase of ventilation. When operated in its mixed conventional and high-frequency mode, this device generates high-pressure, short, and nonvariable inspiratory flow with a variable shut-off phase, allowing passive lung deflation. One attractive feature is the minimal patient disturbance involved in changing from high-frequency to conventional forms of ventilation. No published study has demonstrated that this device offers any significant advantage as primary or rescue therapy compared to other types of high-frequency ventilation.

High-Frequency Oscillatory Ventilation

HFOV differs from the other two types by delivering smaller tidal volumes at higher rates and has an active expiratory phase. The Sensormedics 3100A high-frequency ventilator (Sensormedics, Anaheim, CA) has an additional feature of operating with an independently adjustable T₁. This device has been licensed for use for primary initial treatment of assisted ventilation and for alternative therapy in intractable respiratory failure unresponsive to conventional mechanical ventilation in neonates. The oscillating movement of the diaphragm causes active inspiratory and expiratory phases that drive the mixing of gas (Fig. 31-14). The amplitude of the pressure wave (measured as "delta pressure") is proportional to the tidal volume of the breath being delivered to the patient, and is adjusted to manipulate changes in ventilation. The mean airway pressure affects oxygenation, by changing the rate of gas flow into the circuit and the resistance to the gas flow out the expiratory side of the circuit (69).

Figure 31-14 HFOV Principle.

Several prospective, randomized, controlled studies have been conducted using different types of HFOV (47-49,67,70-73) compared to conventional ventilation. The rationale for the postulated superiority of HFOV was that diminished distending pressures, combined with more adequate recruitment of and maintenance of lung volume, would be associated with fewer dysplastic cellular changes of the lung and less frequent or milder BPD. Cumulatively, these studies provide evidence that HFOV can be used safely and effectively in a wide variety of newborn infants, although its effectiveness as rescue therapy is still debated (74,75).

One question raised, but not answered, by clinical studies of HFOV is the potential benefit gained by its application at birth. Two studies using premature primate models of RDS demonstrated improved gas exchange if HFOV was used without any prior conventional mechanical ventilation (76,77). Jackson and associates (76) found decreased proteinaceous alveolar edema and improved gas exchange after 6 hours of HFOV applied from the first breath. However, all animals in both treatment groups had evidence of pulmonary cellular injury. The finding of both short-term benefit and concomitant cellular damage implies that HFOV used from birth could still be associated with significant lung injury. These findings are consistent with those of Solimano and associates (78), who showed that fluid and protein leaks in preterm lambs still occurred, although HFOV was applied from the first breath after delivery.

A possible second indication for high-frequency ventilation is to preclude the need for more invasive pulmonary support with extracorporeal membrane oxygenation (ECMO). Studies enrolling patients eligible for ECMO demonstrated that approximately one-half responded favorably to HFOV and did not need ECMO (79,80). Most babies responding to high-frequency ventilation were larger infants suffering from severe RDS. Other acute pulmonary disorders, such as meconium aspiration pneumonia with severe airway obstructive changes as shown by chest radiography, may not respond as well to oscillatory ventilation. Kinsella and associates (81) showed that the delivery of inhaled nitric oxide (INO), in association with HFOV, produced an improved outcome compared to either conventional ventilation with nitric oxide (NO) or HFOV alone. There was a reduced need for ECMO, especially in near-term infants with RDS or meconium aspiration syndrome (Fig. 31-15). The synergistic effect of these two treatment modalities may help reduce dependence on invasive ECMO support in this group of fragile term infants.

Two large contemporary trials comparing high-frequency oscillatory ventilation and conventional ventilation in preterm infants at high risk were done in the United Kingdom (49) and in the United States (48). The results of the study by Johnson and associates (49) (that enrolled infants with a gestational age of 23 to 28 weeks, assigned either to HFOV ($n = 400$) or to conventional ventilation

P.618

($n = 397$)) were similar to those of a previous recent trial that also showed no difference between the modes of ventilation (47); the combined primary outcome, death or chronic lung disease (BPD), occurred in approximately two thirds of the infants, and similar proportions of infants in the two treatment groups survived without BPD. In contrast, Courtney and associates (48) found that in infants with birth weight of 601 to 1200 g, high-frequency oscillatory ventilation conferred a small but significant benefit in survival without bronchopulmonary dysplasia (56% vs. 47%; $p = 0.046$). Infants assigned to HFOV ($n = 234$) had a lower rate of pulmonary hemorrhage, a slightly higher rate of pulmonary interstitial emphysema, and were successfully extubated one week earlier compared to infants assigned to synchronized intermittent mandatory ventilation ($n = 250$). Neither trial showed an in-creased incidence of intracranial abnormalities or risk for air leak, two previously described complications

Figure 31-15 Percentage of patients responding to high-frequency oscillatory ventilation (HFOV); inhaled nitric oxide (INO); or combined HFOV plus INO by disease category. More patients with RDS or MAS responded to combination therapy with HFOV plus INO than to either treatment alone. Response to INO during conventional ventilation was more effective than response to HFOV in patients without significant lung disease ("other" category). Asterisk indicates $p < 0.05$. From Kinsella JP, Truog WE, Walsh WF, et al. Randomized, multicenter trial of INO and high-frequency oscillatory ventilation in severe, persistent pulmonary hypertension of the newborn. *J Pediatr* 1997;130:55, with permission.

There are differences between the designs of both trials that could explain the different results. However, the majority of available evidence suggests that in the usual clinical circumstances, the choice of the mode of ventilation does not affect the pulmonary outcome, which may be influenced more by prenatal risk factors, initial resuscitation, and other aspects of neonatal care (84).

Complications of Assisted Ventilation

Airway-Associated Problems

Acute and chronic complications of mechanical ventilation may develop in neonates. All patients with tracheal intubation demonstrate some degree of mucosal injury, usually squamous metaplasia or mucosal necrosis. In most infants, there seems to be spontaneous healing without significant sequelae. Hoarseness and stridor often occur after prolonged intubation but usually resolve in a few days. Persistent lesions, including laryngomalacia and subglottic stenosis, may develop in some patients occasionally requiring tracheostomy. Duration of intubation, pressure from oversized tubes, inadequate humidification, and airway pressure produced by the ventilator contribute to the development of laryngotracheal lesions.

The duration of intubation is dictated by the need for continued ventilatory support. In some infants requiring lengthy assisted ventilation tracheostomy may facilitate development of normal feeding patterns and social interaction and bypass already traumatized areas of the upper airway. However, infant tracheostomy itself is associated with a significant morbidity and mortality (85,86). Complications can include fatal loss of airway after accidental extrusion of the tube, paratracheal soft tissue infection, severe paratracheal air leak resulting in inadequate generation of PIP, and tracheal cartilage softening, making decannulation difficult. A bedside evaluation of the airway using flexible fiberoptic endoscopy can be helpful in assessing need for additional, more invasive procedures (87).

Pulmonary Air Leak Complications

Pulmonary air leak may occur as a complication of any of the life-threatening disorders of the newborn or as a result of their treatment. The air leak may take the form of pulmonary interstitial emphysema, pneumomediastinum, pneumoperitoneum, pneumopericardium, or pneumothorax. Pneumopericardium and pneumothorax occurring

during positive-pressure ventilation require immediate treatment by evacuation of the free air.

Pneumothorax must be considered if there is abrupt worsening of the respiratory or circulatory status of an infant at risk. Unilateral hyperresonance, decreased breath sounds, a shift of the apical cardiac impulse, and skin mottling are useful clinical clues. High-intensity illumination may demonstrate the presence of a pneumothorax if the room can be adequately darkened. A definite diagnosis often can be made only by radiographic examination. The volume of the extrapulmonary air collection is not always a valid indication of tension. Interstitial emphysema, often a precursor of pneumothorax, causes the lung to remain partly expanded, even when intrapleural pressure is high. Bilateral pneumothorax may lead rapidly to death and must always be considered in cases of severe deterioration.

Pneumothorax in otherwise asymptomatic infants often resolves without therapy. However, marked mediastinal shift, coexisting pulmonary disease, or use of mechanical ventilation indicates a need for evacuation of the air. Aspiration with a syringe and needle may be done as an emergency procedure but is rarely adequate by itself and should be followed with tube thoracostomy.

Thoracostomy tubes should be sterile and made of nonreactive rubber or plastic. The wall thickness should be sufficient to prevent kinking, and the lumen should be large enough to prevent occlusion by exudate. The presence of at least two holes in the tube reduces the likelihood of occlusion by tissue. Polyvinylchloride feeding tubes or 8Fr (2.6 mm) to 10Fr (3.3 mm) catheters are suitable for thoracostomy use. The tube is inserted by grasping the tip with a clamp and pressing through a previously made incision through the pleura. The catheter is inserted after a skin incision has been made and can be Z-tracked over a rib for a better seal. Catheters with a trocar within the lumen often require considerable force to insert, and puncture of the lung and liver has been reported with their use.

The thoracostomy tube is connected to continuous suction at a negative pressure of 10 to 15 cm H₂O with an underwater seal. A chest radiograph should be obtained soon after thoracostomy. If the pneumothorax has not been evacuated, the infant should be repositioned and the tube stripped or, if necessary, a second tube should be inserted.

A thoracostomy tube is left in place until air ceases to bubble from the tube and until the risk of recurrent pneumothorax is reduced (i.e., until respiratory distress has subsided or mechanical ventilation is no longer required). The tube is then clamped. If there is neither clinical nor radiographic evidence of recurrent pneumothorax, the thoracostomy tube can be removed.

Liquid Ventilation

One experimental approach to reducing the lung injury associated with gas ventilation is liquid ventilation. Lung injury may be the result of abnormal inflation patterns produced because of elevated alveolar surface tension. Liquid inflation of the lungs with saline eliminates the alveolar gas-lung liquid interface with its tendency to induce collapse and perhaps injury. However, saline is too poor a carrier of oxygen to supply the body. Liquid perfluorocarbon solutions are able to dissolve large volumes of oxygen and carbon dioxide at 1 atm. Perfluorocarbon solutions have been used as carriers for O₂ and CO₂ in moribund human infants (88).

Two methods of liquid ventilation are being tested. The first is total liquid ventilation, which uses a completely perfluorocarbon-filled ventilator circuit, and a membrane oxygenator to prime the inspired liquid flow. The second is perfluorocarbon-assisted gas exchange, in which a portion of the lung volume, the EEV, is filled with perfluorocarbon liquids and the lungs are ventilated with a conventional infant mechanical ventilator. Liquid ventilation is an attractive form of pulmonary rescue therapy because the perfluorocarbons seem to be nontoxic and the technique is less invasive than ECMO. Definitive trials in neonates are yet to be reported.

MANAGEMENT IN THE INTENSIVE CARE SETTING

Management of respiratory problems requires specialized personnel working effectively as a team and specialized equipment. A physician skilled in neonatal intensive care techniques should be available within the unit at all times, and other specialists should be immediately accessible for consultation.

Nurses must be carefully trained in the techniques for the intensive care of infants. Necessary skills include application of ventilatory support equipment, recognition of equipment malfunction, airway management, assessment of ventilation, and use of monitoring equipment. Respiratory therapists are critical to the effective

use of respiratory equipment. Maintenance and calibration of all oxygen administration and oxygen-measuring devices require the presence of a respiratory therapist within the hospital at all times.

Equipment needs for neonatal intensive care include wall sources of compressed air and oxygen, oxygen dilutors, heating and humidification devices, and oxygen-monitoring systems with alarms. Critically ill infants need continuous monitoring of temperature, respiratory rate, and heart rate by electrical devices with alarm systems. In the acute phase of illness, or if an umbilical or peripheral arterial catheter is in use, blood pressure monitoring and electrocardiographic display must be available.

The parents of severely ill infants need understanding and support. They experience feelings of anxiety, fear, guilt, and hostility. Most families are ill equipped for the unexpected emotional and financial burden imposed by the child's hospitalization. A social worker should be available exclusively to the neonatal intensive care unit to provide assistance to parents by delineating parental concerns and

P.620

helping coordinate communication with the medical and nursing staff and other hospital personnel.

The physical design of the intensive care unit must facilitate the management of acute respiratory problems. Each patient area should be large enough to accommodate the necessary personnel and the enormous amount of equipment, without generating intolerable crowding. A small number of patients in each area of the nursery facilitates parental visits and alleviates the overall level of stress. The proliferation of monitors and alarms may result in monitor fatigue, with the risk that monitors are ignored. Although neonatology is often thought of as an acute care specialty, it more accurately is categorized as a chronic care specialty, because of the many days and weeks of specialized care that small, sick infants require. The physical design of intensive care units is catching up to that new reality.

Adequate attention paid to these ancillary features of intensive respiratory care of the newborn helps ensure the optimal outcome expected for critically ill infants.

Chapter 32

Extracorporeal Membrane Oxygenation

Billie Lou Short

In 1944 Kolff and Berk observed that blood became oxygenated as it passed through cellophane chambers of their artificial kidney membrane (1). This historic observation led to the recognition by those involved in the fast-developing field of cardiopulmonary bypass that blood could be oxygenated through a semipermeable membrane lung. In the bubble and disk oxygenators used during the early 1950s for open-heart surgery, oxygen and blood were mixed directly. This mixing resulted in considerable damage to blood products and the potential for producing lethal fibrin emboli, making these systems unsuitable for prolonged clinical use (2). For this reason, and in light of Kolff and Berk's findings, attention was directed to the development of semipermeable membrane oxygenators that separated blood and oxygen, decreasing or eliminating the risks of the earlier oxygenators.

The first membrane lung, which used an ethylcellulose membrane, was described by Clowes in 1956 and was used successfully in open-heart surgery 1 year later (3). With this report began the study of prolonged cardiopulmonary bypass and potential application of extracorporeal membrane oxygenation (ECMO) as an artificial lung.

The 1960s witnessed intensive research on materials and techniques (2). Silicone polymers, available in thin sheets that enhanced gas transfer through membranes, began to be characterized and developed. The development of the Kolobow silicone membrane lung made the field of ECMO possible, and clinical trials, using prolonged bypass or ECMO as an artificial lung, began in the late 1960s (2,4,5 and 6).

The concept of an artificial placenta, a device capable of continuing *ex utero* the gas-exchange functions of the placenta, developed in parallel with that of an artificial lung. In 1961 Callaghan and colleagues began using animal models of respiratory distress syndrome of the newborn to test the efficacy of an extracorporeal oxygenation circuit as an artificial placenta (7). During the early 1960s investigators, including Rashkind, White, Dorson, and Avery, used ECMO as an artificial placenta for premature infants (8,9 and 10). Although the infants died, this was an extremely important period for the development and refinement of the mechanical and surgical techniques that laid the foundation for the subsequent success of ECMO.

It was not until ECMO therapy was applied to the term infant through the pioneering work of Bartlett and colleagues that its full potential as a powerful therapy for infants in severe respiratory failure was recognized. In 1976 Bartlett and his associates reported the first neonatal ECMO survivor, a term infant with severe meconium aspiration syndrome (MAS) (11). During the next 10 years, neonatal ECMO was used to treat 99 term infants with respiratory failure in three centers in the United States and produced an overall survival rate of 65%. Since 1986, ECMO therapy has developed explosively, and more than 19,000 infants have been treated in more than 90 ECMO programs, with an overall survival rate of 77% (12). ECMO is also being used to support the cardiac patient postoperatively and the older child in respiratory failure. This chapter will only address the use of ECMO in the

neonatal patient in respiratory failure.

The most common use for ECMO is in the term or near-term infant with failure to oxygenate as a result of MAS, idiopathic persistent pulmonary hypertension (PPHN), congenital diaphragmatic hernia (CDH), sepsis and pneumonia, or hyaline membrane disease. Although overall survival is 77% nationally, the best results are for the MAS (94%) and PPHN (79%) groups (Table 32-1). In the last 3 years, the survival rate for the MAS patient at Children's National Medical Center in Washington, DC has been 100%, PPHN 94%, and sepsis/pneumonia 100%. So although new therapies such as inhaled nitric oxide (iNO) and high frequency ventilation (HFV) may be delaying the initiation of ECMO, it does not appear that they have affected survival (13). As with Gill and associates, the time at Children's National Medical Center on ECMO has increased from 5 days to 8.9 days with the initiation

P.623

of these additional therapies pre-ECMO. At Children's National Medical Center, a 34- to 36-week gestation infant with respiratory failure has not been placed on ECMO in the last 3 years due to therapies such as surfactant therapy and HFV. The survival rate for the CDH population requiring ECMO has not increased over time and remains between 50% to 60% nationally, perhaps because of the heterogeneity of this group of infants, who have various degrees of pulmonary hypoplasia and pulmonary hypertension (14,15). Only 30% to 40% of the CDH population require ECMO therapy, and those patients not requiring ECMO have a survival rate close to 100%. Therefore, with ECMO therapy, the overall survival rate for the CDH population as a whole has increased to more than 70% and in some centers has been reported to be as high as 80% (16,17). Most centers are now repairing the diaphragmatic defect in the critical CDH either on ECMO or immediately post-ECMO (14).

TABLE 32-1 RESULTS OF EXTRACORPOREAL OXYGENATION^a

Diagnosis	Survival After Therapy (%)
Meconium aspiration syndrome	94
Persistent pulmonary hypertension	79
Sepsis and pneumonia	75
Respiratory distress syndrome	84
Congenital diaphragmatic hernia	53
Total	77

^a From the Extracorporeal Life Support Neonatal Registry, July 2003, 19,061 patients.

INDICATIONS

Among the most controversial aspects of ECMO therapy have been the clinical criteria used to determine its use (18,19,20,21,22,23,24,25 and 26). Because of the invasive nature of ECMO therapy and the potential risks associated with this therapy, the criteria

are designed to select a population of infants who have an 80% or greater mortality risk with conventional therapy. Assumptions about the ability of ECMO to increase survival are valid only if the criteria are specific for each high-risk population. The ultimate test for the efficacy of ECMO, and the predictive value of ECMO criteria, is a prospective, randomized trial. Although two randomized trials have been completed, most centers have used historic controls to develop their criteria (18,19,24,26). In the prospective, randomized trial reported by O'Rourke and colleagues, a crossover design was used, which may have skewed the predictions of their criteria. The criteria used in O'Rourke's study, which were thought to predict a mortality over 80% based on retrospective data, predicted a mortality of only 40% when used prospectively (24). It is imperative that all centers continually evaluate their criteria, especially as less invasive therapies become available. The United Kingdom collaborative randomized trial did not involve a crossover design and therefore represents a more ideal trial for ECMO therapy (27). Of the 185 patients enrolled in the study, 93 were allocated to ECMO therapy and 92 to conventional therapy, which included high-frequency ventilation and iNO therapy. Mortality was significantly different between the ECMO and conventional groups, 32% versus 59% ($P = 0.0005$). This benefit of ECMO was sustained when severe disability at 1 year of age was taken into account ($P = 0.002$). The CDH population in this study had the highest mortality rate, 82% in the ECMO group and 100% in the conventional group. Severity of illness was also a predictor, with mortality higher in the patients with an oxygen index (OI) of 60 or greater at the time of entry into the study, indicating that early transfer of these patients to an ECMO center is essential. The authors also noted that mortality was lower if the referring hospital was a teaching hospital.

The potential risks associated with ECMO therapy include those associated with ligation of the carotid artery (in venoarterial ECMO) and jugular vein, prolonged exposure to systemic heparinization, alterations in pulsatile blood flow patterns, exposure to potential toxins such as phthalate esters (i.e., plasticizer) from the circuit, and others yet to be determined (28,29). With its long-term outcome still unknown, use of ECMO should be limited to the term or near-term infant who has a 20% or less chance of survival with conventional therapy. Although criteria developed at other centers are available, they are based on the clinical management and patient populations in those centers and may not be valid when applied to patients in other institutions (19,20,24). What is considered maximal conventional therapy (e.g., hyperventilation) in one institution may not be used in others. Differences in patient populations, such as the percentage of patients who are inborn versus outborn, may significantly alter applicability of criteria from one center to another. All ECMO centers should attempt to develop criteria based on their own management techniques and patient population.

Several important inclusion criteria for ECMO are based on known complications of the procedure. These are listed in Table 32-2.

Age and Weight Limitations

The requirement for systemic heparinization of the ECMO patient places significant limitations on the population

that can be treated. Use of ECMO in the late 1960s and early 1970s in premature infants

weighing less than 2,000 grams or younger than 34 weeks of gestation resulted in a significant mortality rate from intracranial hemorrhage (ICH) (30,31 and 32). This increased risk may be a result of the combination of systemic heparinization with a more direct effect of ECMO on the brain (33,34). Data from a review of the premature infant treated with ECMO by Hirschl and colleagues indicates that the ICH rate in the infant down to 32 weeks of gestation is lower than previously noted (35). Although the ICH rate is lower in infants at 32 to 33 weeks of gestation than in the earlier experience with this group, the rate is still close to 50%; thus, if one is considering ECMO therapy for this population, the information given to parents should appropriately address the high risk for ICH. A better understanding of the pathophysiology of the intracranial bleeds seen in the ECMO population may allow alteration of the risk for this complication and thus lower the gestational age cutoff in the future (33,34).

TABLE 32-2 INCLUSION CRITERIA FOR EXTRACORPOREAL MEMBRANE OXYGENATION

Gestational age \geq 34 weeks or birth weight \geq 2,000 g
No uncontrolled bleeding complications
No major intracranial hemorrhage, e.g., not greater than grade II
Mechanical ventilation provided for 10 to 14 days
Reversible lung disease

Hematologic Limitations

The requirement for systemic heparinization places the infant with a significant coagulopathy or with bleeding complications at extreme risk. All attempts should be made to correct any coagulopathy before instituting ECMO.

The septic infant is of particular concern because of the commonly associated coagulopathy. Although these infants are at an increased risk for bleeding complications on ECMO, correction of their coagulopathy and meticulous heparin management have resulted in successful treatment (36).

The necessity for heparinization during ECMO precludes the treatment of any infant with a major ICH. Infants with grade I to II intraventricular hemorrhages or small parenchymal hemorrhages can be treated if heparin management is monitored closely and activated clotting times (ACTs) are kept low (e.g., 160 to 180 seconds).

Prior Mechanical Ventilation

The limit of 10 to 14 days of assisted ventilation before ECMO therapy is imposed because of the probable development of chronic lung disease after aggressive assisted ventilation

of this duration. ECMO is unable to reverse this disease process within a safe period. After 3 weeks of ECMO, the risks for complications related to the ECMO procedure itself, such as clot formation, nosocomial infections (e.g., neck wound infections), and mechanical failures (e.g., tubing ruptures), begin to increase. The maximal time that a neonatal patient can be kept on the ECMO circuit is unknown, but in view of the increasing risk of complications and usual lack of response beyond this time period, most centers limit time on the circuit to around 3 weeks. Infants with diseases, such as chronic lung disease, that do not improve in a short period should not be considered for ECMO unless there is a life-threatening underlying disease state, such as acute pulmonary hypertension or sepsis/pneumonia, that can be rapidly reversed by ECMO.

Cardiopulmonary Disease

Candidates for ECMO must have reversible lung disease. Because of the cardiopulmonary support provided by this therapy, ECMO has allowed many infants thought to have irreversible lung disease to live. The diagnosis of irreversible lung disease has become progressively more difficult to make (14,37,38).

Significant cardiac disease must be ruled out before ECMO, but infants with severe reversible lung disease superimposed on congenital heart disease may be candidates for ECMO support before cardiac surgery.

Risk Assessment and Mortality Criteria

If the infant is failing maximal conventional therapy, ECMO should be considered. The next task is to predict which infants have a high mortality risk without ECMO.

Commonly used criteria (Table 32-3) are the alveolar-arterial oxygen gradient ($AaDO_2$), OI, and arterial partial pressure of oxygen (PaO_2) levels less than 50 mm Hg over a specific time period (19,20,23,39). The $AaDO_2$ can be calculated as follows:

$$AaDO_2 = P_B - 47 - PaCO_2 - PaO_2$$

when the fraction of inspired oxygen (FiO_2) is 1.00, P_B is the barometric pressure, 47 is the water vapor pressure, and $PaCO_2$ is the arterial carbon dioxide pressure. The OI can be calculated with the following equation:

$$OI = MAP \times FiO_2 \times 100/PaO_2$$

in which MAP is the mean airway pressure.

Deciding when to transfer an infant to an ECMO center is a difficult task. Most infants with disorders treated by ECMO improve without ECMO. Before the infant becomes too moribund for transport, the referring physician must attempt to determine which infants are at high risk for failing maximal conventional therapy. This is an enormous responsibility, which can be eased by early consultation

with ECMO center personnel. Earlier studies by Boedy and associates (40) found that 12% of their ECMO referrals died before arrival of the transport team or during interhospital transport. Of importance, 32% of the deaths occurred in infants with CDH, indicating that

early referral of these patients was warranted. This concern becomes even more important with the addition of therapies such as iNO. Centers providing iNO without ECMO capabilities need to have a close association with an ECMO center, so consultation can be obtained to determine when infants should be transported to the ECMO center (41,42).

TABLE 32-3 NEONATAL EXTRACORPOREAL MEMBRANE OXYGENATION CRITERIA^a

aaDO₂ 605-620 mm Hg^b for 4 to 12 hr^b

Oxygen index 35 to 60^b for 0.5 to 6 hr^b

PaO₂ 35 to 50^b mm Hg for 2 to 12 hr^b

pH <7.25 for 2 hr with hypotension

Acute deterioration PaO₂ <30 to 40 mm Hg

^a Criteria used only after maximal therapy instituted; 50% of centers use more than one criterion.

AaDO₂, alveolar-arterial oxygen gradient; PaO₂, arterial partial pressure of oxygen.

^b Represents the ranges used in various centers

The studies that are performed before transfer of a patient to an ECMO center include an echocardiogram to rule out heart disease; cranial ultrasound scan to rule out significant ICH; coagulation studies, including a partial thromboplastin time, prothrombin time, fibrinogen level, fibrin degradation products, and platelet count; calcium and electrolyte levels; leukocyte count with a differential analysis; and hemoglobin and hematocrit levels. These studies help the team at the ECMO center determine whether the patient should be considered for ECMO and if so, assist them in anticipating difficulties.

Once the patient is admitted to the ECMO center, it must be determined if the patient is an appropriate ECMO candidate. The ultrasound examination of the central nervous system (CNS) is repeated to ensure that an ICH did not occur during transport. The cardiac evaluation is repeated if there is any residual question about the possibility of cardiac disease. Doppler flow techniques are used to document the severity of pulmonary hypertension. This information can be used later if the infant does not wean from ECMO appropriately. Serum electrolyte and calcium levels; hemoglobin and hematocrit; clotting studies including fibrinogen level, fibrin degradation products, partial thromboplastin and prothrombin times; platelet count; and baseline ACT should be obtained on admission to detect abnormalities that require correction before ECMO.

Many ECMO candidates receive muscle relaxants before admission, making the neurologic status difficult to evaluate. It is imperative to obtain a complete perinatal history, including Apgar scores, resuscitation and seizure activity, and description of the neurologic status of the infant before paralysis. Infants who have sustained severe irreversible neurologic damage should not be considered for ECMO.

PROCEDURE

Venoarterial Method

Venoarterial (VA) ECMO involves the use of two catheters: the venous outflow catheter in the right internal jugular vein with the tip in the right atrium and the arterial return catheter in the right carotid artery with the tip at the junction with the aortic arch. Blood is removed through the jugular catheter by means of gravity drainage into a venous reservoir (Fig. 32-1). Blood is pulled out of the reservoir by a roller occlusion pump and pushed through the membrane lung, where gas exchange occurs. Gas transfers across the silicone membrane lung into the blood because of pressure gradients, increasing the oxygen level and removing carbon dioxide (Fig. 32-2). Blood then enters the heat exchanger, where it is warmed to body temperature and returned to the infant through the arterial catheter.

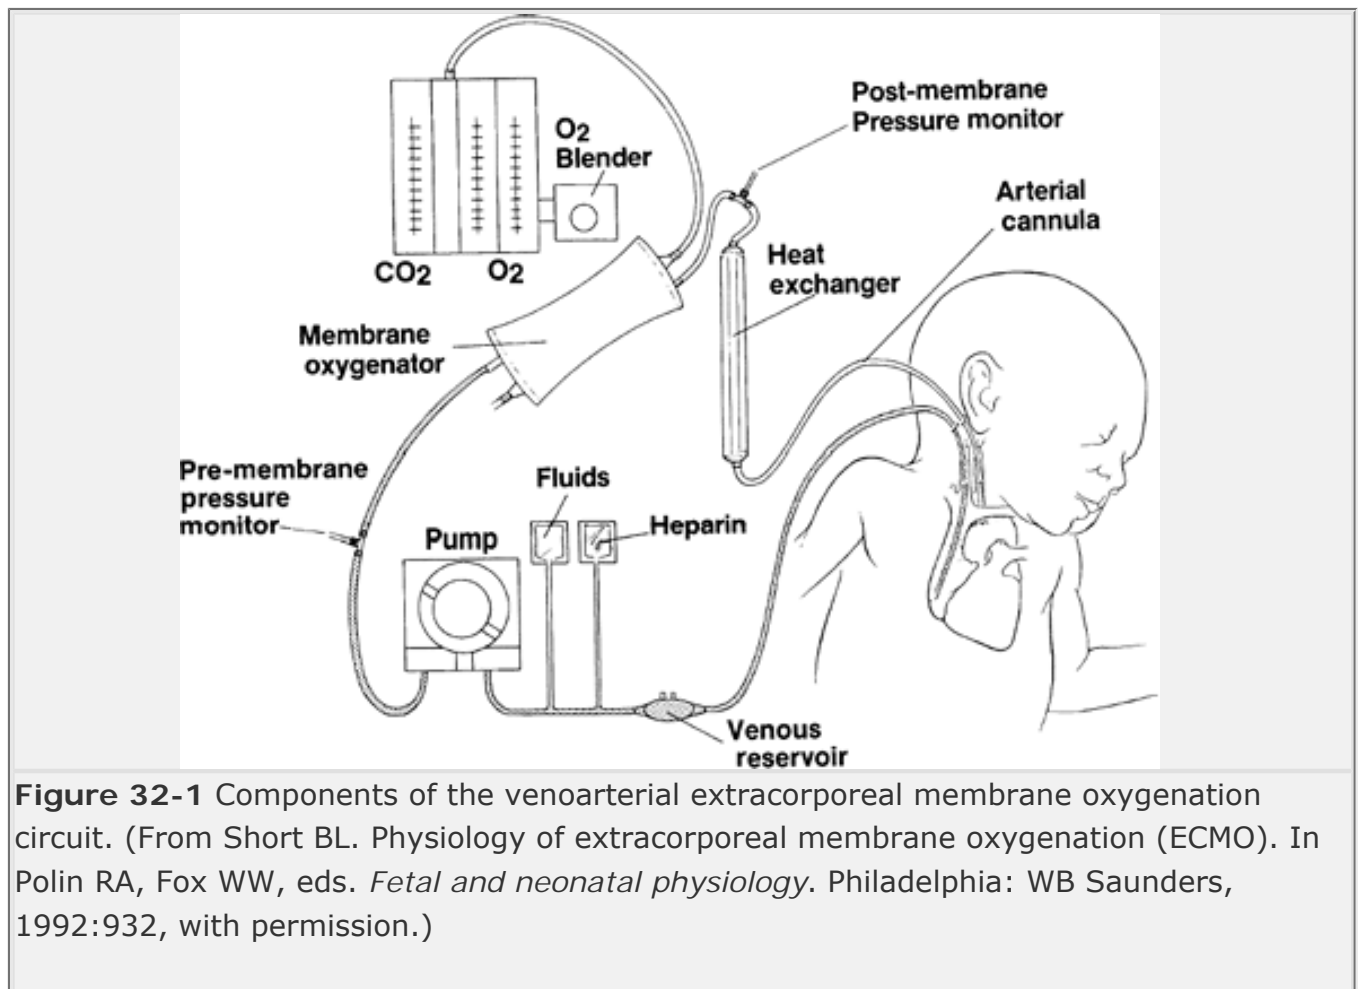

Figure 32-1 Components of the venoarterial extracorporeal membrane oxygenation circuit. (From Short BL. Physiology of extracorporeal membrane oxygenation (ECMO). In Polin RA, Fox WW, eds. *Fetal and neonatal physiology*. Philadelphia: WB Saunders, 1992:932, with permission.)

This form of bypass provides pulmonary and cardiac support. Although most infants requiring ECMO have only a pulmonary disorder, some have cardiac dysfunction secondary to severe hypoxia and require the cardiac support that VA ECMO provides. Oxygenation is achieved by allowing the pump to support as much of the cardiac output as is needed to oxygenate the infant, usually 120 to 150 mL/kg/minute in the first few days.

It is easy to support and oxygenate with VA ECMO, and it remains the gold standard for ECMO therapy. However, ligation of the carotid artery, alteration of pulsatile arterial blood flow patterns, and the possibility that particles or air in the circuit may enter the cerebral or coronary circulation remain concerns.

Venovenous Method

Venovenous (VV) techniques for ECMO have been developed because of the concerns

about carotid ligation. VV ECMO is currently achieved using a single double-lumen catheter placed through the internal jugular vein into the right atrium (Fig. 32-3) (43,44). This catheter has inflow and outflow ports that attach into the circuit. Because blood return and outflow happen in the right atrium, recirculation can occur, resulting in limited oxygenation with this technique (Fig. 32-4). Because the heart is the pump for VV ECMO, the use of this catheter depends on intact cardiac function (43,44). The advantages of this technique are the lack of necessity for ligation of the carotid artery,

P.626

maintenance of normal pulsatile blood flow, and the theoretical advantage that particles entering the circuit enter the lungs rather than the cerebral or coronary circulation. Disadvantages are the lack of cardiac support and limited oxygenation.

Figure 32-2 The silicone membrane lung promotes gas transfer across a gradient for oxygen and carbon dioxide. The pore size does not allow blood products to cross. PCO_2 , carbon dioxide partial pressure; PO_2 , oxygen pressure; $PvCO_2$, mixed venous carbon dioxide partial pressure; PvO_2 , mixed venous oxygen partial pressure. (From Short BL. Physiology of extracorporeal membrane oxygenation (ECMO). In Polin RA, Fox WW, eds. *Fetal and neonatal physiology*. Philadelphia: WB Saunders, 1992:932, with permission.)

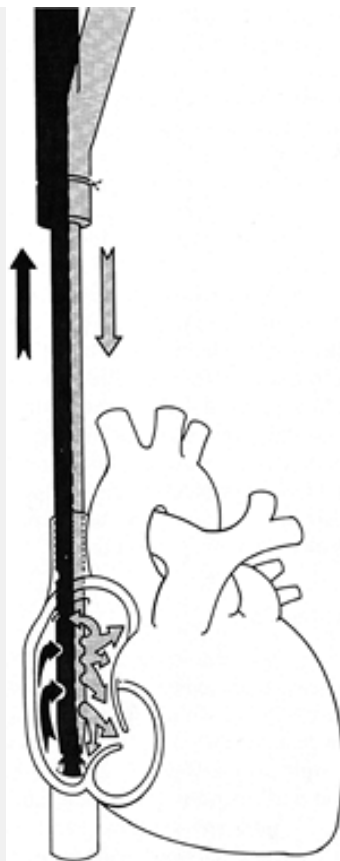

Figure 32-3 The inflow and outflow characteristics of the venovenous catheter in the right atrium. (From Short BL, O'Brien A, Poindexter C, eds. *CNMC ECMO training manual*. Washington, DC: Children's National Medical Center, 1993, with permission.)

EQUIPMENT AND SYSTEMS

Most equipment currently used for ECMO therapy is modified cardiopulmonary bypass equipment designed for short-term use. To ensure safe and effective use of the ECMO equipment, the limitations of each piece of equipment should be understood and considered before it is used for long-term bypass.

Figure 32-4 Recirculation occurs with the use of the venovenous extracorporeal membrane oxygenation catheter. Flows greater than 400 mL/min result in greater than 50% recirculation and decreased oxygenation. (From Anderson HL 3rd, Otsu T, Chapman RA, et al. Venovenous extracorporeal life support in neonates using a double lumen catheter. *ASAIO Trans* 1989;35: 650-653, with permission.)

There is no single ECMO machine. Each ECMO center must design an ECMO system by using equipment evaluated and designed to meet space and other specific requirements of their center. Bioengineering experts and cardiopulmonary perfusionists should be consulted in the design and evaluation of the ECMO system. The basic equipment needed for a complete system is listed in Table 32-4.

Space requirements and the possible need to transport the patient on ECMO should be taken into consideration in the design of an ECMO system (Figs. 32-1 and 32-5). The system should be on a cart or other movable base. The nondisposable equipment required includes a roller occlusion pump, water bath to maintain normothermic bypass temperatures, venous return monitor (VRM) or pressure monitoring system to insure adequate blood flow through the circuit, gas flow meters for CO₂ and O₂ delivery into the membrane lung, an inline venous saturation monitor, and membrane pressure monitors. Necessary disposable equipment includes the ECMO catheters (i.e., venous and arterial for VA ECMO; double-lumen venous for VV ECMO), tubing packs designed for the system, venous reservoir, heat exchanger, and membrane lung.

Figure 32-5 The extracorporeal membrane oxygenation system used at the Children's National Medical Center has a modular design.

Those involved in providing ECMO therapy must know the potential complications related to each piece of equipment, especially the thrombogenic characteristics and flow dynamics. Several of these concepts are discussed in this chapter; however, additional information can be found elsewhere (45).

In VA ECMO, the venous catheter is the oxygenation catheter because the rate of blood flow through this catheter determines the percentage of the cardiac output that is supported by the ECMO pump. Oxygenation is determined by the percentage of cardiac output passing through the ECMO membrane (i.e., artificial lung) and bypassing the patient's lungs. If a small-gauge venous catheter is placed, minimal flow through the ECMO circuit occurs, and oxygenation may be compromised. Blood flow rates (Q) are directly proportional to the fourth power of the radius (r) of the tubing and inversely proportional to the length (L) of the tubing:

$$Q \propto r^4$$
$$Q \propto 1/L$$

To maximize flow into the circuit, a relatively short venous catheter with as large a lumen as possible is used.

The arterial catheter, which supplies return of flow from the circuit into the arch of the aorta, is the smallest-diameter component in the circuit and acts as the major resistance component in the circuit. A small arterial catheter may cause significant backpressure and lead to restricted blood flow, hemolysis, or eventual rupture of the circuit. Resistance to flow (R) depends on the dimensions and geometry of the tubing and the characteristics of the fluid used. Poiseuille's Law defines this concept by the following equation:

$$R = 8\eta L/\pi r^4$$

in which $8/\pi$ is the constant of proportionality, L (cm) is the length of the tubing, η is the coefficient of viscosity (i.e., Poise = dyne X sec/cm²), and r (cm) is the radius of the tubing. The longer the tubing and the smaller the radius, the greater is the resistance. An 8-F (2.6-mm) catheter has much greater resistance than a 10-F (3.3-mm) catheter. A short, large-lumen catheter is ideal, but the size of catheter placed is limited by the diameter of the patient's carotid artery (46).

The double-lumen catheter used in VV ECMO has a small lumen for blood return, which produces a relatively

P.628

high backpressure in the circuit. Kinking of this catheter significantly increases circuit pressures and must be diligently avoided.

The VRM is an electronic device that monitors the blood flow from the patient into the ECMO circuit (Fig. 32-1). Some systems do this through pressure monitoring instead of volume monitoring. The VRM functions as a servoregulator for the ECMO system and sounds an alarm and stops the pump if venous flow from the patient slows, ensuring that aortic blood input equals venous output. If a VRM system is not in place and venous return decreases without servoregulation, the roller pump continues to pump and causes the tubing to collapse, creating a negative pressure that pulls gas out of solution in the blood and air into the circuit at the connection points. The most common causes of loss of venous return are malplacement of the venous catheter (usually in the inferior vena cava), pneumothorax, or pneumopericardium; unrecognized bleeding (e.g., ICH, hemothorax); kinking of the venous catheter; or placing an anchoring suture too tightly around the catheter during cannulation.

The only membrane lung approved for long-term ECMO use in the United States is the silicone membrane lung made by Medtronic (Minneapolis, MN). The 0.8-m² membrane is most commonly used for neonates and can support oxygenation up to a blood flow rate of 1 L/min. CO₂ transfer is so efficient with this membrane that CO₂ must be added to the gases flowing into the membrane.

PATIENT MANAGEMENT

A team approach to the management of the ECMO patient is critical. Duties of the bedside nurse, respiratory therapist, and ECMO specialist should be clearly delineated to ensure efficient and effective care (47).

Daily Medical Management

Most neonatal patients, with the exception of those with CDH, require ECMO support for 7

to 8 days. During this period, the patient who was in respiratory failure and dying before ECMO shows evidence of reversal of disease, can be slowly weaned off ECMO to minimal ventilator settings, and can usually be extubated within 24 to 48 hours after coming off the ECMO circuit. The rapidity of recovery is remarkable, given the severity of the illness suffered by these infants before ECMO. For this level of recovery to occur in such a short time, many physiologic changes must take place rapidly, making daily care of the infant a fine art. Routine care must incorporate the fact that these infants are systemically heparinized, and tasks such as suctioning of the airway should be done with caution.

As the lungs improve, less blood flow is required to pass through the artificial lung, and the ECMO blood flow can be reduced. In the first few days, a blood flow rate of 120 to 150 mL/kg/min is required to oxygenate the infant (47). With improvement of the infant's lungs, arterial blood gases improve, and the ECMO blood flow can be decreased by 10 to 20 mL/min. The venous saturation of blood in the ECMO circuit can be monitored continuously, providing a representation of a mixed venous saturation level. However, this saturation is measured in blood from the right atrium, and right atrial blood saturation does not represent true mixed venous saturation if there are intracardiac shunts. Because most infants on ECMO develop left-to-right shunts, often occurring at the level of the foramen ovale, venous saturations must be interpreted in terms of other clinical signs. The following concepts must be understood:

$$C_vO_2 = CaO_2 - \dot{V}O_2/\text{flow}$$
$$\text{Oxygen content} = (\text{Hb})(\% \text{ saturation})1.36 + 0.0031(\text{PO}_2)$$

in which C_vO_2 is venous oxygen content, CaO_2 is arterial oxygen content, [\dot{V} with dot above] O_2 is oxygen consumption, flow is cardiac output, Hb is hemoglobin, and PO_2 is oxygen pressure.

For venous oxygen saturation to represent a true indication of relative arterial oxygen content, several assumptions must be made: the cardiac output remains stable, hemoglobin concentrations remain stable, and metabolic rate of the patient does not change. Any one of these factors can cause a change in the venous saturation. Therefore, the patient should be carefully evaluated before this parameter is used alone to wean the ECMO flows. Obviously this parameter cannot be used in VV ECMO, where the venous saturation only represents recirculation. Patient arterial blood gases are needed to determine the pH and $PaCO_2$ status of the patient and membrane lung. If the arterial $PaCO_2$ of the membrane decreases below 35 mm Hg during VA ECMO, a decrease in respiratory rate may result because the brain detects the blood gas levels in blood from the membrane lung during VA ECMO. If the patient's respiratory rate falls, and he or she is on low bypass, the result is deterioration in blood gas status. The problem is corrected by increasing the CO_2 coming from the membrane to stimulate the infant to breathe. A high membrane PCO_2 may indicate membrane failure and is an emergency, and a normal membrane PCO_2 with an abnormal patient PCO_2 indicates a change in the patient's clinical condition such as development of pneumothorax or secondary pneumonia.

After being stabilized on ECMO, the infant is placed on lung-rest settings on the ventilator

(e.g., $FiO_2 = 0.21$, peak inspiratory pressures [PIP] = 15 to 18 cm H₂O; peak end-expiratory pressures [PEEP] = 5 to 6 cm H₂O; rate = 10 to 15 breaths/min). It is typical for the lungs to appear opaque on chest radiographs during the first 1 to 3 days of ECMO (48,49,50). This is probably caused by the acute decrease in ventilatory settings, capillary leak, activation of complement as a result of interaction of blood products with the artificial surfaces in the circuit, and surfactant deficiency secondary to lung injury (51,52). Lotze and associates (53,54) showed that surfactant replacement therapy in infants on ECMO can decrease time on ECMO for all infants except those with CDH. A study conducted

P.629

using surfactant before ECMO revealed that a significant number of infants in the low-mortality group (OI 15 to 22) could be kept off ECMO with the use of surfactant (55). Lung compliance studies can help in predicting successful decannulation, especially in the infant who is borderline, and when a decision is being made about removing an infant from ECMO because of complications (49). A typical lung compliance curve is shown in Fig. 32-6. An old-fashioned but effective technique for assessing pulmonary improvement is to hand-ventilate the infant daily. When the chest moves easily with a peak pressure of 20 cm H₂O or less, the infant can successfully come off ECMO.

Heparin is administered continuously into the ECMO circuit to prevent clotting (47). Heparin management varies, depending on events before and during ECMO. Optimal heparin management can achieve the level of heparinization needed to decrease the risk for fibrin and clot formation in the circuit while minimizing the risk for bleeding complications in the patient. Because heparinization must be evaluated rapidly and at the bedside, most centers use the ACT (56). The ACT is determined in a system that uses

activators, such as glass beads, to initiate the clotting cascade. The specimen is warmed to accelerate the clotting process. This test gives values of 80 to 120 seconds in a nonheparinized infant, compared with standard nonactivated bleeding time values longer than 5 minutes (56,57).

The primary cause of death in the ECMO population is ICH (30,31,58). The risk factors associated with the development of an ICH include significant hypoxic or ischemic cerebral insult before ECMO, sepsis with coagulopathy, or gestational age less than 37 weeks. Initial heparin management is based on pretreatment risk factors (45).

Fibrin formation is related to flow rate; if there are low blood flow rates in the circuit, the heparin dose is increased to decrease the risk for clot formation. At the beginning of an ECMO run, blood flows are high, and the ACTs can be maintained in a lower range. At the end of a run, the ACTs are increased, especially when the idling phase (i.e., 60 to 80 mL/min) is reached. When the blood flow rate in the circuit is below 150 mL/min, ACTs are increased to 200 to 220 seconds. Clinical factors that affect the ACT values are renal function (heparin excretion is directly proportional to urine output), transfusion of nonheparinized blood products or platelets, and a significant patent ductus arteriosus with a left-to-right shunt that may decrease renal blood flow.

Fluid requirements while on ECMO range from 80 to 120 mL/kg/day. Electrolyte requirements are significantly different from those before ECMO is started. Most infants require little sodium, usually 1 to 2 mEq/kg/day, and a large amount of potassium, usually 4 to 5 mEq/kg/day. The rationale for these requirements is unknown. Although renin levels increase on bypass, aldosterone levels decrease, and atrial natriuretic peptide levels do not change (59,60). Calcium requirements range from 40 to 50 mg/kg of elemental calcium per day.

Systemic hypertension is a common medical complication of ECMO (59,60 and 61). Hypertension (mean blood pressure greater than 65 mm Hg for more than 3 hours) can affect as many as 70% of these patients. Hypertension usually develops shortly after cannulation and is transient, but 1% to 5% of infants require long-term antihypertensive therapy. The risk of ICH is increased by hypertension (60). Although a subject of controversy, the hypertension may be related to an increase in serum renin levels (59,60). Fluid restriction and diuretic therapy may decrease the risk for prolonged hypertension.

As pulmonary vascular resistance decreases, it is common to develop a left-to-right shunt across the patent ductus arteriosus, resulting in oxygenation difficulty (62). Most of these shunts close with fluid restriction and diuretic therapy. Few patients require surgical intervention. Indomethacin should not be used in this population because it decreases platelet aggregation. After the shunt closes, an immediate increase in the patient's PaO₂ is observed.

Cardiac stun is an interesting complication of ECMO therapy that also occurs in patients on cardiopulmonary bypass (63). Cardiac stun occurs in infants with severe hypoxia or in infants in whom the tip of the arterial catheter is placed too close to the coronary arteries. This syndrome is characterized by a pulse pressure of 10 mm Hg or less on ECMO, with the patient's PaO₂ equal to or within 50 to 100 mm Hg of the pump PO₂ (e.g., a pump PO₂ of 400 mm Hg while on an FiO₂ of 1.00, with a patient PaO₂ between 300 and 350 mm

Hg). The electrocardiographic pattern is normal, indicating that electrical conduction is normal, but cardiac output is markedly reduced. The pathophysiology is not understood (63,64). When data on infants with cardiac stun while on ECMO at the Children's National Medical Center were evaluated, there was a significant difference in pre-ECMO blood gases relative to infants who did not develop cardiac stun. Infants in stun were sicker before ECMO and had a higher

P.630

incidence of death from ICH, indicating the marked hypoxic-ischemic insult suffered by these patients before ECMO. Treatment of cardiac stun consists of maintaining ECMO blood flow rates high enough to supply appropriate cardiac output. Afterload reduction does not improve cardiac function in this population (65). As stun resolves, the pulse pressure returns to normal, and the patient's PaO₂ no longer mirrors the pump PO₂.

Weaning from VA ECMO occurs slowly as the arterial blood gases and venous saturations improve. Idling flows, defined as flows at 10% of the cardiac output (i.e., 60 to 80 mL/minute) are continued for 6 to 8 hours, and if blood gases are normal during this period, most infants can be successfully taken off ECMO. A lung compliance measurement of at least 0.8 mL/cm H₂O/kg indicates that the infant can successfully come off ECMO (Fig. 32-6) (50). For patients on VV ECMO, the flows can be kept high and the membrane lung can be capped off, so no gas flow occurs. Monitoring blood gases for 2 to 4 hours will determine if the patient is ready to come off ECMO. Typical ventilator settings for infants after completing an ECMO course are FiO₂ of 0.30 to 0.40; rate of 30 to 40 breaths/minute; PIP of 18 to 20 cm H₂O; and PEEP of 5 to 6 cm H₂O.

Patient Care after Extracorporeal Membrane Oxygenation

A neuromuscular blocking agent with an intermediate half-life is used at decannulation to help the patient breathe spontaneously as soon as possible after coming off ECMO. By the end of the ECMO run, it is common for the ECMO patient to require high PaCO₂ levels (i.e., 45 to 55 mm Hg) to stimulate respiratory drive. Many of these infants have been receiving narcotics such as fentanyl and may need to be weaned slowly from this therapy to avoid withdrawal symptoms. PaO₂ levels of 60 to 70 mm Hg are accepted, and every effort is made to wean the patient from the ventilator. At Children's National Medical Center, the average time to extubation post ECMO is 23 hours. The CDH patient is an exception; these patients require slower weaning to ensure that pulmonary hypertension does not recur.

Hemoglobin, hematocrit, calcium, and electrolyte measurements should be obtained 6 to 8 hours after ECMO. These can then be monitored every 24 hours or as clinically indicated. The platelet count should be followed closely (i.e., values every 12 hours for 24 hours) because rebound thrombocytopenia may occur. Intravenous sodium is increased to 2 to 3 mEq/kg/day, and potassium supplementation is decreased to 1 to 2 mEq/kg/day.

After extubation, the infant usually requires oxygen therapy for another 5 to 7 days. Most ECMO infants feed poorly and may require feeding by tube for a few days. The cause of this problem is uncertain, but it is usually transient and does not indicate long-term

developmental problems.

Because not all intracranial abnormalities are detected by ultrasound, a computed tomographic or magnetic resonance scan is recommended before discharge (66). A baseline hearing screen and neurologic assessment are also recommended before discharge. All infants should be followed in a neonatal high-risk follow-up program.

Outcome Data

Developmental outcome is encouraging, with most centers reporting that 60% to 70% of ECMO survivors are normal at 1 to 2 years of age (67,68 and 69). Risk factors associated with poor outcome include finding a severe abnormality on neuroimaging, chronic lung disease, prematurity, and group B streptococcal sepsis (67,70-72). When ECMO survivors were evaluated at 5 years of age though, Glass and associates (73) found that 37% were at risk for school failure; however, Rais-Bahrami and colleagues (74) found a similar risk in the population of "near-miss" ECMO patients, defined as those referred for ECMO but who improved without ECMO. Wagner and associates (75) followed the ECMO population studied in the Glass study into school and found that indeed, a high percentage had academic problems (37%). Therefore, although a great majority of post-ECMO patients are doing well, a thorough neuropsychologic evaluation prior to starting school should be considered to identify those children who may benefit from special education programs.

The need for carotid artery ligation for VA ECMO has caused concern that right-sided CNS lesions may result, but most studies have not shown this to be true (58,66,70,72). Analysis of the first 360 patients treated at Children's National Medical Center did not reveal lateralizing hemorrhagic or nonhemorrhagic abnormalities, but there was a high incidence of posterior fossa hemorrhage, raising the concern that jugular venous ligation might increase venous backpressure and the risk of hemorrhage (76). Data published by Taylor and Walker (77) showed that decreased sagittal sinus blood flow velocity is associated with ICH (70%) in the ECMO population. Whether this is cause or effect has yet to be determined. Also noted in this study was a marked decrease in sagittal sinus blood flow when the infant's head was turned to the left, obviously obstructing the left internal jugular vein when the right was ligated, resulting in obstruction of venous flow. The association of this with cerebral hemorrhage could not be determined because of the small number of patients, but it does address the need for keeping the infants head midline during the ECMO run. Because of this concern, many ECMO teams are now placing jugular bulb catheters in the right internal jugular vein, advanced up to the jugular bulb area, to drain the venous outflow from the brain into the venous side of the circuit, and thus reduce the potential obstruction caused by the venous catheter and ligation of the jugular vein.

The infant with CDH may have unique long-term problems, including significant gastroesophageal reflux and chronic lung disease (14,38). These infants require close follow-up in a multidisciplinary clinic to prevent problems such as failure to thrive and respiratory compromise.

Care of the ECMO patient requires highly trained nurses, respiratory therapists, perfusionists, and physicians. The team must continually evaluate the treatment modalities and use the information to improve techniques and define the indications for ECMO therapy. Prior to the use of iNO, it was estimated that only 1,000 to 2,500 term infants required ECMO each year in the United States (78). That number is obviously going to be smaller since iNO has been shown to reduce the need for ECMO, making the need for tailoring the development and expansion of ECMO centers based on regional need even more important. Regionalization of ECMO programs can help to maintain cost control and optimize quality of care.

Chapter 33

CARDIAC DISEASE

Michael F. Flanagan M.D. Scott B. Yeager M.D.

Incidence

The incidence of congenital heart disease detectable by routine clinical examination has been estimated to be 7.5 per 1,000 live births (1). The incidence of congenital heart anomalies in neonates seen with detailed echocardiographic examination is four- to 10-fold higher, with most of the difference being clinically insignificant ventricular septal defects (20-50 per 1,000) and nonstenotic bicommissural aortic valves (2). Severe forms of cardiac anomalies requiring cardiac catheterization or surgery, or resulting in death, occur in 2.5 to 3 infants per 1,000 births (2,3). Almost one-half of these are diagnosed during the first week of life. Additionally, moderately severe forms of cardiac anomalies occur in another 3 per 1,000 live births, and another 13 of 1,000 live births have a bicommissural aortic valve that may require care eventually (2). The distributions of congenital heart anomalies in newborns seen at a primary and a tertiary pediatric cardiac center are shown in Table 33-1.

Infant Mortality

Before aggressive intervention, Mitchell found that 2.3 of 1,000 live births died with cardiac problems in infancy (1). Infant cardiac mortality in developed countries has progressively declined over the last several decades with better prenatal and postnatal recognition, and with the development and refinement of definitive interventions and peri-procedural management. The infant cardiac fatality rate in the United States was 0.15 per 1,000 births in 2000, ranking tenth among leading causes of infant death (4). At high-volume surgical centers more commonly occurring cyanotic cardiac anomalies such as transposition of the great arteries and tetralogy of Fallot have surgical mortality rates of 1% to 5% or less. Complex anomalies with the highest risk have also had significant improvements in neonatal survival in developed countries. For example, surgical survival of neonates with hypoplastic left heart syndrome increased from 40% to 60% to 75% to 93% at specialized surgical centers (5), with overall mortality in infancy approximately twice this. Although surgical surgery outcomes are much improved, including in babies with prematurity and multiple anomalies, prematurity and associated noncardiac anomalies still strongly influence the potential for salvaging infants with cardiac disease (Table 33-2) (4). In some situations, the mortality attributable to these problems is considerable.

Long-Term Survival

This chapter focuses on infancy; however, discussions with parents concerning their newborn with a cardiac anomaly often quickly, and appropriately, move to the length and quality of life anticipated in later childhood and adulthood. It is important that parents are accurately advised of likely and potential long-term outcomes with current therapies by cardiologists or other practitioners up-to-date with recent advances and outcome findings. In general, those with common acyanotic anomalies such as uncomplicated septal defects or pulmonary valve stenosis, and most of those with cyanotic anomalies such as simple transposition of the great arteries now can anticipate an essentially near-normal life after appropriate intervention. Even with many complicated anomalies, most can expect to survive to at least mid-adulthood, although long-term survival is highly dependent on the specific diagnosis, with the highest mortality now generally occurring in infancy (see [Table 33-2](#)). With few exceptions, a cardiac operation or catheter intervention can lengthen and improve the quality of life of a child with heart disease. Even when the nature of the long-term management is unclear, care has proceeded with the conviction that childhood survival often allows yet to be planned later interventions, resulting from future progress in the field, to provide even longer and better survival. The palliative shunt operations of 20 to 40 years ago unexpectedly produced candidates for later Fontan procedures. The central principle continues to be “where there is life, there is hope.”

With reductions in mortality, and new generations of adults and older children with repaired and palliated cardiac anomalies, it has become evident that cardiac anomalies, and procedures utilized to treat them, sometimes have late residua and sequelae, including neurologic and cognitive morbidity not evident until preschool or school

P.634

age ([6,7](#) and [8](#)), and arrhythmias and ventricular dysfunction developing in adolescence and adulthood. Most difficult, and not yet fully delineated have been the neurologic and cognitive morbidity. These abnormalities appear rarely with common septal and valvar malformations, and tend to be more frequent and severe with more complicated anomalies and repairs. Cardiac, neurologic and cognitive outcomes after repair of septal defects have appeared generally normal ([8](#)). Although most children with complex anomalies and procedures, such as hypoplastic left heart syndrome and operative circulatory arrest, have neuro-cognitive outcome within the normal range, on average, they have slower development, lower IQ scores, and higher rates of learning disabilities and special needs than normal. Moreover, a significant number have major impairments ([8](#)). The etiologies are complex, and include possible genetic issues, coexistent brain

anomaly, potentially diminished cerebral blood flow or oxygenation in utero with some anomalies (e.g., hypoplastic left heart syndrome), pre- and/or peri-operative low cardiac output, cyanosis (See [color plate](#)), thrombo-embolism, or intracerebral hemorrhage, and operative use of hypothermic circulatory arrest ([6,7](#) and [8](#)). The possibility that brain injury or other injury may be acquired prenatally, pretreatment or in the process of treatment should be understood.

TABLE 33-1 NEONATAL (FIRST MONTH) CARDIAC DIAGNOSTIC DISTRIBUTION^a

	Percent
Ventricular septal defect	41

Pulmonary atresia and intact interventricular septum	<1
Single ventricle	<1

^a Based on 361 patients diagnosed by echocardiography by age 1 month at Childrens Hospital at Dartmouth. Neonates with patent ductus arteriosus, persistent fetal circulation, arrhythmia and normal heart exams are not included.

The goal is to provide a satisfying life through childhood and adulthood. The long-range future of patients undergoing intracardiac repair, arterial switch operations, staged multiple complex palliative operations, Fontan operations, or cardiac transplantation requires detailed discussion. The ramifications of treating a child who has major anomalies must be discussed with the parents in understandable language. The expected physical capabilities of the patient after treatment should

be delineated. After the physician is confident that the parents thoroughly understand the known facts, he or she is free to express an opinion about what may be best for the child.

Etiology

Heart formation is a fantastic metamorphosis regulated by many sequences of genes. Given the remarkably complex orchestration of molecular and morphologic processes in formation of the heart, even small genetic and/or environmental changes in the control of these processes can have major, and variable, consequences. Truly, it is wonderful that development occurs and it does, as often as it does. Nevertheless, understandably, parents ask why their baby was born with a cardiac abnormality and whether it is likely to recur with a subsequent pregnancy.

Occasionally, children with isolated cardiac anomaly have a parent who has survived with cardiac anomaly, or another family member with a cardiac anomaly, but more often, there is no family history. However, an inheritable defect in a single gene (e.g., Marfan syndrome) or a chromosomal anomaly (e.g., trisomy) is identified in a significant minority of patients with cardiac malformations. More commonly there may be susceptibility from inherited or acquired mutations in two or more genes, perhaps with additional alterations in gene transcription or posttranscriptional processes from maternal-fetal folate metabolism, or fetal exposure to specific pharmacologic, biochemical, infectious and environmental factors that cumulatively surpass a threshold of liability (9). These result in pathogenetic changes in embryonic development, including defects in mesenchymal tissue migration (tetralogy of Fallot, truncus arteriosus, interrupted aortic arch, malalignment conal-septal ventricular septal defects, transposition of great arteries), extracellular matrix defects (endocardial cushion defects), abnormal cell death (muscular ventricular septal defect, Ebstein anomaly), targeted growth (anomalous pulmonary vein connection, single atrium), defective situs and cardiac looping (heterotaxy syndromes, L-transposition), and secondary effects from alterations in blood flow in the right heart (secundum atrial septal defect, pulmonary valve stenosis and atresia) or left heart (hypoplastic left heart syndrome, coarctation of aorta, aortic valve stenosis, patent ductus arteriosus) (9,10,11 and 12).

Approximately 13% of children with cardiac anomalies have chromosomal syndromes associated with cardiovascular malformation. Another approximately 8% to 13% of children have inheritable syndromes with associated cardiovascular abnormalities (11,12 and 13). The genes affected in many of these syndromes have been identified (9,14,15 and 16) (Table 33-3). The most common human mutations are in a critical 30 gene region of chromosome 22q11 involved in neural crest and cardiac development that cause DiGeorge

and velocardiofacial syndromes and associated conotruncal and aortic arch malformations (15). Other mutations in the genes encoding the extracellular matrix proteins fibrillin-1 and elastin are responsible, respectively, for Marfan and Williams syndrome. Genetic syndromes associated with abnormal cardiac development are generally associated with specific cardiac malformations, for instance Down syndrome and endocardial cushion defects, Williams syndrome and supravalvar aortic stenosis, DiGeorge syndrome and tetralogy of Fallot, truncus arteriosus, and interrupted aortic arch (Table 33-3). Recognition that a child has a syndrome associated with a cardiac anomaly, or vice versa, should prompt an investigation for possible associated anomalies (16,17,18,19 and 20).

TABLE 33-2 INFANT (FIRST-YEAR) CARDIAC DIAGNOSTIC DISTRIBUTION AND MORTALITY

Diagnosis	Frequency (%)	Mortality (%)
Ventricular Septal Defect	31	0.7
Pulmonary Valve Stenosis	19	0.5
Atrial Septal defect	12	0.2
Aortic Valve Stenosis	8	4
Atrio-ventricular Canal	5	1.8
Septal Defects		
Coarctation of Aorta	4	3.5
D-Transposition of Great Arteries	4	1.0
Tetralogy of Fallot with pulmonary outflow stenosis	4	2.2
Malposition	3	9
Hypoplastic Left Heart Syndrome	2	22
Pulmonary Valve Atresia with Intact Ventricular Septum	2	4
Pulmonary Valve Atresia with Tetralogy of Fallot	1	11
Double Outlet Right Ventricle	0.9	6
Total anomalous pulmonary venous connection	0.8	7
Truncus arteriosus	0.7	5
Single Ventricle	0.7	<0.1
Tricuspid Atresia	0.5	<0.1
Interrupted Aortic Arch	0.3	<0.1
Aortic-Pulmonary window	0.2	<0.1
Hemitruncus	0.1	<0.1

L-Transposition of Great Arteries	0.1	<0.1
Total	2.2	

Data is based on 5,182 infants diagnosed at Childrens Hospital, Boston between January 1,1998 and January 1,2002, and their overall mortality by age 1 year. Babies with patent ductus arteriosus and primary cardiomyopathy were not included. Mortality by age 1 year was significantly influenced by coexistent prematurity and noncardiac disease.

Most children with cardiac malformations, even those with tetralogy of Fallot, have isolated cardiac anomalies, without generalized syndrome or other apparent abnormality. Many specific cardiac anomalies are rarely associated with a noncardiac syndrome, for example, transposition of the great arteries, and pulmonary atresia with intact ventricular septum (Table 33-4). Although the molecular biology of cardiovascular development is being unraveled, the specific genetic and/or environmental causes of isolated cardiac anomalies remain unknown in most individual cases (14,15,21). Mutations in 22q11 cause 20% to 30% of isolated conotruncal and aortic arch malformations. Other mutations are involved with at least some of the remainder (15). For example, alterations in cardiac specific transcription factor control genes, or their function (e.g., NKX2.5, TBX5), sometimes in combination with genes that they control, are being identified in children with isolated cardiac anomalies (15).

Although the occurrence of cardiac malformation has been mostly constant year by year, and by location, there are exceptions. Biochemical and chance events during fetal development may play roles in causation of new genetic mutations and in transcriptional and posttranscriptional processes (9,14,15,22). For instance, the risk for development of conotruncal anomalies is significantly influenced by maternal-fetal intake and metabolism of folic acid and homocysteine (24,25,26,27 and 28). Although fetal exposure to specific pharmacologic, biochemical, infectious and environmental factors may increase the risk for developing a cardiac abnormality (Table 33-5) (9,29,30 and 31), these factors alone do not appear to explain most cases. In individual cases, it is usually difficult or impossible to identify specific extrinsic factors that may have modified the baby's genotype or genotypic expression.

A singular abnormality results in characteristic complex cardiac malformation by altering migration or function of embryonic primordial cells, such as in the neural crest or endocardial cushion, before formation of cardiac structures in the conotruncus or atrioventricular valves, respectively. Animal studies have demonstrated that embryonic

cervical neural crest cells migrate into the thorax and contribute to formation of the aortic arch and conotruncal outflow region of the heart. Blockage of the normal function of these embryonic neural crest cells results in aortic arch anomalies including aortic interruption; conotruncal abnormalities including tetralogy of Fallot, truncus arteriosus, and transposition; and ventricular inlet anomalies including tricuspid atresia and double-inlet single left ventricle (11,14). Cells in the embryonic endocardial tissue undergo a different developmental sequential process controlled by a large number of factors. Perturbation of specific steps in these embryonic cell process changes developmental sequences in characteristic ways and alters blood flow patterns affecting vascular growth downstream in characteristic ways (9,10 and 11). Because growth of specific cardiovascular structures is flow dependent, limitation of flow can cause additional hypoplasia of downstream structures (10,11). For example, a mildly stenotic bicommissural aortic valve may decrease blood flow through the aortic isthmus and result in coarctation.

TABLE 33-3 CONGENITAL DISORDERS ASSOCIATED WITH CARDIAC DISEASE

Selected Disorders	Identified Gene (s)	Chromosome Location	% Heart Disease	Cardiovascular Anomalies
Autosomal Dominant				
Alagille Arteriohepatic dysplasia	Jagged 1	20p12	100	multiple PA stenosis and hypoplasia, PDA, ASD, VSD
Apert acrocephalosyndactyly	FGFR-2	10q26		VSD, hypoplastic
Beckwith-Wiedemann syndrome	BWS	11pter-p15.4	15 ?	PDA
de Lange syndrome	CDL	3q26.3	30	HCM, ASD, VSD, TF, PDA
CATCH 22/ DiGeorge syndrome	DiGeorge chromosome region	22q11	>50	VSD, ASD, PDA, AS, EFE TF, interrupted Ao arch, truncus arteriosus, right Ao arch
Goldenhar hemifacial microsomia	HFM endoglin	14q32 9q34.1	15 100	TF, VSD, PDA, COARC

^a It is generally accepted that these prenatal factors increase the risk for congenital heart disease. From refs. 9,12,13,18,23,24,25,26,27,28,29,30,31,114.

Certain cardiac anomalies are associated with prematurity or low birth weight. Because closure of the ventricular septum may be delayed until the first months of life, it is not surprising that there is a somewhat greater incidence of ventricular septal defect among premature infants. The increased incidence of patent ductus arteriosus in prematurely born infants can be viewed as the result of birth long before the programmed time for closure of the ductus. Hypoxemia of pulmonary origin also promotes ductal patency.

As with gross anatomic cardiac anomalies, specific causes of cardiac muscle diseases unknown until recently are being identified. Many of the hypertrophic and dilated cardiomyopathies previously known as idiopathic are now known to be caused by specific gene mutations and pathogenetic mechanisms (9,16,32,33 and 34). Most patients with isolated hypertrophic cardiomyopathy have newly acquired or autosomally dominant inherited mutations in the genes encoding sarcomeric contractile proteins, most commonly cardiac B-myosin heavy chain, cardiac myosin-binding protein C or troponin T2 (32,33). Isolated dilated cardiomyopathy has been associated to date with 19 genetic loci, involving contractile, cytoskeletal and other proteins, and identification of more is likely (9,16,33). Dilated and hypertrophic cardiomyopathies also occur in association with a large number of more generalized neuromuscular and metabolic disorders occurring from specific nuclear and mitochondrial genetic mutations (see Cardiomyopathy and Tables 33-16 and 33-17) (9,16,34).

Some specific arrhythmia syndromes are also caused by specific genetic mutations. These include patients with ventricular tachycardia associated with prolonged QT syndrome and arrhythmogenic right ventricular dysplasia and rare forms of Wolf-Parkinson-White syndrome with supraventricular tachycardia. Long QT syndrome results from mutations in genes encoding specific cardiac potassium and sodium ion channels that regulate repolarization (35); the ensuing prolongation of repolarization results in ventricular tachycardia.

Fetal Cardiology

Extensive information about the circulatory physiology of the fetus and newborn has accumulated. The works of Barcroft (37), Dawes (38), Lind and associates (39), and Rudolph (40) should be consulted for details, but the central features are discussed here. The circulation before birth consists of parallel circuits (Fig. 33-1). Blood in the aorta may follow several routes to a capillary bed in the fetus or the placenta, back to the heart, passing through either ventricle, and out again to the aorta. The stream of newly oxygenated blood from the placenta passes through the umbilical vein, the ductus venosus, the inferior vena cava,

P.639

and the right atrium. Unlike the circulation after birth, the streams of oxygenated and unoxygenated blood are not completely separated, although the more oxygenated blood from the inferior vena cava is mostly diverted through the foramen ovale into the left atrium. Consequently, blood from the left ventricle entering the ascending aorta and coronary and carotid circulations is somewhat higher in oxygen than that entering the descending aorta from the right ventricle by way of the ductus arteriosus.

The volume pumped by the right ventricle is normally about 55% of the combined output of both ventricles. Because both ventricles pump against the systemic resistance, the level of pressure in the two ventricles is comparable. The resistance to blood flow through the lungs is relatively great; only minimal flow through the lungs occurs *in utero*, and almost all of the right ventricular output into the pulmonary artery passes through the ductus arteriosus to the descending aorta. The parallel arrangement of the ventricles allows fetal survival despite a wide variety of cardiac lesions. With total obstruction of either ventricle, the other ventricle assumes the entire cardiac output. Reversal of the pulmonary arterial and aortic streams of blood, as occurs in transposition of the great arteries, produces no deleterious effect on the fetus. Additionally, ductal or ascending

Figure 33-1 Fetal circulation is in parallel, and the amount of blood handled by the left and right ventricles is 125 and 90 mL, respectively. Only 40 mL passes through the aortic arch to the descending aorta, and only a small fraction passes through the lungs. The numbers inside the diagram represent relative blood flow (mL); the numbers in italics are pressure measurements. Modified from Rudolph AM. *Congenital diseases of the heart*. Chicago: Year Book, 1974, with permission.

aortic flow may reverse in the presence of severe semilunar valvar stenosis or atresia. Despite this remarkable ability to adapt, grow, and survive, the fetus is affected by limitations in myocardial contractility. Prolonged, severe pressure or volume loading of the heart or primary myocardial disease may result in congestive heart failure, manifested by hydrops fetalis. The interplay between the metabolic effects of congestion in the fetus and the possible compensatory role of the placenta is not understood. Because lesions that may be expected to cause gross intrauterine difficulty are tolerated surprisingly well, the postulate that the placenta helps compensate for the metabolic abnormalities resulting from congestive heart failure is tenable.

Circulatory Adjustments at Birth

Changes in the Source of Oxygenated Blood and in the Ductus Venosus and Ductus Arteriosus

With the first breath, the resistance to pulmonary blood flow drops sharply. The oxygen content of the left heart and systemic circulation rapidly reaches levels well above that of the fetal circulation. Oxygen saturation in the ascending aorta rises from about 65% in the fetus, to about 93% immediately after birth. The ductus venosus functionally closes, establishing the portal circulation as an independent loop between two capillary beds. With removal of the low-resistance placenta, systemic resistance increases. The relative fall in the pulmonary resistance and rise in the systemic resistance result in a transitory left-to-right shunt through the ductus arteriosus. In half of term babies the ductus is completely constricted by the end of the first day of life, and is normally becoming anatomically obliterated at about 10 days of age. Even among cyanotic newborns who are duct dependent, the ductus may inexorably close, often severing the infant's only source of pulmonary or systemic blood flow. The mechanisms causing closure of the ductus arteriosus are not completely understood but involve decreased prostaglandins and increased blood oxygen. Prostaglandin levels in the blood decrease at birth as a result of removal of their placental source of production from the circulation and increase in perfusion of the lungs, in which prostaglandins are metabolized.

Foramen Ovale

Functional closure of the foramen ovale occurs soon after birth, largely as a result of increased left atrial volume and pressure secondary to the increased pulmonary venous return, the ductal left-to-right shunt, and the developing differences in diastolic pressure of the two ventricles. Anatomic closure normally is delayed for months or years.

Among infants with cardiac defects, lesions with increased right atrial pressure favor indefinite patency of the foramen ovale (e.g., pulmonary stenosis), but abnormally increased left atrial pressure promotes early anatomic closure (e.g., ventricular septal defect). Before birth, the pulmonary arterioles are relatively muscular and constricted.

Pulmonary Vasculature

With the first breath, total pulmonary resistance falls rapidly because of the uninking of the vessels with expansion of the lungs and because of the vasodilatory effect of inspired oxygen. The muscular constriction relaxes, and gradually, during the subsequent days and weeks, the muscular wall of the pulmonary arterioles thins. During the first weeks of life, the muscular arterioles retain a significant capacity for constriction. Pulmonary alveolar hypoxia normally produces an increase in pulmonary artery pressure at all ages, but in the young infant, the response is more profound and occurs more rapidly. Therefore, pulmonary hypertension equal to or greater than systemic pressure occurs commonly in neonates with severe respiratory disease.

Ventricular Work

Before birth, the two ventricles share in supplying systemic blood flow and placental flow, and after birth, the two ventricles sequentially and independently handle the entire cardiac output. At birth, the volume of blood to be pumped by the right ventricle decreases to the level of the systemic blood flow; right ventricular pressure falls as a result of the decrease in pulmonary resistance and closure of the ductus arteriosus. Although right ventricular work decreases, left ventricular work increases (Fig. 33-2). At birth, the left ventricle abruptly becomes the sole supplier of systemic blood flow, and the volume that it pumps is fractionally increased. The left-to-right shunt through the ductus arteriosus adds further volume work, and the elevated systemic resistance must be overcome. Although this is a stressful time for the left ventricle, the magnitude of these suddenly acquired burdens is not so great that detectable left ventricular difficulties are seen normally, but any impairment of myocardial function may be magnified as a consequence. Myocardial disease as a cause of symptoms is more common in the first days of life than at any other time during infancy; 25% of infants with myocardial disease presented in the first week of life (4).

Myocardial Function

Important changes occur in the fetus and neonate in many aspects of myocardial biochemistry and structure. These include myocyte size and number, microvascular structure, myocyte utilization of lactate and fatty acids, and

antioxidant systems. Many structures and proteins involved in calcium handling within the myocyte, such as t-tubules, sarcoplasmic reticulum, Na⁺-Ca²⁺ exchange, Ca²⁺-ATPase, and phospholamban, have important developmental changes. These changes influence the effects on ventricular rhythm and function of normal development, prematurity, ischemia, cardioplegia, and various inborn errors of metabolism.

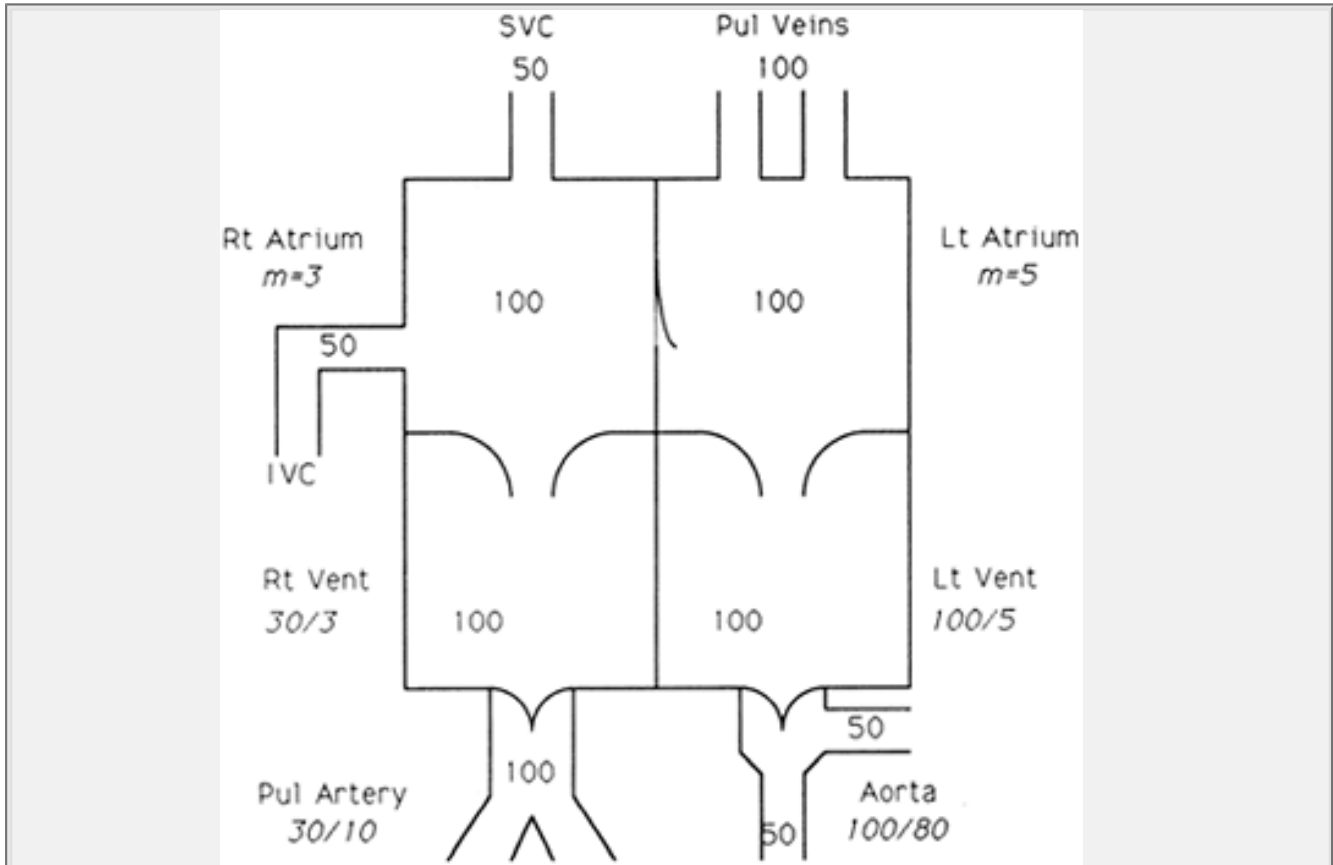

Figure 33-2 Mature circulation is in series, and the amount of blood carried by the two ventricles is approximately the same as before birth. The lungs carry an amount equivalent to the cardiac output, as does the ascending aorta. The numbers inside the diagram represent relative blood flow (mL); the numbers in italics are pressure measurements.

Fetal Echocardiography

High-resolution two-dimensional ultrasound evaluation of the fetal heart is a useful and accurate technique in the diagnosis and management of the fetus at risk for structural or functional cardiac abnormalities. Indications for prenatal echocardiography may include maternal, fetal, and genetic considerations (Table 33-6). The optimal time for performing fetal echocardiography is 18 to 24 weeks of gestation. At this age, the fetal heart is usually large enough for detailed anatomic evaluation, and the images are unimpaired by dense rib or spine calcification. There is also a relatively large volume of amniotic fluid that facilitates imaging from a variety of angles. For accurate diagnoses the examiner must be

experienced in the technical aspects of fetal ultrasonography and knowledgeable in the anatomic patterns and physiologic consequences of congenital heart defects (46). Trans-vaginal ultrasound can provide diagnostic information as early as 10 to 12 weeks gestation, and may be useful when there is a high suspicion of major cardiac anomalies. Three dimensional echocardiography and magnetic resonance imaging has been applied to fetal cardiac evaluation and may improve diagnostic accuracy, although difficulty gating to the fetal heart rate has limited their utility to date.

Maternal drug exposure, including:
Lithium
Hormones
Anticonvulsants
Chemotherapy
Alcohol

Cardiac Anatomy

Virtually all major cardiac malformations can be detected prenatally using high-resolution two-dimensional, real-time sector scanning by an experienced examiner. The details of systemic and pulmonary venous connections, arterial alignment, chamber size and orientation, and valve position and function can be determined (Fig. 33-3) and abnormal structures demonstrated (Figs. 33-4 and 33-5).

Cardiac Physiology

Color Doppler provides a quick and sensitive means of evaluating the function of atrioventricular and semilunar valves, the direction of flow in fetal vessels, and the presence of normal and abnormal connections (Fig. 33-5). If abnormal flow is detected, it can be evaluated further using the quantitative capabilities of pulsed or continuous-wave Doppler.

Figure 33-3 Echocardiogram of the normal fetal heart in a four-chamber view demonstrating the position of the heart and the cardiac chambers in a cross-section of the chest. A, anterior; L, left; LA, left atrium; LV, left ventricle; P, posterior; R, right; RA, right atrium; RV, right ventricle; arrow denotes the spine.

Figure 33-4 Echocardiographic cross-sectional views of the fetal chest in an infant with Ebstein anomaly of the tricuspid valve. The right atrium (RA) is markedly dilated and fills much of the thorax. The left atrium (LA) and left ventricle (LV) are of normal size but are dwarfed by the right-sided structures. The severely regurgitant tricuspid valve has apical displacement of the septal leaflet into the right ventricle (RV).

Cardiac Function

A qualitative assessment of cardiac function is obtained by visual inspection of ventricular motion during real-time

P.642

sector scanning. When more quantitative information is desired, M-mode recording can provide precise dimensions and an accurate measure of ventricular shortening (Fig. 33-6). Doppler derived indices of cardiac function may also provide insight into fetal cardiac performance and three-dimensional imaging and fetal MRI may ultimately prove useful as well. Severe ventricular dysfunction may manifest as generalized hydrops fetalis, which is readily recognized by ultrasound as pleural and peritoneal fluid accumulation and cutaneous edema.

Figure 33-5 Echocardiographic cross-sectional view of a fetus with multiple intramyocardial rhabdomyomas (arrows). The infant was subsequently diagnosed with tuberous sclerosis. A, anterior; L, left; LA, left atrium; LV, left ventricle; P, posterior; R, right; RA, right atrium; RV, right ventricle.

Figure 33-6 Echocardiogram of a fetus with a premature atrial beat. The upper left image is a two-dimensional view with a cursor (line) through the fetal right atrium (RA) and aortic valve (AOV), demonstrating the axis of the simultaneous M-mode echocardiogram seen in the lower panel. The M-mode tracing depicts the motion of the fetal right atrial wall and aortic valve in the cursor line over a time frame of 3 seconds. A series of normal atrial wall contractions are interrupted by a premature contraction (large arrow) followed by opening of the aortic valve (small arrow), demonstrating a premature atrial beat conducted to the ventricle. LV, left ventricle; RV, right ventricle.

Arrhythmias

Tachyarrhythmias, bradyarrhythmias, and irregular cardiac rhythms are common reasons for referral for evaluation. Structural and functional abnormalities should be excluded, as described above. The mechanism of the rhythm disturbance can usually be elucidated by determining the timing of atrial and ventricular contraction using an M-mode (Fig. 33-6), two-dimensional and Doppler echocardiography, which simultaneously display atrial and ventricular wall and

valve motions and flows. By this means, the timing and sequence of atrial and ventricular activation can be deduced. The most common rhythm disturbance is isolated premature atrial contractions in a structurally normal heart or in association with an atrial septal aneurysm. Sustained tachyarrhythmia usually represents a reentrant or ectopic atrial tachycardia. These infants must be monitored closely for the development of congestive heart failure and hydrops fetalis, which would be an indication for induced delivery of the mature fetus or maternal antidysrhythmic therapy in the immature fetus. Sustained bradyarrhythmias may be secondary to heart block, nonconducted premature atrial contractions, or noncardiac sources of fetal distress. The mechanism can be inferred as described above and appropriate therapy initiated if indicated (see Arrhythmias).

Fetal Cardiac Intervention

Improvements in prenatal diagnostic techniques have led to renewed interest in fetal cardiac intervention. The restoration of more normal flow and pressure relationships in the developing heart may encourage normal or near normal growth and function, improving the postnatal outcomes and surgical and medical options. Exteriorization of the fetus and surgical intervention has been performed, but the inevitable development of premature labor remains a major obstacle to the development of fetal cardiac surgical techniques. Improvements in fetal imaging techniques are compatible with interventional catheterization methodology. The technical feasibility of aortic valve dilation in the fetus using new, low-profile coronary balloons and wires to dilate aortic valves in fetuses likely to acquire hypoplastic left heart syndrome without intervention has recently been demonstrated. Additionally, there has been some success in creating atrial communications in fetuses with premature closure of the foramen ovale in association with left sided obstruction. Attempts have also been made to re-establish communication between the right ventricle and pulmonary arteries in fetuses with valvar pulmonary atresia. Issues of patient selection, timing and outcome are only beginning to be addressed, and the clinical utility of prenatal interventions is yet to be determined.

Prematurity

The circulatory adjustments and myocardial biochemical changes at birth and in the neonatal period are modified in direct relation to the degree of prematurity. The muscular coat of the pulmonary arterioles develops late in gestation; the more premature the infant, the less muscular are the pulmonary arterioles at birth. The most notable consequence of this is that the difference between systemic and pulmonary resistance after birth is greater among premature than among normal infants. Shunting through a ductus arteriosus is often audible. Developmental biological factors in the ductus arteriosus and hypoxia, so common among premature infants, may be factors that contribute to the delay in closure of the ductus in premature infants. The

P.643

propensity of the ductus to close at around 41 weeks after conception is clinically recognized. Developmental changes in myocardial structure and biochemistry may influence the function of the left ventricle in response to stress such as volume overload associated with the left-to-right shunt through a patent ductus arteriosus.

Recognition of Clinical Features

Only a few infants are born in hospitals equipped for all eventualities. Infants with serious heart anomalies require transportation to a specialized pediatric cardiac center for detailed diagnostic assessment with echocardiography, and treatment that may include cardiac catheterization and/or surgery. Timely clinical recognition of the likely presence of a specific cardiac anomaly, that without intervention will result in serious deterioration of the baby's condition (e.g., critical coarctation of the aorta, pulmonary valve atresia), is necessary for initiation of medical therapy to prevent and/or reverse clinical deterioration (e.g., administration of prostaglandin, inotropic agents, oxygen, and ventilation) and thereby provide the time and conditions necessary to transfer, evaluate, and treat the baby.

Initial evaluation includes assessment for cyanosis (See Color Plate) and of the infant's well-being, perfusion, pulses and blood pressure in the extremities, respiratory work and rate, precordial activity, second heart sound splitting, and murmur intensity, quality, pitch, and timing. Chest radiograph and electrocardiogram (ECG) remain cost- and time-efficient tests that aid in the initial evaluation of suspected congenital heart disease. Any

Figure 33-7 The differential diagnosis of cardiac exam findings in cyanotic neonates. Anomalies in larger print are more common. +/-, sometimes; up arrow, increased; down arrow, decreased; AP window, aorticopulmonary window; AS, aortic stenosis; ASD, atrial septal defect; CAVC, complete atrioventricular canal defect; CoAo, coarctation of the aorta; DCM, dilated cardiomyopathy; HCM, hypertrophic cardiomyopathy; Interrup. Ao, interrupted aortic arch; MS, mitral stenosis; PDA, patent ductus arteriosus; PS, pulmonary stenosis; VSD, ventricular septal defect.

one of these alone is rarely diagnostic. A number of lesions result in cyanosis; quite a number of lesions are also associated with loud murmurs; others are associated with little or no murmur; some cause shock (see Fig. 33-7 and 33-8). Others have chest

P.644

radiographs with increased pulmonary arterial or venous markings, others have diminished pulmonary vascular markings. Most have an undistinguished electrocardiogram at birth, although some have left axis deviation on electrocardiogram (see Fig. 33-9 and 33-10). Most cardiac anomalies vary in their characteristics at presentation. Furthermore, often it is not possible to determine with certainty if the second heart sound is split or not, or if the pulmonary vascular markings on chest radiograph are normal vs. increased or normal versus decreased. Clinical analysis requires weighting of the categories of evidence regarding its certainty and other possibilities. A classical diagnostic approach based on sequential analysis of data categories is limited by these types of weakness in the clinical information and is no stronger than the weakest link in the chain of information. However, interweaving of the findings provides a matrix of diagnostic information that remains intact even when one category of findings is weak. Overlapping possible anomalies suggested from history, physical examination, chest radiograph and electrocardiogram, as if with a series of Venn diagrams (see Figs. 33-7, 33-8, 33-9 and 33-10), provides information that allows a careful observer to quickly determine which anomaly, or which two or three possible anomalies, is likely present. Comparing the anomalies consistent with the clinical presentation with the anomalies consistent with the murmur findings, other physical exam findings, chest radiograph findings, and electrocardiographic findings, usually focuses the list of possible anomalies on one or two primary choices (see Fig. 33-11). This may provide an important advantage in the timely and efficient management of potentially life threatening anomalies. For example, the combination of cyanosis, soft or no murmur, single S2, chest radiograph with decreased pulmonary vascular markings and normal heart size, and electrocardiogram R axis of 50° suggests pulmonary atresia, which is an anomaly in which life depends on maintaining ductal patency (see Fig. 33-8 and 33-10). Two-dimensional echocardiogram should be obtained promptly if significant cardiac disease is suspected. This technique when done by personnel trained for evaluation

P.645

of congenital cardiac anomalies in neonates accurately demonstrates the anatomy, occasionally uncovering a potentially lethal lesion before symptoms. Appropriate initial management (e.g., infusion of PGE1 in a cyanotic infant suspected to have pulmonary atresia) need not await availability of echocardiography (see Fig. 33-12 and Management Procedures for Severe Cardiac Disease).

Age of Presentation

Most children with critical congenital cardiac anomaly develop symptoms within the first weeks of life (8). The age when infants develop cardiac symptoms is diagnostically useful. For instance, although ventricular septal defect is far more common (Table 33-2), transposition of the great arteries, coarctation of the aorta, and the hypoplastic left heart syndrome are the most common life-threatening anomalies presenting in the first days of life (see Table 33-7). Isolated ventricular septal defect is not associated with cyanosis, the associated murmur

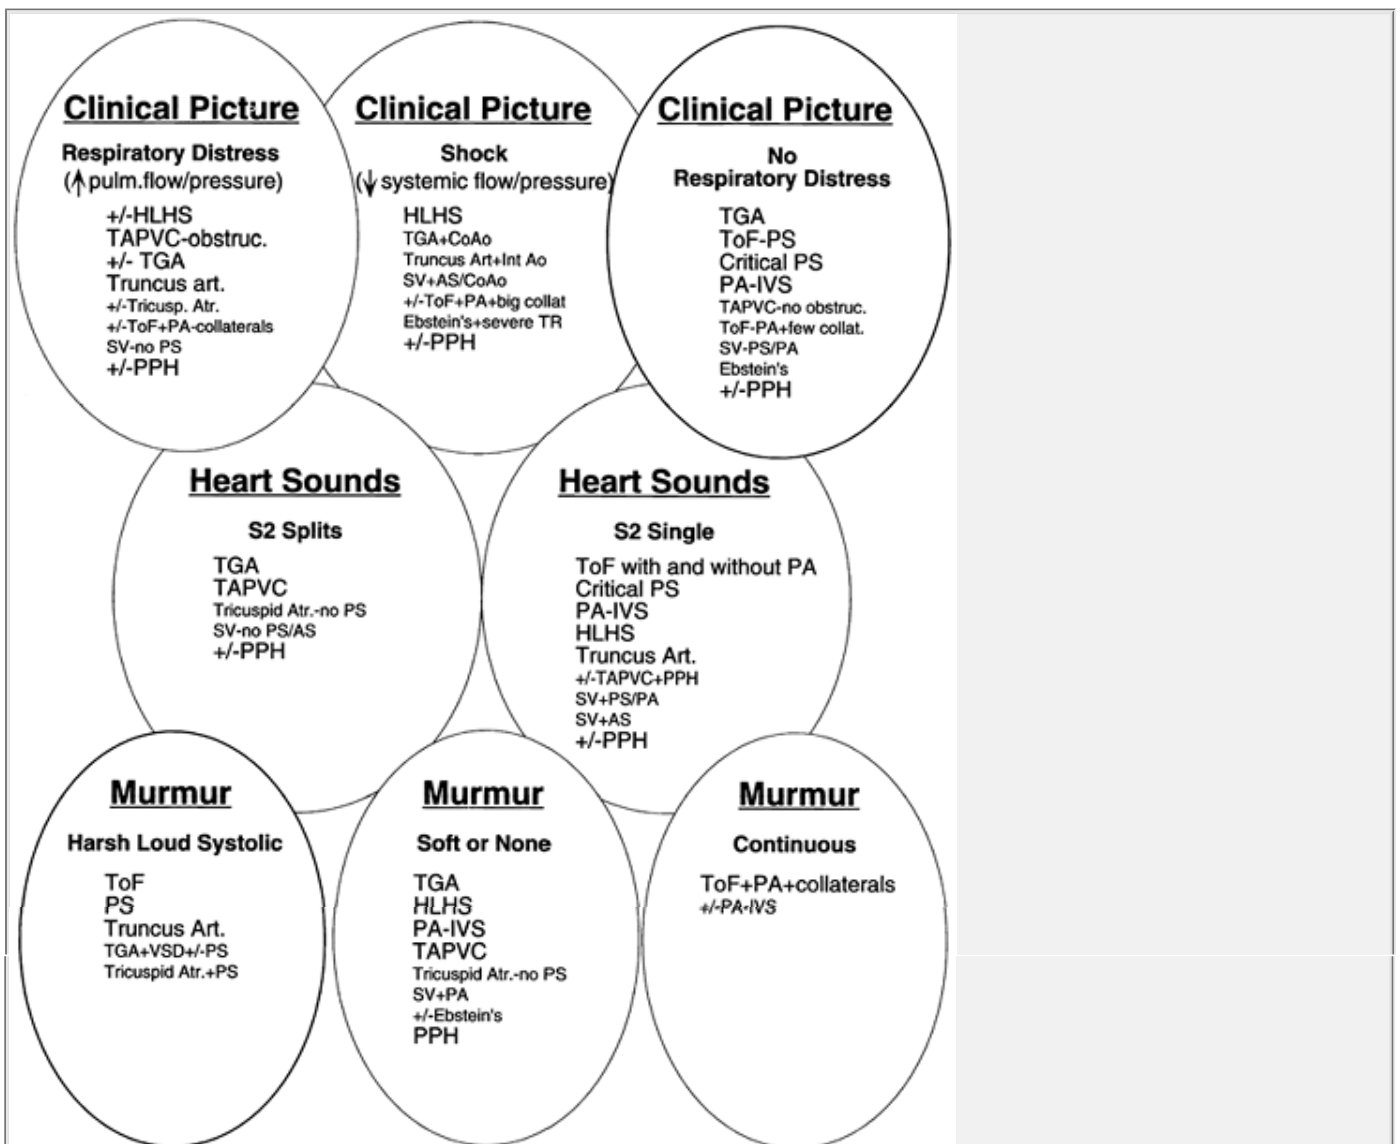

Figure 33-8 The differential diagnosis of cardiac exam findings in cyanotic neonates. +/-, sometimes; up arrow, increased; down arrow, decreased; AS, aortic stenosis; CoAo, coarctation of aorta; collat., systemic to pulmonary artery collateral vessels; Ebstein's, Ebstein anomaly of the tricuspid valve; HLHS, hypoplastic left heart syndrome; Int Ao, interrupted aorta; PA, pulmonary atresia; PA-IVS, pulmonary atresia with intact interventricular septum; PPH, persistent pulmonary hypertension syndrome; PS, pulmonary stenosis; SV, single ventricle; TAPVC, totally anomalous pulmonary venous connection; TGA, transposition of great arteries; ToF, tetralogy of Fallot; tricuspid atr., tricuspid atresia.

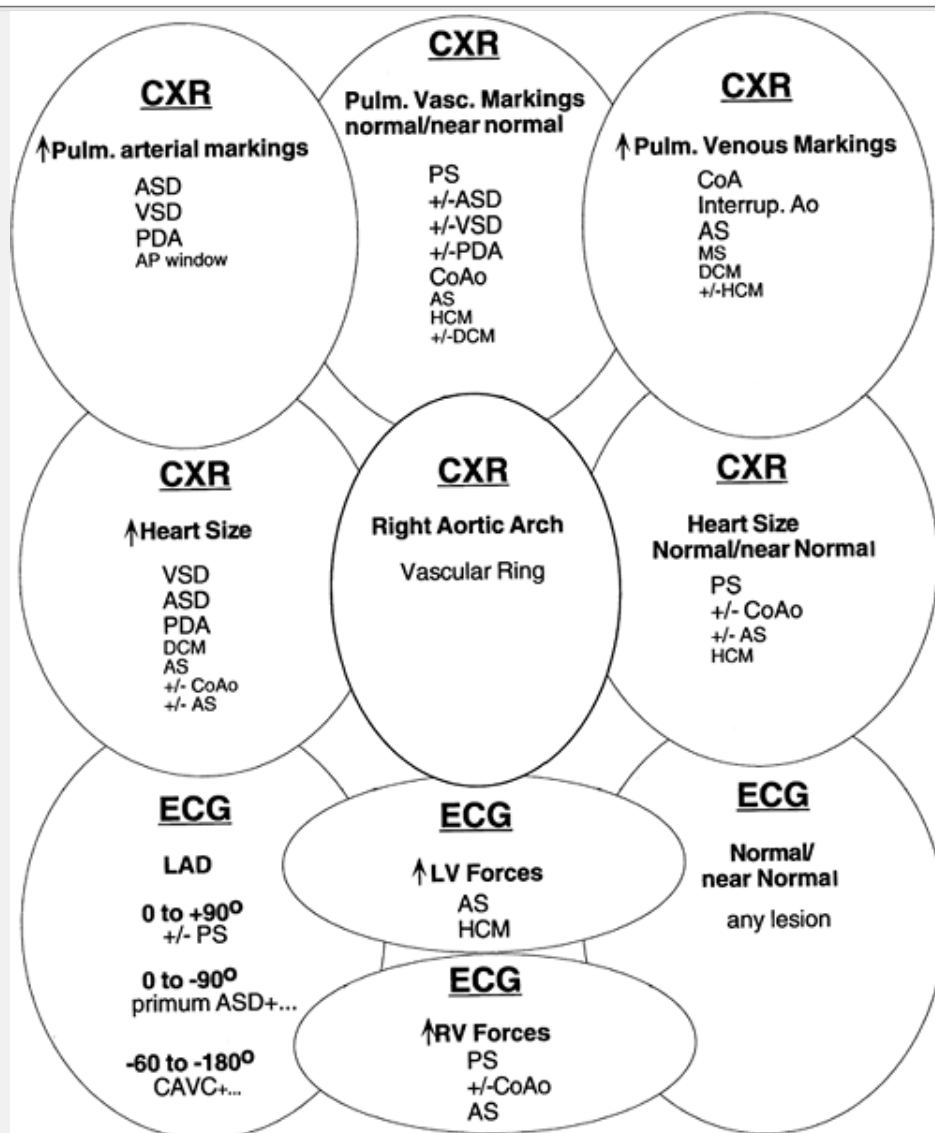

Figure 33-9 The differential diagnosis of chest radiographic and electrocardiographic findings in acyanotic neonates. Abbreviations, see Fig. 33-7; CXR, chest radiograph; LAD; left axis deviation; LV, left ventricle; Pulm. vasc. markings, pulmonary vascular markings; RV, right ventricle.

generally develops after several days or more, and respiratory symptoms usually do not develop until after the first week of life. Among those whose problem is cyanosis, transposition of the great arteries is the leading cause through the third week of life; after that time, tetralogy of Fallot becomes the dominant cause of cyanosis. Among neonatal cardiac patients admitted because of respiratory symptoms, the hypoplastic left heart syndrome is the leading cause in the first week, complex coarctation leads in the second week, and thereafter, ventricular septal defect becomes the main cause (see Table 33-6).

Physical Examination

Respiratory Symptoms

Persistent tachypnea may be the first clue to heart disease or lung disease. Cardiac abnormalities with excessive pulmonary arterial flow or pulmonary venous hypertension cause pulmonary vascular engorgement, pulmonary edema, and decreased lung compliance that often result in

P.646

increased respiratory effort and rate. Cardiac anomalies with decreased pulmonary blood flow often have intense cyanosis that elicits a reflex "peaceful" tachypnea without respiratory distress. Experienced parents often observe that the affected baby had always breathed too fast. Persistent respiratory rates of 60 per minute or greater, often with minimally labored but persistently increased depth of respiration, commonly precede other findings and may presage clinical deterioration. A chest radiograph may differentiate cardiac from pulmonary disease.

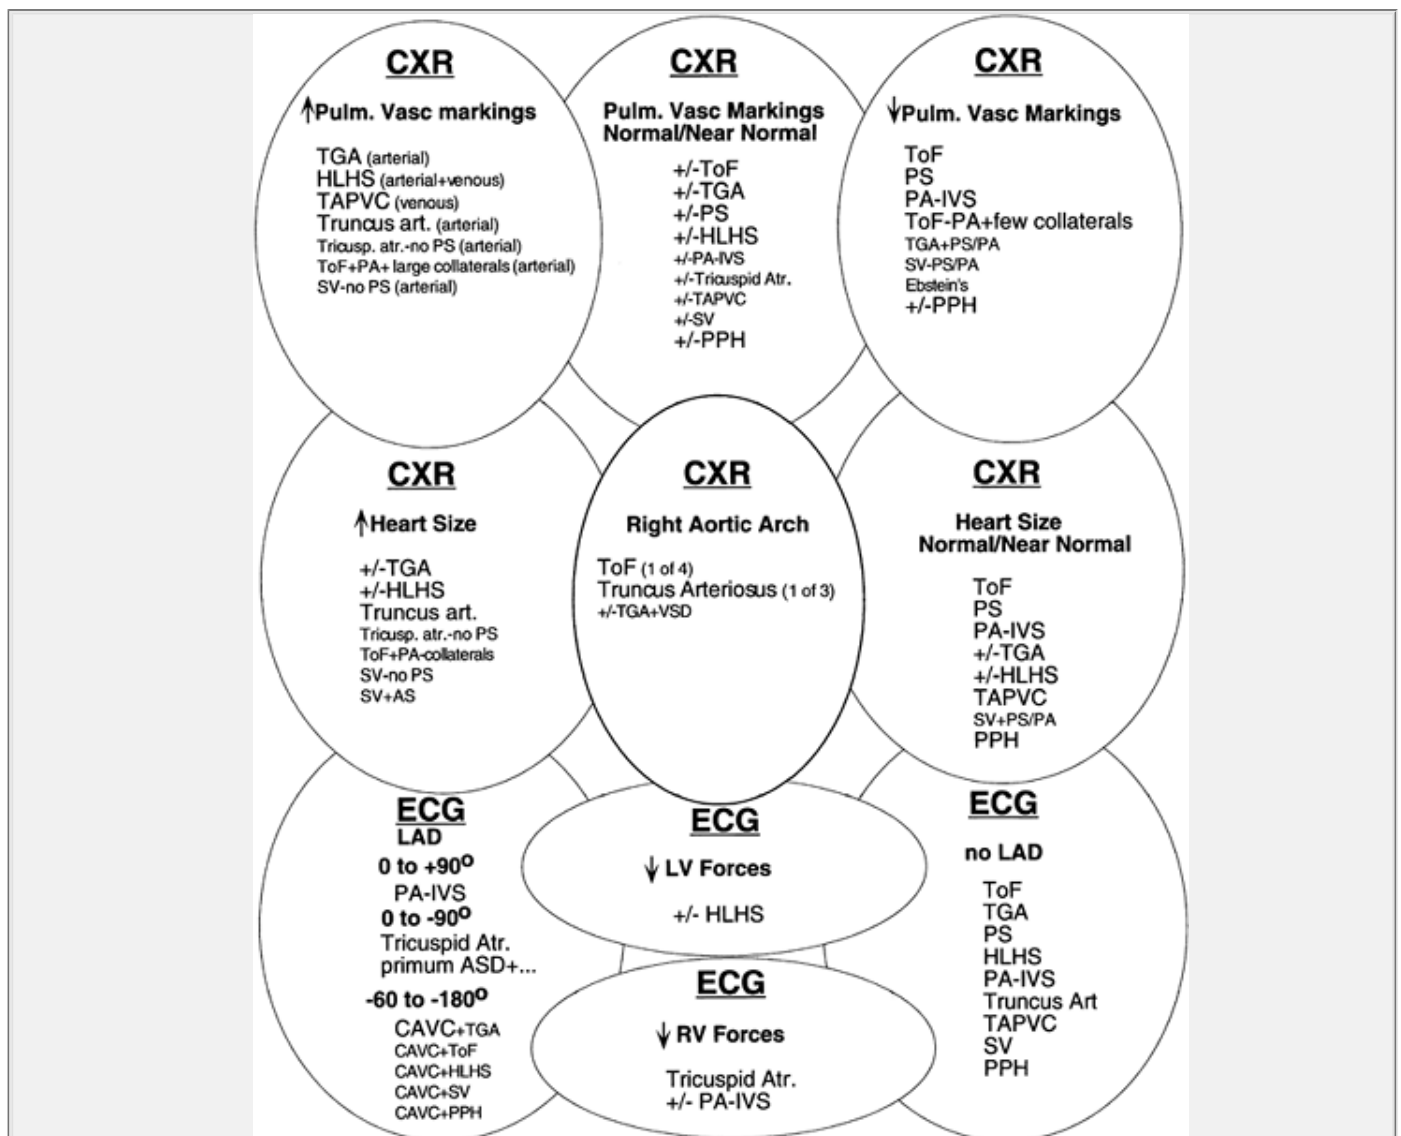

Figure 33-10 The differential diagnosis of chest radiographic and electrocardiographic findings in cyanotic neonates. Abbreviations, see Fig. 33-8 and 33-9.

Systemic Perfusion and Pressure

Decreased systemic cardiac output is an ominous sign that requires rapid assessment and rapid appropriate management for the infant to survive. There are many potential noncardiac causes, the most common being sepsis, and important cardiac causes (see Fig. 33-7 and 33-8). Signs of diminished systemic perfusion include poorly perfused, cool, and/or mottled skin, listlessness, diminished peripheral pulse intensity, diminished systolic and pulse pressure, decreased urine output, and metabolic acidosis. Blood pressure should be measured in all four extremities in an infant who appears severely ill with these signs, particularly with coexistence of a murmur or cyanosis. Oscillometric devices can quickly and noninvasively measure blood pressure, although their correlation with centrally measured blood pressure declines in the presence of very low perfusion and pressure. It is very important to establish if the pulse amplitude and systolic blood pressure are diminished only in the postductal arterial distribution or throughout the body, that is, if the right arm systolic blood pressure is similar to or higher than that in the other extremities. Significant differential in the systolic blood pressure between the arms (usually right) and the legs (and umbilical artery) is diagnostic of an aortic obstruction. The additional presence of a murmur, gallop, hepatomegaly, or cyanosis further strongly suggests that a cardiac anomaly is causative of poor perfusion.

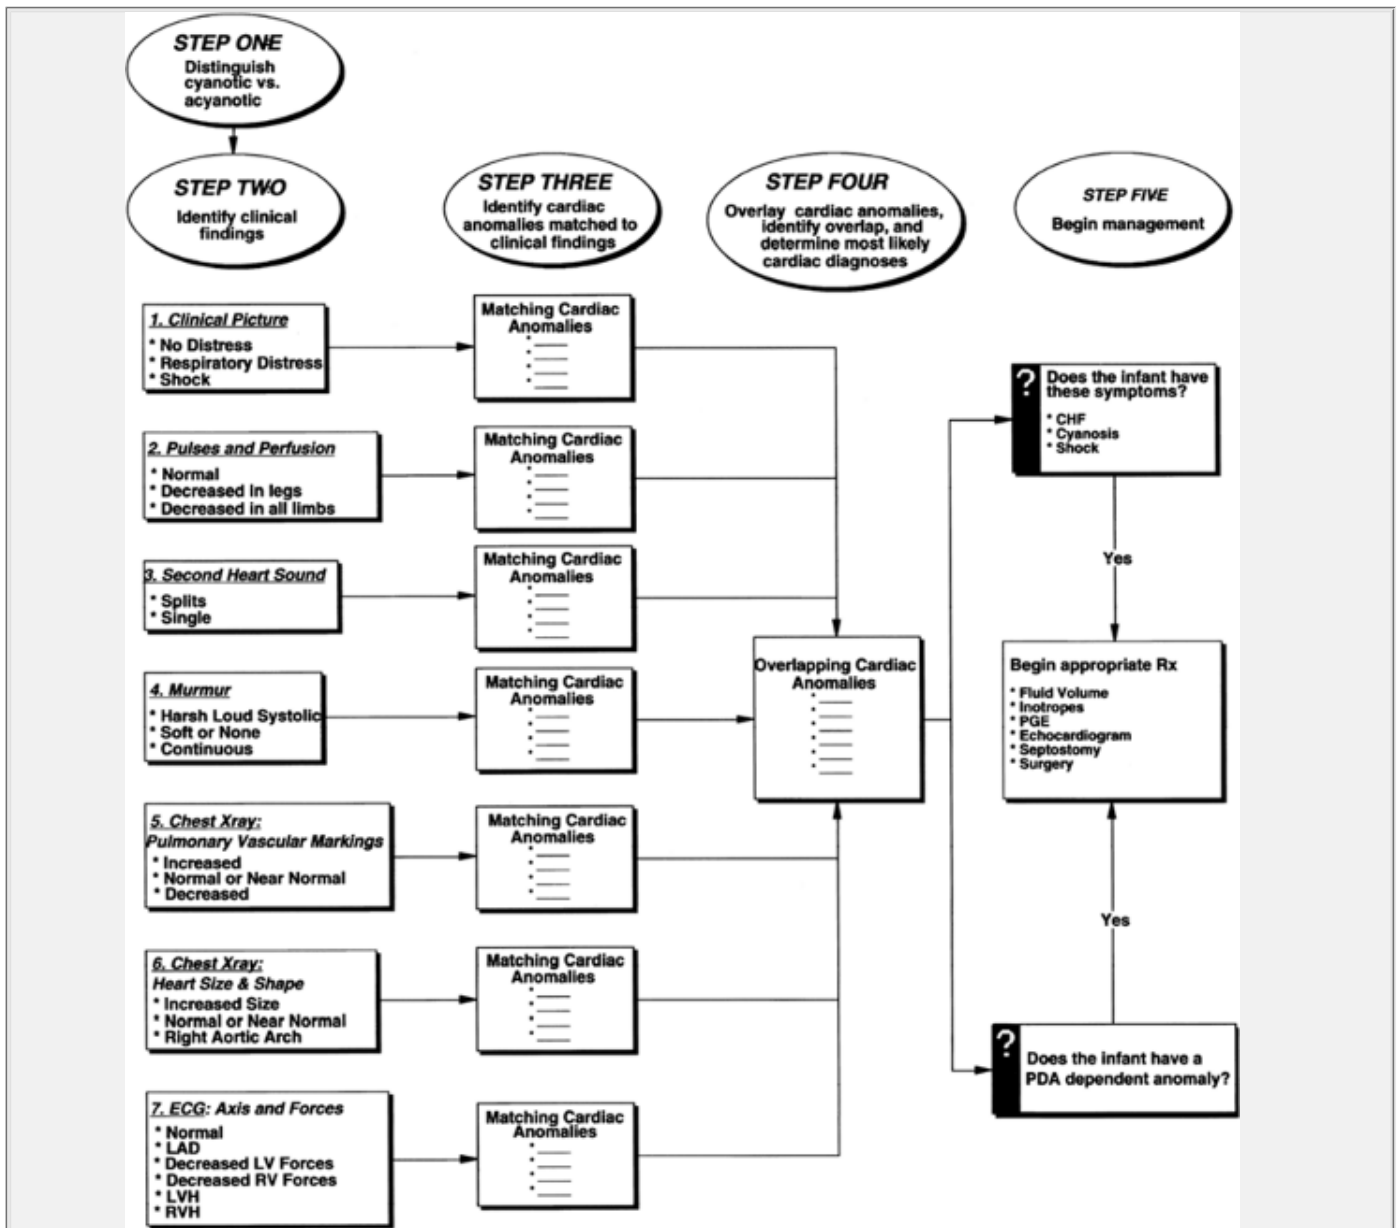

Figure 33-11 A process for diagnosing cardiac anomalies from findings on cardiac exam, chest radiograph, and electrocardiogram. ASAP, as soon as possible; c/w, consistent with; FiO₂, fractional percentage of inspired oxygen; PDA, patent ductus arteriosus.

Murmur

Hearing a murmur is the most common means of recognizing the presence of heart disease in an infant. Determining the diagnosis requires ascertaining the characteristics of the murmur. These include the history of the baby's age when the murmur was first audible and examination findings of murmur timing in systole versus diastole, loudness, pitch and the association of a thrill. The murmurs of valvar regurgitation and stenosis are audible immediately after birth, and the murmurs of septal defects are usually delayed days to weeks, or as long as several months in the case of atrial septal defects. Diastolic murmurs are rare but indicative of cardiac pathology. A prominent continuous murmur in a cyanotic neonate, particularly in the back or axilla, is rare but is very characteristic of tetralogy of Fallot with

P.648

pulmonary atresia and systemic-to-pulmonary-artery collateral vessels (the latter being the cause of the murmur). The loudness of a murmur, in combination with other findings, may suggest the likelihood of various anomalies but is often not proportional to the severity of the lesion. The absence of a murmur does not preclude serious heart disease. To the contrary, many life-threatening cardiac anomalies may be associated with little or no murmur. In a neonate with cyanosis and/or shock and suspected cardiac anomaly, the presence of little or no murmur provides a diagnostic clue (see Fig. 33-7 and 33-8). The pitch of a murmur is associated with the pressure gradient across the abnormality causing the murmur. Tiny ventricular septal defects develop a characteristic fairly high-pitched murmur when the right ventricular pressure decreases to much less than the left ventricular pressure. Severe pulmonary or aortic stenosis can sometimes be distinguished from mild stenosis by a high-pitched harsh loud murmur and an associated thrill.

Heart Sounds

Auscultation of the heart sound splitting is the most difficult part of the cardiac examination in neonates because of the relatively rapid heart and respiratory rates in neonates. However, when abnormalities of the first and second heart sounds are strongly suspected or excluded, it provides important information. Detection of splitting of the heart

P.649

sounds requires practice and a minute or so of focused attention on just that sound, using a quality stethoscope, in a quieted baby. The absence of splitting may result from a heart rate too fast to discern splitting or a truly single-component sound. A split first heart sound in a neonate suggests a click. The second heart sound emanates from closure of the aortic and pulmonary valves. Determining that the second heart sound is split (i. e., has two components) suggests that both aortic and pulmonary valves are not severely abnormal; that is, it is against the presence of aortic or pulmonary valve atresia or severe stenosis. However, other serious anomalies with two semilunar valves may still be present, for example, simple transposition of the great arteries. A second heart sound that always appears single, particularly at heart rates not greater than 120 per minute, may be caused by relatively early pulmonary valve closure associated with elevation of pulmonary artery pressures comparable to aortic pressures, but it suggests that the pulmonary or aortic valve may be abnormal (as in pulmonary atresia or critical stenosis, hypoplastic left heart syndrome, truncus arteriosus). Although difficult to detect, constant splitting of the second heart sound, as opposed to the usual intermittent splitting, suggests a atrial septal defect.

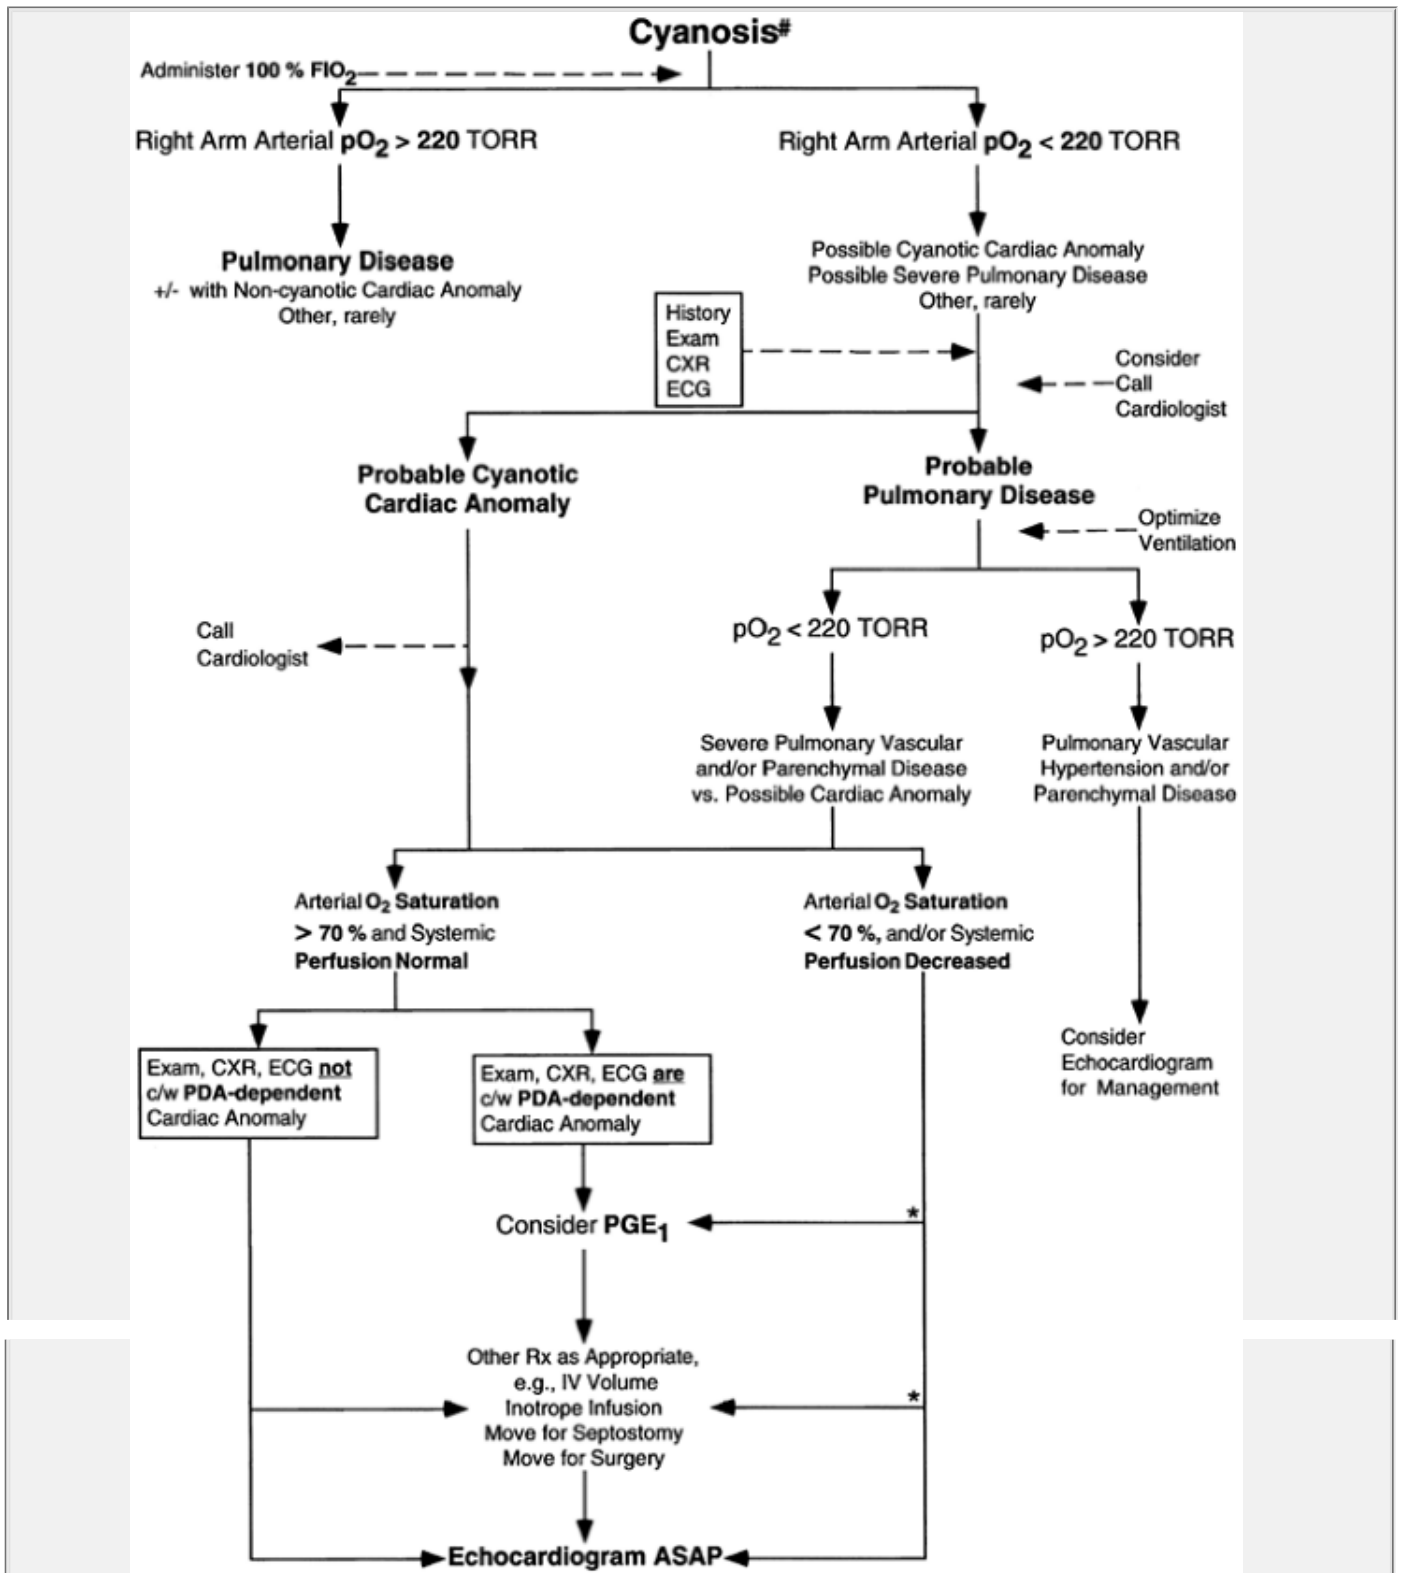

Figure 33-12 An approach to the diagnosis and management of cyanotic infants. #, cyanosis; see text for additional details of assessment of cyanosis; +/-, possibly; *, see text concerning management of specific anomalies; ASAP, as soon as possible; c/w, consistent with; FiO₂, fraction inspired oxygen; Rx, treatment.

Cyanosis

Much more threatening than a murmur is the presence of cyanosis. Cyanosis without pulmonary disease is almost invariably the result of a serious cardiac abnormality. Cyanosis may result from poor mixing of separate parallel circulations (e.g., transposition of the great arteries, other anomalies with transposition physiology such as Taussig- Bing-type double-outlet right ventricle); restricted pulmonary blood flow and right-to-left shunting of un-oxygenated systemic venous blood to the systemic arterial circulation (e.g., tetralogy of Fallot, critical pulmonary stenosis, tricuspid atresia); or right-to-left shunting from intracardiac mixing with normal or increased pulmonary blood flow (e.g., total anomalous pulmonary venous connection without obstruction, truncus arteriosus, single ventricle without pulmonary stenosis, hypoplastic left heart syndrome). Especially in the first week of life, cyanosis may be the sole evidence of an important cardiac lesion. One-third of infants with potentially lethal congenital heart disease have cyanosis as their major symptom; another one-third have cyanosis associated with respiratory symptoms. Prompt cardiac evaluation of all cyanotic babies is mandatory because prompt infusion of prostaglandin endothelin (E1) to open the ductus arteriosus or catheter intervention to create an atrial septal defect may be necessary for survival, and most of the responsible lesions are amenable to surgery.

The clinical recognition of cyanosis is dependent on the amount of oxygen desaturation of arterial hemoglobin and therefore is influenced by the total blood hemoglobin concentration. An anemic infant may have severe arterial oxygen unsaturation without obvious cyanosis, and infants with polycythemia may appear cyanotic with near normal arterial oxygen levels. Hypothermic infants may seem blue; babies viewed in fluorescent lighting or in blue surroundings may make the estimation of cyanosis more difficult. Persistent cyanosis secondary to hypoglycemia or methemoglobinemia is rare. Cyanosis is particularly evident in the lips. Peri-oral or nail-bed cyanosis without lip cyanosis is usually not caused by cyanotic heart disease. When cyanosis is suspected, indirect assessment of arterial oxygen saturation by the transcutaneous method can provide a rapid noninvasive check.

Acute Lung Disease and Cardiac Disease

Rapid determination of the diagnosis and initiation of appropriate management is most pressing when the infant is dyspneic and cyanotic. A chest radiograph may suggest lung disease, particularly if the findings are asymmetric. In the presence of diffuse symmetric changes possibly compatible with pulmonary edema or increased vascular markings, caution is necessary, particularly in the full-term neonate. The differential diagnosis between primary lung disease and heart disease causing pulmonary edema (e.g., total anomalous pulmonary venous connection with obstruction) can be difficult. Persistent pulmonary arterial hypertension with right-to-left shunting may coexist with lung disease and cause severe cyanosis. Although carbon dioxide retention is usually prominent among babies with primary lung disease, some severely cyanotic infants with cardiac anomalies can have marked hypercarbia. It can also

P.650

be difficult to differentiate cardiac anomalies with diminished pulmonary blood flow and little murmur (e.g., pulmonary valve atresia) from persistent pulmonary arterial hypertension without other, radiographically apparent, lung parenchymal disease. Although the absence of hypercarbia suggests cardiac disease, some severely cyanotic infants with pulmonary vascular disease have normal partial pressure of CO₂ (PCO₂) values.

The response of the arterial partial pressure of oxygen (PO₂) to administration of 100% oxygen, with the exceptions noted below, can differentiate cyanotic heart disease from lung disease. The infant who responds to breathing pure oxygen with a rise in arterial PO₂ to 220 mm Hg or more does not have cyanotic heart disease, and the infant who does not raise his preductal arterial PO₂ above 100 mm Hg is likely to have heart disease.

Transcutaneous estimation of arterial oxygen saturation is not an accurate alternative because any arterial PO₂ greater than 70 mm Hg will result in arterial oxygen saturation greater than 95%. Because the hyperoxia test is inconclusive when the arterial PO₂ is between 100 and 220 mm Hg, these babies should be approached as possibly having cyanotic heart disease (see Fig. 33-12). The arterial PO₂ while the baby is breathing 100% oxygen may initially be most rapidly measured from an umbilical artery catheter positioned in the descending aorta. However, a low arterial PO₂ measured in the descending aorta may be from right-to-left shunting through

a ductus arteriosus from coexisting persistent pulmonary hypertension. Comparison of the PO₂ measured in blood from the right radial artery with the PO₂ measured in blood from the umbilical arterial catheter may help to differentiate persistent pulmonary hypertension from cyanotic cardiac anomaly. The former may have a high PO₂ in the right radial artery. Simultaneous mechanical hyperventilation and administration of oxygen may decrease pulmonary resistance and increase pulmonary flow, increasing the PO₂ to greater than 220 mm Hg in the descending aortic and/or right radial arterial blood, allowing differentiation of lung disease or persistent pulmonary hypertension from cyanotic cardiac anomaly. Difficulties arise when pulmonary and cardiac pathology coexist. For example, in the baby with both lung and heart disease or those with coexistence of persistent pulmonary hypertension and predominant right-to-left shunting through the foramen ovale (see Chapters 29 and 32) or the baby with heart disease causing pulmonary venous hypertension and pulmonary edema, results may be confusing. Arterial PO₂ may not significantly increase in response to 100% oxygen with severe persistent pulmonary hypertension and predominant right-to-left shunting through the foramen ovale. If doubt persists, the physician can make the diagnosis with two-dimensional echocardiography (see Fig. 33-12).

Noncardiac Anomalies

It is useful to know the relative frequency of the cardiac diagnostic possibilities when there are associated noncardiac anomalies (see Tables 33-3 and 33-4) or prematurity. Among premature infants, patent ductus arteriosus, coarctation of the aorta, and ventricular septal defect occur more often. Chromosomal abnormalities and congenital syndromes are also associated with lower birth weight cardiac malformations (e.g., Down syndrome).

TABLE 33-7 TOP FIVE DIAGNOSES PRESENTING AT DIFFERENT AGES	
Diagnosis	Percentage of Patients
Age on admission: 0-6 days (<i>n</i> = 537)	
D-Transposition of great arteries	19
Hypoplastic left ventricle	14
Tetralogy of Fallot	8
Coarctation of aorta	7
Ventricular septal defect	3
Others	49
Age on admission: 7-13 days (<i>n</i> = 195)	
Coarctation of aorta	16
Ventricular septal defect	14
Hypoplastic left ventricle	8
D-Transposition of great arteries	7
Tetralogy of Fallot	7
Others	48
Age on admission: 14-28 days (<i>n</i> = 177)

Coarctation of aorta	12
Tetralogy of Fallot	7
D-Transposition of great arteries	7
Patent ductus arteriosus	5
Others	53

Diagnostic Tools

Chest Radiography

Chest radiography is rarely diagnostic of specific cardiac lesions, but it is a relatively quick and relatively inexpensive method to identify lung disease and screen for suspected cardiac anomaly in symptomatic infants. Chest radiographs often appear normal or near normal in the first day or days of life with many cardiac anomalies, and may not be cost effective in asymptomatic infants with an isolated murmur (i.e., no cyanosis (See Color Plate) or congestive signs or symptoms). However, in cyanotic or symptomatic infants, the presence or absence of cardiomegaly, increased pulmonary arterial or venous markings, diminished pulmonary arterial markings, or right aortic arch provides important information regarding the presence of a cardiac anomaly (see Fig. 33-9 and 33-10). In combination with physical exam and electrocardiographic findings, chest radiographic findings may provide important information concerning the possible presence of specific cardiac anomalies that may aid in early management before an echocardiogram can be obtained. The heart size should be differentiated from the thymic shadow. Cardiomegaly is indicated by a cardiothoracic ratio greater than 0.6 in an anterior-posterior projection in the presence of an adequate inspiration. The aortic arch position can be assessed, even in the presence of a large overlying thymus, by deviation of the trachea to the opposite side. Associated noncardiac anomalies that provide clues to the cardiac diagnosis may be discovered by radiographic findings, for example, heterotaxy (asplenia syndrome, malrotation), absence of the thymus gland (DiGeorge syndrome), vertebral anomalies (VACTERL association), and abnormal sternal ossification (Down syndrome).

Electrocardiography

Electrocardiography can be useful in evaluation for cardiac anomaly and arrhythmogenic disorders and in particular for diagnosis and management of arrhythmia (see Arrhythmias). Electrocardiographic interpretation in neonates has several caveats. However, when placed within the context of other physical exam and radiographic findings, electrocardiographic findings can provide a timely advantage in diagnosis and management of suspected cardiac anomaly (see Fig. 33-9 and 33-10). Electrocardiography is also useful for timely recognition of life-threatening arrhythmogenic disorders, particularly within the context of other findings; for example family history and borderline prolonged QT interval (QTc).

TABLE 33-8 NORMAL MATURATIONAL ECG CHANGES

Age	Heart Rate* (beats per min)	R Axis* (+ degrees)	R Amplitude V1* (mm)	R Amplitude V6* (mm)	T Amplitude V1* (mm)
0-1 day	93-154 (123)	59-192 (135)	5-26	0-11	-30-+40
1-3 days	91-159 (123)	64-197 (134)	5-27	0-12	-41-+41
3-7 days	90-166 (129)	77-187 (132)	3-24	0.5-12	-45-+25

from ref 43,45

Interpretation of neonatal electrocardiograms requires knowledge of maturational changes in heart rate, and electrocardiographic intervals, axes, voltages and repolarization that occur normally during the first days and weeks of life (see Table 33-8 and Fig. 33-13) (43,44 and 45). Within the first days of life, there are significant changes in repolarization, including T axis and rate-corrected QTc, and changes in R and S wave amplitudes, that influence interpretation. Compared with a 1 year old, 1 day old babies normally have relatively fast heart rates (93-154, average 123/minute), relatively rightward R axis (60-195, average 123 degrees) and relative right ventricular hypertrophy (R in V1 5-16 mm) (44). During the first 4 days of life there is variability of the QTc, an evolution of changes in T wave polarity and

voltage (e.g., in V1 from upright to inverted), and nonspecific ST segment changes are common. QTc is 440 milliseconds or less in 97.5% of newborns, but can be much longer with electrolyte abnormality (e.g., hypocalcemia, hypokalemia), drug effect, brain injury and genetic prolonged QT syndromes. Premature neonates tend to have higher heart rates (141-160/min), slightly more leftward R axis 107-135 degrees), slightly less R amplitude in V3R (median 3 mm), slightly greater R amplitude in V6 (median 6-7 mm) and slightly longer QTc interval (411-412 ms) (46).

Figure 33-13 Electrocardiograms from healthy ½ day old (top) and 5 day old infants (lower) demonstrate normal neonatal repolarization changes. V1 T wave morphology changes from upright to inverted.

Ventricular hypertrophy in the electrocardiogram at birth is a consequence of the hemodynamic abnormalities imposed on the fetal circulation. The hemodynamic changes and the ventricular hypertrophy associated with various cardiac anomalies are often much different in the fetal circulation than postnatal. For example, neonates with coarctation, and other obstructive anomalies with less than normal blood flow volume through the fetal left ventricle and more than normal flow through the fetal right ventricle, often have right ventricular hypertrophy from increased fetal right ventricular workload. Furthermore, anomalies associated with systemic-level right ventricular hypertension later in infancy often have neonatal electrocardiographic right ventricular forces that are difficult to differentiate unambiguously from normal in the neonate. Therefore, the differential diagnosis of ventricular hypertrophy in the neonate is different from later in infancy (see Fig. 33-9 and 33-10). In term neonates electrocardiographic findings of right ventricular hypertrophy include R amplitude in V1 above the 98th percentile (44) (>26 mm in 1st week, >21 mm in 2nd to 4th week), presence of Q wave in V1, or persistence of upright T waves in V1 beyond age 1 week. Findings of left ventricular hypertrophy include elevated R amplitude in V6 (44) (>12 mm in 1st week, >16 mm in 2nd to 4th week) and deep Q wave in V6 (>4 mm), often accompanied by T wave flattening or inversion in V6.

Although most anomalies do not have R axis deviation at birth, when axis deviation is present the electrocardiogram can be very helpful in diagnosis (see Fig. 33-9 and 33-10). Left axis deviation in acyanotic newborns is most often associated with endocardial cushion anomaly (e.g., primum atrial septal defect, complete atrioventricular canal defect), although in cyanotic newborns left axis deviation occurs with tricuspid atresia and other cyanotic anomalies in combination with an endocardial cushion anomaly (e.g., tetralogy or double outlet right ventricle with complete atrioventricular canal defect).

Echocardiography

Examination of the heart by two-dimensional echocardiography with color Doppler ultrasound allows excellent analysis of the intracardiac anatomy in small infants. The equipment is portable and can be readily brought to the bedside of critically ill neonates thus avoiding transport elsewhere, interruption of ongoing care, or anesthesia. The examination in neonates requires no or little sedation. Neonates are particularly good candidates for echocardiographic imaging because they are less active and have excellent echocardiographic imaging windows. Detailed segmental examination from sub-xiphoid, parasternal, apical, supra-sternal notch, and additional modified views as necessary delineates almost all relevant cardiac anatomy and anomalies in most neonates. The situs, ventricular relationship, great artery relationships, systemic and pulmonary venous cardiac connections, atrial and ventricular septum, valve structure, great artery anatomy and coronary origins can be accurately determined.

Doppler echocardiography demonstrates the direction and velocity of blood flow within the heart and vessels. Color Doppler visualizes valve regurgitation and blood flow in valvar and sub-valvar stenoses, patent ductus arteriosus, septal defects, abnormal coronary arteries, systemic venous anomalies, and arterio-venous malformation. Pulsed and continuous-wave Doppler techniques enable estimation of physiologic measurements such as the pressure gradient across stenotic valves, septal defects, and patent ductus arteriosus (see Fig. 33-14). When physiologic or pathologic tricuspid regurgitation is present, right ventricular peak systolic pressure may be estimated by Doppler measurement of the magnitude of the pressure gradient between the right ventricle and right atrium and the addition of the right atrial V-wave pressure, whether assumed or directly measured through an umbilical vein catheter (usually 3 to 10 mm Hg) (see Fig. 33-15). Right ventricular systolic pressure relative to left ventricular pressure can also be qualitatively assessed by the curvature of the interventricular septum. Contrast echocardiography with injection of agitated saline or albumin into intravenous or umbilical artery catheters can sometimes serve as a useful adjunct to color Doppler in detection of shunts.

The ventricular systolic performance, size, and wall thickness can be assessed. The shortening fraction of the left ventricular internal short-axis dimension is the most commonly used measurement to assess left ventricular systolic function in children. In the sick neonate right ventricular systolic pressure often is close to left ventricular systolic pressure, resulting in flattening of the ventricular septal curvature; such that shortening fraction may not be indicative of global systolic performance. When regional wall motion abnormalities are present, ventricular systolic performance is assessed by estimation or measurement of the relative change in ventricular volume with contraction, the ejection fraction. The shortening and ejection fractions measure left ventricular performance, which is a function of contractility, afterload, preload, and heart rate. Contractility can be independently assessed by measuring the relationship of end-systolic wall stress velocity to fiber shortening using directed M-mode echocardiography, indirect central pulse tracing, and phonocardiography. This technique is also impaired when right ventricular hypertension results in ventricular septal systole flattening.

Echocardiography has limitations. Because complete examination of cardiac anatomy in neonates is labor intensive and requires expensive additional technology, the cost is often nearly that of a computerized tomography

P.653

or magnetic resonance scans. The evaluation has often been unsatisfactory when performed in which the use of echocardiography to recognize heart disease in neonates is infrequent and echocardiographic transducers with frequencies appropriate for infants are not available. Training and performance standards for echocardiographic examination of congenital heart disease in fetuses and children have been disseminated (46). Cases of delayed transfer of babies because of erroneous diagnoses of inoperable congenital heart disease and erroneous impression that there is no significant lesion have been encountered. With limited experience in the diagnosis of congenital heart disease in neonates, it may be best to transport the infant to the nearest center for echocardiographic examination. If personnel adequately trained in performing a complete study for congenital heart disease are available, it may be possible to send or transmit a tape of the examination for a second opinion.

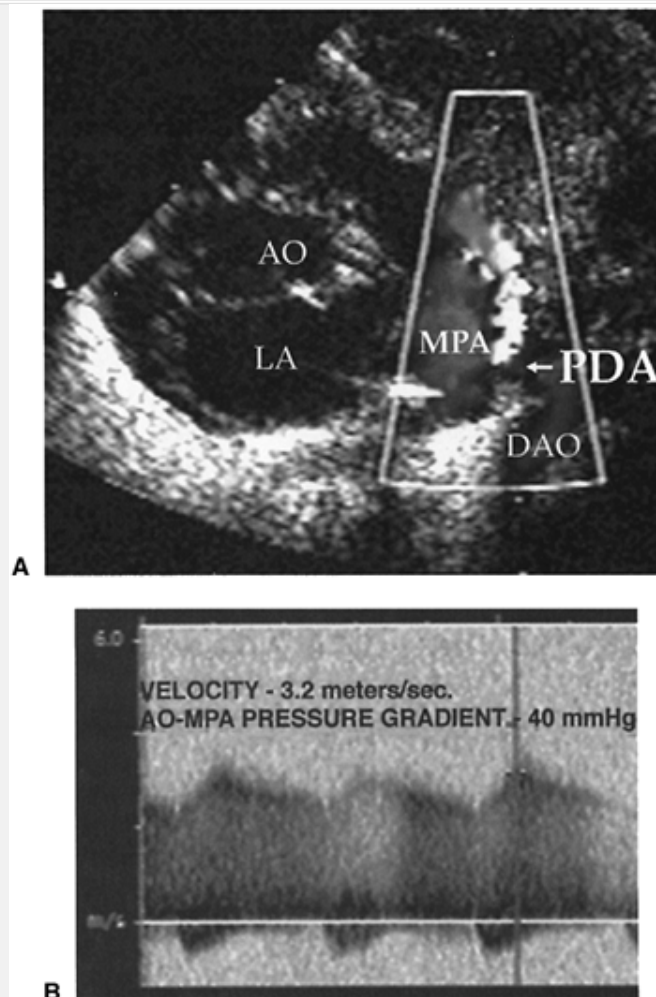

Figure 33-14 Echocardiographic parasagittal parasternal view of a patent ductus arteriosus. Doppler analysis demonstrates flow away from the transducer within the pulmonary artery and aortic isthmus and, in white, a jet of flow toward the transducer through the patent ductus arteriosus into the pulmonary artery. **B:** Quantification of the velocity of the flow jet through the ductus arteriosus with a continuous-wave Doppler technique and application of the Bernoulli principle allows the aortic-to-pulmonary-artery systolic pressure gradient to be measured. The pressure gradient by this technique is $4 \times (\text{maximum instantaneous velocity})^2$. The pulmonary artery peak systolic pressure can be estimated by the difference in the arterial systolic pressure and the pressure gradient across the ductus arteriosus. AO, aorta; DAO, descending aorta; LA, left atrium; MPA, main pulmonary artery; PDA, patent ductus arteriosus.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) can provide accurate assessment of intracardiac anatomy and function, and perhaps more importantly, can provide detailed images of intrathoracic structures, such as peripheral pulmonary arteries, systemic-to-pulmonary collateral vessels, and right ventricular function, that often are not adequately provided by echocardiography (see Coarctation, Fig. 33-35). Use of echocardiography and magnetic resonance imaging, in conjunction with the history and physical examination, enables precise diagnosis without resorting to diagnostic cardiac catheterization in most neonates.

Diagnostic Cardiac Catheterization and Angiography

Anatomy

Catheterization is rarely used to learn the basic anatomy of the heart. The diagnostic information necessary for most cardiac surgical procedures in neonates is now obtained noninvasively by echocardiography. Diagnostic cardiac catheterization is used to provide specific data unavailable through echocardiography that are useful in planning management (47). What is the anatomy of the pulmonary arteries and systemic-to-pulmonary collaterals in the patient with tetralogy of Fallot and pulmonary atresia? (see Tetralogy, Fig. 33-22) Is catheter closure of the collaterals possible? What is the anatomy of the coronary arteries in the patient with pulmonary atresia and intact ventricular septum? (see Pulmonary Atresia, Fig. 33-26) What is the anatomy of the coronary arteries with tetralogy of Fallot or transposition in which abnormality is suspected and/or echocardiographic imaging is nondiagnostic? In selected patients with cardiomyopathy, light and electron microscopic analysis of ultrastructural anatomy and biochemical analysis of myocardium obtained by biopsy may provide a diagnosis. In many situations diagnostic catheterization may be safer or more useful after initial palliative surgery, such as in hypoplastic left heart syndrome or following shunt procedures in those with complex intracardiac anomalies and pulmonary atresia.

The decision to perform a cardiac catheterization should be guided by a careful assessment of the long-term benefits in management versus the risk of the procedure. Before catheterization the medical condition is optimized for the anomalies present and the rapidity with which catheterization may provide critical information to further stabilize the situation. Infants with a duct-dependent anomaly are best managed with an infusion of prostaglandin E1, begun before and continued throughout the

P.654

catheterization. The potential for procedural morbidity and mortality is greater in the sick newborn (47). Potential morbidity includes blood loss, hypothermia, metabolic and respiratory acidosis, arrhythmia, electrolyte imbalance, hypoglycemia, thrombosis of femoral arteries, and angiographic myocardial stains.

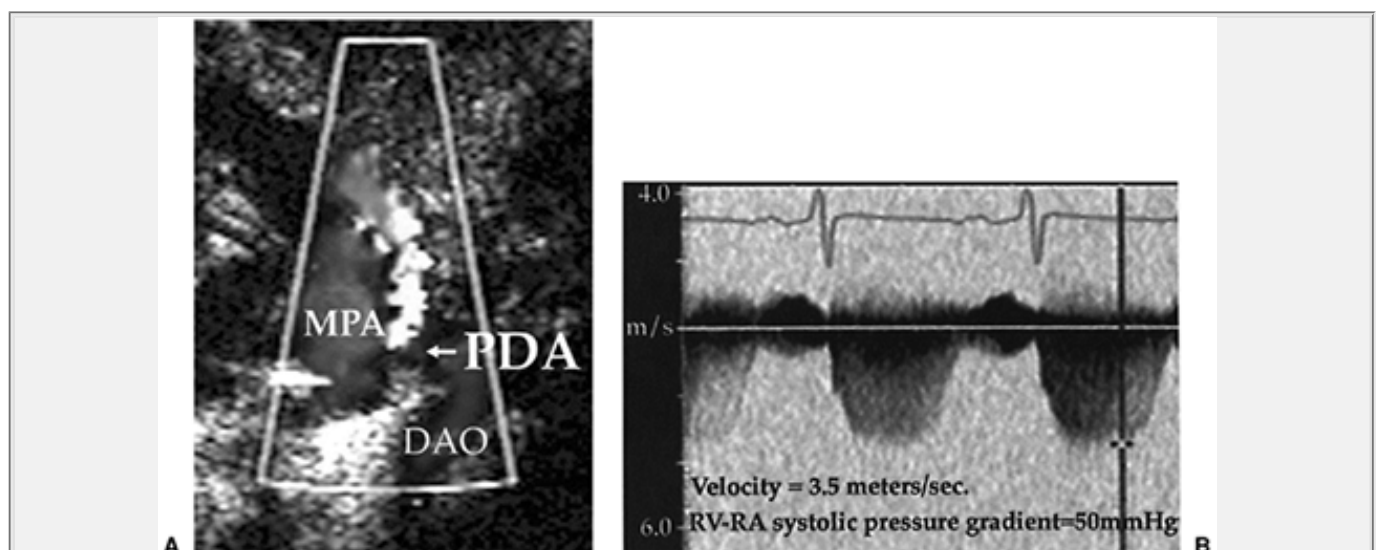

Figure 33-15 A: Echocardiographic apical four-chamber view in systole. Color Doppler analysis of the right heart demonstrates a jet of tricuspid regurgitation depicted by the blue flow jet (white arrow). **B:** Quantification of the velocity of the regurgitant jet by application of continuous-wave Doppler technique along the axis of the dotted line in the upper panel. Application of the measured tricuspid regurgitant velocity within the Bernoulli equation allows the right-ventricle-to-right-atrial peak pressure gradient to be measured and estimation of the right ventricular pressure (LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; TR tricuspid regurgitation). (See color plate)

Hemodynamic Measurements

Hemodynamic data obtained by catheterization can now largely be deduced from noninvasive measurements of blood pressure, oxygen saturation, and echocardiographic Doppler measurements of pressure gradients. Direct measurement does not help preoperative neonatal surgical management of most anomalies. When catheterization is done primarily for delineation of anatomy, hemodynamic measurements can be readily obtained and can facilitate delineating the clinical status and management. Hemodynamic measurements are often used to guide interventional catheterization such as valvuloplasty. Sometimes, particularly postoperatively, information from implanted catheters is useful for management of sick babies in the intensive care unit. Catheters in the right atrium placed through an umbilical vein, systemic vein, or trans-thoracically in the operating room may be used to obtain central venous pressure and blood oxygen saturation. These data can be used to infer preload and adequacy of cardiac output and, in combination with blood pressure measurements, to infer relative afterload. Catheters in the pulmonary artery, placed trans-thoracically at surgery or trans-venously, can be used to measure left-to-right shunts and to measure pulmonary pressure to titrate pulmonary vasodilators.

The hemodynamic principals for these calculations are based on Ohm's law and the Fick principle (see Table 33-9) (47). The former, when applied to hemodynamics, is the pressure drop across a vascular bed equals the product of the flow and resistance across it. Therefore, the resistance equals the difference of the arterial and venous pressure divided by the flow. The flow can be calculated from the Fick principal, which is based on the premise that oxygen delivery to the body equals oxygen consumption by the body. Oxygen consumption is routinely measured in the catheterization laboratory and, in the intensive care unit, can be assumed to be 200 to 240 mL/min/m² in neonates (48). Oxygen delivery is the product of flow and the arterial-venous oxygen content difference. Arterial and venous oxygen contents are calculated from the products of the measured blood oxygen saturations and blood hemoglobin concentration and the hemoglobin oxygen-carrying capacity (1.36 mL O₂/g hemoglobin). Systemic and pulmonary flow can be calculated as in Table 33-8. In those without a hemodynamic shunt, cardiac output can be measured by the thermodilution method.

Management Procedures for Severe Cardiac Disease

Preprocedure

An infant in difficulty in the first days of life because of heart disease has the potential for rapid deterioration. Too often, the baby looks as though he will survive but is near death hours later. The earlier symptoms appear, the faster deterioration can take place. By the time the infant has

P.655

reached 1 or 2 months of age, concern about sudden shifts in status is less warranted.

TABLE 33-9 HEMODYNAMIC FORMULATIONS

O_2 consumption = O_2 delivery

$$= Q \times (\text{arterial } O_2 \text{ content} - \text{venous } O_2 \text{ content})$$

Blood O_2 content (mL/L) = Hgb (g/dl) \times 10 (dL/L) \times 1.36 (ml O_2 /g Hgb) \times Hgb O_2 Sat.

Average neonate O_2 consumption = 200-220 mL/min/m²

Q_s (L/min/m²) = O_2 consumption/Hgb \times 13.6 \times (arterial O_2 Sat. - venous O_2 Sat.)

Q_p (L/min/m²) = O_2 consumption/Hgb \times 13.6 \times (pulm. venous O_2 Sat. - pulm. arterial O_2 Sat.)

Q_p/Q_s = (arterial O_2 Sat. - venous O_2 Sat.)

ΔP (mmHg) = $Q \times R$ (Woods units)

R_s = $Q_s / (\text{arterial mean pressure} - \text{RA mean pressure})$

R_p = $Q_p / (\text{pulm. arterial mean pressure} - \text{LA mean pressure})$

Q , cardiac output or blood flow; Hgb, blood hemoglobin concentration; Sat., saturation; Q_s , systemic flow or cardiac output; Q_p , pulmonary flow;

ΔP , arterial mean pressure minus arterial atrial mean pressure; pulm., pulmonary; R , vascular resistance; R_s , systemic vascular resistance; R_p , pulmonary vascular resistance.

From ref. 47.

Infants who present with severe cyanosis (See Color Plate) in the first days to weeks of life may do so because right ventricular outflow is critically obstructed and adequate pulmonary blood flow is dependent on a closing ductus arteriosus, or because the great arteries are transposed and adequate mixing of the pulmonary and systemic circulations is decreasing as the ductus arteriosus constricts. Babies with congestive heart failure in the first week of life often have obstructed left ventricular or aortic outflow, with descending aortic flow supplied by a closing ductus arteriosus. In these babies, survival may depend on persistent patency of the ductus arteriosus; dependency should be suspected, and prostaglandin E1 therapy considered. If possible, echocardiography should be used to confirm a specific anatomic diagnosis, but this may not be available in many primary care facilities, and the infant's condition may not provide the time before starting treatments to transport to a facility in which echocardiography is available. If a duct-dependent anomaly is suspected from physical examination, ECG, and chest radiograph (e.g., pulmonary atresia, hypoplastic left heart syndrome), or if the condition of a baby with undiagnosed cardiac anomaly is significantly worsening so that arterial oxygen saturation is less than 70% (e.g., as in d-transposition of the great arteries or critical pulmonary stenosis) or there is severe congestive heart failure because of ductal closure (e.g., as in critical aortic stenosis or coarctation), prostaglandin E1 therapy should be initiated even if echocardiography is not available (see Fig. 33-12). The usual starting dose of 0.1 mg/kg/min can frequently be reduced to 0.05 to 0.02 mg/kg/min after stabilization. The occurrence of relatively common side effects, particularly central apnea, vasodilation with hypotension, and fever should be anticipated. Endotracheal intubation should be performed prior to transport in infants receiving prostaglandins, to reduce the risk should later-onset apnea occur.

Despite prostaglandin therapy, these critically ill infants may have low cardiac output that may respond to the correction of common metabolic perturbations including hypothermia, intravascular hypovolemia, hypocalcemia, and hypoglycemia, but frequently, inotropic support is needed (Tables 33-10 and 33-11). Measurement of pressure in a central venous catheter may guide fluid therapy and permit administration of concentrated infusions of dextrose, calcium, and vasoactive amines. After appropriate steps to correct contributing metabolic abnormalities, fluid can be given in 5- to 10-mL/kg doses until adequate response is achieved or circulatory congestion occurs. Infusion of dopamine or dobutamine (5 to 20 mg/kg/min) or amrinone, should be added to support pump function as needed. Higher doses or continuous infusion of epinephrine can be considered to support refractory neonates until surgical palliation can be achieved. Digitalis preparations are much less desirable for acute inotropic support of critically ill infants who have variable renal and hepatic functions and electrolyte status.

Hyperventilation should be avoided in babies with certain lesions in which the pulmonary and systemic circulations are in parallel, such as hypoplastic left heart syndrome. Hyperventilation and oxygen administration in these babies can drop

pulmonary vascular resistance to low levels, resulting in runoff into the pulmonary vasculature, systemic hypotension, and very low systemic blood flow.

The acyanotic cardiac infant who develops symptoms of increased respiratory work and poor feeding after 2 to 4 weeks of life often has congestive heart failure from decreasing pulmonary vascular resistance and increasing left-to-right shunt. Treatment with digoxin, diuretics, and, in refractory cases, systemic vasodilators is often indicated (see Table 33-10). Rarely, these infants have left-sided obstructive lesions or myocardial disease (e.g., anomalous left coronary artery) that requires different treatment (see Therapeutic Catheterization).

Therapeutic Catheterization

Interventions now performed on neonates in the catheterization laboratory include balloon atrial septostomy by

P.656

P.657

P.658

P.659

Rashkind technique for transposition of the great arteries, creation of an atrial septal defect in mitral atresia or hypoplastic left heart syndrome with restrictive atrial communication using Brockenbrough atrial puncture and balloon dilation, pulmonary and aortic valvuloplasty, pulmonary artery angioplasty, angioplasty of discrete aortic coarctation with otherwise normal caliber aortic arch, and closure of systemic-to-pulmonary arterial collateral vessels (47,49,50,51 and 52). To perform a therapeutic procedure and to extract vital diagnostic information with the least danger to the patient requires vigilance against a multitude of treacherous pitfalls and acute sense of the clinical cost and benefit of each maneuver contemplated. The neonate undergoing study is ill, often critically ill, and may have a widely fluctuating physiologic state. Before catheterization the baby is medically stabilized as best possible as dictated by the baby's anomalies, condition, and the rapidity with which catheterization may be required to further stabilize the situation. Duct-dependent infants are managed with an infusion of prostaglandin E1 (53,54). Careful and constant attention to maintenance of proper thermal environment, minimization of blood loss, vascular access and hemostasis, anticoagulation, metabolic status, respiratory status, and catheter manipulation optimizes the outcome.

TABLE 33-10 COMMON ORAL DRUGS FOR THE TREATMENT OF CONGESTIVE HEART FAILURE

Generic Drug	Proprietary Name	Form	Dose	Action	Toxicity
Digoxin	Lanoxin	Elixir: 50 µg = 0.05 mg/mL	Digitalizing dose: Premature, 20 µg/kg Term, 30 µg/kg Initial dose, ½ In 6 h, ¼ In 12h, ¼ Maintenance dose: Premature, 3–4 µg/kg/12 hr Term, 4–5 µg/kg/12 hr	Na–K ATPase inhibitor, increases contractility	Atrioventricular block (monitor ECG during loading), tachydysrhythmias, vomiting; use with caution in renal failure and myocarditis; decrease dose by one-half if used with quinidine
Furosemide	Lasix	Suspension: 10 mg/mL	1 mg/kg/12 hr PRN to 2.0 mg/kg/8 hr	Loop of Henle Cl-pump inhibition, diuretic	Hyponatremia, hypokalemia, hypochloremic alkalosis, nephrocalcinosis
Chlorothiazide	Diuril	Suspension: 10 mg/mL	10–15 mg/kg/12 hr	Blocks distal tubular Na reabsorption, diuretic	Hyponatremia, hypokalemia, hypochloremic alkalosis, hyperbilirubinemia, hyperuricemia, hyperglycemia
Spironolactone	Aldactone	Suspension: 5 mg/mL Tablet: 25 mg	1–3 mg/kg/d, ¼ tab–½ tab, crushed qod–qd	Blocks tubular aldosterone receptor diuretic	Hyperkalemia
Captopril	Capoten	Tablet: 12.5 mg, 25 mg	Term, 0.1–1.0 mg/kg/8 hr Preterm, 0.05–0.2 mg/kg/8–12 hr	Angiotensin-converting enzyme inhibition decreases afterload	Hypotension, azotemia, proteinuria, may cause hyperkalemia when given with spironolactone or potassium; use with caution in low dose in premature neonates

TABLE 33-11 INTRAVENOUS VASOACTIVE DRUGS

Drug	Dose (µg/kg/min)	Action	Preload	Systemic Resistance	Pulmonary Resistance	Contractility	Heart Rate	Use	Toxicity
Dopamine	2–5 5–20	D, β ₁ D, β, α	+/- ↓ ↓	+/- ↓ ↓, ↑↑	0 ↑	↑ ↑↑	+/- ↑ ↑↑	↑CO, ↑ BP	Tachycardia, dysrhythmias, necrosis with extravasation, ↓ renal blood flow at higher doses
Dobutamine	2–20	β ₁ mild β ₂ , α	+/- ↓	↓	↓	↑↑	↑	↑ CO	Tachycardia, dysrhythmias, necrosis with extravasation
Epinephrine	0.05–1.0	α, β ₁ , β ₂	↓, ↑	↓, ↑↑	↓, ↑	↑↑↑	↑↑↑	↑ CO, ↑ BP, ↑ HR	Tachycardia, dysrhythmias, necrosis with extravasation ↓ renal blood flow

Isoproterenol	0.05–2.0	β_1, β_2	↓	↓↓	↓	↑↑↑	↑↑↑	↑ CO, ↑ HR	Marked tachycardia, dysrhythmias, hypotension when volume depleted
Amrinone	5–10 (load: 1.0 mg/ kg)	Phosphodiesterase inhibition	↓	↓↓	↓,↑↑	↑	0	↑ CO	Thrombocytopenia, dysrhythmias
Nitroprusside	0.5–5	EDRF-like action	↓↓	↓↓↓	↑	0	↑	↑ CO ↓ BP	Hypotension, V/Q mismatch, thiocyanate toxicity
Nitroglycerin	1–5	EDRF-like action	↓↓↓	↓↓	↓	0	↑	↑ CO, ↓ preload	Hypotension, V/Q mismatch, methemoglobinemia,
Phenylephrine	0.5–4.0	α	↑	↑↑↑	↑	+/- ↑	+/- ↓	TF, cyanotic spells	Cardiac output, ↓renal blood flow

+/-, may or may not; ↓, decrease; ↑, increase; α , α -adrenergic; β , β -adrenergic; BP, blood pressure; CO, cardiac output; D, dopaminergic; EDRF, endothelial-derived relaxing factor; HR, heart rate; TF, tetralogy of Fallot; V/Q, pulmonary ventilation–perfusion ratio.

TABLE 33-12 DIFFERENTIAL DIAGNOSIS OF CYANOTIC HEART DISEASE

Diagnosis	Physical Examination	Radiographic Findings	Electrocardiographic Findings
Hypoplastic left heart syndrome	Single S ₂ , ↑respiratory work, ↓pulse amplitude, ↓perfusion, +/- SRM	↑ Pulmonary arterial markings, cardiomegaly	↓ LV force usually, develops RAE, RAD, RVH
Transposition of great arteries (IVS, VSD) ^a	Split S ₂ , +/- murmur, +/- ↑respiratory work (<i>i.e.</i> , peaceful cyanosis)	↑ Pulmonary arterial markings, +/- cardiomegaly with narrow mediastinum (<i>i.e.</i> , "egg on a string")	Develops RAE, RAD, RVH
Truncus arteriosus	Split S ₂ , multiple clicks, soft to loud SEM, +/- DRM, ↑ respiratory work	↑ Pulmonary arterial markings, cardiomegaly	Develops RAE, RAD, BVH
Total anomalous pulmonary venous connection	Narrow S ₂ split, +/- murmur, ↑ respiratory work	↑ Pulmonary venous markings, ↑ diffuse interstitial markings	Develops RAE, RAD, RVH
Tricuspid atresia			
Without PS	Split S ₂ , heave, SRM	↑ Pulmonary arterial markings, cardiomegaly	Left axis deviation
With PS	Single S ₂ , SEM	↓ Pulmonary arterial markings +/- cardiomegaly	

Tetralogy of Fallot				Develops RAE, RAD RVH/
With PS	Single S ₂ , SEM		+/- ↓ Pulmonary arterial markings, +/- boot-shaped heart	
With PA	Single S ₂ continuous murmur, LSB back, axillae		↑, ↓ Pulmonary arterial markings and heart size	
Pulmonary stenosis (IVS or SV)	Single S ₂ , click, SEM		↓ Pulmonary arterial markings	In IVS QRS axis 0°- 100°, develops RAE RAD, RVH
Pulmonary atresia (IVS or SV)	Single S ₂ , soft SRM		↓ Pulmonary arterial markings	In IVS QRs axis 0-80°, ↓RV forces, +/- develops Q waves
Persistent pulmonary hypertension	Narrow split or single S ₂ , ↑S ₂ loudness, +/- SRMs		↓ Pulmonary arterial markings +/- parenchymal infiltrates +/- cardiomegaly	Develops RAE, RAD, RVH

^a Single ventricle is usually associated with transposition of the great arteries, and in the absence of PS or PA, it presents similar to transposition with ventricular septal defects.

+/-, may or may not be present; ↓, decreased; ↑, increased; BVH, biventricular hypertrophy; DRM, diastolic regurgitant murmur; IVS, intact ventricular septum; LSB, left sternal border; LV, left ventricle; PA, pulmonary atresia; PS, pulmonary stenosis; RAD, right axis deviation; RAE, right atrial enlargement; RV, right ventricle; RVH, right ventricular hypertrophy; SEM, systolic ejection murmur; SRM, systolic regurgitant murmur; SV, single ventricle; VSD, ventricular septal defect.

Surgery

Life threatening heart disease in neonates often requires surgery. Early recognition, safe transport to a cardiac center, accurate diagnosis, and an experienced surgical team are needed for success. Anesthesiologists familiar with the problems of neonatal cardiac patients and a well-equipped intensive care unit with trained personnel contribute to successful management of these babies. The postoperative care requires fine adjustment of blood volume, body temperature, fluid and electrolyte balance, oxygenation, ventilation, and hemodynamic measurements. Close cooperation between the cardiologists, intensivists, and surgeons responsible for the care of these infants is mandatory.

The timing of surgical intervention depends on the anatomic diagnosis and the relative outcome of surgery sooner or later. Single-stage repair should be used if possible when outcomes are at least equivalent to those for staged procedures to avoid the added jeopardy of performing an additional procedure before a definitive procedure is done. There is also increasing evidence that early repair results in improved cardiac status and neurologic function (12,55). For complex anomalies, particularly those with one functional ventricle, a staged approach is often required, with initial life-saving, palliative operation done in infancy, followed months or years later by additional reparative surgery.

Cyanotic Lesions

The differential diagnosis of cyanotic heart disease includes many disorders (Table 33-12). Lesions usually associated with decreased pulmonary flow include the tetralogy of Fallot, pulmonary stenosis, tricuspid atresia, pulmonary atresia with intact ventricular septum, and Ebstein disease. Cyanotic lesions usually associated with increased pulmonary vascular markings include d-transposition of the great arteries, hypoplastic left heart syndrome, total anomalous pulmonary veins, truncus arteriosus, and single ventricle.

Anomalies with Cyanosis Caused by Separate Transposed Systemic and Pulmonary Circulations

d-Transposition of the Great Arteries

With transposition of the great arteries, the aorta arises from the right ventricle and the pulmonary artery from the left ventricle. In the most common form, d-transposition, the aorta is anterior to and to the right of the pulmonary artery rather than in its normal rightward and posterior position.

Transposition of the great arteries is one of the most common congenital heart lesions presenting in the newborn period (see Tables 33-1 and 33-2), and is a frequent cause of death among un-operated neonates with congenital heart disease. The male-female ratio is 1.8:1, and the average birth weight is greater than that for other patients with congenital heart disease, although not for the general population. Transposition is associated with other cardiac abnormalities, including ventricular septal defect, patent ductus arteriosus, pulmonary valve stenosis, hypoplastic right ventricle, and coarctation.

Pathophysiology

The systemic and pulmonary circulations are normally in series with each other, but in complete transposition, the circulations are in parallel. Deoxygenated systemic venous blood returns to the right atrium, enters the right ventricle, and exits through the aorta. Maximally oxygenated pulmonary venous blood enters the left atrium and the left ventricle, and then returns to the pulmonary arteries and the lungs. Without some communication between the pulmonary and systemic circulations, survival is impossible; oxygenated blood cannot be delivered to the systemic circulation, nor can systemic venous blood be directed to the lung to become oxygenated. An atrial communication, ventricular defect, or patent ductus arteriosus, singly or in combination, may provide for mixing between the circulations (Fig. 33-16 and 33-17). The foramen ovale and ductus arteriosus, both normally patent in the fetus, usually close soon after birth. Infants with transposition and intact ventricular septum become extremely cyanotic within the first few hours or days after delivery, as closure of the foramen ovale and ductus arteriosus occurs and mixing between the circulations diminishes. The severe hypoxemia may lead to metabolic acidosis. Survival depends on prompt supportive medical care and reestablishment of patency of the ductus arteriosus and interatrial communication to improve mixing and oxygenation.

Figure 33-17 Diagram of the anatomy and physiology of transposition with intact ventricular septum in a 1-day-old girl who was cyanotic at birth. At catheterization, she had less than systemic pressure in the left (i.e., pulmonary) ventricle. The patent ductus arteriosus shunts blood into the pulmonary circuit, and the foramen ovale shunts an equal amount out of the pulmonary circuit. If this were not the case, relative blood volume would shift to one side of the circulation in a matter of minutes. If the ductus spontaneously closed, the infant's condition would become precarious. If the ductus were dilated with prostaglandins, the infant would become pinker but might experience respiratory difficulty because of excess pulmonary flow. The numbers below the chamber name are pressure measurements (mm Hg) determined at cardiac catheterization; the percentages indicate oxygen saturation. LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava. Adapted from Mullins CE, Mayer DC. *Congenital heart disease: a diagrammatic atlas*. New York: Alan R Liss, 1988, with permission.

Infants born with transposition and a large ventricular septal defect are less cyanotic because the ventricular defect allows mixing. These babies may not be recognized in the newborn period but appear in subsequent weeks with congestive failure. The combination of a large pulmonary flow, pulmonary hypertension, and elevation of left atrial pressure leads to the development of congestive heart failure (see Fig. 33-16) and later pulmonary vascular obstructive disease. Anatomic changes during the first few months of life may result in important hemodynamic changes. A large ventricular septal defect may spontaneously diminish in size or close, reducing mixing and increasing hypoxemia. Increasing pulmonary stenosis may decrease pulmonary flow and thereby increase cyanosis (See Color Plate) but improve congestive heart failure. Atrial septal defects created by balloon septostomy and those made by surgical septectomy may spontaneously diminish in size or close.

Clinical Findings

Infants with transposition of the great arteries and an intact ventricular septum develop marked cyanosis accompanied by mild tachypnea soon after birth. Often the infants, although tachypneic, do not seem distressed (i.e., peaceful cyanosis). The cardiac examination, chest radiograph, and ECG may otherwise be normal. The heart sounds are normal (i.e., the second heart sound splits), and there may be no significant murmur. Because the usual clinical findings, besides cyanosis, can be unremarkable, one of the most important diagnostic tests is the hyperoxia test. Failure of the arterial oxygen pressure (PaO_2) (often <30 mm Hg in room air) to rise significantly after the inhalation of 100% oxygen for a 10-minute period is strong presumptive evidence for cyanotic heart disease, most commonly complete transposition.

Figure 33-16 Diagram of the anatomy and physiology of transposition of the great arteries with a single membranous ventricular septal defect in a 1-month-old baby who had mild cyanosis and controlled congestive heart failure. There is equilibration of pressure between the ventricles and elevation of left-sided diastolic pressures. After balloon septostomy, the arterial saturation rose to 75%. The numbers below the chamber name are pressure measurements (mm Hg) determined at cardiac catheterization; the percentages indicate oxygen saturation. LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava. Adapted from Mullins CE, Mayer DC. *Congenital heart disease: a diagrammatic atlas*. New York: Alan R Liss, 1988, with permission.

The ECG may show some excessive right ventricular forces. On chest radiograph the heart and pulmonary vascularity may initially appear normal, although cardiac enlargement, a narrow mediastinum, and pulmonary plethora are frequently present or develop.

Figure 33-18 Echocardiographic subxiphoid view of a neonate with transposition of the great arteries. (AO aorta; ARCH, aortic arch; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RV, right ventricle; TV, tricuspid valve.)

Subcostal echocardiography reveals the diagnosis. The great artery arising from the left ventricle has an abnormal course and then bifurcates into the right and left pulmonary artery. The right ventricle gives rise to a great artery that passes relatively straight superiorly to the posterior arching aorta (Fig. 33-18). Echocardiographic examination can also determine the patency of the foramen ovale and ductus arteriosus, the nature of associated anomalies, and the coronary anatomy relevant to the surgical arterial switch procedure.

Infants with transposition and a large ventricular septal defect usually present with congestive failure and mild cyanosis, between zero and 6 weeks of age. Poor weight gain, tachypnea, and excessive diaphoresis are common, and wheezing occurs in older infants. A loud systolic murmur is present maximally at the lower left sternal border, often associated with a mid-diastolic flow rumble. An S3 may produce a gallop rhythm. Rales may be audible in the lungs.

ECG reveals right axis deviation and right atrial and right ventricular hypertrophy. Infrequently, if the right ventricle is hypoplastic, right ventricular forces may be absent or reduced, and left ventricular hypertrophy is present. Chest radiograph characteristically shows considerable cardiomegaly and pulmonary plethora.

Echocardiographic examination should identify the location of the ventricular septal defect, its relation to the great arteries and the atrioventricular valves, and complex associated problems including straddling or abnormal tricuspid valve, hypoplastic right ventricle, valvar or sub-valvar pulmonary stenosis, coarctation of the aorta, juxtaposition of the atrial appendages, and anomalous systemic or pulmonary venous drainage.

Differential Diagnosis

Most infants with transposition and intact ventricular septum are readily recognized as cyanotic infants with little respiratory distress and without significant murmur. Often a split second heart sound can be distinguished on exam, and chest radiograph demonstrates cardiomegaly and increased pulmonary flow, helping to distinguish transposition from other lesions with cyanosis and little murmur, pulmonary valve atresia with intact ventricular septum, and total anomalous pulmonary venous connection. Diagnosis of transposition of the great arteries can be complicated if other abnormalities, such as straddling tricuspid valve, hypoplastic right ventricle, coarctation of the aorta, or pulmonary stenosis, exist (see Table 33-12). Depending on the type and severity of the associated cardiac malformations, the clinical symptoms and findings in infants with complicated transposition of the great arteries may closely resemble those of almost any other cyanotic heart lesion.

The clinical picture in infants with transposition of the great arteries, ventricular septal defect, and pulmonary stenosis or atresia is virtually indistinguishable from that of tetralogy of Fallot or pulmonary atresia with a ventricular septal defect. If d-transposition of the great arteries is associated with a large ventricular septal defect and limited cyanosis, it is sometimes mistaken for other lesions with a large left-to-right shunt, such as a ventricular septal defect with normal aortic root or total anomalous pulmonary venous return without obstruction. The absence of cyanosis identifies the former, and echocardiography can differentiate all of these anomalies.

Treatment

In those with established or suspected transposition with intact ventricular septum, prostaglandin E1 is infused to open and maintain patency of the ductus arteriosus, to improve mixing and systemic oxygenation. Because prostaglandin E1 may cause apnea and vasodilation, support with mechanical ventilation, volume infusion, and sometimes inotropic agents may be required. Some babies also require a widely open atrial defect for adequate oxygenation, and most do better with one. Balloon atrial septostomy usually results in considerable clinical improvement in those sick from severe cyanosis, and some require it promptly for survival (see Fig. 33-19). The anatomy of the coronary arteries and associated lesions may also be established by catheterization. The type of surgical procedure employed depends on the associated cardiac defects. "Anatomic repair" with an arterial switch operation has been demonstrated to be the procedure of choice in neonates with uncomplicated transposition (56,57). The aorta and pulmonary arteries are transected, and the distal vessels are rejoined to provide normal physiologic connections. A button of proximal aortic tissue surrounding each coronary artery origin is cut, and both coronaries with the surrounding aortic button are moved from the native transposed aorta and attached to the neo-aorta. The ductus arteriosus is ligated, and the atrial septostomy is closed. Infants with transposition and isolated ventricular septal defect undergo arterial switch procedure and closure of the ventricular septal defect. Long-term outcome of arterial

switch procedure is not yet known but appears promising (58). Although a small number have difficulty with the coronary artery kinking, pulmonary artery compression, or anastomotic narrowing, the large majority do very well and lead essentially normal lives in childhood.

Figure 33-19 Echocardiographic subxiphoid view demonstrating a balloon septostomy catheter with the inflated balloon (arrow) being pulled from the left atrium (LA) to the right atrium (RA) through the foramen ovale. This septostomy technique is used in neonates with transposition of the great arteries to create an atrial septal defect to increase intracardiac mixing of fully and incompletely oxygenated blood, thereby improving systemic oxygenation.

The additional presence of significant pulmonary or aortic valvar or sub-valvar stenosis can prohibit a straightforward arterial switch procedure. Severe pulmonary valve stenosis generally occurs with a large ventricular septal defect, and a Rastelli procedure or variation of it is done by placing a patch from the crest of the ventricular septum into the upper right ventricle to direct left ventricular blood to the transposed aorta and directing blood flow from the lower right ventricle to the pulmonary artery by interposition of a conduit (generally homograft) from a right ventriculotomy to the distal transected main pulmonary artery. The presence of native aortic valve stenosis can be dealt with by a modification of the Damus-Kaye-Stansel type in which left ventricular blood flow to the body is through anastomosis of the transected proximal main pulmonary artery to the ascending aorta, and pulmonary blood flow is through a conduit interposed between the right ventricle and distal main pulmonary artery. These procedures require revision of the surgically implanted conduits with growth and in the not infrequent occurrence of extrinsic compression. Without therapy, 95% of infants born with transpositions die within 1 year. With aggressive medical and surgical treatment, mortality is less than 5% to 10%.

Anomalies with Cyanosis from Decreased Pulmonary Blood Flow

Tetralogy of Fallot

The tetralogy of Fallot is characterized by a large ventricular septal defect and infundibular pulmonary stenosis or pulmonary atresia. Both environmental factors and a number of genetic disorders are associated with tetralogy of Fallot. Many have microdeletions in a critical region of chromosome 22q11 (25,30). The primary anatomic pathologic abnormality appears to be anterior deviation of the upper part of the ventricular septum, known as the conal septum that separates the anterior pulmonary outflow of the right ventricle from the sub-aortic left ventricular outflow. This results in the sub-aortic anterior malalignment ventricular septal defect and in the right ventricular infundibulum being hypoplastic and narrow. There is often considerable valvar pulmonary stenosis, hypoplasia of the pulmonary arteries, right ventricular hypertrophy, a relatively large ascending aorta, and a right aortic arch (25%). In infants with pulmonary atresia, pulmonary perfusion occurs by way of a patent ductus arteriosus or by systemic-to-pulmonary arterial collateral vessels. Five percent of patients have abnormal coronary distribution that may influence surgical correction. Tetralogy is one of the most common cyanotic congenital heart lesions presenting in the newborn period (see Tables 33-1 and 33-2) and is occasionally (10%) associated with severe extra-cardiac malformations.

Pathophysiology

Depending on the severity of right ventricular outflow obstruction, there may be intracardiac left-to-right flow or right-to-left shunt and hypoxemia. Pressures equalize between the ventricles through the large septal defect. The peripheral arterial oxygen saturation depends on the amount of systemic venous admixture and the absolute pulmonary flow (Fig. 33-20). The extent of systemic venous admixture, that is, right-to-left shunting of

systemic venous blood away from the pulmonary outflow through the ventricular septal defect to the aorta, is directly related to the severity of the pulmonary stenosis and inversely related to the systemic vascular resistance. The amount of pulmonary blood flow depends on the amount of antegrade flow through the right ventricle outflow and the existence of alternative sources of flow (through a ductus arteriosus or systemic-to-pulmonary arterial collateral vessels). For example, in pulmonary atresia with a ventricular septal defect, the entire right heart output passes right to left through the ventricular defect, and pulmonary flow is supplied by a ductus arteriosus or collateral vessels and is usually less than normal. Cyanosis is the result. If the newborn has large aortic-pulmonary collateral vessels perfusing the lung, pulmonary blood flow may be large; and the infant may be barely cyanotic and some have congestive heart failure.

The pulmonary outflow stenosis in tetralogy of Fallot is progressive. Clinically significant cyanosis is present at birth in 25%, by 1 year of age in 75%, and almost all have become cyanotic by 20 years of age. Infundibular hypoplasia and stenosis are progressive in both absolute and relative terms. Progression of the stenosis during the first 6 months of life is most often largely relative because of a lack of adequate infundibular expansion during rapid somatic growth and need for proportionately greater pulmonary flow (59).

P.663

With time, complete atresia can occur. A patent ductus arteriosus usually closes within the first week of life, resulting in severe and often sudden hypoxemia or cyanotic spells.

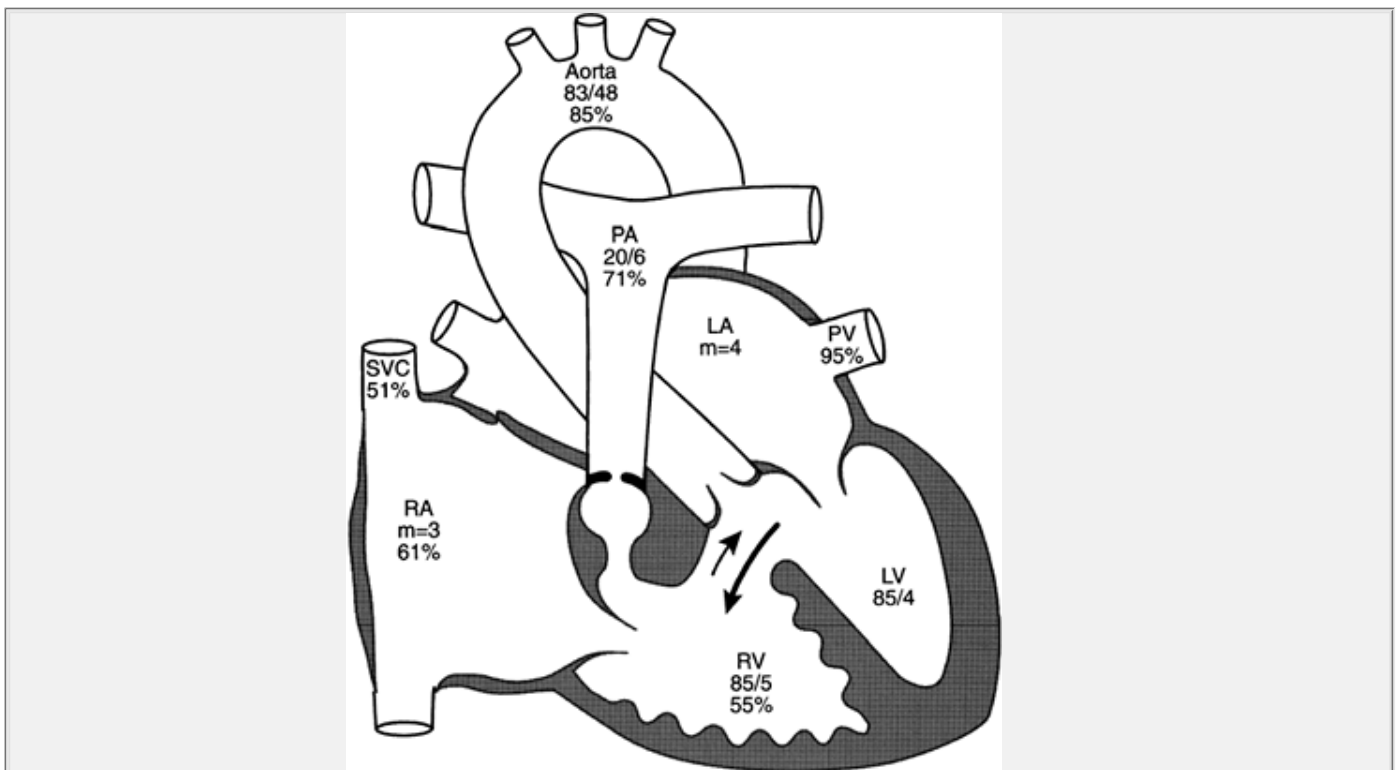

Figure 33-20 Diagram of the cardiac anatomy and physiology in a girl with mild cyanosis and a loud murmur audible at birth. She was found to have tetralogy of Fallot and was followed without medication prior to primary reparative surgery. The numbers below the chamber name are pressure measurements (mm Hg) determined at cardiac catheterization; the percentages indicate oxygen saturation. LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (Adapted from Mullins CE, Mayer DC. *Congenital heart disease: a diagrammatic atlas*. New York: Alan R Liss, 1988, with permission.)

Hypoxemia of rapid onset is characteristic of a "tet" spell secondary to an infundibular spasm. This may be associated with an increased adrenergic contractile state, systemic vasodilation associated with a meal, warm bath, or certain types of anesthesia, or constriction of a ductus arteriosus. Hypoxemia may result in a fall in systemic vascular resistance, metabolic acidosis, hyperpnea, and further hypoxemia. Hyperventilatory compensation for the metabolic acidosis may be ineffective because of inadequate pulmonary blood flow. The self-aggravating cycle of increasing hypoxemia and metabolic acidosis can progress to unconsciousness and convulsions.

Clinical Findings

Cyanosis of various degree and mild tachypnea often develop soon after delivery. If hypoxemia becomes severe, the infant may become hypotonic, hypotensive, and bradycardic. "Tet" spells characterized by a sudden onset of irritability, hyperpnea, and increasing cyanosis may develop. Spells may end in a loss of consciousness, seizures, cerebral injury, hemiparesis, or death. The disappearance of a previously heard right ventricular outflow systolic murmur with increased cyanosis suggests a spell and constitutes an indication for immediate therapy.

The second heart sound is single. With typical tetralogy, systolic murmurs from the pulmonary stenosis and/or ventricular septal defect are at the left upper and mid sternal border, respectively. With pulmonary atresia, when the systolic murmur is absent; there may be a constant apical systolic ejection click and prominent continuous murmurs of a patent ductus arteriosus or aortic-pulmonary collaterals, audible at the base, in the axillae, and/or over the back. A patent ductus arteriosus usually does not cause a continuous murmur in the first months of life; therefore, the presence of murmurs with cyanosis and a single S2 in a neonate strongly suggests tetralogy of Fallot with pulmonary atresia. Delay in height, weight, and skeletal maturation is common, particularly when DiGeorge syndrome is present, but some infants flourish despite severe hypoxemia.

Some young infants with the anatomic but acyanotic tetralogy of Fallot experience congestive heart failure from left-to-right ventricular septal shunting, later develop increased pulmonary stenosis, recover from congestion, and become cyanotic. Congestive heart failure also sometimes occurs in infants with pulmonary atresia when numerous or very large aortic-pulmonary collaterals are present. Although sub-acute bacterial endocarditis and brain abscess are common in older children with tetralogy of Fallot, these complications are extremely rare in infancy. However, spontaneous cerebrovascular accidents are common, particularly in infants with severe hypoxemia and relative anemia (<6-8 g/dL of oxyhemoglobin).

Chest radiograph shows a normal-sized heart, sometimes with right ventricular enlargement resulting in an upturned apex and an absent or diminished main pulmonary artery segment (i.e., boot-shaped heart), diminution of the pulmonary vasculature, and, in 25%, the aorta arching to the right.

ECG demonstrates right axis deviation, right atrial enlargement, and right ventricular hypertrophy, which at birth is often difficult to differentiate from normally prominent right ventricular forces.

Echocardiographic examination shows anterior and leftward deviation of the infundibular septum, creating sub-pulmonary stenosis and a malalignment ventricular septal defect with a large overriding aortic root (Fig. 33-21). Additional ventricular or atrial septal defects, central pulmonary artery hypoplasia, and coronary artery anatomy can usually be delineated by echocardiography but may sometimes require cardiac catheterization for clarification.

Angiography (Fig. 33-22), and often magnetic resonance imaging, may be used to determine presence and anatomy of distal pulmonary artery stenoses and systemic-arterial-to-pulmonary-arterial collaterals.

Differential Diagnosis

The features of cyanosis, a harsh systolic ejection murmur, chest radiographic findings of diminished pulmonary

P.664

vasculature with a normal-sized heart, and ECG evidence of right ventricular hypertrophy are characteristic of tetralogy of Fallot (see Table 33-12). The same findings with a continuous murmur suggest tetralogy of Fallot with pulmonary atresia. A few infants with tetralogy of Fallot and an underdeveloped pulmonary valve present with a characteristic to-and-fro murmur (i.e., steam engine sound) and severe respiratory distress caused by bronchial or tracheal compression by aneurysmally dilated pulmonary arteries.

Figure 33-21 Echocardiographic subxiphoid (A) and parasternal short-axis (B) views of an infant with tetralogy of Fallot. Anterior deviation of the conal septum (above the arrow) is associated with malalignment ventricular septal defect and obstruction of the right ventricular outflow above the pulmonary artery; arrow, ventricular septal defect and narrowed right ventricular outflow; ANT, anterior; AV, aortic valve; LA, left atrium; LV, left ventricle; LVOT, left ventricular outflow tract; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Treatment

Initial treatment and timing of surgery depend on the severity of the pulmonary stenosis. If severe cyanosis develops in the newborn, prostaglandin E1 should be employed to reopen the ductus arteriosus, improve pulmonary perfusion and stabilize the infant, and surgery should be done. Cyanotic "tet" spells are much more likely to occur in the infant with a moderate or greater degree of preexisting cyanosis, and echocardiographic findings of severe sub-valvar infundibular stenosis and hypoplasia. Later onset cyanotic "tet" spells should be treated with oxygen, intramuscular or subcutaneous morphine sulfate (0.1 mg/kg), intravenous administration of saline boluses and sodium bicarbonate (approximately 1 mmol/kg), and, if needed, phenylephrine (0.1 mg/kg subcutaneously; 5 to 20 mg/kg by intravenous bolus; 0.1 to 0.5 mg/kg/min by intravenous infusion) titrated to elevate systemic vascular resistance and pressure. Propranolol may be of some value in treating the infant with a reactive infundibulum. The hemoglobin concentration should be maintained high enough to permit adequate oxygen transport. The occurrence of a single "tet" spell is an indication for surgery, possibly as an emergency procedure.

The newborn with tetralogy of Fallot and little or mild cyanosis can be carefully observed with repeated measurement of transcutaneous systemic oxygen saturation until a stable level is apparent after ductal closure. Many remain asymptomatic through the first 4 to 6 months of life, and can then undergo surgery with greater likelihood of preserving adequate pulmonary valve function. However, because the right ventricular outflow obstruction is often progressive, careful serial follow-up is prudent.

In the past, critically ill infants who required surgery underwent palliative procedures, usually a shunt between the subclavian artery and branch pulmonary artery (Blalock-Taussig). The shunt was ligated during a reparative operation when the child was older. Infants with uncomplicated tetralogy of Fallot requiring surgery now undergo one-stage reparative procedures with excellent results (60). Using sternotomy and cardiopulmonary bypass, the right ventricular outflow tract is enlarged with a pericardial patch, and the ventricular septal defect is closed with a Dacron patch. There are several potential late sequelae, including late dysrhythmias and problematic pulmonary regurgitation, but most patients with uncomplicated tetralogy of Fallot have an asymptomatic course into young-mid adulthood (61). Those with very low birth weight, anomalous origin of the left anterior descending coronary from the right coronary artery and those with pulmonary atresia and hypoplastic-distorted pulmonary arteries may require a palliative shunt with a more definitive repair, entailing a conduit from the right ventricle to the pulmonary artery, when the child is older.

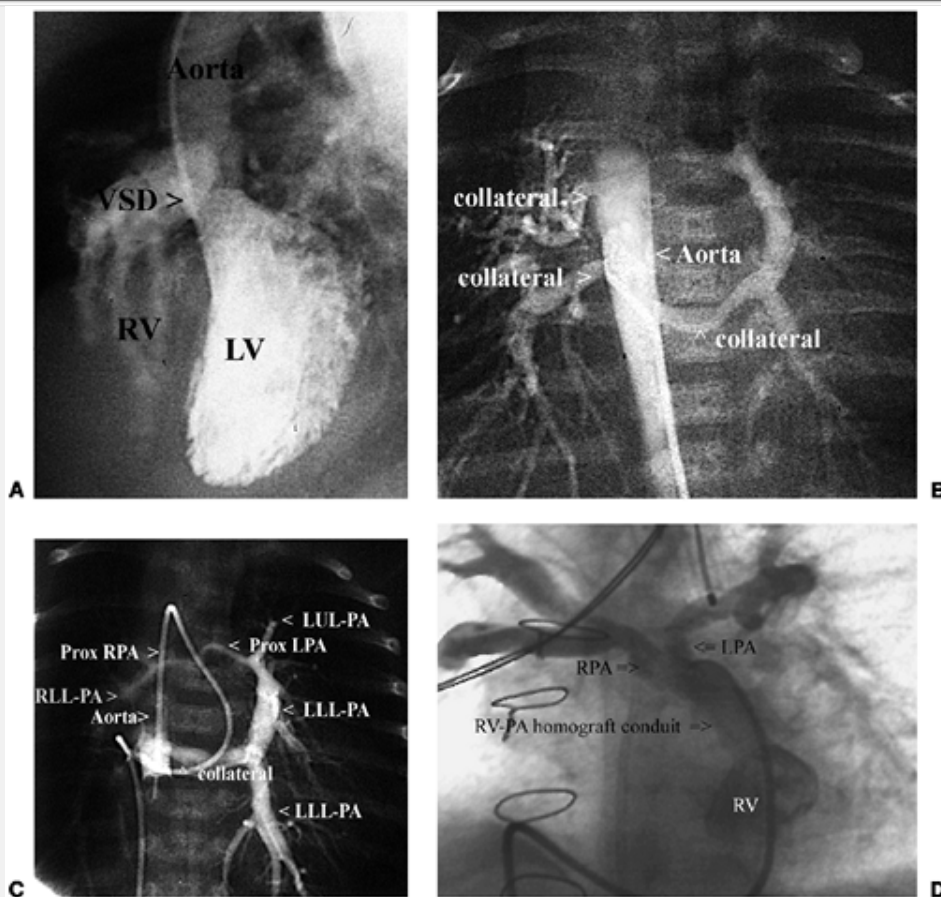

Figure 33-22 Angiograms from a cyanotic infant with complex tetralogy of Fallot with atresia of the right ventricular outflow, pulmonary valve and proximal main pulmonary artery demonstrate the anatomy of the hypoplastic mediastinal pulmonary arteries and collateral vessels that perfuse them. **A.** Left ventricular angiogram demonstrates tetralogy of Fallot with sub-aortic ventricular septal defect and pulmonary outflow atresia. **B.** Balloon occlusion angiography in the descending thoracic aorta demonstrates collateral vessels from the aorta to the right and left lung. **C.** Additional balloon occlusion aortography demonstrates the collateral vessel to the left lower pulmonary artery is in continuity with hypoplastic central mediastinal and right pulmonary arteries. Left subclavian arteriography, not shown, demonstrated an additional collateral solely supplying much of the left upper lung lobe. **D.** Right ventricular angiography after surgical implantation of a homograft conduit from right ventricle to the central pulmonary artery, and catheter balloon angioplasties of the left and right pulmonary arteries demonstrates substantial increases in sizes of the pulmonary arteries. LV, left ventricle; LLL-PA, left lower lobe pulmonary artery; LPA, left pulmonary artery; LUL-PA, left upper lobe pulmonary artery; PA, central pulmonary artery; prox, proximal; RLL-PA, right lower lobe pulmonary artery; RPA, right pulmonary artery; RV, right ventricle; VSD, ventricular septal defect.

P.665

In general, the earlier severe hypoxemia develops, the more severe is the tetralogy of Fallot, and the poorer the prognosis without surgery. The overall mortality rate without surgery was approximately 35% by 1 year of age.

Pulmonary Stenosis

Pulmonary Valve and Subvalvar Stenosis

Pulmonary valve stenosis is one of the more common intracardiac anomalies detected in the first month of life (Table 33-1). It is usually mild and not progressive. Even mild obstruction (<10 mm Hg systolic pressure gradient across the obstruction) produces a readily audible murmur. Moderate and severe pulmonary valve stenosis detected in the first week of life often progresses for a limited time over the following weeks or months. It generally presents with an isolated murmur radiating to the suprasternal notch, often but not always with an early systolic click resembling a split S1, little or no cyanosis, and no signs of congestive heart failure. A parasternal thrill, high-pitched systolic ejection murmur, and single second heart sound indicate severe pulmonary valve stenosis. Severe valvar obstruction may produce cyanosis (Fig. 33-23)

because of right-to-left shunting through a foramen ovale or rarely may present with the findings of right-sided congestive heart failure. In its most severe form, a very immobile, critically stenotic pulmonary valve requires ductal patency for adequate pulmonary blood flow and systemic arterial oxygenation. The right ventricular chamber may be small and noncompliant, resulting in some degree of right-to-left shunting although the foramen ovale, even after removal of the stenosis. Infundibular (i.e., sub-valvar) obstruction as an isolated lesion is rare; its presence usually indicates an associated ventricular defect.

Figure 33-23 Diagram of the cardiac anatomy and physiology in a 3-day-old baby with cyanosis from birth. There was no murmur. The pulmonary valve was nearly atretic with only a tiny orifice. A valvotomy was done, and the cyanosis resolved in 3 weeks. The numbers below the chamber name are pressure measurements (mm Hg) determined at cardiac catheterization; the percentages indicate oxygen saturation. LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (Adapted from Mullins CE, Mayer DC. *Congenital heart disease: a diagrammatic atlas*. New York: Alan R Liss, 1988, with permission.

Figure 33-24 A: Lateral view of the right ventriculogram of a neonate with mild cyanosis, loud murmur, and severe pulmonary valve stenosis. Cineangiography during injection of contrast through a catheter (C) into the right ventricle (RV) demonstrates a jet of contrast through the small orifice (arrow) of a thickened doming stenotic pulmonary valve (PV). There is poststenotic dilation of the main pulmonary artery. **B:** Immediately following the angiogram seen above, the pulmonary valve was crossed with a catheter, and balloon pulmonary valvuloplasty performed over a guide wire, reducing the peak-to-peak systolic pressure gradient from 82 mm Hg to 2 mm Hg.

associated with other cardiovascular or somatic malformations.

Chest radiography demonstrates normal heart size with fairly normal contour except for occasional upturning of the apex and normal or decreased pulmonary vascular markings. The electrocardiogram is usually normal at birth, although with severe and critical stenosis there may be relative mild left axis deviation for age (R axis 60 to 90 degrees) and increased or decreased right ventricular forces (see Table 33-12).

Echocardiography can determine the valve leaflet mobility, systolic pressure gradient, presence of right ventricular or infundibular hypoplasia, ductal patency, and possible associated anomalies such as atrial septal defect.

Only reassurance and observation are required for the mild stenoses because progressive obstruction is rare. Because moderate obstructions in early infancy often become progressively worse with growth, the patients should be periodically examined with this in mind. The severe and critical obstructions are relieved by catheter balloon dilation (Fig. 33-24) (47,49). Recurrence is unusual. Bacterial endocarditis is rare, but the administration of antibiotics

P.667

for prophylaxis before procedures that may be accompanied by bacteremia is recommended.

Pulmonary Artery Stenosis

Proximal pulmonary artery stenosis is probably the most common form of congenital heart disease discovered by hearing a murmur. The abnormality most often appears to be acute angulation, sometimes with mild narrowing of the proximal pulmonary artery branches. Minimal obstruction produces a readily audible murmur in the left upper sternal border, radiating to the clavicular regions, axillae, and back. Echocardiography can detect proximal pulmonary artery narrowing and pressure gradient and, when bilateral and severe, the presence of right ventricular hypertension. Severe peripheral pulmonary stenosis is rare and is usually associated with other problems such as tetralogy of Fallot, Williams syndrome, Alagille arteriohepatic dysplasia, and infants born of mothers with rubella. Angiography or magnetic resonance imaging is required to visualize the more distal pulmonary arteries. Pulmonary artery stenoses are usually amenable to catheter angioplasty and/or stenting.

Pulmonary Atresia with Intact Ventricular Septum

When the pulmonary valve is atretic and there is no ventricular septal defect, blood cannot pass through the right ventricle in the fetus. Without normal flow, the right ventricle cavity cannot grow normally and changes little in nature and size. If a severely stenotic valve becomes atretic late in gestation, the right ventricle can be near normal and quite adequate in size. However, when atresia occurs earlier in gestation the right ventricle at term is frequently coarsely trabeculated and pea sized. There is membranous pulmonary valvar atresia and, in approximately one-third of the cases, associated infundibular hypoplasia or atresia. The tricuspid valve annulus remains proportionately small and may be stenotic or incompetent. When the atresia occurs early in gestation and the right ventricle is hypoplastic, fistulous tracts connecting the hypertensive right ventricular sinus and the distal coronary arteries often persist, sometimes with proximal coronary artery stenosis. The right ventricle without outflow usually generates supra-systemic pressures. The high pressure probably contributes to the enlargement of fistulas that connect the right ventricle to the coronary arteries. The resultant severe coronary hypertension in utero may cause the coronary arteriopathy, proximal coronary artery stenoses, and myocardial fibrosis frequently seen. The pulmonary arteries are of adequate size and are perfused through a patent ductus arteriosus or, rarely, through aortic-pulmonary collaterals. An unrestrictive interatrial communication is essential to intrauterine survival and is present at birth. Pulmonary atresia with an intact ventricular septum is rarely associated with other cardiovascular or somatic malformations.

Pathophysiology

The major hemodynamic consequence of pulmonary atresia with intact septum is the obligatory right-to-left passage of the total systemic venous return through the foramen ovale to the left atrium. A patent ductus arteriosus provides the only entrance to the pulmonary circulation. As it closes, pulmonary perfusion declines, which results in progressively severe hypoxemia, metabolic acidosis, and death. In those infants with fistulas from the right ventricle to the left anterior descending and/or right coronary arteries and proximal coronary artery stenosis, perfusion of the coronary arteries distal to the stenoses occurs from the high pressure right ventricle through the fistulas. Surgical establishment of continuity between the right ventricle and the pulmonary artery may result in sufficient decrease in the right ventricle pressure to cause hypoperfusion of coronary beds supplied solely by fistulas and produce myocardial infarction. The size of the infarct and its impact directly correlate with the area of distribution of the coronary vessel involved (62).

Clinical Findings

Most infants with pulmonary atresia develop progressively severe cyanosis within the first week of life. As the ductal arteriosus constricts, severe cyanosis, hypotension, bradycardia, hypotonia, and marked acidosis occur. Signs of right-sided failure may develop but are usually absent. The precordium is quiet, and there is no thrill. S2 is single, and there is often a pan-systolic murmur of tricuspid incompetence.

Chest radiography, generally shows normal or mildly enlarged heart size, reduced lung vascular markings, and a left aortic arch (Fig. 33-25). ECG usually reveals a QRS axis in the frontal plane between zero and 80 degrees, absent or diminished right ventricular forces, and a pattern of left ventricular dominance reflecting right ventricular hypoplasia.

Figure 33-25 A chest radiograph shows decreased pulmonary vascularity and mild cardiomegaly in a 1-day-old infant with pulmonary atresia and an intact ventricular septum.

Figure 33-26 Cineangiogram of the right ventricle (RV) in an infant who presented with severe cyanosis, no murmur, single S2, and oligemic pulmonary vascular markings on chest radiograph. Echocardiogram confirmed pulmonary valve atresia, intact interventricular septum, and a closing ductus arteriosus. The aortic origin of the right coronary artery could not be visualized, and there was evidence for coronary fistula. Prostaglandin infusion was started. Selective coronary arteriography and right ventriculography demonstrated atresia of the proximal right coronary artery. A large fistula (FISTULA, black print) from the small right ventricle perfuses the distal right coronary artery and, through collaterals, the circumflex (C). There was also fistula (FISTULA, white print) from the right ventricle to the left anterior descending (LAD). The baby successfully underwent implantation of a modified Blalock-Taussig shunt, with no attempt to connect the right ventricle to the pulmonary artery.

P.668

Echocardiographic examination shows normal or somewhat enlarged left-sided structures, a small tricuspid valve and right ventricle, and atresia of the pulmonary valve. If there is membranous atresia of the pulmonary valve, the membrane can move like a critically stenotic valve, and the diagnosis cannot be made with certainty without a careful Doppler flow examination. Limitations in the size of the tricuspid valve and right ventricle and the presence of tricuspid stenosis can be quantified. High-resolution two-dimensional imaging and color Doppler can detect fistulas between the right ventricle and the coronary arteries. After the presumptive clinical diagnosis is made, prostaglandin should be given to dilate and maintain patency of the ductus arteriosus and increase pulmonary blood flow. In those babies diagnosed after ductal constriction, there should be rapid improvement in oxygenation and relief of acidosis.

Cardiac catheterization with selective right ventriculography and ascending aortography is done to determine the presence of fistulas and stenosis in the coronary arteries, essential for planning surgery (Fig. 33-26).

Differential Diagnosis

Pulmonary atresia with an intact septum needs to be differentiated from other cardiac causes of severe cyanosis in the first week of life (see Table 33-12). The combination of peaceful cyanosis, little murmur, single S2, chest radiograph with normal heart size and diminished pulmonary markings, and ECG with R axis of 0 to 80 degrees and diminished V1 R wave amplitude is characteristic. Critical valvar pulmonary stenosis alone, or with tetralogy of Fallot, are accompanied by a systolic ejection murmur, and right ventricular hypertrophy. Tetralogy of Fallot with pulmonary atresia has a continuous murmur and ECG with normal axis for age and prominent right ventricular forces. Transposition of the great arteries with an intact ventricular septum causes peaceful cyanosis and little murmur but is associated with a split S2, chest radiograph with cardiomegaly and increased vascular markings, and ECG with normal axis for age and evidence of prominent right ventricular forces. Infants with tricuspid atresia often have a prominent murmur and have a superior frontal plane axis on the ECG. In Ebstein anomaly of the tricuspid valve, the ECG has tall wide P waves and an rsR8S8 pattern, and chest radiograph demonstrates severe cardiac enlargement (Fig. 33-29). Echocardiographic examination differentiates all of these.

Treatment

After stabilization with prostaglandins, the treatment of choice is surgery, which is indicated as soon as feasible after the anatomy is established by catheterization. For infants with an adequately sized right ventricle, pulmonary valvotomy or valvectomy is performed. Some infants may require placement of a patch across the right ventricular outflow tract and valve annulus for adequate relief of obstruction. Often, even when of adequate size, the right ventricle is noncompliant, resulting in persistence of marked right to left atrial shunting. In infants with severe right ventricular noncompliance or hypoplasia a systemic-to-pulmonary shunt also may be necessary for relief of hypoxemia. After a period during which the right ventricular capacity and compliance improve and the pulmonary vascular resistance decreases, these infants may no longer require shunts for maintenance of adequate pulmonary blood flow. Even infants with initially diminutive right ventricular chambers may sometimes demonstrate adequate growth of the chamber if flow through the ventricle is provided by establishing continuity between the right ventricle and pulmonary artery, and the tricuspid valve is adequate. The right ventricle cannot be decompressed in infants who have fistulas between the right ventricle and coronary arteries and stenoses involving at least two separate proximal coronary vessels, without risk of fatal infarction (62). Infants with two or more major coronary stenoses, and those with persistent severe right ventricular hypoplasia, require a staged approach with an initial neonatal shunt and a later Fontan-type cavo-

pulmonary anastomosis or transplantation. Without therapy, the malformation is usually fatal, and with surgical treatment, more than 80% to 95% of these newborns survive to 1 year of age.

Tricuspid Atresia

Tricuspid atresia is a relatively uncommon disease that is characterized by absence of the tricuspid valve. Except in rare cases, no valve exists, and tricuspid agenesis is therefore a more precise description of this anomaly.

Pathophysiology

The entire systemic venous return (i.e., cardiac output) enters the right atrium and exits through the foramen ovale to the left heart. The systemic and pulmonary venous streams mix in the left atrium. After passage to the left ventricle, the cardiac output passes to the aorta, and a variable amount gains access to the pulmonary artery through a ventricular septal defect, diminutive right ventricle, and a variable degree of pulmonary stenosis. Flow to the pulmonary artery is limited by the size of the ventricular defect and the amount of infundibular and valvar pulmonary stenosis. The level of cyanosis is determined by the amount of pulmonary blood flow. If no ventricular septal defect is present there is also pulmonary valve atresia and like infants with isolated pulmonary atresia, all pulmonary flow is dependent on the ductus arteriosus. If the ventricular septal defect and right ventricular outflow are small and the infant is very cyanotic in early infancy, the pulmonary blood flow can be increased by maintaining a patent ductus arteriosus and subsequently surgically implanting of a Blalock-Taussig shunt. Some infants have naturally balanced circulations with sufficient flow to the pulmonary arteries to allow an adequate arterial oxygen saturation of 75% to 88%, although not so much regarding cause pulmonary hypertension or congestive heart failure. Infants with a large ventricular septal defect and unobstructed right ventricular outflow are minimally cyanotic and develop congestive heart failure and pulmonary artery hypertension. Occasionally, the great vessels are transposed, with the aorta arising from the right ventricle, and the systemic output may be limited by the size of the ventricular defect. A left superior vena cava is a common associated anomaly of importance to later surgery.

Figure 33-27 Electrocardiogram of a cyanotic newborn with tricuspid atresia shows the characteristic left axis deviation and low right precordial forces.

Clinical Findings

Babies are usually discovered to have tricuspid atresia during the first days or weeks of life because of cyanosis. Some have a harsh mixed frequency systolic murmur of left to right flow through the ventricular septal defect or ductus arteriosus, and/or a harsh high-pitched systolic ejection murmur from pulmonary stenosis. The S2 is most often single.

ECG characteristically has features distinguishing it from most other cyanotic lesions. There is a leftward

superior axis similar to endocardial cushion defects, but usually with diminished right precordial forces (see Fig. 33-27 and 33-10).

On chest radiograph, the heart is normal size or minimally enlarged and the pulmonary vasculature is diminished when the ventricular septal defect is restrictive, although heart size and pulmonary vascularity are increased when the ventricular septal defect is large and unrestrictive.

Figure 33-28 Echocardiographic apical four-chamber view in a baby with tricuspid atresia. Systemic venous blood flows from the right atrium (RA) across a widely patent foramen ovale (double arrows) to the left atrium (LA) and into the left ventricle (LV). Some of the outflow of the left ventricle passes through a ventricular septal defect (single arrow) and hypoplastic right ventricle (RV) to the pulmonary arteries (not shown).

P.670

The diagnosis is readily confirmed by echocardiographic identification of a diminutive right ventricle, absent tricuspid valve, and right-to-left flow through the foramen ovale (Fig. 33-28). The size of the ventricular septal defect and the degree of sub-valvar and valvar pulmonary stenosis can be accurately determined.

Treatment

Infants with small or no ventricular septal defect and severe obstruction of blood flow through the right ventricle may require infusion of prostaglandin E1 before palliative surgery. Surgical implantation of a modified or classic Blalock-Taussig type shunt from a subclavian or innominate artery to a pulmonary artery provides the means for adequate arterial oxygenation, survival, and growth in those infants with severe intracardiac obstruction to pulmonary blood flow. After several months of age the pulmonary vascular resistance usually decreases sufficiently to permit success of bidirectional Glenn surgery, connecting the upper superior vena cava carrying systemic venous blood return from the upper half of the body directly into the pulmonary artery. Variations on the Fontan operation, in which the systemic venous return from the remainder of the body is directed into the pulmonary arteries, are undertaken at or beyond the age of 1 year (63). More than 75% of infants with tricuspid atresia survive with Fontan physiology (64).

Rarely, in an infant with a large ventricular defect and no pulmonary stenosis, the pulmonary blood flow may be excessive enough to cause congestive heart failure. Anticongestive medications are usually sufficient to allow growth, although a pulmonary artery banding or other procedure may be necessary to diminish pulmonary vascular pressure and resistance.

Ebstein's Anomaly of the Tricuspid Valve

Ebstein's anomaly of the tricuspid valve is encountered rarely in the newborn period. The septal leaflet of the tricuspid valve is displaced downward and adheres to the ventricular septum to various degrees. The result is a dysfunction of the tricuspid valve with regurgitation, and sometimes stenosis, to varying degrees. The dysfunction is compounded by the fact that the right atrium and right ventricle contract at different times, and there is an area of atrialized ventricle or ventricularized atrium, depending on the point of view. This discordant

pumping of parts of each chamber contributes to the dysfunction. Those with severe prenatal tricuspid regurgitation often have massive cardiomegaly and may have pulmonary hypoplasia that is rapidly fatal after birth (Fig. 33-4). The effective right ventricular volume is reduced, and there is limited passage of blood through the right ventricle. Some right atrial blood courses through the patent foramen ovale, causing cyanosis. The severity of the defect can be described by the degree of cyanosis that, in the newborn period, can be severe because of the concomitant unresolved elevation of the pulmonary vascular resistance left over from fetal life. As the newborn's pulmonary vascular resistance regresses, the cyanosis often improves, sometimes markedly, although babies with severe regurgitation and pulmonary hypoplasia have a high mortality rate. After surviving the newborn period, the infant has a course determined by the degree of abnormality; some patients survive into late adulthood without important limitation, but others remain cyanotic and prone to supraventricular tachycardia.

Ebstein's disease is recognized because of minimal or prominent systolic low-pitched murmur of tricuspid regurgitation, multiple clicks, and minimal to severe cyanosis.

Chest radiography demonstrates cardiomegaly that may vary from minimal to some of the largest hearts encountered in the newborn period (see Fig. 33-29).

ECG has tall wide P waves and an rsR'S' pattern (see Table 33-12).

Figure 33-29 A chest radiograph of a 1-day-old cyanotic infant with Ebstein anomaly of the tricuspid valve shows marked cardiomegaly.

P.671

Echocardiographic examination confirms the diagnosis and delineates the extent and precise nature of the tricuspid anomaly, the amount of tricuspid regurgitation, the effective right ventricular volume, the atrial septal defect and associated abnormalities. Treatment is usually supportive. A surgical Blalock-Taussig shunt may be required in infants who remain severely cyanotic. Treatment for episodic supraventricular tachycardia may be needed.

Anomalies with Cyanosis as a Result of Complete Mixing of Systemic and Pulmonary Circulations

Hypoplastic Left Heart Syndrome

The hypoplastic left heart syndrome encompasses a variety of specific cardiovascular malformations producing similar hemodynamic and clinical manifestations, including aortic atresia, mitral atresia, premature closure of the foramen ovale, hypoplastic left ventricle with critical mitral stenosis, and aortic stenosis. Some cases of severe complex coarctation, critical aortic valve stenosis, and malaligned atrioventricular canal defects are also included in this category. The left heart chamber is usually very small, and endocardial fibroelastosis in it is common. Hypoplastic left heart syndrome occurs in 10.2% of infants with serious heart disease and is one of the most common lesions presenting in the first week of life (see Tables 33-1, 33-2, and 33-7). It is less common in very premature infants (<1.85 kg). It is usually an isolated lesion, although it has been described in association with trisomy syndromes and in infants of diabetic mothers. Familial cases occur.

Pathophysiology

Obstruction or atresia of the mitral or aortic valves limits or prevents flow through the left heart. The systemic venous return enters the right heart and is ejected into the pulmonary artery. The systemic circulation is largely or totally supplied by right-to-left flow through the ductus arteriosus. Blood traversing the lung enters the left atrium, flows through an atrial septal defect or dilated foramen ovale, and returns to the right atrium to join the incoming systemic venous return. Complete mixing takes place in the right atrium, with similar oxygen saturation measured in the right ventricle, pulmonary artery, and aorta. With little or no egress through the left heart, pulmonary flow must pass left to right through an interatrial communication. Any limitation of flow through the atrial septum produces pulmonary venous hypertension.

The maintenance of adequate systemic circulation requires patency of the ductus arteriosus. In aortic atresia, the ascending aorta, brachiocephalic vessels, and coronary arteries are perfused in a retrograde fashion with blood originating from the patent ductus arteriosus. Spontaneous constriction of the ductus results in flooding of the pulmonary circulation simultaneous with low systemic blood flow, poor coronary perfusion, congestive failure, and shock with metabolic acidosis, electrolyte imbalance, and coagulation abnormalities. Closure of the ductus stops blood flow to the body and causes immediate death.

Clinical Findings

These infants usually become symptomatic within the first week of life. Congestive failure and a shock-like picture may develop precipitously. The baby becomes ashen gray with poor peripheral perfusion, and all pulses are weak. Ductal constriction or flow may appear intermittent, with femoral pulses intermittently palpable. Symptoms and signs of congestive failure are associated with hypotension and, terminally, with bradycardia. S2 is single, and a gallop may be heard.

Chest radiograph shows cardiac enlargement and pulmonary plethora.

ECG can be near-normal, but usually has abnormalities including markedly diminished or absent left ventricular forces, left precordial T wave flattening or inversion, right atrial enlargement, right ventricular hypertrophy, and sometimes right axis deviation (see Fig. 33-30).

Echocardiographic examination demonstrates a small or tiny left ventricle. The ascending aorta is small with retrograde flow in cases of aortic atresia, and there is frequently aortic arch hypoplasia and juxta-ductal coarctation (Fig. 33-31).

Differential Diagnosis

The clinical picture of the hypoplastic left heart syndrome may be simulated by respiratory distress syndrome, interrupted aortic arch, severe complex coarctation, early neonatal myocarditis, isolated critical valvar aortic stenosis, sepsis or some inherited metabolic disorders (see Table 33-12).

Treatment

Without surgery, the mortality rate is 98% by 1 year of age. Surgical therapy consists of converting the circulation to single-ventricle Fontan-type physiology and/or to transplant a new heart. Previously the survival with the first stage of surgical palliation or with attempt to neonatal transplantation was only 1 in 2, or less, and comfort care was often presented as an option. Outcomes have significantly improved; currently survival with stage 1 surgery is 80% to 90% at specialized surgical centers.

Preoperatively the infant must be stabilized with prostaglandin E1, inotropic agents, volume infusion, and bicarbonate. Hyperventilation (i.e., arterial partial pressure of carbon dioxide, PaCO₂ < 40 mm Hg) and unnecessary supplemental oxygen administration are avoided. These measures decrease pulmonary vascular resistance and increase preferential flow of the right ventricular output into the pulmonary vascular bed instead of across the ductus to the systemic vasculature, worsening the shock. Often for preoperative stabilization, mechanical hypoventilation with muscle relaxation to maintain the PaCO₂ 45 to

55 mm Hg, and sometimes FiO₂ less than 0.21 to maintain arterial O₂ saturation 70% to 75%, are required to elicit sufficient pulmonary vasoconstriction to induce adequate systemic blood flow.

Figure 33-30 Electrocardiogram shows low left precordial forces in a cyanotic newborn with hypoplastic left heart syndrome.

Palliative surgical therapy consists of staged surgical procedures that convert the circulation to a systemic-right-ventricle perfusing the aorta, with pulmonary arterial Fontan-type physiology. The first-stage, modified Norwood procedure connects the right ventricle to the aorta, reconstructs the hypoplastic aortic arch, and provides an interim source of pulmonary blood flow with arterial pressure sufficient to overcome physiologically relatively elevated neonatal pulmonary vascular resistance. Cardiopulmonary bypass is used during cooling of the infant's body temperature to 15 to 18 degrees centigrade and usually temporarily discontinued (i.e., complete deep hypothermic circulatory arrest), the ductus arteriosus is ligated, the obliquely transected main pulmonary artery is anastomosed to the underside of the aortic arch and further augmented with homograft patch, and an atrial septectomy done to allow unimpeded pulmonary venous return to the right atrium. Following re-establishment of cardiopulmonary bypass, blood flow to the pulmonary artery is provided by insertion of a modified Blalock-Taussig, or direct central systemic-to-pulmonary artery shunt, or anastomosis of a small conduit from a superior right ventriculotomy (65).

Figure 33-31 Echocardiographic parasternal long-axis view in an infant with hypoplastic left heart syndrome. The right ventricle (RV) is near normal in size. The left atrium (LA), left ventricle (LV) and ascending aorta (AO) are tiny. Both the mitral and aortic valves are atretic.

Several months later, when the pulmonary resistance has dropped from relatively high neonatal values, pulmonary circulation can be supplied relatively directly with systemic venous return. A second-stage bidirectional Glenn procedure is done. The systemic venous return from the upper body is placed directly into the lung through a anastomosis of the upper superior vena cava to the right pulmonary artery, and the systemic-arterial-to-pulmonary-arterial shunt (with its obligate ventricular volume overload) is taken down. Finally, at a third Fontan-type procedure, systemic venous return from the lower body is also diverted directly into the pulmonary artery through a lateral tunnel within or adjacent to the right atrium, directing flow to a second,

pulmonary artery (65). The perinatal and first-stage surgical survival is 85-90%, and with the second and third stage procedures are greater than 98% and 95% to 99%, respectively (66,67). Adult survival is not yet determined.

Cardiac transplantation has been used as an alternative approach with good survival and childhood functional capacity, but there are critical limitations in the timely availability of neonatal donors and long-term morbidities and risks (68,69 and 70).

Neither reconstructive surgery leading to a Fontan procedure nor cardiac transplantation can be viewed as curative. Both methods of treatment have high fiscal and emotional costs. However, many survivors eventually do remarkably well in childhood.

Total Anomalous Pulmonary Veins

In the event of failure to connect the common pulmonary vein to the left atrium in the embryo, communications are established with available systemic venous channels that then drain the pulmonary veins. Anatomically abnormal drainage may be supra-cardiac (i.e., into the right or left superior vena cava), intracardiac (i.e., into the coronary sinus, right atrium), or sub-diaphragmatic (i.e., through the inferior vena cava or porta hepatis). Mixed sites of drainage occur in approximately 10% of these patients. A patent foramen ovale or atrial septal defect is invariably present, permitting venous return to the left heart. Anomalous pulmonary venous return is often associated with heterotaxy.

Although isolated total anomalous venous return accounts for only 2% of newborns with serious cardiac disease (see Table 33-2), it is an important lesion because it is potentially curable and often misdiagnosed as pulmonary disease.

Figure 33-32 A: A chest radiograph of a 3-day-old term infant with obstructed total anomalous pulmonary venous drainage shows a ground-glass appearance of the lungs with normal heart size, similar to the radiographic appearance of respiratory distress syndrome in preterm neonates. **B:** Postmortem angiography shows obstruction of the common pulmonary venous channel below the diaphragm (arrow). **C:** Echocardiographic supra-sternal notch view of another neonate with similar anatomy demonstrated the left lobar pulmonary veins (>) and right lobar pulmonary veins (<) connecting to retro-cardiac posterior confluence, that drained via a vertical vein inferiorly across the diaphragm. Additional images not shown demonstrated intrahepatic connection of the vertical vein through a constricted ductus venosus to the inferior vena cava. The baby did well after emergent surgical anastomosis of the pulmonary venous confluence to the posterior left atrium, ligation of the vertical vein inferiorly, and closure of the foramen ovale.

Pathophysiology

Infants with anomalous pulmonary venous drainage can be divided into two major categories on the basis of the hemodynamic changes produced: those with unobstructed veins and those with obstructed veins. Unobstructed pulmonary veins entering the systemic venous circulation or directly into the right heart result in a large left-to-right shunt, congestive heart failure, and pulmonary artery hypertension. Systemic output is maintained through

right-to-left flow across an interatrial communication. Despite the obligatory right-to-left shunt through the atrium, the large pulmonary blood flow mixing with the systemic venous return at the right atrium allows a reasonable peripheral oxygen tension and produces only mild or moderate cyanosis.

If pulmonary venous return is obstructed, the circulatory effects are drastically different. The obstruction may take the form of increased resistance to flow produced by a long, common, pulmonary venous channel or localized intrinsic or extrinsic obstruction. Sub-diaphragmatic anomalous pulmonary venous return is almost always obstructed by constriction of the ductus venosus, obstructing flow into the inferior vena cava (Fig. 33-32). Obstruction to supra-cardiac pulmonary venous return may occur because of compression of the common pulmonary venous channel between the left primary bronchus and left pulmonary artery or because of narrowing at the entry of the common pulmonary vein into the right superior vena cava. Obstruction at the foramen ovale is uncommon. After birth, significant resistance to flow through the pulmonary veins becomes evident, causing pulmonary venous hypertension, pulmonary edema, marked pulmonary artery hypertension and diminished flow, and severe cyanosis. The arterial

P.674

oxygen tension is low because pulmonary blood flow is markedly reduced, and the relative contribution of fully oxygenated blood to the venous return to the heart mixing in the right atrium is less than in the unobstructed form of this disorder.

Clinical Findings

Infants with total anomalous pulmonary venous return without significant obstruction usually become symptomatic after the neonatal period, when the pulmonary vascular resistance decreases and a large left-to-right shunt and congestive heart failure develop. They are mildly cyanotic with increased respiratory rate and work, often have frank congestive heart failure, and have a large heart revealed on chest radiographs.

Infants with obstructed pulmonary venous return are usually critically ill, severely cyanotic, and tachypneic within the first week of life. There are congestive heart failure and poor peripheral perfusion. In the absence of associated anomalies such as malposition with pulmonary valve or sub-valvar stenosis, there is generally only a relatively soft murmur of a patent ductus arteriosus and/or tricuspid valve regurgitation.

As seen on the chest radiograph, heart size is often normal, and there is evidence of pulmonary edema (Fig. 33-32). The clinical and the radiographic pictures may resemble hyaline membrane disease or diffuse pneumonia complicated by persistent pulmonary hypertension.

ECG at birth may be normal or may show right axis deviation, right atrial hypertrophy, and right ventricular hypertrophy.

Echocardiographic findings include absence of pulmonary venous connections to the left atrium, right-to-left bulging of the atrial septum, right-to-left atrial shunt, and pulmonary venous confluence posterior to the left atrium connecting to a systemic venous channel.

The findings of severe cyanosis, little murmur, and a roentgenographic picture of a normal heart size associated with pulmonary edema are characteristic (see Fig. 33-28A and Table 33-11).

Differential Diagnosis

Respiratory distress syndrome and interstitial pneumonia can be clinically indistinguishable from obstructed total anomalous pulmonary venous connection. Any suggestion of an atypical course mandates echocardiography, particularly in term neonates with equally diffuse involvement of both lungs, a failed or inconclusive hyperoxia test, or a murmur. Two-dimensional echocardiography shows the anomalous common venous connections and obstructions and the presence or absence of other cardiac anomaly.

Treatment

The treatment of total anomalous pulmonary veins is surgical, and success is related to the anatomy (e.g., results are poorer in the mixed variety) and to the age of onset of symptoms, as in patients with the infra-diaphragmatic type. The success rate is better for infants with intracardiac drainage. Using cardiopulmonary bypass and deep hypothermic circulatory arrest, continuity or redirection of the pulmonary venous drainage into the left atrium is established, usually by anastomosis of the retro-atrial common pulmonary venous confluence

to a parallel posterior left atriotomy. Although inotropic agents, diuretics, and supportive medical treatment may help temporarily and partially with stabilization, infants with severely obstructed anomalous venous return require immediate surgical intervention. Prostaglandin E1 therapy is not beneficial and can lead to dramatic worsening of the pulmonary edema. In most patients, surgery can be done on the basis of information from echocardiography without the delays involved with cardiac catheterization or magnetic resonance imaging. If there are associated complex congenital anomalies (e.g., heterotaxy syndrome) or intrinsic pulmonary vein stenosis is suspected, preoperative catheterization may sometimes help determine the best management. Those with unobstructed pulmonary veins and congestive heart failure with relatively normal pulmonary artery pressure may be improved with medical treatment, and corrective surgery may be delayed for a few weeks. Among those without additional lesions, the postoperative survivors have an excellent prognosis for a relatively normal life. A few infants develop atrial dysrhythmias postoperatively. Because life threatening, progressive and recurring pulmonary vein obstruction develops in approximately 5% to 10% of infants 1 to 12 months postoperatively, particularly in those with associated heterotaxy syndrome and preoperative pulmonary vein stenosis, initial close follow-up is mandatory.

Truncus Arteriosus

Failure of the cono-truncus to septate into the aorta and main pulmonary artery results in the clinical problem described as truncus arteriosus. It is often associated with microdeletions in a critical region of chromosome 22q11 containing genes responsible for conotruncal development, and with related extra-cardiac anomalies (e.g., DiGeorge syndrome). Other factors can be responsible (28,29). The only artery arising from the heart is the common truncus arteriosus. There is one semilunar valve that may have extra valve leaflets (e.g., four or five) and is often incompetent and rarely stenotic. The pulmonary arteries arise from the left anterior aspect of the truncal root as a single main pulmonary artery, at their bifurcation, or with separate right and left branches. Classifications in vogue are based on the level at which the pulmonary vessels take off, but they are not especially pertinent to the physiology and the clinical picture. Almost universally, there is a ventricular septal defect, usually in the sub-aortic septum, similar to that seen in tetralogy of Fallot. Interrupted aortic arch is an infrequent associated anomaly that should be borne in mind for timely recognition and management.

P.675

Pathophysiology

Because of the large ventricular defect and the common arterial trunk, the systemic and pulmonary venous returns are mixed, and the patient is cyanotic. The degree of cyanosis is determined by the pulmonary flow, which is a function of obstruction in the proximal pulmonary arteries. These obstructions are common, rarely severe, and located at the junction of the pulmonary artery and the trunk. If there is no obstruction, which is likely, pulmonary flow exceeds systemic output several-fold, obligating a high-output state and resulting in congestive heart failure and poor survival without surgery. Without surgery, irreversible pulmonary vascular disease is likely to develop as early as the patient's first birthday. Congestive heart failure is less of a problem if there is branch pulmonary artery stenosis, although the degree of cyanosis is greater. Proximal pulmonary artery obstructions frequently develop after surgery. When there is also interrupted aortic arch, a ductus is present, and its untreated closure results in lower body hypotension and hypo-perfusion, followed by death.

Clinical Findings

Infants with truncus arteriosus resemble those with ventricular defect more than the other cyanotic defects. Except cyanosis, which may be mild, development of symptoms is delayed until the pulmonary vascular resistance has resolved enough to allow a large pulmonary flow and the features of a left-to-right shunt. Tachypnea and the other signs of congestion predominate, although cyanosis may be recognized and documented in the first days of life. There is usually a murmur that sounds like a ventricular defect, the peripheral pulses are bounding, and other signs of an aortic runoff are present. The S2 is loud and single, and systolic clicks may be heard. If interrupted aortic arch is also present, diminished pulses, pulse pressure in the lower body, azotemia, and metabolic acidosis develop as the ductus constricts

On chest radiographs, the heart is enlarged, the pulmonary vasculature is engorged, and the aortic arch may be rightward (33%).

ECG inexplicably varies, showing right, left, or combined ventricular hypertrophy (see Table 33-11).

Echocardiographic examination demonstrates the anatomy (Fig. 33-33).

Treatment

Anticongestive measures to control congestion and promote growth have limited effect. Surgical correction is usually undertaken within the first 1 to 6 weeks of life. The later the surgery the more likely that the early postoperative course and survival will be threatened by severe elevation in pulmonary vascular resistance. Although banding of the pulmonary arteries on both sides is possible and is sometimes the only choice, it is easy to understand the difficulty of applying bands on each side equally. For this reason, and because of empirically poor results, most centers perform one-stage repair in infancy (71). This surgery consists of separating the pulmonary arteries from the trunk, establishing a conduit from the right ventricle to the pulmonary arteries, and closing the ventricular defect. Postoperative management and outcome are aided by the early use of potent pulmonary vasodilators such as nitric oxide. The long-range outcome of this type of repair involves two or three surgical revisions with larger pulmonary artery conduits to accommodate growth during childhood. Severe compression of the conduits and natural or surgery-related proximal pulmonary artery stenoses can develop and require catheter-based interventions in early childhood. The truncal semilunar valve may rarely be sufficiently incompetent to influence the outcome. However, with staged surgical intervention, the long-term survival and outcome are good (72).

Figure 33-33 Echocardiographic subxiphoid view in a neonate with truncus arteriosus. The right ventricle (RV) and left ventricle (LV) both pump blood through a subaortic ventricular septal defect (arrow) and common truncal valve into the ascending aorta (AO). The main pulmonary artery (PA) arises from the side of the ascending aorta.

Anomalies with Cyanosis with Variable and Mixed Anatomy and Physiology

Single Ventricle

There are few patients who have only one ventricle, with either two atrioventricular valves or a common atrioventricular valve. Most patients characterized as having a single ventricle have one dominant ventricle and a second diminutive structure that is often characterized as an outflow chamber. Because of the similarity of this syndrome to tricuspid atresia, some physicians have preferred the term univentricular heart to describe all patients with a functionally single ventricle, whether they have two atrioventricular valves, tricuspid atresia, or mitral atresia.

Seventy percent of these patients have a single left ventricle with a rudimentary anatomic right ventricular

P.676

outflow chamber that is left sided (l-transposed position). The ventricular outflow chamber leads to an anterior and leftward aorta, similar to that seen in corrected transposition. Most of the remainder of patients have a single left ventricle with a rudimentary right ventricular outflow chamber that is right-sided (d-transposed position). Pulmonary stenosis coexists in 50% of these patients. In those without pulmonary stenosis, sub-aortic

stenosis and coarctation can occur. Almost any other cardiac anomaly may be associated with single ventricle. Single right ventricles also occur, particularly with heterotaxy syndrome.

Pathophysiology

Depending on the presence or absence of pulmonary stenosis, the clinical picture may be dominated by diminished pulmonary flow and cyanosis or by excessive pulmonary flow and high-output congestive heart failure, respectively. Occasionally the pulmonary and systemic flow are balanced, and the patient is only mildly cyanotic and otherwise asymptomatic. The problems peculiar to corrected transposition, such as the tendency to develop complete heart block or develop an incompetent atrioventricular valve (usually the left), are risks. The connection between the single ventricle and the outflow chamber (i.e., ventricular defect) tends to get smaller with time in approximately 50% of patients. This has the physiologic effect of sub-aortic stenosis and must be considered in any management program.

Clinical Findings

The patient usually is visibly cyanotic during the neonatal period. Sometimes those with excessive pulmonary blood flow, minimal cyanosis, and congestive heart failure present later because of growth failure or tachypnea. Most have systolic murmurs from pulmonary stenosis, atrioventricular valve regurgitation, or from other associated defects. The detailed diagnosis is obtained by echocardiographic examination. Catheterization or magnetic resonance imaging are sometimes used preoperatively to delineate anatomic or physiologic details that may influence surgical management.

Treatment

The ultimate goal of management is to separate the pulmonary and systemic circulations by directing all systemic venous return through a cava-pulmonary or atrial-pulmonary anastomosis (e.g., Fontan procedure) and utilizing the single ventricle solely for pumping oxygenated blood to the aorta. Rare patients who have perfectly balanced pulmonary and systemic circulations, and are only mildly cyanotic and virtually asymptomatic, fare well with no surgery for years. Most require a pulmonary artery band to limit pulmonary flow or a shunt procedure to increase pulmonary flow and arterial oxygenation until a modified Fontan procedure (i.e., connection of systemic venous return to the pulmonary arteries) can be performed.

Double-Outlet Right Ventricle

Double-outlet right ventricle is a rare, anatomically and physiologically heterogeneous group of anomalies. The diagnosis is applied when imaging studies demonstrate that both great arteries arise principally from the morphologic right ventricle, invariably in the presence of a ventricular septal defect. A muscular conus commonly underlies both of the great artery outflows. Although various types of double-outlet right ventricle share a common ventricular-arterial relationship, the anatomy of the ventricles, ventricular conotruncal outflows, the relationship of the great arteries, and the presence of additional anomalies are variable. Of primary importance is the relationship of the great arteries to each other and, as a consequence, to the ventricular septal defect. This determines the basic physiology and the surgical management options (73).

Pathophysiology and Clinical Findings

The most common great artery arrangement is a normal relationship, with the aortic valve posterior and rightward and the pulmonary valve leftward and anterior. The ventricular septal defect usually relates to the sub-aortic outflow. Many will have sub-valvar and valvar pulmonary stenosis. Depending on the presence or absence of pulmonary stenosis, the physiology, clinical findings, clinical course, and therapeutic approach are, respectively, like those with tetralogy of Fallot with diminished pulmonary flow or like those with an isolated large sub-aortic ventricular septal defect and pulmonary hyperemia and hypertension.

The second most frequent great artery relationship in double-outlet right ventricle is with the aortic valve to the right, and anterior to or alongside the pulmonary valve, and the great arteries side-by-side. The ventricular septal defect is below the pulmonary outflow. The hemodynamics, clinical findings, and course are as in transposition.

Less common types of double-outlet right ventricle include those with the aorta anterior and leftward, those with

a remote uncommitted ventricular septal defect that does relate to either great artery outflow (e.g., atrioventricular inlet type defect), and those with a doubly committed ventricular septal defect that relates to both great artery outflows. Important associated anomalies in those without pulmonary stenosis, with either normally related or side-by-side great arteries, include mitral stenosis or atresia, sub-aortic outflow obstruction, and aortic arch hypoplasia and coarctation. Other less common associated anomalies include heterotaxy with its many related defects (see below and Table 33-13), pulmonary or aortic atresia, multiple ventricular septal defects, and superior-inferior ventricles. These associated anomalies can profoundly influence the hemodynamics, clinical course, and management.

Echocardiographic examination determines the diagnosis by showing the right ventricular-great arteries relationship and can usually determine the great artery and ventricular septal defect relationships and delineate the various associated defects. The need and timing of

P.677

catheterization depend on the anatomy demonstrated by echocardiography and the therapeutic management.

TABLE 33-13 COMMON ABNORMALITIES IN ASPLENIA AND POLYSPLENIA SYNDROMES

Asplenia	Polysplenia
Isolated levocardia or dextrocardia	Dextrocardia or levocardia
Visceral isomerism (midline liver and stomach)	Absent inferior vena cava (renal to hepatic segment)
Transposition of the great arteries	Endocardial cushion defect
Double-outlet right ventricle	Total anomalous pulmonary venous return
Total anomalous pulmonary venous return	Coronary sinus rhythm
Endocardial cushion defect	Bilateral epiarterial bronchi
Pulmonary atresia or pulmonary stenosis	
Single ventricle	
Bilateral superior vena cava	
Absent coronary sinus	
Ipsilateral inferior vena cava and abdominal aorta	
P-wave axis of atrial inversion	
Bilateral eparterial bronchi	
Bilateral trilobed lung	

Treatment

Management depends on the specific anatomic abnormalities. Medical and surgical treatment in those with normally related great arteries and no pulmonary stenosis is as with a large ventricular septal defect and in those with pulmonary stenosis as with tetralogy of Fallot. Those infants with side-by-side great arteries and transposition-like physiology may be managed by intracardiac repair or arterial switch procedure. Associated anomalies may require other approaches including systemic-to-pulmonary arterial shunts, Norwood-like procedure, aortic arch repair, and later Fontan-like approach.

I-Transposition of the Great Arteries

In I-transposition of the great arteries with situs solitus, also called corrected transposition, the circulation is often physiologically corrected. The terminology refers to the position of the aorta, which is abnormally positioned, anterior and usually to the left of the pulmonary artery, and to the position of the ventricles. I-Transposition of the great arteries is most commonly associated with ventricular inversion as well, i.e., the ventricles undergo I-looping instead of the usual d-looping. The systemic venous blood enters the right atrium and flows into a right-sided, morphologically left, ventricle and out to the pulmonary artery. Pulmonary venous blood returns to the left atrium and by way of the tricuspid valve into the left-sided, morphologically right, ventricle to the aorta. The aorta is abnormally positioned, anterior and usually to the left of the pulmonary artery. The hemodynamic changes in patients with I-transposition of the great arteries are caused by the commonly associated cardiac abnormalities that include ventricular septal defect (50%), single ventricle (42%), and pulmonary stenosis or atresia (45%). The latter three result in cyanosis. Left atrioventricular valve regurgitation (23%), conduction disturbances, and arrhythmias, particularly supraventricular tachycardia and complete heart block, are common. This diagnosis should be considered for newborns with complete heart block

or supraventricular tachycardia. Medical management and surgery are directed toward correction or palliation of the associated cardiovascular malformations, such as closure of the ventricular septal defect, pulmonary valvotomy, and a cardiac pacemaker if needed.

Malpositions

The term cardiac malposition describes abnormal position of the heart within the thorax or relative to the abdominal viscera. Cardiac position, or malposition, is relatively independent of the intracardiac segmental anatomy or interrelationships. For instance, dextrocardia, positioning of the heart in the right chest, and mesocardia, midline cardiac positioning, may occur with normal positioning of the abdominal viscera and atrial situs as a result of displacement from pulmonary disease or diaphragmatic hernia. Dextrocardia may also occur from genetically orchestrated complete inversion of thoracic and abdominal sidedness (i.e., situs inversus totalis), and with heterotaxic, "ambiguous" malpositioning of the viscera resulting from loss of control of sidedness during embryonic development, (e.g., asplenia and polysplenia syndromes). Cardiac malposition is also present when the heart is in the left thorax (levocardia) when there is heterotaxy or discordant sidedness of the viscera. The term malposition also describes misplacement of the heart as in ectopia cordis.

Fixed cardiac malposition most commonly occurs with heterotaxic malposition of the viscera, as occurs with the

P.678

asplenia and polysplenia syndromes (Fig. 33-34), and is characterized by discordant sidedness (e.g., dextrocardia with rightward or midline liver, or levocardia with leftward or midline liver). If the heart is displaced into the right chest or if there is total situs inversus, there is no heterotaxy. Situs inversus totalis is rare, and the heart may be anatomically normal, unlike the more common forms of malposition.

Pragmatically, finding cardiac or abdominal malposition is important as evidence that the patient has a high likelihood of complex combinations of congenital cardiac anomalies. Heterotaxy may be discovered by physical examination or chest radiographs because of abnormal sidedness of the abdominal contents or because the heart is located in the right chest. The cardiac anomalies are remarkably variable, often multiple and complex, and often life-threatening. Table 33-13 shows the anatomic abnormalities encountered in asplenic and polysplenic patients. Incredibly, often all of these occur in combination. For example, a baby with asplenia may have the combination of inferior vena cava crossing from one side of the midline to the other, single left or bilateral superior vena cava, dextrocardia, total and sometimes mixed pulmonary venous connections, single atrium, common atrioventricular valve, single right ventricle with double outlet, and pulmonary stenosis or atresia. Clinically, the initial objective is to determine the details of anatomy and anomaly in each central systemic and pulmonary vein, cardiac chamber, valve, and great artery on a segment-by-segment basis, delineate the interconnections of the various segments of the heart and plan the procedure or sequence of procedures required to repair or optimally palliate the baby's heart. When evidence of cardiac or abdominal malposition are detected, and regardless of the clinical appearance of the baby, it is safest to promptly proceed with a detailed diagnostic evaluation by a cardiac team that has the facilities and experience to accurately determine the anomalies and management. Most patients can be palliated. The overall mortality rate tends to be higher because of the combination of lesions, particularly in those with obstruction of anomalous pulmonary veins (see Table 33-2). Those with asplenia should receive lifetime prophylactic antibiotics because of their propensity for sepsis.

Figure 33-34 A chest radiograph of a neonate with asplenia syndrome, tricuspid atresia, transposition of the great arteries, and a right aortic arch. The liver and stomach are on the right side.

Acyanotic Lesions

Acyanotic diseases associated with normal pulmonary flow include those with systemic outflow obstruction such as coarctation of the aorta and aortic stenosis, mild and moderate pulmonary outflow stenosis, myocardial diseases, and arrhythmias. Acyanotic lesions usually associated with increased pulmonary blood flow include ventricular septal defect, atrial septal defect, endocardial cushion defects, patent ductus arteriosus, aortopulmonary window, and arteriovenous malformations (see Tables 33-14 and 33-15).

Acyanotic Anomalies with Systemic Outflow Obstruction

Coarctation and Interruption of the Aorta

For clinical, prognostic, and probably etiologic reasons, coarctation of the aorta is best considered in two separate categories: simple and complex. Simple coarctation is usually a discrete constriction of the aortic isthmus area, occasionally associated with a patent ductus arteriosus inserting just at or below it. Complex coarctation involves tubular hypoplasia of the aortic arch, with or without discrete aortic narrowing and one or more of the following lesions: patent ductus arteriosus, ventricular septal defect, endocardial cushion defect, aortic stenosis, sub-aortic stenosis, mitral stenosis or regurgitation, hypoplasia of the left ventricle and ascending aorta, other cyanotic anomalies, and endocardial fibroelastosis. In its most severe form the aortic arch may be atretic and completely interrupted as in DiGeorge syndrome. In complex coarctation and interruption of the aorta, the amalgam of left-sided involvement may be secondary to reduced intrauterine flow through the left heart, with consequent underdevelopment and hypoplasia extending from the left atrium to the aortic isthmus. In simple and complex coarctation, there are great variations possible in the extent and location of the coarctation.

Coarctation occurs in 6% to 7% of newborns with heart disease (see Tables 33-1 and 33-2). It is one of the common causes of congestive failure in the neonate (see Tables 33-7). Among symptomatic infants, 82% have complex coarctation, and 18% have simple coarctation. It is more common in male and premature infants. Girls sometimes have Turner

P.679

syndrome. Severe extra-cardiac anomalies, usually renal or gastrointestinal, occur in 6% to 9% of these patients (see Table 33-4).

TABLE 33-14 FINDINGS IN ACYANOTIC 0- TO 2-WEEK-OLD NEONATES WITH CONGESTIVE HEART FAILURE^a

Diagnosis	Physical Examination	Radiographic Findings	Electrocardiographic Findings
Coarctation	↓ Leg pulses and leg BP, soft SEM in back, +/- SRM, +/- click, S ₃ , +/- differential cyanosis, shocklike sepsis picture	↑ Heart size, pulmonary edema	+/- RVH, develops LVH, BVH
Critical aortic stenosis	Shock, ↓ pulses and perfusion, SEM, click, S ₃ , single S ₂	↑ Heart size, pulmonary edema	LVH, T-wave abnormalities
Patent ductus arteriosus in premature infant	Heave, ↑ pulses, ↑ pulse pressure, continuous or SRM	↑ Heart size (LV, LA), ↑ pulmonary arterial markings	Develops RVH, LVH, BVH

Cardiomyopathy	↓ Pulses, ↓ perfusion, ↓ pulse pressure, ↑ HR, SRM	Large globular heart, pulmonary edema	↓ or ↑ voltage, T-wave changes, Q waves in ALCA
Critical pulmonary stenosis	SEM, click, single S ₂ , most have cyanosis	Normal or ↓ pulmonary arterial markings, RAE	QRS axis 0°-90°, +/- LVH, develops RVH
Systemic arteriovenous fistula	Heave, ↑ pulses, wide pulse pressure, soft SEM or SRM, bruit, shock, +/- cyanosis	↑ Heart size, ↑ pulmonary arterial markings	Develops RVH, LVH, BVH

^a Congestive heart failure with cyanosis may be caused by hypoplastic left heart syndrome, transposition of the great arteries, truncus arteriosus, total anomalous pulmonary venous connection, pulmonary atresia with tetralogy, tricuspid atresia, Ebstein malformation, or persistent pulmonary hypertension.

+/-, may or may not be present; ↓, decreased; ↑, increased; ALCA, anomalous left coronary artery; BVH, biventricular hypertrophy; HR, heart rate; LA, left atrium; LV, left ventricle; LVH, left ventricular hypertrophy; RAE, right atrial enlargement; RVH, right ventricular hypertrophy; S₂, second heart sound; S₃, third heart sound; SEM, systolic ejection murmur; SRM, systolic regurgitant murmur.

Pathophysiology

Simple Coarctation. The isthmus is normally smaller than the ascending or descending aorta in newborn infants because only 10% of the combined ventricular output during fetal life passes through the isthmus into the descending aorta, whereas approximately 60% passes through the ductus arteriosus to the descending aorta. After birth, the isthmus gradually grows, but in simple coarctation, there is a constricting band just above the point of connection to the ductus arteriosus. Aortic coarctation may acutely further constrict in the neonatal period, as constriction of the adjacent ductal tissue occurs. During infancy, there may be relative progression of the coarctation from inadequate,

P.680

disproportionately small aortic isthmus growth, and perhaps aortic wall hypertrophy and endothelial thickening at the coarctation site. Collateral circulation may be present at birth. In simple coarctation, the increased resistance to flow results in a pressure overload on the left ventricle. If the coarctation is not severe and there is a patent ductus arteriosus, with fall in pulmonary vascular resistance after birth, there is a reversal of flow through the ductus arteriosus from the aorta to the pulmonary artery, and a considerable left-to-right shunt may develop. If the increased pressure and volume load exceed the ability of the heart to compensate by hypertrophy or dilation, congestive failure with diminution of systemic output ensues. Left ventricular end-diastolic pressure is elevated, resulting in increased pulmonary venous pressure and development of pulmonary edema. The increased pulmonary venous pressure also produces pulmonary artery hypertension and right heart failure.

TABLE 33-15 FINDINGS IN ACYANOTIC 2- TO 8-WEEK-OLD NEONATES WITH CONGESTIVE HEART FAILURE^a

Diagnosis	Physical Examination	Radiographic Findings	
		Radiographic Findings	Electrocardiographic Findings
Ventricular septal defect	Heave, harsh SRM, +/- S ₃ , +/- diastolic rumble, normal pulses	↑ Heart size (RV, LV, LA), ↑ pulmonary arterial markings	Develops RAE, RVH, LVH, BVH
Endocardial cushion defect	Same as ventricular septal defect, fixed split S ₂	Same as ventricular septal defect	Left axis deviation, develops RAE, RVH, LVH, BVH

Atrial septal defect	Hyperdynamic precordium, soft SEM, fixed split S ₂ , +/- diastolic rumble	↑ Heart size (RV, normal LA and LV), ↑ pulmonary arterial markings	Develops RAD, RVH
Patent ductus arteriosus in full-term infants	Same as presentation at 0-2 weeks of age		
Cardiomyopathy	Same as presentation at 0-2 weeks of age		

^a Murmur may be present earlier than 2 weeks of age, and congestive heart failure may occur earlier in premature infants.

+/-, may or may not be present; ↓, decreased; ↑, increased; BVH, biventricular hypertrophy; LA, left atrium; LV, left ventricle; LVH, left ventricular hypertrophy; RAD, right axis deviation; RAE, right atrial enlargement; RV, right ventricle; RVH, right ventricular hypertrophy; S₂, second heart sound; S₃, third heart sound; SRM, systolic regurgitant murmur.

Complex Coarctation and Aortic Interruption. Complex coarctation and aortic interruption are characterized by pulmonary artery hypertension with a ductus arteriosus supplying the descending aorta, usually a large intracardiac left-to-right shunt, and increased pulmonary flow. The right-sided structures are dilated and hypertrophied. There is a pressure and volume overload on both ventricles and congestive heart failure. In those with a large ventricular septal defect and patent ductus arteriosus, the systolic pressures in the pulmonary artery, descending aorta, ascending aorta, and right ventricle are identical. Peripheral pulse pressure is normal, and the pulses are equal throughout. With ductal constriction, the femoral arterial pulsations diminish. If the aortic arch obstruction is severe or complete, perfusion to the lower one-half of the body, previously supplied by the open ductus, is reduced. Manifestations of shock, renal and mesenteric hypoperfusion, and metabolic acidosis develop. Ductus closure causes death.

Clinical Findings

Simple Coarctation. Infants with isolated discrete coarctation may be asymptomatic, although some develop congestive heart failure, often after the age of 1 month. The femoral and pedal pulses are absent or diminished compared with brachial or carotid pulses. Radial and brachial pulses may be decreased if the subclavian artery on that side arises at or below the coarctation. Systolic blood pressure in the upper extremities is higher than in the lower extremities, but marked hypertension is uncommon. Pulse pressure in the lower extremities is narrowed, often 10 to 15 mm Hg. S₃ is often present, and there may be an apical systolic ejection click (~ half have a bicuspid aortic valve). A systolic ejection murmur from the coarctation may be heard at the left interscapular area over the back, and at the left upper sternal border. In the neonate a continuous murmur, when present, is usually from a left-to-right shunt across the ductus arteriosus, as collateral vessel flow is generally not audible until older age. Manifestations of congestive heart failure are those of combined left and right heart failure.

Chest radiograph can be nearly normal, but usually shows cardiac enlargement and pulmonary venous congestion.

ECG can be normal, but usually reveals right ventricular hypertrophy in the early months and left ventricular hypertrophy later.

Echocardiographic visualization of the aortic arch usually shows the site, length, and severity of coarctation and the aortic arch branching pattern. There is characteristically a constriction from the outer posterior curvature of the aortic wall, and an anterior peri-ductal shelf may be identified. An instantaneous systolic gradient may be derived from the velocities across the coarctation but may underestimate the severity of the lesion if cardiac output is depressed. The descending aortic flow has a characteristically diminished systolic upstroke velocity and prolonged antegrade flow.

Magnetic resonance and CT imaging can be used to delineate anatomic features not evident with echocardiography (Fig. 33-35).

Complex Coarctation and Aortic Interruption

Infants with severe isolated and complex coarctation usually present with congestive heart failure in the early

neonatal period. Generally, the younger the infant, the more severe and complex are the combined malformations. Complete interruption of the aortic arch is usually associated with a ventricular septal defect and a systemic patent ductus arteriosus and is clinically indistinguishable from complicated coarctation. It is frequently seen as part of DiGeorge syndrome, which may have additional manifestations of hypocalcemia, absent thymic shadow on the initial chest radiograph, and possible impaired immune response to transfused viable nonirradiated leukocytes. Besides the findings described for simple coarctation, there is evidence of a large left-to-right shunt and pulmonary artery hypertension. Femoral pulsations may wax and wane, depending on ductal

P.681

caliber. A pan-systolic murmur of a septal defect or mitral regurgitation may be found. Ductal closure may result in a critically ill baby with poor perfusion, metabolic acidosis, and possibly disseminated intravascular coagulation, necrotizing enterocolitis, and renal and hepatic dysfunction.

Figure 33-35 Magnetic resonance image of aortic coarctation in a 1 day old. Arrow indicates focal coarctation in the distal end of a hypoplastic aortic arch.

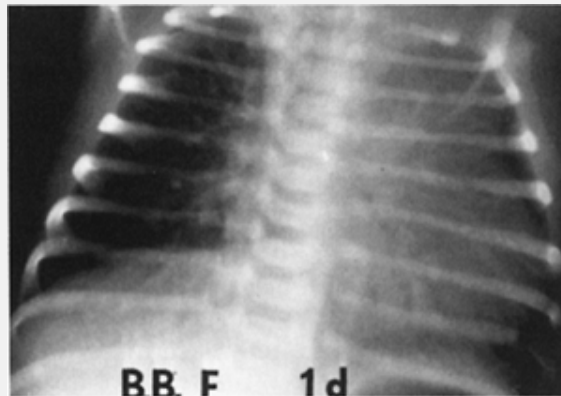

Figure 33-36 A chest radiograph of a 1-day-old infant with complex coarctation of the aorta shows marked cardiac enlargement and pulmonary vascular engorgement.

Chest radiographs show considerable cardiac enlargement, pulmonary plethora, and edema (Fig. 33-36).

ECG can be normal, but often has right axis deviation, right atrial hypertrophy, right ventricular hypertrophy, and sometimes diminished left ventricular forces.

Echocardiographic examination delineates the aortic arch anatomy, and reveals associated lesions, including mitral and aortic stenosis, ventricular septal defect, sub-aortic obstruction, and conotruncal abnormalities.

Differential Diagnosis

Aortic arch obstruction should be suspected in any critically ill term baby with a septic-like shock. It should also

be suspected as an associated anomaly in young babies with intracardiac anomalies such as ventricular septal defect, single ventricle, truncus arteriosus, and aortic or mitral valve disease who develop signs of poor systemic output. A thorough examination, with careful pulse palpation and blood pressure measurement in all 4 extremities, should lead to the correct diagnosis (see Tables 33-14 and 33-15). Infants presenting before 1 month of age usually have severe or complex coarctation. The presence of a ductus arteriosus supplying the descending aorta may be demonstrated by the finding of a lower arterial PO₂ in the legs than in the arms. The hypoplastic left heart syndrome produces a similar shock-like picture or congestive failure in the first week as the ductus arteriosus closes. In these patients, there is cyanosis (See Color Plate), the peripheral pulses are diminished throughout, and the ECG shows marked diminution in left ventricular forces.

Treatment

All neonates with congestive heart failure thought to have coarctation of the aorta should be promptly hospitalized, treated, and examined by echocardiography. Infants with complex coarctation and aortic interruption become symptomatic because of constriction of the ductus arteriosus. Prostaglandin E₁ infusion can dilate the ductus, restore systemic perfusion, improve metabolic abnormalities, and support life during the time needed to study the anatomy and arrange for surgery. Inotropic support with intravenous dopamine or adrenergic agents is often needed. In critically ill babies, there may be adverse ischemic consequences for the gastrointestinal, renal, hepatic, and coagulation systems. Echocardiographic examination usually provides the anatomic detail needed for surgery. If needed, cardiac catheterization, digital subtraction angiography, or magnetic resonance imaging may be useful for additional delineation of the aortic arch and intracardiac anatomy.

If after initial clinical management to effect stabilization, improvement or deterioration occurs, surgery should not be unduly delayed. The surgical procedures employed depend on the severity of the lesion and include resection of the coarctation with primary anastomosis, subclavian or prosthetic patch aortoplasty, or construction of a conduit from ascending to descending aorta; division of the patent ductus arteriosus; and, if needed, intracardiac repair of additional defects such as a large ventricular septal defect. The mortality rate for infants with complicated coarctation is 85% without surgery. Surgery increases the survival rate to 85%. Regardless of the type of coarctation, the mortality is related to age of presentation and is higher for those with duct-dependent descending aortic flow. In some infants with simple and milder coarctation who respond well to medical therapy, surgery may be delayed. Those who undergo surgical coarctation repair early in infancy may develop re-stenosis later, which may require re-operation or catheter balloon dilation. The survivors need close medical supervision throughout childhood and may require other operations for various associated abnormalities later. Catheter balloon dilation of un-operated primary discrete coarctation can offer palliation in the complex critically ill infant, but only in selected infants with an otherwise good size aortic arch does it appear to provide long-lasting relief (50).

Aortic Stenosis

Fusion of the right-left or right-non commissures of the aortic valve, resulting in a bicommissural, functional "bicuspid aortic valve, is one of the most common congenital anomalies, occurring in 1.5% of the population. The resulting valve orifice may be diminished, but the effective stenosis is usually mild in neonates. Only very severe aortic valve narrowing produces symptoms or requires intervention in early infancy (Fig. 33-37). Critical isolated aortic valve stenosis is rare, and usually the result of fusion of both the right-non and right-left commissures, with the valve orifice too small to allow adequate cardiac output at physiologically obtainable left ventricular pressures. In this situation, adequate systemic blood flow (before relief of the aortic stenosis) is dependent on a patent ductus arteriosus that

allows right-to-left blood flow from the pulmonary artery into the aorta.

Figure 33-37 Diagram of the cardiac anatomy and physiology in a 1-month-old infant with valvular aortic stenosis had a systolic pressure gradient of 70 mmHg across the aortic valve. The blood passing from left to right through the ductus must return again through the aortic valve, with the excess flow compounding the obstruction. The large atrial shunt, whether a true anomaly or a sprung foramen ovale, elevates left atrial pressure. The numbers below the chamber name are pressure measurements in mmHg determined at cardiac catheterization; the percentages indicate oxygen saturation data. LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava. Adapted from Mullins CE, Mayer DC. *Congenital heart disease: a diagrammatic atlas*. New York: Alan R Liss, 1988, with permission.

The symptoms are those of congestive heart failure, pulmonary edema, and sometimes peripheral vascular collapse. The baby may appear ashen and cyanotic if the pulmonary edema is severe. The cardinal features are tachypnea, a blowing systolic murmur at the upper right or middle left sternal border and an apical early systolic click resembling a split S1. If the valve orifice is very small, forward valve flow is small, and the murmur may be soft.

Chest radiographs show cardiac enlargement and pulmonary venous congestion.

ECG usually has biventricular hypertrophy with T-wave changes (see Table 33-14).

Echocardiographic examination demonstrates a deformed immobile aortic valve with commissural fusion. In severe aortic obstruction, trans-valvar flow is diminished, and the systolic murmur and the Doppler-derived pressure gradient are of low amplitude and do not reflect the severity of the lesion. The left ventricle appears hypertrophied and may have decreased or dilated internal dimensions and poor or hyperdynamic systolic function. Some patients may have coarctation and mitral valve abnormalities. Echocardiography can also identify those neonates with associated hypoplasia of the left ventricular chamber, mitral and aortic annuli and aortic root that do not benefit adequately from valvuloplasty and require a staged hypoplastic left-heart-type surgical approach for survival (51).

Treatment of critical stenosis consists of stabilization with administration of inotropic support, oxygen, and frequently prostaglandin E1 to allow right ventricular support to the systemic circulation; to be followed as soon as feasible by balloon valvuloplasty or surgical valvotomy (52). This provides effective palliation in infancy. Although many require repeat valvuloplasty during childhood, this is usually accomplished with success. Ultimately, and hopefully after childhood growth, many of the worse valves will require surgical replacement with a prosthetic valve or pulmonary autograft (Ross procedure). The asymptomatic infant with auscultatory findings of aortic stenosis and those after valvuloplasty require serial evaluation because, over the long term, valvular aortic stenosis very frequently progresses and recurs to some degree.

Acyanotic Anomalies with Left-to-Right Shunt

Ventricular Septal Defect

Ventricular septal defects may be small or large, single or multiple, and isolated or associated with other cardiovascular malformations. They are an integral part of complex congenital heart disease lesions, such as tetralogy of Fallot, truncus arteriosus, double-outlet right ventricle, and atrioventricular canal, and they have been associated with virtually every other known congenital cardiac malformation. Small, isolated self-closing muscular ventricular septal defects, frequently detectable only by echocardiography, are the most common congenital cardiac anomaly, occurring in 2% to 3% of term newborns (2) and more frequently in infants born prematurely (see Tables 33-1 and 33-2). Large defects occur most commonly singly in the membranous septum, less often in the low portion of the muscular septum, infrequently beneath the pulmonary valve, or posterior next to the tricuspid valve. Even though only 10% of ventricular septal defects cause symptoms, they remain the most common cause of congestive heart failure after the second week of life (see Tables 33-7). Although small defects are usually isolated anomalies, extra-cardiac malformations occur in up to 24% of the patients with large defects. Recognition of a large ventricular septal defect remains paramount because without closure a large defect with pulmonary hypertension can lead to irreversible Eisenmenger-type pulmonary vascular disease by as early as the first birthday.

Pathophysiology

The common small ventricular septal defect has minimal hemodynamic functional effect and does not produce symptoms, but a moderate or large defect in a neonate may

P.683

cause significant hemodynamic alterations. If the defect is large, right and left ventricular pressures equilibrate, and pulmonary hypertension results (Fig. 33-38). The decreasing pulmonary resistance after birth allows an increasing left-to-right shunt through the defect. The normal regression of pulmonary resistance in the first week of life is usually delayed in these babies. Nonetheless, sufficient reduction in pulmonary resistance occurs by the second week of life to cause symptoms in many patients. Others, with smaller defects or further delay in the reduction of pulmonary vascular resistance, develop symptoms as late as 3 to 4 months of age.

Symptoms are the result of congestive heart failure, sometimes presenting with superimposed pulmonary problems such as bronchiolitis, pneumonia and atelectasis. Congestive heart failure is caused by the obligate high resting cardiac output associated with recirculation of large amounts of blood through the heart and lungs although simultaneously attempting to meet the demand for systemic flow. Cardiac pump reserve for exertions such as feeding is therefore diminished. Excessive pulmonary vascular flow and pressure decrease lung compliance, resulting in more rapid and labored, but shallower, breaths. The fixed tachypnea impairs feeding and increases caloric expenditure, resulting in diminished growth. Pulmonary congestion may not only decrease the tolerance for but increase susceptibility to recurrent respiratory infections. Enlarged left pulmonary artery and atrium may compress bronchi and result in pulmonary atelectasis. Because pulmonary vascular resistance is lower in premature infants at birth, the development of symptoms from a ventricular septal defect occurs earlier.

Figure 33-38 Diagram of the anatomy and physiology with a large ventricular septal defect in a 1-month-old baby. The defect allows equilibration of pressure between the two ventricles. With pulmonary resistance much less than systemic resistance, there is a very large left-to-right shunt that caused congestive heart failure, as evidenced by the elevated atrial pressures and the reduced pulmonary venous oxygen saturation because of pulmonary edema. The numbers below the chamber name are pressure measurements in mmHg determined at cardiac catheterization; the percentages indicate oxygen saturation data. LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava. Adapted from Mullins CE, Mayer DC. *Congenital heart disease: a diagrammatic atlas*. New York: Alan R Liss, 1988, with permission.

Gradual improvement and diminution in pulmonary blood flow in an infant with a moderate or large ventricular defect may occur if there is an anatomic decrease in the size of the defect. Many defects spontaneously close, and most—particularly muscular and membranous defects—become smaller with time. During childhood, but rarely in infancy, there may be progressive and irreversible development of anatomic obstructive changes in the pulmonary arterioles.

Clinical Findings

A small ventricular septal defect is characterized by an isolated mid-higher pitched blowing systolic murmur, which is fairly localized along the left sternal border or at the apex. Infants with large septal defects develop congestive failure in the first few months of life with symptoms of tachypnea (i.e., rate consistently > 60/min), fatigue with feeding, decreased oral intake. Increased respiratory work and retractions, excessive diaphoresis, and recurrent respiratory infections are later manifestations. Weight gain lags considerably behind height maturation. The infant often presents with a respiratory infection that may precipitate or mask underlying congestive failure.

On examination, the infant is scrawny and tachypneic. The cardiac impulse is hyperdynamic. If pulmonary artery hypertension exists, the second heart sound may appear single and loud from early accentuated pulmonary closure. A gallop sound may be heard and is often associated with a mid-diastolic rumble. A mixed frequency holo-systolic murmur, heard best at the lower left sternal border, is soft at birth and usually becomes loud, rough and well transmitted throughout the precordium below the suprasternal notch. There is hepatomegaly and infrequently pulmonary wheezing and rales. Peripheral pulses can be rapid and peripheral edema is rare.

Chest radiograph shows considerable cardiac enlargement, increased pulmonary blood flow, and sometimes pulmonary edema. The main pulmonary artery segment and left atrium are often enlarged. Atelectasis and parenchymal infiltrates are common. ECG usually reveals left ventricular hypertrophy, and if the lesion is associated with pulmonary artery hypertension, right ventricular hypertrophy is detected.

Echocardiographic exam can demonstrate the size, location, and number of ventricular septal defects (Fig. 33-39). Associated lesions not appreciated on physical examination, including atrial septal defect, patent ductus arteriosus,

coarctation of the aorta, and left and right ventricular outflow obstructions, are revealed by echocardiography. Right ventricular and pulmonary hypertension can be assessed both from the curvature of the ventricular septum and by comparison of Doppler measurement of the instantaneous systolic pressure gradient across the defect with simultaneous blood pressure. Often there is at least a trivial degree of tricuspid regurgitation providing means to also estimate right ventricular pressure from the pressure gradient between the right ventricle and right atrium. Defects with a large amount of shunt across them also show evidence of left ventricular volume overload, with large left atrial and left ventricular dimensions and hyperdynamic left ventricular function. Occasionally, an infant with moderate congestive symptoms or findings, or evidence of borderline pulmonary hypertension, or of elevated pulmonary vascular resistance may require cardiac catheterization to delineate the hemodynamics.

Figure 33-39 Echocardiogram 4 chamber view with color Doppler analysis demonstrates an apical muscular ventricular septal defect. (LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; VSD, ventricular septal defect.) (See color plate)

Differential Diagnosis

In the neonate, the murmur of a small ventricular septal defect is generally characteristic, but sometimes can be difficult to differentiate from that caused by a small patent ductus arteriosus or tricuspid regurgitation (see Table 33-15). Some infants with large sub-aortic defects have or develop progressive pulmonary stenosis that prohibits left-to-right shunting, cardiomegaly, and congestive heart failure. These babies may develop the features of the tetralogy of Fallot. Later increasing right ventricular hypertrophy on the ECG suggests the development of pulmonary stenosis or increasing pulmonary vascular resistance and the need for careful reevaluation. The coexistence with a large ventricular septal defect of additional malformations resulting in a large left-to-right shunt (e.g., truncus arteriosus) can be difficult to differentiate clinically from isolated large ventricular septal defects; ascertaining their presence often requires echocardiographic examination.

Treatment

An infant with a small ventricular septal defect requires no specific treatment but should be followed. In infants with congestive heart failure, administration of digitalis and diuretics may produce considerable improvement in respiratory symptoms and growth. Systemic afterload reduction with ACE inhibitors (e.g., captopril) moderately decreases the pulmonary/systemic flow ratio and often has additional moderate symptomatic benefit in refractory patients (see Table 33-10). The use of high-caloric formulas, made by supplementation of standard formulas with additional carbohydrate (e.g., corn syrup or polydose) and oil (e.g., corn oil or MCT oil) up to a total of 30 kcal per ounce, is often needed for growth in babies with large defects. The total ad libitum oral intake should not be restricted, because growth failure and small size are a common issue in these infants.

Timely surgical closure of the defect is indicated if the infant does not begin to grow with timely escalation of

optimal medical therapy, or has persistent significant pulmonary artery hypertension after 6 months of age. Primary repair in infants entails cardiopulmonary bypass, and, in most patients, atriotomy with patch closure through the tricuspid valve. Some patients require closure through the pulmonary valve or right ventriculotomy. Very low birth weight premature infants and those with multiple large muscular defects may require an initial pulmonary artery banding procedure with corrective surgery done at a later age. Of infants born with isolated large defects requiring closure in the first year of life, mortality is now 1% to 2% or less. Mortality is greater if there are associated severe extra-cardiac congenital anomalies, pulmonary complications, or prematurity. The long-term prognosis after trans-atrial surgical closure of an isolated ventricular septal defect in the first year of life is excellent, with essentially normal hemodynamics and a small risk for symptomatic dysrhythmias for most patients.

Secundum and Sinus Venosus Atrial Septal Defects

Virtually all babies have a patent foramen ovale at birth. Many foramen ovale functionally close within hours of birth, but many others remain at least partly open for several months and in about 20% the foramen has some blood flow across it throughout life. This is important to the neonatologist, because umbilical vein catheters tend to follow the course of the circulation for the preceding 9 months and may pass through the foramen ovale into the left heart,

P.685

providing erroneous measures of oxygen levels and allowing passage of intravenously injected air or thrombus to the brain, occasionally with disastrous results.

Pathophysiology and Clinical Features

Secundum atrial septal defects are a common anomaly resulting from an opening in the primum atrial septum around the region of the foramen ovale that rarely causes symptoms or a murmur loud enough to attract attention in infants, and often close spontaneously (2). Much more rare sinus venosus atrial septal defects occur in the atrial septum in which the cavae enter, usually the superior vena cava, often with partial anomalous connection of one or more right pulmonary veins, and are clinically indistinguishable from secundum atrial septal defects. As systolic blood pressure, arterial stiffness, and left ventricular stiffness increase with age, left to right shunting develops across the defect, resulting in increased flow across right heart valves, systolic pulmonary flow murmur at the left upper sternal border and suprasternal notch, diastolic tricuspid flow rumble at the left lower sternal border, persistent delayed closure of the pulmonary valve (and relatively wide fixed splitting of the second heart sound), increased right ventricular workload and increased pulmonary blood flow. Most are found because a murmur of mild pulmonary stenosis is heard and an echocardiographic examination is performed (Fig. 33-40). Others are discovered during evaluation of coexisting cardiac anomaly, or evaluation initiated by extra-cardiac anomalies or failure to thrive. Most small secundum defects (<5 mm diameter), many moderate-size ones (5-8 mm diameter), and some large defects spontaneously close, or nearly close in the first several years of life (2,74). Sinus venosus defects rarely if ever close spontaneously. Because there is rarely significant congestive heart failure, initial management consists of observation and, if the defect persists, it may be closed by surgical or catheter techniques. If a large defect remains open, approximately 10% of those develop Eisenmenger-type pulmonary vascular disease later in life.

Figure 33-40 Echocardiogram 4 subcostal view with color Doppler analysis demonstrates an secundum atrial septal defect. (ASD, ventricular septal defect; LA, left atrium; RA, right atrium.) (See color plate)

Differential Diagnosis

Rarely, a large atrial septal defect is associated with an early decrease in the pulmonary resistance and a large left-to-right shunt in the first months of life. Growth failure and congestive heart failure may raise the question of early cardiac surgery. This is a potentially more complicated and treacherous situation because occult left-sided heart disease (e.g., myocardial disease, aortic stenosis, coarctation) is often responsible for the unusually large imbalance of ventricular compliances, causing a large left-to-right atrial shunt in infancy. Surgical closure of the defect without dealing with the additional problem may have a poor outcome. The simple rule of thumb is to search diligently for associated anomalies and proceed to surgery for isolated atrial septal in early infancy with caution.

Endocardial Cushion Defects

Defects of endocardial cushion development may be partial, resulting in an ostium primum atrial septal defect; complete, resulting in additional total deficiency of the posterior inlet ventricular septum and a common atrioventricular valve (i.e., complete atrioventricular canal); or transitional with a combination of a smaller restrictive defect of the inlet ventricular septum and primum atrial septal defect, (i.e., transitional atrioventricular canal defect). The atrioventricular valves, particularly the anterior mitral valve leaflet, are usually malformed, deficient, or abnormally attached to the ventricular septum. With ostium primum defect, there is usually a cleft in the mitral valve and frequently mitral regurgitation. In complete atrioventricular canal, the primitive atrioventricular valve floats like a sail over both ventricles. This malformation results in a large communication between the right and left atria and the right and left ventricles. Significant atrioventricular valve regurgitation is less common than in those with only an ostium primum defect. Occasionally, but more often in those without trisomy 21, the mitral valve has abnormal chordal attachments and is stenotic. Rarely the large atrioventricular valve is laterally shifted and primarily centered over one ventricle, and the contralateral ventricle is much smaller than normal. Endocardial cushion defects as primary lesions account for 4% of all newborns with serious heart disease (see Tables 33-1 and 33-2).

Pathophysiology

The hemodynamic consequence of an ostium primum atrial septal defect is right ventricular volume overload, which is caused by a left-to-right shunt across the atrial septal defect, and variable biventricular volume overload from regurgitation from the left ventricle through the cleft mitral valve to the atria. The volume load, if aggravated by significant mitral regurgitation, can be large and result in congestive heart failure. Streaming of

inferior vena cava blood across the large, low-lying defect and cleft common valve leads to mild systemic arterial oxygen desaturation. In complete atrioventricular canal, there is an additional left-to-right shunt through a ventricular septal defect and right ventricular and pulmonary artery hypertension at a systemic level. Infants with pulmonary artery hypertension are particularly susceptible to the development of pulmonary vascular obstructive disease and its complications in later childhood.

Clinical Findings

Isolated primum atrial septal defects without mitral regurgitation results in physical findings similar to secundum and sinus venosus defects with pulmonary flow murmur, fixed second heart sound splitting and sometimes tricuspid diastolic rumble, and is distinguished by ECG left axis deviation. Infants with ostium primum atrial septal defects who are symptomatic in the neonatal period usually have severe mitral regurgitation. Growth retardation may be marked, and weight lags considerably behind height maturation. Recurrent pulmonary infections are common.

Figure 33-41 Diagram of the anatomy and physiology of an atrioventricular canal in an asymptomatic girl with Down syndrome. There was no murmur. **A:** Although she was breathing room air, the pulmonary resistance was high; there was no left-to-right shunt, and she had arterial oxygen unsaturation. **B:** When breathing oxygen, a large left-to-right shunt developed and the estimated pulmonary resistance fell sharply. The percentages indicate oxygen saturation; the numbers in italics are pressure measurements. The numbers below the chamber name are pressure measurements (mm Hg) determined at cardiac catheterization; the percentages indicate oxygen saturation data. LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava. Adapted from Mullins CE, Mayer DC. *Congenital heart disease: a diagrammatic atlas*. New York: Alan R Liss, 1988, with permission.

With complete atrioventricular canal, there is frequently mild cyanosis. The cardiac impulse is hyperdynamic, and S1 is obscured by a loud pan-systolic murmur audible at the apex or left sternal border. There is usually pulmonary hypertension, and the S2 is accentuated. A S3 and an apical mid-diastolic rumble are often heard. Occasionally, particularly among neonates with Down syndrome, there may be no perceptible auscultatory abnormality. When the murmur is subdued, cardinal features of cardiac anomaly are a hyperdynamic precordium, abnormal second heart sound, and ECG leftward superior axis.

Approximately half of those with isolated complete atrioventricular canal defects have trisomy 21 (75). Forty percent of infants with Down syndrome have congenital heart disease, complete atrioventricular canals being most common. Because babies who have Down syndrome have a tendency to under-ventilate, causing pulmonary venous oxygen desaturation, they may have pulmonary hypertension that, associated with a common atrioventricular canal, may limit left-to-right shunting to amounts that do not produce a murmur (Fig. 33-41). All infants with Down

Figure 33-42 Electrocardiogram of infant with atrio-ventricular cushion septal defect shows the characteristic left axis deviation.

Chest radiograph shows cardiac enlargement, sometimes out of proportion to the increased pulmonary vasculature, attributable to the large atria. The main pulmonary artery segment is prominent, and there is pulmonary vascular engorgement.

ECG characteristically shows a left superior QRS axis in the frontal plane, commonly 0° to -60° in primum defects and -60° to -100° in complete canal with a small Q wave in lead aVL (see Fig. 33-42). Significant right ventricular hypertrophy usually indicates right ventricular hypertension (Fig. 33-41).

Echocardiographic examination demonstrates the anatomic features relevant to surgical repair, including the anatomy of the atrioventricular valve with its chordal attachments, papillary muscles, ventricular relationships, possible regurgitation or stenosis of the atrioventricular valves (Fig. 33-43), and possible associated anomalies including systemic and pulmonary venous anomalies, secundum atrial septal defect, muscular ventricular septal defects, ventricular hypoplasia, left or right ventricular outflow stenosis. Preoperative cardiac catheterization is generally not required except to evaluate pulmonary vascular resistance if there is evidence of pulmonary vascular disease.

Treatment

In many patients, palliative or corrective surgery has to be performed in infancy because of refractory congestive heart failure or pulmonary hypertension. Timely treatment with digitalis, diuretics, afterload reduction and caloric supplementation of feedings may result in sufficient improvement in respiratory work and growth to allow substantial increase in the baby's size and well being for several months before operative repair (see Table 33-10). Infants with refractory symptoms of congestive heart failure should proceed to surgery. In infants with complete atrioventricular canals, there is pulmonary artery hypertension, and surgery is mandatory within the first year to prevent irreversible pulmonary vascular changes.

Primary complete repair is the preferred treatment. This entails cardiopulmonary bypass, atriotomy, patch closure of the atrial and ventricular septal defects, and attachment of the common valve leaflet to the patch or patches. In infants with refractory congestive heart failure weighing less than approximately 2 kg or those with serious

confounding noncardiac illness (e.g., duodenal atresia), pulmonary artery banding may be helpful, with complete repair accomplished later. Children with isolated uncomplicated ostium primum atrial septal defects and few symptoms can undergo complete repair at several years of age. The long-term prognosis after surgery in infancy is excellent (76). Late dysrhythmias occasionally occur. There is often some postoperative regurgitation of the atrioventricular valve, but in most infants this is not a significant problem. Systemic vasodilators can reduce the volume of regurgitation and may help preserve ventricular function in patients with significant postoperative mitral regurgitation. When there is severe mitral regurgitation, closure of the septal defect with valvuloplasty may result in clinical improvement, but residual mitral regurgitation may later require valve palliation or replacement. Without surgery, the prognosis is poor. Only 50% of patients with endocardial cushion defects who become symptomatic in the first month of life survive beyond 1 year of age without surgical treatment, and

many of these have significant growth failure.

Patent Ductus Arteriosus

The ductus arteriosus, arising from the distal dorsal sixth aortic arch, is well developed by the sixth week of gestation and forms a bridge between the pulmonary artery and the dorsal aorta, inserting at the aortic isthmus. At term, it is a muscular contractile structure. In the full-term infant, functional closure occurs during the first day of life. Persistence of patency of the ductus arteriosus alone or in association with other cardiovascular lesions may produce no symptoms or severe hemodynamic changes, depending on its size.

Isolated patent ductus arteriosus, without hyaline membrane disease, is common, accounting for 4% of all newborns symptomatic with heart disease (4). It is more prevalent in female than male infants. Patent ductus arteriosus is a frequent complication of hyaline membrane disease in the premature infant, in surviving premature infants, and in infants born at high altitudes; in these patients, there is no sex difference. It is common in combination with other congenital heart lesions (e.g., coarctation of the aorta, ventricular septal defect, vascular ring). It occurs in 60% to 70% of infants born with congenital rubella.

Pathophysiology

Ductal closure occurs by constriction and then remodeling with apoptosis (77). At birth, ductal constriction is caused by multiple factors, the most important of which appear to be increased oxygen tension, the levels of prostaglandins, and ductus muscle mass. Prostaglandin E1 is used to dilate a closing ductus in several forms of congenital heart disease in which patency of the ductus arteriosus is necessary to support pulmonary or systemic blood flow (53,54). Delayed closure frequently occurs in premature infants with respiratory distress syndrome. An inhibitor of prostaglandin synthesis (e.g., indomethacin) is used to promote closure of the ductus in this situation (78,79). The ductus arteriosus that remains patent in the term infant is abnormal and is rarely susceptible to pharmacologic closure.

Within the first hours after birth a small right-to-left or bidirectional shunt may occur. With fall in pulmonary vascular resistance and a rise in systemic resistance, a left-to-right shunt develops through the ductus arteriosus. If spontaneous closure does not occur and the ductus is small, the left-to-right shunt remains small. However, a moderate-sized patent ductus arteriosus is usually associated with a significant left-to-right shunt, increased pulmonary blood flow, left ventricular volume overload, increased left ventricular end-diastolic volume and pressure, elevation of left atrial pressure, and the development of congestive heart failure. The run off of flow from the aorta into the ductus produces wide pulse pressure, and generates bounding peripheral pulsations. A large patent ductus arteriosus produces pulmonary artery hypertension because the pressure is transmitted directly from the aorta to the pulmonary artery through the large defect. Those with moderate and large ducts are prone to the development of pulmonary vascular obstructive disease by 1 year of age or beyond.

The premature infant may develop congestive heart failure earlier because of incomplete development of the

medial musculature in the small pulmonary arterioles. The contractile function of the heart, required to handle the increased volume load, may be incompletely developed. Among those with respiratory distress syndrome, there may be an initial period of improvement as the pulmonary status improves, followed by clinical deterioration as left-to-right shunting through the ductus arteriosus increases.

Clinical Findings

Term Infants

In the neonate with a patent ductus arteriosus, as in all left-to-right shunts, the elevated but decreasing pulmonary vascular resistance determines the clinical manifestations. There is usually a crescendo systolic murmur, often with clicks, sometimes detectably spilling into diastole. Often, S₂ is not clearly audible. A continuous murmur develops later. The infant with a large patent ductus arteriosus has bounding peripheral pulses, wide pulse pressure (defined as the difference between systolic and diastolic pressure exceeding half of the systolic blood pressure), and hyperactive cardiac impulse at the apex (see Table 33-15). There may be an apical diastolic rumble and symptoms and signs of congestive heart failure, poor weight gain, and recurrent pulmonary infections. In a full-term infant with a large patent ductus arteriosus, overt failure usually does not develop until 3 to 6 weeks of age. If the pulmonary resistance remains high, there may be little murmur.

Chest radiograph shows cardiac enlargement, pulmonary plethora, a prominent main pulmonary artery, and left atrial enlargement. ECG develops left ventricular hypertrophy, occasionally left atrial hypertrophy, and in severe failure, ST-T wave changes.

P.689

Echocardiography demonstrates the ductus arteriosus, its size, and the direction of the flow across the defect. Disturbed flow in the pulmonary artery, seen best with color Doppler techniques, is particularly helpful in identifying a patent ductus arteriosus. Continuous-wave Doppler allows measurement of the pressure gradient across the defect and, thereby, estimation of pulmonary pressure (Fig. 33-14). Right ventricular hypertension is also indicated by flattening of the ventricular septum curvature. A large left-to-right shunt is indicated by left heart volume overload and a large left atrium and left ventricle. If there is associated pulmonary disease, the pulmonary resistance may be high, allowing only right-to-left shunting. Right-to-left ductal shunting also occurs with left heart obstructive lesions and coarctation of the aorta.

Preterm Infants

Preterm infants with a patent ductus arteriosus often have the same clinical findings as term babies. Many have a systolic murmur and some have a classic continuous murmur. However, many premature neonates with a large ductus arteriosus have no murmur. Most will have an increase in pulse pressure, at least intermittently. Because arterial pressure varies with age, gestational age, and illness, a rule of thumb for elevation of pulse pressure is when it exceeds half the systolic arterial pressure. Although preterm infants with a large patent ductus arteriosus may develop circulatory overload within the first week of life, some have no specific clinical or radiographic signs discernible from respiratory illness. Unlike term infants, there is no substantial increased incidence of additional cardiac anomalies. However, if examination raises the likelihood of other cardiac or aortic arch anomalies, echocardiographic examination should be done before pharmacologic treatment.

Echocardiographic examination of ductal diameter and length, ductal pressure gradient to estimate pulmonary artery pressure, aortic arch anatomy, and possible associated cardiovascular anomalies is indicated prior to surgical closure (Fig. 33-14).

Differential Diagnosis

The infant with congestive failure and a large left-to-right shunt caused by a ventricular septal defect may be clinically indistinguishable from the one with a large patent ductus arteriosus. Other lesions that may result in a large aortic runoff and mimic a patent ductus arteriosus include truncus arteriosus, hemitruncus (i.e., right pulmonary artery from the ascending aorta), aortopulmonary window, aneurysm of the sinus of Valsalva, and large arteriovenous malformations (see Table 33-15). In the sick neonate, clinical differentiation from other lesions is possible using echocardiography.

Treatment

Term Infants. The full-term baby with a persistent patent ductus arteriosus and no evidence of cardiovascular embarrassment should be followed, and catheter closure or thoracoscopic or surgical division of the ductus performed later. The choice of method and timing of closure depend on a number of factors, including ductal size. Before therapeutic closure, term infants with congestive heart failure often have symptomatic improvement from treatment with digoxin and diuretics (Table 33-10).

Preterm Infants. Among preterm infants with significant patent ductus arteriosus, indomethacin treatment produces closure in approximately 85% of patients. In symptomatic babies there is a corresponding resolution of findings of congestive heart failure, reduction in required respiratory support and improvement in survival (80). Its use in premature infants with a patent ductus arteriosus who do not yet manifest obvious symptoms from circulatory overload appears to improve many outcome variables including development of congestive failure symptoms, duration of ventilatory and oxygen treatment, and growth (80). Prophylactic administration of indomethacin early after birth in very premature infants decreases the incidence of patent ductus arteriosus, congestive symptoms, cerebral intraventricular hemorrhage, and possibly mortality (81,82,83 and 84). However, until there are data demonstrating an acceptable effect on neurologic function long term, there is uncertainty about the routine prophylactic early use of indomethacin because of the demonstrated negative effects of the drug on neonatal vasoregulation and cerebral blood flow and a theoretical increased risk for cerebral leukomalacia (83). Indomethacin can also cause deterioration of renal and platelet function, and its prophylactic use increases the incidence of oliguria and necrotizing enterocolitis (80,82). It should be avoided if there is significant renal dysfunction, thrombocytopenia, or bleeding. When available, newer prostaglandin synthesis inhibitors such as ibuprofen may have fewer side effects (85). The ductus arteriosus occasionally reopens after initially successful indomethacin treatment and may respond to a second course of treatment. Failure of indomethacin does not adversely affect subsequent surgery (86,87). Avoiding or correcting anemia diminishes the left ventricular volume overload and increases the arterial oxygen content. Surgical interruption of the ductus arteriosus is indicated, regardless of age or weight, in any infant with a persistent hemodynamically significant left-to-right shunt, particularly if there is pulmonary artery hypertension. Surgical mortality is low, and dramatic improvement often occurs. The procedure is performed using a left thoracotomy, or thoracoscope, in the intensive care nursery or the operating room under intravenous or inhalation general anesthesia. Catheter closure is not yet readily technically achievable in small preterm neonates.

Aortopulmonary Window

Defects in the aortopulmonary septum are a rare anomaly resulting in a communication, usually large, between the ascending aorta and main pulmonary artery. Unlike truncus arteriosus, there are usually two normal semilunar valves, and most do not have a ventricular septal defect.

P.690

In the approximately half without other cardiovascular anomalies, the physiology and clinical course are similar to truncus arteriosus with large left-to-right shunt, congestive symptoms, and pulmonary hypertension. The half with other cardiovascular anomalies most often have interrupted aortic arch and present with signs of aortic arch obstruction. Anomalous origin of the right pulmonary artery from the aortic trunk (right hemitruncus), anomalous origin of the coronary arteries from the pulmonary trunk, and other anomalies also occur with it. The diagnosis is established by echocardiography. Angiography is sometimes needed to delineate details of the anatomy needed for management. Treatment is surgical (88).

Arteriovenous Malformations

Malformation of the developing peripheral vascular system can result in abnormal connections of arteries, arterioles, and capillaries to the venous system (i.e., arteriovenous fistulae) that create a large shunt. These fistulas can involve vessels of any size and location. Large malformations presenting soon after birth with congestive heart failure occur more often in the liver and head. Capillary hemangiomas involve ongoing abnormal neovascularization. Rarely, infants with prolonged respiratory disease complicated by pneumothorax requiring multiple chest tubes may develop collateral vessels from systemic arteries in the chest wall to the pulmonary arteries. Although most infants with arteriovenous malformations have no other cardiovascular anomaly, abnormal congenital systemic-to-pulmonary vascular corrections can occur with tetralogy of Fallot with pulmonary atresia, partial anomalous pulmonary venous connection (i.e., scimitar syndrome), and bronchopulmonary sequestration.

Pathophysiology

Although most infants do not develop cardiovascular symptoms, a large systemic arteriovenous malformation can result in significant left-to-right shunt and congestive heart failure. Symptomatic babies usually have connections of relatively large arteries and veins in the cerebral or hepatic vasculature. Pulmonary arteriovenous malformations result in an intrapulmonary right-to-left shunt and cyanosis, but they do not produce congestive heart failure.

Clinical Findings

Arteriovenous fistula is one of the few cardiovascular defects that may produce severe congestive heart failure in the first day of life. Cardiovascular shock may be the predominant clinical picture. There may be a hyperdynamic precordium and pulses, flow murmur, severe congestive heart failure, and cyanosis. Bruits over the fontanelle, posterior neck, or abdomen may be audible, and there may be an enlarged head or liver. Echocardiography can demonstrate biventricular dilation and sometimes an enlarged cava with increased flow. Arterial contrast injection demonstrates systemic arteriovenous fistulas. Systemic venous or pulmonary artery injection of contrast demonstrates pulmonary arteriovenous malformations. Ultrasonography, computed tomography, MRI, and angiography may be useful in finding and delineating the lesion.

Treatment

Malformations causing congestive heart failure usually do not spontaneously improve, except for capillary malformations that may respond to steroid or antiangiogenic drugs such as interferon. Large vessel malformations require mechanical occlusion. Surgery carries a considerable risk, and transcatheter occlusion with a variety of devices, including coils and detachable balloons, has been successful in many, usually older, patients.

Vascular Rings and Slings

A variety of intrathoracic vascular anomalies may encircle the trachea and esophagus and result in symptoms in the neonatal period. Depending on the degree of compression of the trachea or esophagus, several may present in infants with stridor, wheezing, cough, recurrent infections, or feeding difficulties. All of these symptoms are more commonly caused by other abnormalities, such as choanal atresia, tracheomalacia, laryngeal web, hemangioma, or gastroesophageal reflux.

Although uncommon, vascular anomalies may result in serious or life-threatening symptoms and therefore should be considered in any infant with persistent unexplained respiratory symptoms.

Right Aortic Arch with Anomalous Left Subclavian Artery

The spectrum of aortic arch anomalies is most commonly explained by the double arch model first proposed by Edwards and subsequently modified by others (89). This hypothesis explains all observed arch variants by abnormal persistence or regression of portions of a double arch present in embryologic development. The most common of the arch anomalies that has been associated with symptoms in the neonate is the right aortic arch with anomalous left subclavian artery. In this malformation, the aortic arch passes to the right of the trachea over the right mainstem bronchus, then giving rise to the left subclavian artery as the last brachiocephalic branch. A left-sided remnant of the ductus arteriosus connects the pulmonary artery with the descending aorta, resulting in a vascular ring encircling the trachea and esophagus.

Symptoms, when present, are usually not severe and commonly occur beyond the newborn period. The diagnosis may be suspected on plain anterior-posterior chest x-ray by leftward shifting of the trachea from the right-sided arch.

Barium swallow may demonstrate a posterior, oblique indentation of the esophagus from the left subclavian artery.

Echocardiography can demonstrate the position of the arch relative to the trachea and the branching pattern.

Associated cardiac malformations, if present, can also be determined at the time of echocardiographic evaluation.

Figure 33-44 Aortogram in the anteroposterior projection in a 2-month-old infant with a history of sudden apnea requiring resuscitation. The anatomy of a typical double aortic arch is displayed. The ascending aorta (AAO) connects to bilateral aortic arches that encircle the airways. The larger and more cephalad right aortic arch (RAA) passes over the right mainstem bronchus. The smaller, lower left aortic arch (LAA) encircles the trachea and passes over the left mainstem bronchus before rejoining the right arch to form the descending aorta (DAO). Solid white lines outline the trachea and mainstem bronchi. Black arrows show the course of the aortic arches.

Magnetic resonance imaging has proven to be a useful tool for determining vascular anatomy, and may display evidence of tracheal compression.

Double Aortic Arch

Failure of the normal regression of the embryologic right arch between the right subclavian artery and the descending aorta results in a double aortic arch. The right-sided arch is the larger and more cephalad in approximately 75% of patients. The resulting vascular structure completely encircles the trachea and esophagus.

Symptoms may be dramatic, even life-threatening, and usually occur within the first few months of life.

The plain chest radiograph is generally nondiagnostic. The anatomy can be imaged by echocardiographic examination, magnetic resonance imaging, or angiography (Fig. 33-44).

Barium swallow demonstrates bilateral indentation of the esophagus. If done, bronchoscopy will show the pulsatile compression of the trachea by the vascular ring.

Surgery is indicated in symptomatic infants and consists of division of the smaller arch, usually the left. The postoperative relief of symptoms and prognosis are usually good.

Anomalous Origin of the Left Pulmonary Artery (Pulmonary Sling)

Anomalous origin of the left pulmonary artery is a rare but serious vascular defect, in which the left pulmonary artery arises from the proximal right pulmonary artery and passes between the trachea and the esophagus before supplying the left lung.

Respiratory symptoms are often severe, and there may be associated hypoplasia or stenosis of the trachea or right mainstem bronchus. Swallowing difficulties are uncommon.

Barium esophagram demonstrates anterior compression from the aberrant vessel. Hyperinflation of the right lung as a result of selective compression of the right bronchus may be noted on plain chest radiograph.

Echocardiography will generally demonstrate the key features of the anatomy, although MRI, angiography, and bronchoscopy have been recommended by some to delineate additional details (90,91).

Surgery is indicated and consists of division of the left pulmonary artery with reanastomosis to the main

pulmonary artery in a more normal location. Outcome after surgical correction of the pulmonary artery origin has been fair, limited in part by associated lesions and by persistent pulmonary complications related to residual airway abnormalities. Residual left pulmonary artery stenosis is common after surgery.

Anomalous Origin of the Innominate Artery

Compression of the trachea by the innominate artery is a controversial source of respiratory distress in neonates and infants. It has been contended that airway compromise may result if the origin of an otherwise normal innominate artery is more distal than usual, resulting in indentation of the trachea as the vessel courses anteriorly and rightward before splitting into the right subclavian artery and right carotid artery.

Bronchoscopy may reveal a pulsatile mass compressing the distal trachea.

Surgical intervention to suspend the innominate from the anterior chest wall has been advocated, with reported relief of respiratory symptoms in some patients. In some series, this situation has represented a significant portion of infants undergoing surgery for airway compression (92). However, others have disputed this mechanism as a common cause of respiratory distress and suggest conservative management (93).

Acyanotic Anomalies with Abnormal Cardiac Function or Structure

Cardiomyopathy

Sick neonates without cardiac anatomic anomaly often develop symptoms of cardiac and myocardial dysfunction. Systolic and/or diastolic dysfunction most often occur secondary to another abnormality such as sepsis or hypothermia, but occasionally from disorders fundamentally involving myocyte biochemistry. Cardiomyopathy is abnormal myocardial cellular function or structure that occurs with

P.692

many abnormalities and disorders (see Tables 33-16 and 33-17). Myocardial dysfunction may be grouped by clinical and echocardiographic determination of the cardiovascular pathophysiology, without regard to etiology, as dilated, hypertrophic, and restrictive cardiomyopathy. The nature of appropriate supportive cardiac treatment depends on this cardiovascular physiologic classification. However, the outcome of supportive therapies alone is limited. Additional improvement in outcome may result from determining causation and directed treatment based on etiology.

TABLE 33-16 DILATED CARDIOMYOPATHIES

Infectious causes

Dilated Cardiomyopathies

Dilated cardiomyopathies are characterized by diminished cardiac contractility, with ventricular enlargement, abnormal diastolic function, and congestive heart failure. Neonates with dilated cardiomyopathy more frequently have an identifiable cause than is currently achievable in older children and adults (see Table 33-16). These include identifiable infection (e.g., bacterial or viral sepsis, Coxsackie or adenovirus myocarditis, toxoplasmosis), ischemia (e.g.,

birth asphyxia, anomalous left coronary artery origin), hemodynamic work overload (e.g., incessant tachyarrhythmia) and electrolyte or metabolic imbalance (e.g., hypothermia, polycythemia, hypoglycemia, hypocalcemia). Increasingly infants are being recognized with primary biochemical disorders of energy production and metabolism that result in isolated cardiomyopathy or generalized myopathy and encephalopathy (33,34 and 35). These infants often have significant deterioration with stress, including that with birth. Caution should be used in attributing permanent or temporary cardiac dysfunction and encephalopathy entirely to "birth asphyxia" in a baby with low Apgar scores without identifiable perinatal cause for asphyxia. Additionally, myocardial diseases that more commonly

P.694

present in older children, such as those associated with neuromuscular disorders; sometimes have unusually early presentations in infancy.

From refs. 33, 34.

Pathophysiology

Although the etiologies are diverse, in most dilated cardiomyopathies the clinical course, pathophysiology, and some molecular mechanisms are similar. Myocyte damage, from infection, cytokines, toxic metabolite, or energy deprivation from metabolic block or ischemia, results in myocardial injury. This results in a sequence of molecular and cellular changes with myocardial dysfunction, stunning, apoptosis, necrosis, and interstitial fibrosis, leading to impaired systolic contractility and diastolic compliance. Ventricular enlargement, because of Frank-Starling phenomenon, and tachycardia partially compensate for diminished

systolic shortening fraction and support resting cardiac output, but use up reserve in pump function. The impairment in diastolic compliance results in generalized edema and in pulmonary venous engorgement with tachypnea. If cardiac function worsens, resting cardiac output diminishes, and multi-system dysfunction results.

Clinical Findings

The primary manifestations are those of combined right and left heart congestive failure, including diminished activity and feeding, hepatomegaly, tachypnea, retractions, S3, variable systolic regurgitant murmur, and variable signs of low cardiac stroke volume, including tachycardia, narrowed pulse pressure, diminished brachial radial and pedal pulses, systolic hypotension, diminished perfusion, and oliguria.

Chest radiograph shows cardiomegaly and pulmonary edema.

ECG has resting tachycardia, often diffusely diminished voltage amplitude, sometimes diffusely increased voltage amplitude, and often diffuse repolarization changes.

Echocardiographic examination demonstrates ventricular enlargement, generally affecting the left ventricle more than right, and often very severe. Mitral and tricuspid regurgitation, atrial enlargement, and pulmonary hypertension occur frequently. Coronary anomalies, or other cardiac structural anomalies with similar presentation, should be detected.

Because the best hope for successful treatment depends on treating the primary cause, diagnostic evaluation should seek causation. Detailed family history can provide information not elicited by cursory generalized questions. Obstetrical history may provide information about possible infectious causes and events with asphyxia. Physical examination may demonstrate malformations consistent with genetic syndromes, dysmorphic features and organomegaly consistent with peroxisomal or infiltrative storage disorders, encephalopathy and hypotonia consistent with various metabolic disorders and less often with neuromuscular disorders. The absence of noncardiac findings also provides diagnostic information. Although the history and exam may help point the direction, the diagnosis depends on laboratory studies. Initial evaluation should usually include blood electrolytes with measurement of total CO₂ or bicarbonate, glucose, blood urea nitrogen, creatinine, and complete blood count. If infection is suspected, appropriate bacterial cultures (blood, endotracheal tube aspirate, urine, cerebrospinal fluid), viral cultures (nasopharyngeal, perirectal, cerebrospinal fluid) and serology should be obtained.

Specific Dilated Cardiomyopathies

Although rare, anomalous origin of the left coronary artery from the pulmonary

artery should be considered in all children with dilated cardiomyopathy, particularly if there is an ECG pattern of anterolateral myocardial infarction. The anomalous origin of the left coronary artery from the pulmonary artery and retrograde flow in the left anterior descending and left main coronary arteries can usually be seen on echocardiographic examination, although angiography may be needed in some cases. Recognition is key; treatment is surgical, and is usually successful if done promptly after ventricular dysfunction and symptoms appear.

Metabolic disorders can present with either dilated or hypertrophic cardiomyopathy, and often clinically deteriorate with intercurrent infection. If metabolic disease is suspected, additional tests should be done; including measurement of blood ammonia, arterial blood gases, total and free carnitine, lactate, pyruvate, liver function tests, creatine kinase and urine quantitative amino acids, organic acids and, if appropriate, mucopolysaccharide and oligosaccharide levels. Expert consultation from a metabolic disease specialist should be obtained. Chromosomal analysis and skeletal x-ray analysis may be helpful if dysmorphic features are present. Fundoscopic examination for retinal disease and cataracts may help in evaluation for disorders accompanied by these findings. Biopsy of skeletal muscle and/or cardiac muscle for light and electron microscopic examination, mitochondrial genomic studies and biochemical studies are often needed in the evaluation of metabolic disease (33).

Neonatal viral myocarditis is an often fulminant disease, frequently associated with hepatitis and encephalitis. The most commonly identified causes are echovirus, Coxsackie virus, particularly type B, and in some locations rubella virus. In individual cases, the cause may not be determined with culturing of nasopharyngeal, tracheal, and stool swabs and serologic tests and PCR analysis may be required for diagnosis. The infection may be acquired perinatally or postnatally. Treatments including immunoglobulin, interferon, steroids, and ribavirin have been under investigation in biopsy-proven myocarditis, but supportive measures are the mainstay of treatment. Several other viruses, bacteria, mycoplasma, rickettsiae, spirochetes, and fungi rarely cause myocarditis. Myocarditis, because of an autoimmune reaction, may occur with maternal lupus erythematosus.

P.695

Maternal IgG Ro antibodies cross the placenta, bind to the fetal myocardium, and may block conduction or cause cardiomyopathy. Steroids may be beneficial in this disease.

Chronic supraventricular and ventricular tachycardia can lead to persistent myocardial dysfunction with the picture of cardiomyopathy. Some incessant supraventricular arrhythmias, such as ectopic atrial tachycardia and permanent junctional reciprocating tachycardia can be relatively occult with heart rates of 180-210 per minute, but distinguished from the sinus tachycardia of other dilated cardiomyopathies by abnormal P waves. Again, recognition is key; effective

treatment of the cardiomyopathy depends on treatment of the arrhythmia.

Treatment

General acute supportive treatment consists of correction of coexistent electrolyte, calcium, and acid-base abnormalities, providing abundant dextrose intravenously to support potentially jeopardized energy production, judiciously providing fluids to maintain cardiac output although minimizing edema, supporting the myocardial function with intravenous inotropic agents (e.g., dopamine, dobutamine, epinephrine, amrinone) (Table 33-11), and using antiarrhythmic medications as needed. (see Tables 33-18 and 33-19). Additionally, antibiotics, hyperventilation, paralysis, sedation, and vasodilators may be employed. In cases with severe, but presumably self-limited, cardiopulmonary failure refractory to conventional therapy, venoarterial extracorporeal membrane oxygenation (ECMO) has been used with success. Although serious complications continue to exist, ECMO has become a standard treatment for critically ill neonates with self-limited cardiopulmonary failure.

Chronic supportive therapy is aimed at general measures to maximize the strength and longevity of cardiovascular performance, control symptoms of congestive heart failure and control arrhythmias (see Tables 33-10 and 33-19). Optimizing outcome of those more severely effected is often best when done with experience and close monitoring and adjustment. Spironolactone, carefully adjusted doses of angiotensin-converting enzyme (ACE) inhibitors, and judicious use of beta adrenergic receptor blockers (e.g., Carvedilol) can produce significant benefit in hemodynamic function and significantly improve survival. Renal function and potassium levels should be monitored carefully with use of spironolactone and ACE inhibitors, and their dose adjusted for gestational age, postnatal age, and concomitant use. Beta-adrenergic receptor blockers, such as Carvedilol, should be started at very low dose and increased slowly as tolerated using standard regimens. ACE inhibitors and Carvedilol are orally administered, and currently require pharmacy compounding from pills. Digitalization should be carried out with caution and orally if possible in infants with myocarditis, because they may be unduly susceptible to drug-induced arrhythmias. Diuretics can help with symptoms related to pulmonary and systemic edema, but do not appear to influence survival. Cardiac transplantation should be considered if the course appears likely to be fatal despite optimal use of stabilizing measures and treatment of the primary disorder, if there is no irreversible severe dysfunction of other organs, and the underlying primary disease is not likely to recur in the transplanted heart or other organs.

TABLE 33-18 TACHYARRHYTHMIA DIAGNOSIS AND TREATMENT

Type of Arrhythmia	AV Reciprocating Tachycardia	Ectopic Atrial Tachycardia	Atrial Flutter	Atrial Fibrillation	Ventricular Tachycardia
Usual QRS in arrhythmia	Unchanged	Unchanged	Unchanged	Unchanged	Abnormal
Onset and termination	Sudden	Gradual	Sudden	Sudden	Sudden or gradual

TABLE 33-19 NEONATAL ANTIARRHYTHMIC DRUGS

Drug (Class)	Currently Commonly Used	Route of Metabolism/ Excretion	Oral Dose	IV Dose	Therapeutic Level	Indications	Contraindications	Toxicity
Adenosine	Yes	Red blood cells and vascular endothelium		0.075–0.10 mg/kg rapid IV push, ↑to 0.15–0.25 mg/kg after 1 min if not effective		Rx-reentry SVT, DX atrial flutter		Transient AV block, ↓HR, ↓BP, and flushing, rare atrial fibrillation
Digoxin	Yes	Renal	Load: 20–30 µg/kg divided in 3 doses, Maintenance: 3–5 µg/kg/12 hours; ↓ w/renal hepatic dysfunction	80% of oral dose	0.8–2.2 ng/mL	SVT, atrial flutter	AV block, VT, many WPW	AV block, ↓HR, tachyarrhythmias, vomiting, use w/ caution w/renal failure, toxicity with hypocalcemia
Quinidine (IA)	Yes	Hepatic	3–15 mg/kg/6 hours; ↓ w/renal or hepatic dysfunction		2–5 µg/mL	SVT, WPW w/ propranolol, PVC, VT	Long QT, known sensitivity, IV use, conduction block, myasthenia gravis	↓ Contractility, ↑ QT, VT, conduction block, vomiting, diarrhea, rash, blood ↑ HR w/ atrial flutter w/o ↑ digoxin level, need to dose by ½
Procainamide (IA)	Yes	Renal hepatic	2.5–8 mg/kg/4 hours	7 mg/kg over 1 hour Infusion: 20–60 g/kg/min	Procainamide ^a 4–10 µg/mL	SVT, WPW, PVC, VT	Conduction block, myasthenia gravis	Similar to quinidine, ↓ BP, lupus like reaction, no effect on level
Disopyramide (IA)	No	Hepatic, renal	3.5–7.5 mg/kg/6 hours		2–5 µg/mL	SVT, WPW, PVC, VT	Conduction block myasthenia gravis	Similar to quinidine, ↓ CNS reactions, seizure, ↓ BP, ↓ respiratory drive
Lidocaine (IB)	Yes	Hepatic		Bolus: 1 mg/kg/ 5–10 min Infusion: 20–50 µg/kg/min; ↓ w/ cyanosis, hepatic dysfunction	2–5 µg/mL	PVC, VT	Conduction block ↓ junctional and ventricular escape rate	

Phenytoin (IB)	No	Renal, hepatic	2–3 mg/kg/12 hours; ↓ w/ hepatic dysfunction	Load: 10 mg/kg over 30–60 min Maintenance: same as oral	10–20 µg/mL	PVC, VT, digitalis intoxication	Not FDA approved for VT	CNS reactions, ↓BP, blood dyscrasias, hepatic hypertrichosis, gingival hyperplasia, coarse facies, rash
Flecainide (IC)	No	Renal, hepatic	0.3–2 mg/kg/8 hours; ↓ w/ renal, hepatic dysfunction		0.2–1.0 µg/mL	Refractory life-threatening SVT, PJRT, PVC, VT	Conduction block, hepatic dysfunction, myocardial dysfunction	Occasional ↑ SVT frequency w/WPW, ↑ pacing threshold conduction block, VT, nausea, ↓ contractility
Esmolol (II)	Yes	RBC esterases	IV only	Load: 0.5 mg/kg over 1 min Infusion: 50–100 g/kg/min 0.02–0.10 mg/kg over 20 min.		Recurrent, sustained SVT, WPW, VT	As per propranolol	As per propranolol
Propranolol (II)	Yes	Hepatic	0.3–1.↓ mg/kg/6 hours; ↓ w/ chronic cyanosis, renal, hepatic dysfunction			SVT, WPW, PVC, VT, hypertrophic cardiomyopathy, long QT	Use w/verapamil, bronchospasm, conduction block, CHF	↓ ?HR, conduction block, bronchospasm, ↓ BP, hypoglycemia, depression, ↓cardiac reflexes w/anesthesia
Sotalol (II/III)	No	Renal	25–70 mg/m ² BSA/ 8 hours			SVT, WPW & VT with structurally normal heart	Use with verapamil, bronchospasm conduction block, ? structural heart disease	As per propranolol plus ventricular arrhythmias
Amiodarone (III)	No	Hepatic	5 mg/kg/12 hours for 1 week; then 5 mg/kg/day; ↓ w/ hepatic dysfunction	Load: 5 mg/kg over 15–30 min Infusion: 10–20 µg/kg/min	1–2 mg/L	Refractory, life-threatening, SVT, VT, recurrent VF	Conduction block	Extremely long half-life, corneal deposits, thyroid and hepatic dysfunction, pulmonary fibrosis, may ↑ conduction block and digoxin and quinidine levels, need to ↓digoxin by, ½hypotension w/IV
Bretylum (III)	No	Renal	Load: 5 mg/kg over 15 min Infusion:			Refractory VT, VF		Transient ↑ BP, arrhythmia, then ↓ BP

Verapamil (IV)	No	Hepatic	2–4 mg/kg/8 hours; ↓ w/ hepatic, renal dysfunction, neuromuscular disease	Refractory SVT, hypertrophic cardiomyopathy some PVC, VT	IV use, conduction dysfunction, CHF, many WPW, propranolol muscular dystrophy, use w/ quinidine, generally avoid in infants	↓ BP, ↓ HR, conduction block, myocardial depression, constipation, may ↑ digoxin level, need to ↓ digoxin dose 1/3 to 1/2
----------------	----	---------	---	--	---	---

^a To differentiate from metabolite measure by some laboratories.

Note: Continuous ECG monitoring should be done during initiation of antiarrhythmic therapy and with IV administration because of potential proarrhythmia and conduction block.

AV arteriovenous; BP, blood pressure; BSA, body surface area; CHF congestive heart failure; CNS, central nervous system; DX, diagnose; FDA, Federal Drug Administration; HR, heart rate; PJRT, permanent junctional reciprocating tachycardia; PVC, premature ventricular contractions; RX, treatment; SVT, supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia; w/, with; WPW, Wolff—Parkinson—White syndrome.

Hypertrophic Cardiomyopathies

Hypertrophic cardiomyopathy is a disorder characterized by inappropriate thickening of the ventricular walls, with normal, hyperdynamic or diminished systolic performance and normal or diminished ventricular chamber size. There are many causes (see Table 33-17). Most commonly, transient cardiomyopathy occurs as secondary disorder in infants of diabetic mother, or with in utero sympathomimetic exposure. Permanent myocardial diseases that more commonly present in older children and adults, such as isolated hypertrophic cardiomyopathy associated with contractile gene mutations, also present in infancy. Hypertrophic cardiomyopathy may occur in infants in association with genetic syndromes (e.g., Noonan syndrome) and infiltrative storage diseases (e.g., Pompe and other glycogen storage diseases, mucopolysaccharidosis). Primary metabolic disorders of energy production (disorders of fatty acid oxidation, nuclear and mitochondrial genome abnormalities in oxidative phosphorylation) cause isolated hypertrophic or dilated cardiomyopathy, or multi-system dysfunction with cardiac and skeletal myopathy and encephalopathy (33,34).

Pathophysiology

Although resulting from diverse etiologies, most hypertrophic cardiomyopathies share certain clinical features and pathophysiology. Specific endocrine, genetic, mitochondrial or metabolite abnormalities elicit a sequence of molecular and cellular changes with myocardial sarcomeric production and often dysfunction, resulting in myocyte thickening, often with interstitial fibrosis, leading to ventricular wall thickening and impaired diastolic compliance. The ventricle walls often become so thick regarding severely narrow ventricular outflow, particularly dynamic with systolic ventricular wall thickening and result in the physiology of aortic stenosis. Sometimes severe thickening of the ventricular walls significantly encroaches and limits ventricular chamber size. Impaired diastolic compliance results in generalized edema and in pulmonary venous engorgement. Metabolic "storage" disorders, such as glycogen storage disease, have ventricular wall thickening from infiltration of the myocardium with accumulated metabolic products, not from deranged myocyte hypertrophy, but present with clinical features of metabolic disease with hypertrophic cardiomyopathy.

Clinical Findings

There may be a history of maternal diabetes, exposure to sympathomimetic or steroid medications, or family history of hypertrophic cardiomyopathy or metabolic disease. A prominent systolic murmur from ventricular outflow stenosis and/or mitral regurgitation are usually present. Signs of right and left heart congestive failure, including diminished activity, hepatomegaly, tachypnea, retractions, and S3, are often present. Signs of low cardiac stroke volume, including tachycardia, narrowed pulse pressure, diffusely diminished pulses, and hypotension may be present. Associated primary conditions may cause dysmorphic features, hypotonia, encephalopathy, and organomegaly seemingly out of proportion to the hemodynamic derangement.

Chest radiograph, in contrast to that seen at older age, often shows cardiomegaly and pulmonary edema.

ECG usually has diffusely increased QRS voltage amplitude and repolarization changes. Additionally, ECG in Pompe's disease characteristically shows a short PR interval.

Echocardiographic examination demonstrates ventricular wall thickening, often extraordinarily severe, variable left and sometimes right ventricular sub-valvar outflow stenosis, and mitral and tricuspid regurgitation. Fixed anatomic sub-aortic stenosis and other structural anomalies that can result in secondary ventricular hypertrophy should be detected.

If there is no family history of known hypertrophic cardiomyopathy and initial laboratory studies screening for metabolic disease are unremarkable, first-degree relatives should be screened with electrocardiography and echocardiography for asymptomatic hypertrophic cardiomyopathy. If physical examination or laboratory studies suggest metabolic disorder, or if echocardiographic evaluation of first degree relatives is negative or unobtainable, then additional laboratory evaluation for metabolic disorder may be helpful (33).

Specific Hypertrophic Cardiomyopathies

Infants of diabetic mothers develop a hypertrophic cardiomyopathy that is generally self-limited, although sometimes is a severe disorder. It results from the myocardial trophic response to fetal hyperinsulinemia provoked by trans-placental passage of high maternal glucose loads. Clinical findings include a systolic ejection murmur, sometimes mild increase in respiratory rate and work and, rarely, evidence of frank congestive heart failure. There is an increased risk of structural heart disease in infants of diabetic mothers.

Echocardiographic examination reveals left ventricular hypertrophy that is sometimes severe, usually with involvement of the septum, and occasionally with outflow obstruction (Fig. 33-45). Treatment is supportive. Inotropes may worsen

outflow obstruction and are contraindicated if the obstruction is severe.

The most common permanent hypertrophic cardiomyopathies are genetic disorders in one of the cardiac contractile proteins, most often myosin heavy chain. In 50% of cases it is inherited as an autosomal condition with variable penetrance, and in the others it occurs as a new mutation. This isolated cardiac disorder is characterized by myocyte hypertrophy and disarray, propensity for development of left ventricular outflow or intracavitary systolic pressure gradients, symptoms of congestive heart failure caused by poor diastolic chamber compliance, ventricular arrhythmias, and sudden death. There can be significant progression with time, and a normal echocardiogram at birth does not exclude the possibility for phenotypic expression later in life. Because it can be sub-clinical and cause sudden death in older children and adults, echocardiograms

P.699

and electrocardiograms should be obtained in all first-degree relatives and symptomatic relatives. Those presenting at birth appear to have the poorest prognosis. Inotropic agents and diuretics are potentially harmful and generally not used. Calcium channel blockers decrease the systolic pressure gradient, improve diastolic compliance, and may improve survival in adults. Because of hazards associated with calcium channel blockers in infants, their use in infants less than 1 year of age remains investigational. β adrenergic receptor blockers can improve symptoms, but do not appear to affect the progression of hypertrophy or survival. Ventricular septal myomectomy may improve symptoms in those refractory to medical treatment. Holter monitoring for ventricular arrhythmias should be routinely performed, and amiodarone considered in those with ventricular tachycardia. Cardiac transplantation may be required for survival in severely affected, refractory patients.

Metabolic disorders of cellular energy production involving pyruvate metabolism, fatty acid oxidation, and oxidative phosphorylation, and metabolic "storage" disorders, such as glycogen storage disease, may present in early infancy with clinical findings of isolated hypertrophic cardiomyopathy. However, these disorders are particularly likely to be present when there is one or more associated findings such as hypotonia, encephalopathy, cataracts, liver enlargement or dysfunction disproportionate to the hemodynamics, hypoglycemia, metabolic acidosis, elevated ketones, lactate or pyruvate. Treatment options depend on the enzyme affected.

Figure 33-45 Echocardiographic parasternal long-axis view of a diabetic mother's infant with severe hypertrophic cardiomyopathy and subaortic ventricular septal defect. >, ventricular septal defect; AV, aortic valve, IVS, interventricular septum; LA, left atrium; LV, left ventricle; RV, right ventricle.

Neonatal Tricuspid Valve Regurgitation

Regurgitation of an anatomically normal tricuspid valve is a common finding in neonates. The regurgitation may be an isolated finding and mild, and cause only a temporary soft regurgitant murmur at the left lower sternal border. Greater degrees of regurgitation of an anatomically normal tricuspid valve often develop with right ventricular myocardial disease, such as cardiomyopathy from asphyxia, and with right ventricular systolic hypertension, as with persistent pulmonary hypertension or pulmonary parenchymal disease. If there is right ventricular diastolic dysfunction, there may be right-to-left shunting through a patent foramen ovale. The explanation for a lower sternal murmur can be documented by echocardiography and managed with observation, because tricuspid regurgitation of this type tends to regress as the underlying right ventricular hypertension or dysfunction resolves (see Fig. 33-15).

Chronic Pulmonary Hypertension and Cor Pulmonale

Cor pulmonale is pulmonary hypertension secondary to ventilatory or pulmonary disease, with right ventricular hypertrophy; it frequently presents as symptoms of congestive heart failure with pulmonary disease. Patients with cor pulmonale have a structurally normal heart, and must be differentiated from those with pulmonary hypertension from intracardiac shunts or pulmonary venous obstruction. The most

frequent cause of cor pulmonale in infants has been bronchopulmonary dysplasia, although its incidence has drastically declined in recent years and there are a large number of other causes, including airway obstruction, central hypoventilation, pulmonary hypoplasia, and diaphragmatic abnormalities.

Pathophysiology

Pulmonary artery pressure is controlled by vascular resistance, which is a function of the number of small pulmonary arteries and the average luminal size. The number of vessels may be diminished by congenital pulmonary hypoplasia or acquired parenchymal damage. Additionally, abundant pulmonary artery musculature sufficient to prevent more than minimal pulmonary flow before birth, is present at birth, and can persist and re-constrict in response to certain circumstances, further aggravating pulmonary hypertension. Factors resulting in persisting postnatal pulmonary hypertension include alveolar hypoxia, acidemia, increased pulmonary venous pressure, polycythemia and bacteremia. When pulmonary resistance is fixed, increases in cardiac output with infection or anemia also elevate pulmonary artery pressure. Pulmonary hypertension induces right ventricular hypertrophy and, if severe, causes right ventricular diastolic dysfunction and dilation. In addition to pulmonary hypertension, bronchopulmonary dysplasia also is frequently associated with systemic hypertension and left ventricular hypertrophy. Shifting of the ventricular septal position, elevated ventricular pressure and biventricular hypertrophy, impair biventricular diastolic compliance and increase sensitivity to intravascular volume.

The pulmonary hypertension and cardiac sequelae seen with chronic lung disease generally resolve when the

P.700

pulmonary parenchymal disease resolves. In contrast, permanent pulmonary vascular change (i.e., Eisenmenger syndrome) occurs in patients with congenital heart disease after 1 year or more of exposure to a large left-to-right shunt with pulmonary artery hypertension.

Clinical Findings

Variable hepatomegaly and systemic venous congestion secondary to right atrial hypertension are predominant findings. Elevated left atrial pressure, especially in the presence of pulmonary parenchymal disease, may predispose to pulmonary symptoms and rales. The right ventricular impulse may be increased and the second heart sound loud and appear single. There may be a relatively soft murmur from tricuspid regurgitation, but a prominent murmur is not common and suggests possible congenital heart disease. Cyanosis (See Color Plate) may result from alveolar dysfunction with intrapulmonary shunting and from right-to-left shunting across a patent foramen ovale. Infants with bronchopulmonary dysplasia

appear to be at increased risk for sudden death (10), similar to older patients with primary pulmonary hypertension. The degree of pulmonary artery hypertension and cardiac symptomatology may vary with labile ventilatory or pulmonary conditions. Several echocardiographic methods, some fairly accurate, some not so accurate, and most applicable to particular circumstances, can be used to assess the right ventricular pressure (see Fig. 33-14). Sedation, sometimes necessary for technically acceptable studies in older, active babies, may depress ventilation and should be used with caution.

Differential Diagnosis

In patients with pulmonary hypertension, even those with lung disease, the presence of congenital heart disease should be sought. The absence of a loud murmur does not exclude a septal defect or patent ductus arteriosus in the presence of elevated pulmonary vascular resistance. Because many of the symptoms of cor pulmonale overlap those of congenital heart disease, echocardiographic examination has been useful for excluding occult cardiovascular lesions that could lead to irreversible Eisenmenger syndrome. However, with lung disease ultrasound windows are often poor. These limitations should be realized, and the results correlated with other findings.

Treatment

The treatment of pulmonary hypertension secondary to pulmonary or ventilatory disease is directed primarily at the underlying disorder. Bronchodilators and diuretics may lessen exacerbating abnormalities in alveolar gas exchange and symptoms. Oxygen may be useful not only to prevent cyanosis and exacerbations of pulmonary hypertension, but also as a pulmonary vasodilator. Digitalis has not been found to be beneficial in most infants with congestive symptoms. With resolution of the underlying ventilatory disease, the pulmonary hypertension also resolves.

Cardiac Tumors

Intracardiac tumors in neonates are rare. Rhabdomyoma accounts for most. Fibromas occur much less frequently, and other types occur rarely. Most babies with cardiac rhabdomyoma have tuberous sclerosis (see Table 33-3), and vice versa (94). The presence of one should prompt an investigation for the other. Cardiac rhabdomyoma may be the only manifestation of tuberous sclerosis in neonates. Neonatal cardiac rhabdomyoma are generally multiple and usually regress, often completely. Cardiac tumors 2 mm or more in diameter are readily demonstrated by echocardiography, even in the fetus. Many babies are asymptomatic, even when the tumors are large and multiple, although peri-valvar masses can obstruct valve flow and development. Serious arrhythmias also sometimes occur.

Arrhythmias

All forms of cardiac arrhythmias can occur in the fetus or newborn. Those most commonly encountered include sinus tachycardia and bradycardia, premature atrial depolarizations, supraventricular tachycardia; and less commonly, atrial flutter, ventricular arrhythmias, and complete heart block. Many arrhythmias are benign, occurring in otherwise normal hearts, and are of no hemodynamic consequence. Others may result in significant acute cardiovascular compromise, particularly if they are very rapid or there is coexistent structural or functional heart disease. Sustained tacharrhythmia can lead to reversible dilated cardiomyopathy (95). Thus, in evaluating patients with arrhythmias it is important to assess the hemodynamic status and cardiac structure and function. Rarely, arrhythmias are the presenting sign of underlying cardiac abnormality such as cardiomyopathy, Ebstein anomaly, or l-transposition of the great arteries. Arrhythmias may also result from noncardiac disease; in neonates, ventricular tachycardia, ventricular fibrillation, sinus arrest, and extreme bradycardia usually occur in association with preceding severe hypoxemia, hypotension, acidosis, electrolyte disturbance, or drug toxicity (e.g., digitalis).

Benign Arrhythmias

Sinus Bradycardia

Many infants have transient bradycardia associated with specific activities such as crying, straining or micturition. Some healthy infants persistently have a heart rate near 80 beats per minute. Sustained bradycardia at less than 70 beats per minute in neonates is abnormal. Noncardiac causes, such as gastroesophageal reflux leading to vagal stimulation, are common. Bradycardia can also be produced by stimulation of the vagus nerve during procedures such as endotracheal, nasogastric and orogastric intubation. Less commonly electrolyte abnormalities, hypothyroidism and exposure to medications (e.g., prenatal beta-adrenergic blockers) are the

P.701

cause. Isolated persistent sinus bradycardia should prompt careful inspection of an ECG for nonconducted P waves as can occur with nonconducted atrial premature depolarizations, second-degree atrioventricular conduction block, and congenital long QT syndrome (96).

Sinus Arrhythmia

Sinus arrhythmia is the most common cause of an irregular heart rate and rhythm, that is more prominent at slower heart rates, such as in older infants. It represents normal physiologic variability in the sinus rate, in phase with respiration and other variables. The P wave morphology and axis do not change. Once recognized, no further evaluation or treatment is necessary.

Sinus Tachycardia

Sinus tachycardia occurs with serious illness, fever, hypovolemia, anemia, anxiety or pain and sympathomimetic medications (e.g., dopamine, dobutamine, isoproterenol, epinephrine, caffeine, theophylline, and aminophylline), at heart rates up to 230 beats per minute in infants. With a sinus tachycardia, there is more rate variability than seen in many tachyarrhythmias and normal P waves precede the QRS complex, often "merged" into the preceding T wave at heart rates greater than 180 beats per minute (P waves positive in leads I, II, and aVF; negative in lead aVR). Pathologic supraventricular tachyarrhythmias can be differentiated from sinus tachycardia by usually faster rates, abnormal P wave axis or PR interval, and (when present) by an abrupt onset and termination or wide QRS complexes.

Atrial Premature Depolarizations

Premature depolarizations can originate from any conducting tissue. Atrial premature depolarizations occur in up to 30% of newborns ([97](#)). The diagnosis is reliably assigned when there is an identifiable, early, nonsinus P wave. However, the P wave may be hidden within the preceding T wave. Atrial premature depolarizations may be conducted to the ventricles normally, or with a bundle branch block pattern resulting in a wide QRS complex (if a bundle branch is refractory from the preceding beat), or may be "blocked" and not conducted to the ventricles (when very early and occurring when the AV node or proximal His bundle is refractory). When frequent, blocked atrial premature depolarizations result in ventricular bradycardia as a result of resetting of the sinus node

with each premature atrial depolarization. In neonates with central venous catheters, frequent atrial premature depolarizations may be as a result of contact of the catheter with an atrial wall, and constitute an indication to withdraw the catheter from the atrium. Atrial premature depolarizations might also be secondary to electrolyte abnormalities or drugs (e.g., dopamine, dobutamine, isoproterenol, epinephrine, caffeine, theophylline, and aminophylline). Very rarely are atrial premature depolarizations secondary to myocarditis or cardiac tumors.

In hemodynamically stable otherwise healthy infants, premature atrial depolarizations generally do not warrant further evaluation. Isolated ectopic atrial depolarizations and atrial bigeminy are only rarely associated with tachycardia, and usually are of no serious consequence. In most infants, these arrhythmias resolve over a few months.

Ventricular Premature Depolarizations

Premature ventricular depolarizations are early QRS complexes with a morphology different from sinus beats and without an identifiable preceding P wave. In newborns, ventricular premature depolarizations may not be much wider than normal QRS complexes. Premature ventricular complexes occur in less than 1% of healthy newborns ([98](#)). Although premature ventricular depolarizations are usually benign, their identification should prompt evaluation for possible structural or functional heart disease, electrolyte abnormalities (e.g., hypokalemia, hyperkalemia, and hypocalcemia), hypoglycemia, hypoxia, or the congenital long-QT syndrome. Premature ventricular complexes may also be related to administration of drugs (e.g., dopamine, dobutamine, epinephrine, caffeine, aminophylline, theophylline, digoxin, or other antiarrhythmic medications). In the absence of these problems, they often resolve over a number of months. There are no data to suggest that the daily number or morphology of these complexes influences the prognosis.

Accelerated Ventricular Rhythm

An accelerated ventricular rhythm is a less common arrhythmia. There is a wide QRS rhythm, generally at a rate not more than 10% greater than the underlying sinus rate. This probably represents enhanced automaticity of a ventricular focus. There may be mild accelerations and decelerations of the rate. Atrioventricular dissociation is usually seen. The duration of episodes is variable. Although this arrhythmia generally occurs in otherwise healthy infants, it has been associated with structural heart disease, electrolyte abnormalities, cardiac tumors, intracardiac catheters, maternal heroine and cocaine use, and respiratory distress. Patients are usually asymptomatic and do not need treatment. This arrhythmia generally resolves within months (99).

Tachyarrhythmias

Heart rate alone is not always enough to establish the diagnosis of a pathologic tachycardia. Infants can have a sinus tachycardia with rates up to at least 230 beats/min in response to serious illnesses, fever, hypovolemia, anemia, pain or infusion of inotropic/chronotropic agents. Additionally, some unusual pathologic supraventricular tachycardias can have rates less than 180 beats/min. In assessing a child with a fast heart rate, one should determine if the

P.702

QRS complex is narrow or wide during tachycardia, if the rate is fixed or variable, if there is a visible P wave and if so, the P wave axis. Supraventricular tachycardias typically have a narrow (normal) QRS complex. In general, if the QRS complex in tachycardia remains wide, the rhythm should be considered ventricular tachycardia. However, it is not uncommon for the first few beats of SVT to be wide because of aberrant conduction (right or left bundle branch block) before changing to a narrow QRS complex.

A patient with an apparently fixed high heart rate should be carefully assessed. The fixed heart rate could represent a sinus tachycardia secondary to a high-catecholamine state in an otherwise sick infant. An electrocardiogram should be obtained, and the P wave morphology clearly established. If there is no clear P wave, or the P wave does not have a sinus morphology (positive in leads I, II, and aVF; negative in lead aVR) one should strongly consider a pathologic tachycardia or structural heart disease with heterotaxy (see Table 33-17).

All neonates with documented tachyarrhythmias should have a complete cardiac evaluation, including 12-lead ECG (during the tachycardia if hemodynamically stable, and later in sinus rhythm), and echocardiography, to assess cardiac structure and function. It is estimated that between 8% and 25% of infants with SVT have structural heart disease, most often Ebstein malformation of the tricuspid valve, corrected transposition of the great arteries, or hypertrophic cardiomyopathy (100). Cardiac tumors and myocarditis rarely are predisposing causes for ventricular arrhythmias.

The clinical status of infants with tachyarrhythmias depends on the ventricular rate, duration of tachycardia, presence of underlying structural or functional heart disease, and other clinical problems. Patients may be completely asymptomatic, with the arrhythmia noted during an otherwise routine evaluation or although monitored for other reasons. The infant may not have been appearing well, with irritability, poor feeding, restlessness, or respiratory difficulty with tachypnea, retractions and wheezing. With persistent tachyarrhythmia, the child may develop signs and symptoms of congestive heart failure or acidosis, becoming pale and listless. If the tachycardia persists for long enough, heart failure and a secondary dilated cardiomyopathy may develop. In the fetus with persistent or recurrent tachycardia, this is manifest as nonimmune hydrops. Whether a tachycardia related cardiomyopathy develops depends on the ventricular rate, whether the tachyarrhythmia is intermittent or incessant, the frequency of recurrences if intermittent, and the presence of structural heart disease.

Figure 33-46 Electrocardiogram during conversion of supraventricular tachycardia to sinus rhythm with administration of adenosine. During tachycardia at a rate of 230 beats/min, there is a normal-appearing QRS complex without a delta wave (no ventricular preexcitation), and there is no distinct P wave. After conversion to sinus rhythm, there is a short PR interval (80 milliseconds) and wide up-sloping QRS complex (90 milliseconds) representing ventricular preexcitation, indicative of the Wolff-Parkinson-White syndrome.

Supraventricular Tachycardias

Atrioventricular Reciprocating Tachycardia and Wolff-Parkinson-White Syndrome

The most common type of fetal and neonatal supraventricular tachycardia is atrioventricular reciprocating tachycardia with a reentry circuit via an accessory atrioventricular conduction pathway (101). Most often these accessory conduction pathways persist as isolated anomalies, but they can occur in association with cardiac structural anomalies such as Ebstein anomaly. Accessory atrioventricular conduction pathways resulting in WPW syndrome are rarely inherited as an autosomal dominant trait, sometimes associated with hypertrophic cardiomyopathy (102).

During supraventricular tachycardia there is antegrade conduction from the atria to the ventricles over the AV node and His-Purkinje system, with retrograde conduction over the accessory pathway from the ventricles to the atria. Because antegrade conduction is normal over the AV node and His-Purkinje system, there usually is a normal (narrow) QRS complex during tachycardia. Commonly the accessory atrioventricular conduction pathway conducts only retrograde. Therefore, during sinus rhythm all antegrade conduction is through only the AV node, and the electrocardiogram appears normal.

Atrioventricular reciprocating tachycardia is characterized by the abrupt onset and termination of a fairly fixed heart rate of 230 to 300 beats/min, abnormal or unidentifiable P waves that may be superimposed on the T waves, and usually a normal QRS morphology (see Fig. 33-46 and Table 33-18). The infant may be asymptomatic initially, but then becomes irritable and fussy and refuses feeding, congestive heart failure develops in approximately 20% after 36 hours and in 50% after 48 hours.

P.703

Some accessory pathways can conduct impulses in both directions, resulting in the Wolff-Parkinson-White (WPW) syndrome. During sinus rhythm, antegrade atrial-to-ventricular conduction over the accessory pathway results in a short PR interval and wide QRS complex with characteristic delta wave, resulting from rapid "ectopic" depolarization of the ventricles, without the delay in conduction that occurs in the A-V node. Depending on the location of the accessory pathway, and the ECG lead examined, a delta wave may be of variable size and direction. Because antegrade conduction during supraventricular tachycardia is usually through the AV node and His-Purkinje system, the diagnosis of WPW syndrome cannot usually be made during tachycardia. Rarely, an atrioventricular reciprocating tachycardia occurs in patients with WPW syndrome with antegrade conduction over the accessory pathway, and retrograde conduction through the A-V node, resulting in a wide QRS tachycardia, which may be electrocardiographically indistinguishable from ventricular tachycardia. Some patients with WPW syndrome have the potential for very rapid antegrade conduction over their accessory pathway; if those individuals develop a primary atrial tachycardia such as atrial fibrillation, it can lead to ventricular fibrillation

(103). Fortunately, atrial fibrillation is rare in children. Patients with WPW syndrome should generally not be treated with digoxin or verapamil, as these medications sometimes enhance antegrade accessory pathway conduction.

Persistent Junctional Reciprocating Tachycardia

One important, but unusual form of accessory pathway has slow retrograde conduction, resulting in a supraventricular tachycardia referred to as persistent junctional reciprocating tachycardia. These tachycardias are usually slower than other supraventricular tachycardias, often less than 200 beats/min in newborns. This often causes an incessant or frequently recurring tachycardia that can result in a reversible dilated cardiomyopathy. Initially this arrhythmia is often well tolerated because of the slower heart rate. It can be recognized by having a fixed rapid heart rate in which there is an abnormal (nonsinus) P-wave axis (usually negative in leads II and aVF, and positive in aVR and aVL). There may be a normal appearing PR interval as a result of slow retrograde conduction, but the abnormal P-wave axis differentiates it from sinus tachycardia. This type of supraventricular tachycardia might terminate with vagal maneuvers, adenosine, atrial pacing or cardioversion, but frequently the arrhythmia rapidly recurs.

Ectopic Atrial Tachycardia

Another potential cause of a dilated cardiomyopathy is an ectopic atrial tachycardia (104). This type of supraventricular tachycardia results from enhanced automaticity of a single cell or small cluster of cells in either atrium. Generally, the P-wave morphology is not normal in at least one lead. The arrhythmia mechanism does not involve the ventricles. Depending on the atrial rate and possible AV block, there may be a variable A:V relationship (with more atrial than ventricular complexes). This type of SVT is characterized by a variable rate and gradual onset and termination (see Table 33-17). Transiently blocking A-V conduction, with vagal maneuvers or adenosine administration, will not terminate the atrial tachycardia but will demonstrate the diagnosis by the presence of unabated rapid P waves. Ectopic atrial tachycardia also does not terminate with pacing maneuvers or cardioversion, but often improves with beta-adrenergic receptor blockers.

Junctional Ectopic Tachycardia

Junctional ectopic tachycardia is a rare, often incessant, tachyarrhythmia due to enhanced automaticity in the A-V node or bundle of His. There is generally a normal (narrow) QRS morphology with variable ventricular rates. If there are visible P-waves, the ventricular rate is greater than the atrial rate and it does not respond to pacing maneuvers or cardioversion, and is often difficult to control with milder antiarrhythmic medications.

Isolated junctional ectopic tachycardia is often familial. Some patients eventually develop complete heart block (105).

Most often junctional ectopic tachycardia is seen early, and temporarily following cardiac surgery in infants, and can result in significant hemodynamic compromise until it is controlled and abates. Intravenous amiodarone may be the best treatment; but cooling the patient down to 33 to 35 C with administration of intravenous procainamide is often helpful.

Atrial Flutter and Fibrillation

Atrial flutter is less common than other types of paroxysmal supraventricular tachycardia in fetuses and neonates. It may be idiopathic, or associated with the same congenital heart lesions as those producing other supraventricular tachycardias. The atrial rate may be 200 to 500 beats/min. The AV node is generally not part of the tachycardia circuit, so that there need not be a 1:1 atrial:ventricular rate relationship. There is often some degree of AV node block resulting in variable conduction, frequently with a 2:1 or 3:1 atrial:ventricular relationship. With a 2:1 block, the ventricular rate at the highest atrial rate would be 250 beats/min, a rate sufficient to produce congestive failure in infancy. The RR interval is constant except when the atrioventricular block changes. The rare infant without AV nodal conduction block may have a very rapid rate and shock. With higher degrees of AV nodal conduction block, a sawtoothed atrial pattern is characteristically seen, often best in leads II or V1. In some patients the diagnosis can not be ascertained from the surface electrocardiogram, especially if there is a 1:1 atrial:ventricular rate relationship. Esophageal recordings may demonstrate the atrial

P.704

activity more clearly, or adenosine might be used to cause transient AV block and demonstrate the flutter waves. Adenosine, although diagnostically helpful, does not convert atrial flutter (Fig. 33-47). Digoxin can be used to slow the ventricular rate, but is unlikely to convert the atrial flutter. Overdrive atrial pacing from the esophagus and, if necessary, cardioversion by DC countershock (initial dose 0.5 to 1 Joule/Kg) can be used to convert the rhythm to sinus. In the absence of structural heart disease, there is generally a benign course once the arrhythmia is converted to sinus rhythm, and subsequent chronic antiarrhythmic therapy is often not necessary (106).

Figure 33-47 Electrocardiogram showing the effect of adenosine on atrial flutter. Before adenosine, there is atrial flutter with 2:1 A-V conduction. The flutter waves are difficult to discern. After adenosine, there is transient slowing of AV node conduction without termination of the atrial flutter. This allows the flutter waves to be readily identified, confirming the diagnosis. The atrial rate during atrial flutter is 500 beats/minute.

Atrial fibrillation is recognized by an irregularly irregular ventricular rhythm. It is rare in newborns and usually seen in patients with structural heart disease. Digoxin can be used to slow the ventricular rate. Cardioversion by DC countershock (initial dose 0.5 to 1 J/Kg) is usually necessary to convert a sustained episode.

Treatments for Supraventricular Tachycardias

Treatment depends in part on the mechanism of tachycardia (see Tables 33-18 and 33-19) (100). In arrhythmias involving the AV node, such as atrioventricular reciprocating tachycardias without or with the WPW syndrome, transiently slowing or blocking AV node conduction can terminate the tachycardia. Vagal maneuvers are often effective in terminating these types of supraventricular tachycardia. These include the application of ice or very cold damp cloth to the face and rectal stimulation. Ocular compression should not be used as a result of risks to the child's vision.

Rapid bolus of intravenous adenosine (0.1 mg/kg, increased to 0.2 mg/kg if needed) is the treatment of choice for most infants with supraventricular arrhythmias involving the AV node that are refractory to vagal maneuvers. Adenosine is an endogenous nucleoside with a very short half-life that can transiently block AV node conduction, interrupting these arrhythmias, resulting in abrupt conversion to sinus rhythm. It is helpful to record the patient's electrocardiogram during attempts at conversion so that one can see if there was an effect of the intervention on the arrhythmia. There also might be transient evidence of WPW syndrome as the AV node conduction is briefly blocked, in the form of a delta wave from antegrade conduction down an accessory conduction pathway. If there was transient termination with rapid resumption of the arrhythmia, a longer-acting agent might be necessary to control the arrhythmia. Significant side effects appear to be rare, but include initiation of atrial fibrillation. Rarely, in patients with WPW syndrome, this can cause a ventricular tachycardia or fibrillation. It is therefore recommended that a defibrillator be readily available when administering adenosine. Methylxanthines (e.g., theophylline and caffeine) are competitive antagonists to adenosine, and might make dosing more difficult.

Other antiarrhythmic agents can be used to terminate and control supraventricular tachycardias in infants, in which vagal maneuvers or adenosine have resulted in only a transient termination of the arrhythmia, or for supraventricular tachycardias that do not involve the AV node (i.e., ectopic atrial tachycardia). These might include β blockers (i.e., esmolol or propranolol), class I

antiarrhythmic agents (i.e., procainamide or flecainide), digoxin, or class III antiarrhythmic agents (i.e., sotalol or amiodarone). For ectopic atrial tachycardias, a β -blocker is often effective, and intravenous infusion of esmolol is a good first-line therapy until the arrhythmia is controlled. However, class I or class III antiarrhythmic medications may be necessary to adequately suppress ectopic atrial or junctional tachycardias. Intravenous verapamil has been associated with cardiovascular collapse and death in neonates and infants and should not be used in patients under 1 year of age (107).

If available, atrial pacing using an esophageal pacing catheter can be effective in terminating AV reciprocating tachycardias and atrial flutter. Atrial pacing will not terminate ectopic atrial tachycardias or junctional ectopic tachycardias, but the atrial catheter can be helpful in confirming the mechanism of the tachycardia.

If the patient is hemodynamically unstable, DC countershock (starting with 0.5-1.0 Joules/kg) should be attempted for known or suspected reentry-type supraventricular tachycardias, including AV reciprocating tachycardia, atrial flutter, and atrial fibrillation.

Prophylactic antiarrhythmic therapy is prescribed for most infants with supraventricular tachycardia, as there is approximately a 20% recurrence risk of atrioventricular reciprocating tachycardias. Often the recurrence risk diminishes after the first 6 to 12 months, and the medication may be discontinued (108).

P.705

Digoxin may be used in patients with atrioventricular reciprocating tachycardia without evident WPW syndrome. The use of digoxin in patients with manifest WPW syndrome is controversial. There is evidence that digoxin can sometimes enhance antegrade accessory pathway conduction, potentially allowing very rapid conduction over the accessory pathway if the patient develops atrial fibrillation, possibly causing a hemodynamically unstable ventricular tachycardia or ventricular fibrillation.

β adrenergic blockers such as propranolol or atenolol are often used in patients with atrioventricular reciprocating tachycardias, especially with WPW syndrome and for ectopic atrial tachycardias. Care may be necessary in using β adrenergic blockers for infants with significant lung disease. For more refractory patients, combination therapy with propranolol and digoxin may be effective (101).

If breakthrough of supraventricular tachycardia occurs, switching to other agents with a greater potency (and toxicity), under the direction of a pediatric cardiologist, may suppress recurrences. These other agents may include drugs with a combination of actions such as sotalol, or others used alone or in combination such as type IA agents (e.g., quinidine, procainamide, disopyramide), type IC agents (e.g., flecainide or propafenone), or amiodarone, and possibly oral verapamil in older infants. The recommended management schemes vary between institutions and will change as more data about existing medications and new medications become available.

Esophageal or intracardiac electrophysiology studies with programmed atrial stimuli can be used to determine probability of recurrence on medications or after medications have been discontinued, for those with reentry supraventricular tachycardia. Rarely, radiofrequency ablation is used in infants with particularly refractory supraventricular tachycardia, often with associated ventricular dysfunction (109). Radiofrequency ablation is more safely and routinely applied in later childhood in those with persistent problematic arrhythmias.

Fetuses with supraventricular tachycardia may be recognized in utero by an unusually rapid heart rate. The mechanism of the arrhythmia can usually be elucidated with echocardiography, and usually involves a reentry mechanism (Fig. 33-6). If the arrhythmia has been present for some

time, these fetuses may develop hydrops. Treatment in utero by the administration of digoxin, flecainide, quinidine, procainamide, or sotalol to the mother, or procainamide or amiodarone directly into the umbilical vein, may be effective in terminating or suppressing the arrhythmia.

Figure 33-48 Electrocardiogram showing ventricular tachycardia in an infant at a rate of 158 beats/min. Because of retrograde conduction block, occasional sinus beats can be conducted to the ventricles through the AV node and His-Purkinje system, resulting in a normal QRS complex. Note that the QRS complex duration of the ventricular tachycardia measures 0.08 seconds, compared a QRS duration of 0.06 seconds for the conducted sinus beats.

Ventricular Tachycardias

Wide complex tachyarrhythmias may represent ventricular tachycardia, SVT with aberrant conduction, atrioventricular reciprocating tachycardia in WPW syndrome with antegrade conduction over the accessory pathway and retrograde conduction over the His-Purkinje system and AV node, or any tachycardia in the presence of bundle branch or intraventricular conduction block (e.g., after cardiac surgery, hyperkalemia). In infants, the QRS complex in ventricular tachycardia may be as narrow as 0.06 to 0.11 seconds, but it is always different than in sinus rhythm (Fig. 33-48).

Although dissociation of the ventricles from the atria, with more ventricular beats, is a hallmark of ventricular tachycardia (ventricular:atrial ratio > 1), there may be a 1:1 ventricular:atrial relationship if there is retrograde conduction over the A-V node. For the purposes of initial management, a wide QRS complex tachycardia should be considered ventricular tachycardia unless one has an ECG in sinus rhythm showing the same, wide QRS complex (generally as a result of a fixed bundle branch block). Chronic recurrent ventricular tachycardias are rare in neonates, and are usually associated with structural or functional heart disease. When there is a polymorphic ventricular arrhythmia in the absence of apparent structural or functional heart disease, one should consider torsades de pointes associated with the long-QT syndrome. Very rarely an incessant, monomorphic ventricular tachycardia is found in infants with cardiac tumors (110).

Long-QT syndrome is a generally congenital abnormality of ventricular repolarization that can cause ventricular tachycardia. The congenital long QT syndrome has recently been subdivided into 7 genotypes, caused by mutations in 1 of 6 proteins involved with transmembrane ion currents or in an associated structural anchoring protein (111). It can be inherited in an autosomal dominant fashion (Romano-Ward syndrome, without sensorineural hearing loss), or less often as an autosomal recessive condition (Jervell and Lange-Nielsen syndrome, with sensorineural hearing loss). Patients with this syndrome, including infants, generally have a prolonged

corrected QT interval ($QT \div (RR)^{1/2} > 0.46$ msec). Rarely, infants with the long QT syndrome have 2:1 A-V conduction block because the ventricles are refractory when the next atrial impulse conducts through the A-V node and His-Purkinje system (96). Patients with the long QT syndrome are at risk for torsades de pointes (a polymorphic ventricular tachycardia characterized by changing QRS morphology/axis that appears to turn around the baseline point) and sudden death.

To help aid in the diagnosis of the long QT syndrome, a scoring system has been developed based on ECG findings, the patient's arrhythmia (ventricular tachycardia) and symptoms (syncope, aborted sudden death) and family history (112). Care must be made in diagnosing the long QT syndrome in the first few days of life, especially without a family history of long QT syndrome or documented torsades de pointes, because many neonates have a QTc greater than 440 msec in the first few days of life.

Patients identified with the long-QT syndrome should be started on β -blockers, although other antiarrhythmic medications might eventually be preferable for some genotypes. Patients with malignant ventricular tachycardia despite β -blockers occasionally require cervicothoracic sympathectomy, pacemakers, or automatic implantable cardiac defibrillators (113).

Acquired long QT syndrome with risk of torsades de pointes can occur secondary to medications, electrolyte abnormalities (e.g., hypokalemia, hypocalcemia, or hypomagnesemia), endocrine abnormalities (e.g., hyperparathyroidism, hypothyroidism, or pheochromocytoma), or CNS disorders (e.g., encephalitis, head trauma, subarachnoid hemorrhage).

Treatments for ventricular Tachycardias

Because ventricular tachycardia can be life threatening, with the potential for degeneration into ventricular fibrillation, it is safest to treat all wide complex tachycardias as ventricular tachycardia.

If the patient is hemodynamically stable with a monomorphic ventricular tachycardia, antiarrhythmic therapy using lidocaine, procainamide, or amiodarone may suppress the arrhythmia (see Table 33-19). Phenytoin can be especially useful if the arrhythmia is related to digoxin toxicity. For torsades de pointes, treatment should include magnesium sulfate, lidocaine, and possibly isoproterenol or cardiac pacing.

If the patient is, or becomes, hemodynamically unstable, DC cardioversion should be initiated with 1 to 2 Joules/kg initially.

Chronic prophylactic antiarrhythmic therapy should be guided by the type of ventricular tachycardia, any underlying heart disease, and hemodynamic alterations associated with the arrhythmia (see Table 33-19). Radiofrequency ablation is rarely necessary for infants with monomorphic ventricular tachycardia not adequately suppressed by antiarrhythmic medications. Rarely, automatic implantable cardiac defibrillators are necessary for infants with recurrent life-threatening ventricular arrhythmias despite antiarrhythmic medications.

Atrioventricular Block

First Degree Atrioventricular Block

First degree A-V block is characterized by an abnormally prolonged P-R interval for age and heart rate. Most commonly, this is as a result of enhanced vagal tone and seen during sleep. Rarely this can be secondary to antiarrhythmic medications (e.g., digoxin), hypothermia, increased parasympathetic tone, hypothyroidism, or electrolyte disorders (hypo- or hyperkalemia, hypo- or hypercalcemia, hypoglycemia, and hypomagnesemia). First-degree AV block is generally well tolerated and requires no specific therapy. However, an infant with a muscular dystrophy, Kearns-Sayre syndrome, neonatal lupus, a family history of complete heart block or maternal connective tissue disease should be followed for possible progression of the conduction abnormality.

Second-Degree Atrioventricular Block

Second-degree AV block is defined as intermittent failure of conduction of some atrial depolarizations to the ventricles. Second-degree AV block is subdivided into Mobitz type I (Wenckebach) and Mobitz type II AV block. In Mobitz type I (Wenckebach) AV block there is progressive delay in A-V conduction before a single atrial beat fails to conduct. Mobitz type I AV block is generally caused by factors similar to those causing first degree A-V block; it is usually well tolerated, and rarely causes symptomatic bradycardia. Mobitz Type II AV block is recognized by the intermittent failure of atrioventricular conduction, without an associated prolongation of the P-R interval. There is often a fixed ratio of atrial to ventricular depolarizations, although this ratio may vary over time. Asymptomatic patients with isolated Mobitz Type II AV block do not require a permanent pacemaker, but should receive close follow-up.

Third-degree (Complete) Atrioventricular Block

Third-degree (complete) atrioventricular (AV) block is defined by the absence of conduction of atrial impulses to the ventricles. The ventricular rhythm may arise from the AV node or His bundle (junctional escape rhythm), in which case there is usually a narrow QRS complex. Alternatively, the ventricular rhythm may arise from the ventricles, resulting in a wide QRS complex. The ventricular rate is related to the origin of the escape rhythm, with AV junctional escape rhythms generally being faster than idioventricular rhythms.

Congenital complete heart block is frequently recognized in utero. It is estimated to occur in 1 of 20,000 live

P.707

births. In approximately 50% of infants with congenital heart block, there is an associated cardiovascular malformation (e.g., l-transposition of the great arteries, heterotaxy syndrome, endocardial cushion defect). In the absence of structural heart disease, the heart block is usually related to maternal autoantibodies (anti-Ro and/or anti-La) that cross the placenta and interact with the developing conduction system ([114](#)). These antibodies are associated with maternal connective tissue disease, particularly lupus erythematosus and Sjögren syndrome. In newborns with heart block and no structural cardiac abnormalities, testing of their mothers for these antibodies is indicated because they may have no signs or symptoms of connective tissue disease.

Occasionally newborns present with second-degree AV block and later progress to complete heart block. Therefore, those infants with persistent second-degree

heart block (especially Mobitz type II) should undergo echocardiography to look for structural heart disease, and their mothers should be tested for these antibodies. Rarely myocarditis and fibrosis of the atrioventricular node or His bundle has been implicated as the cause of neonatal heart block. Complete heart block may occur as a complication of cardiac surgery, particularly in the correction of l-transposition, endocardial cushion defects, tetralogy of Fallot, and ventricular septal defects.

Infants with congenital complete heart block generally have a narrow, junctional, escape rhythm between 30 and 110 beats/min. The ventricular rate tends to decrease with increasing age. The stroke volume increases to compensate for the low ventricular rate, to maintain an adequate cardiac output. Examination usually reveals cardiac enlargement from an increased left ventricular end-diastolic volume, and a systolic ejection murmur and apical mid-diastolic rumble from increased stroke flow.

Most infants with isolated congenital complete heart block without hemodynamically significant cardiac malformation often tolerate the bradycardia well, without symptoms, with normal growth and development, and do not require immediate intervention. Symptoms are usually related to the severity of the associated cardiovascular malformation and the degree of bradycardia. Less often, an infant or fetus with isolated complete heart block develops congestive heart failure or hydrops and some do not survive ([115](#)).

Patients with syncope or near syncope (Stokes-Adams attacks), congestive heart failure, or postsurgical block require early initiation of permanent ventricular pacing. Medical therapy with isoproterenol or with transcutaneous or transvenous cardiac pacing is helpful in the acute situation, prior to surgery. The timing of pacemaker implantation in other patients is more controversial. Criteria used to select patients for permanent pacing in infants have included: awake, resting ventricular rates less than 50 beats/min; awake, resting atrial rates greater than 140 beats/min; wide QRS escape rhythms; prolonged QT intervals; frequent, complex ventricular ectopy; or ventricular tachycardia ([116](#)).

Chapter 34

Preoperative and Postoperative Care of the Infant with Critical Congenital Heart Disease

John M. Costello

Wayne H. Franklin

INTRODUCTION

The contemporary strategy of early, complete repair for congenital heart defects originated in the 1970s, as evidenced by the first report in 1976 of complete anatomic correction of d-transposition of the great arteries (d-TGA) with ventricular septal defect (VSD) in early infancy (1). Aided by advances in surgical technique and equipment, myocardial protection, cardiac anesthesia and perioperative care, the strategy of early primary repair is now applied to many other complex congenital heart lesions, such as tetralogy of Fallot and truncus arteriosus (2,3). Furthermore, infants with certain lesions that were considered before the 1980s to be inoperable, such as hypoplastic left heart syndrome (HLHS), currently undergo staged surgical palliation with constantly improving outcomes (4). The first stage of surgical palliation for infants with single ventricle physiology usually must be performed in the neonatal period to minimize early morbidity and mortality, and to optimize the cardiovascular physiology for the subsequent Fontan operation. Early repair or palliation (for single ventricle lesions) benefits infants because prolonged preoperative periods of cyanosis (See Color Plate) and heart failure, and the many associated complications are minimized (5,6,7). These potential associated complications include impairment of cognitive function as a result of chronic hypoxemia, central nervous system embolic events, and the development of pulmonary vascular obstructive disease. Postoperative complications including pulmonary hypertensive crises are also reduced using a strategy of early surgical intervention (8). The incidence of vascular complications and infection related to central lines in infants requiring prolonged hospitalization prior to cardiac repair or palliation will also be minimized.

As a result of this early intervention strategy, approximately one-third of all patients with congenital heart defects undergo primary repair or palliation in early infancy. Due to the immaturity of many organ systems, these neonates possess limited physiologic reserve. They have limited ability to increase stroke volume, limited functional residual capacity in the lung, limited fat and carbohydrate reserves, and a limited ability to regulate temperature. Drug metabolism is altered by hepatic and renal immaturity, and total body water content. All of these factors complicate the care of infants in the perioperative period, and some have prolonged intensive care unit (ICU) stays, presenting a challenge for physicians involved with their management.

A variety of pediatric personnel with expertise in pediatric cardiology are involved in the day-to-day management of these patients. These personnel include neonatologists, intensivists, cardiologists, cardiac surgeons, anesthesiologists, nurses, and respiratory therapists. Because of the complexity inherent to this field, and to ensure an optimal outcome for each patient, seamless communication of pertinent anatomic, pathophysiologic, and operational/interventional details is required across all specialties.

This chapter will complement Chapter 33 by providing an overview of the key issues, concepts, and strategies pertaining to the care of infants with critical congenital heart

P.711

disease. We have allowed some overlap of information between chapters in the interest of clarity. The expected presentation and clinical course of specific congenital heart lesions will be discussed, and the general principles that are widely applied to patient management will be reviewed. This chapter will not provide a comprehensive description of every congenital heart defect and associated variants that may present in infancy. The reader must appropriately apply the concepts and principles discussed in the following pages to each unique patient. The first section will cover general preoperative issues, and the presentation, physiology and management of common types of critical congenital heart disease. The second section will provide an overview of cardiopulmonary bypass (CPB) and its sequelae, followed by a lesion specific discussion of operative intervention, postoperative physiology and common complications.

PREOPERATIVE CARE

Fetal Diagnosis

Fetal echocardiography plays an important role in the management of critical congenital heart disease for a variety of reasons (9). The identification of severe congenital heart disease during the second trimester allows time for family counseling. Fetuses that are likely to require surgical or transcatheter intervention in the neonatal period should ideally be delivered at an institution with a level II or III nursery that is located at or in close proximity to a tertiary care pediatric cardiology center. In the absence of nonimmune hydrops fetalis, fetuses with known critical congenital heart disease should be delivered at term to minimize the potential complications of prematurity, such as respiratory distress syndrome, intraventricular hemorrhage and necrotizing enterocolitis (NEC). As discussed below, infants with unrecognized critical congenital heart disease may develop severe cyanosis (See Color Plate), shock, myocardial dysfunction and end organ damage. Information from the fetal echocardiogram thus guides planning for initial stabilization upon delivery, such as the need for a prostaglandin E₁ (PGE₁) infusion. Prenatal diagnosis is associated with reduced preoperative morbidity and mortality in large series of neonates with HLHS and TGA (10,11,12,13). Management strategies may be developed in advance for the uncommon patient with congenital heart disease who may become critically ill in the first few minutes of life, such as some neonates with absent pulmonary valve syndrome, or HLHS with an intact atrial septum. The impact of in utero diagnosis of critical congenital heart disease on postoperative mortality is controversial. Some centers have reported lower postoperative mortality in patients with a fetal diagnosis of HLHS or d-TGA, whereas others found no such impact (12,13,14,15,16).

TABLE 34-1 RISK FACTORS FOR CONGENITAL HEART DISEASE THAT WARRANT FETAL ECHOCARDIOGRAPHY (SEE ALSO TABLE 33-6)

Maternal Risk Factors	Fetal Risk Factors
1. Family history of congenital heart disease	1. Extracardiac anomalies
2. Maternal disease (lupus, diabetes mellitus)	2. Chromosomal anomalies
3. Environmental (alcohol, certain viruses, medications)	3. Arrhythmia
	4. Abnormal fetal growth
	5. Fetal distress
	6. Obstetrician's suspicion of CHD from screening US

CHD, congenital heart disease; US, ultrasound.

Known risk factors for congenital heart disease that warrant referral to a pediatric cardiologist for fetal echocardiography are listed in Table 34-1 (17). Even if these screening guidelines are followed, the majority of patients with congenital heart disease will not be detected until after birth. Fetal echocardiography has several known limitations, most notably sub-optimal windows in mothers with large body habitus, and difficulty with precise imaging of extracardiac vessels. Two serious congenital heart lesions that may not be always appreciated with fetal echocardiography deserve comment. Isolated coarctation of the aorta may be difficult to definitively diagnose or exclude in utero as a result of the obligatory presence of the ductus arteriosus (18). Total anomalous pulmonary venous return may also be unrecognized. Thus, any diagnosis of fetal congenital heart disease must be confirmed, and the anatomic details clarified, as soon as possible after birth with a transthoracic echocardiogram.

Routine screening fetal ultrasound studies, which are interpreted by obstetricians, are usually limited to the demonstration of a heart with four chambers. Doppler assessment of blood flow patterns and valvar function is not usually performed, and data regarding longitudinal growth of the ventricular chamber sizes are not available when a single study is performed in the second trimester. Thus, a history of a normal fetal ultrasound does not exclude the possibility of critical congenital heart disease.

Transitional Circulation

An appreciation of the fetal-placental circulation, and the normal transition from fetal to newborn circulation, is required to understand the timing and presentation of symptoms in the neonate with critical heart disease (19).

In the placenta, gas, nutrient, and waste exchange occur between the fetal and maternal circulations. Oxygenated blood then returns from the placenta to the fetus through the umbilical vein and partially bypasses the liver, via the ductus venosus, into the inferior vena cava. The oxygenated blood is preferentially shunted through the foramen ovale to the left atrium (20). The oxygen-rich blood then enters the left ventricle, from where it is pumped out the aorta to supply the coronary circulation and the brain. Deoxygenated blood from the superior vena cava and distal inferior vena cava preferentially enters the right ventricle, and is then pumped to the pulmonary artery. This preferential blood flow phenomenon is known as streaming. Due to the high pulmonary vascular resistance *in utero*, the majority of the deoxygenated pulmonary artery blood bypasses the lungs, and flows through the ductus arteriosus into the descending aorta, supplying the lower body and placenta.

An elegant series of events occur when the umbilical cord is clamped immediately after birth. The ductus venosus functionally closes in large part as a result of decreased flow from the placenta (21). The low resistance placental circulation is gone and thus systemic vascular resistance rises, although pulmonary vascular resistance falls as a result of mechanical expansion of the lungs with respiration and higher oxygen tension (22,23). Blood ejected from the right ventricle now perfuses the lungs rather than entering the ductus arteriosus, and the increased blood returning to the left atrium leads to functional closure of the foramen ovale. The increased oxygen tension also contributes to functional closure of the ductus arteriosus.

When the aforementioned events, in particular the fall in pulmonary vascular resistance and closure of the ductus arteriosus, occur in the setting of critical congenital heart disease, a physiologic state of either inadequate systemic or pulmonary blood flow exists which, if unrecognized, may progress to multi-organ system failure and death.

Presentation of Critical Congenital Heart Disease

Despite the broad spectrum of congenital heart lesions, neonates with critical congenital heart disease undetected in utero present in a limited number of ways: with cyanosis (inadequate pulmonary blood flow), shock (inadequate systemic blood flow) or some combination of these physiologic states. Older neonates and infants with significant left to right shunting at the ventricular or great artery level may present with congestive heart failure. Critical congenital heart disease may be detected prior to the onset of symptoms as a result of abnormal findings on cardiovascular examination or during echocardiographic screening performed in neonates with known chromosomal abnormalities or noncardiac congenital malformations.

Critical coarctation of the aorta, critical aortic valve stenosis, and HLHS are frequently encountered lesions that present in the neonatal period with symptomatic obstruction of the left ventricular outflow tract. In each case, constriction or closure of the ductus arteriosus leads to inadequate systemic blood flow. These patients will typically present within the first week or two of life with feeding difficulties, tachypnea, poor perfusion and metabolic acidosis, a constellation of findings that may be mistaken for septic shock. Due to low systemic cardiac output, findings such as pathologic heart murmurs may not be present and accurate four-extremity blood pressure measurements may be difficult to obtain. Diminished or absent pulses in the lower extremities and an increased right ventricular impulse are more reliable findings on physical examination, and a high index of suspicion is required to make a timely diagnosis.

Critical pulmonary valve stenosis, severe tetralogy of Fallot, and pulmonary atresia are examples of lesions with right ventricular outflow tract obstruction that manifest with progressive cyanosis in the newborn period as constriction of the ductus arteriosus limits pulmonary blood flow.

Lesions with complete intracardiac mixing of the systemic venous and pulmonary venous circulations, such as tricuspid atresia, truncus arteriosus, or complex single ventricles usually have variable degrees of obstruction to either the systemic or pulmonary circulations, depending upon the anatomic details of the individual lesion. Less commonly, they have no obstruction to either systemic or pulmonary blood flow, leading to mild hypoxemia (less commonly clinical cyanosis) but substantial heart failure that presents later in the neonatal period or during early infancy.

d-TGA is a common cyanotic lesion with the unique physiology of systemic and pulmonary circulations that run in parallel. Infants with d-TGA, an intact ventricular septum, and no significant outflow tract obstruction usually present with cyanosis soon after birth. Those with a significant VSD have less desaturation and can present later with congestive heart failure.

The neonate with nonimmune hydrops fetalis may have an underlying cardiac problem. The differential diagnosis includes serious congenital heart disease (particularly with significant atrioventricular valve regurgitation), obstructive cardiac tumors, congenital myocarditis, tachyarrhythmias and bradycardia.

Initial Evaluation and Stabilization of the Neonate with Suspected Congenital Heart Disease

A careful history and cardiovascular examination will often reveal abnormal findings in the infant with critical congenital heart disease, even before the onset of symptoms. Review of maternal records may identify a known risk factor for congenital heart disease (Table 34-1) (17). The course of labor

P.713

should be reviewed, and factors that suggest acute infection, respiratory distress syndrome, or meconium aspiration should be noted, as they may indicate a primary respiratory cause for hypoxemia. The physical examination focuses on the detection of dysmorphic features, cyanosis, an abnormal precordium, abnormal femoral and peripheral pulses, and/or a pathologic heart murmur. Measurement of blood pressure in all four extremities is useful if an arm-leg gradient of greater than 10 mm Hg is detected, but in the setting of a large patent ductus arteriosus, the pressures may be equal despite the presence of a critical aortic coarctation or interrupted aortic arch. Although respiratory distress may be present in neonates with critical congenital heart disease or pulmonary problems, those with heart disease typically have a shallow rapid respiratory pattern ("quiet tachypnea"), as opposed to the more labored breathing pattern of neonates with a primary pulmonary process.

The term differential cyanosis refers to a condition in which the lower body is visibly more cyanotic than the upper body as a result of right to left shunting at the ductal level. The presence of differential cyanosis, occasionally seen with severe pulmonary hypertension, may also be indicative of aortic arch obstruction or coarctation of the aorta. In neonates with d-TGA, reverse differential cyanosis may be present if aortic arch obstruction or severe pulmonary hypertension also exists. In such patients, oxygenated blood is ejected from the left ventricle to the pulmonary artery, and then passes through the patent ductus arteriosus to the descending aorta.

In newborns that present with cyanosis, a right radial arterial blood gas analysis on room air and 100% inspired oxygen (the "hyperoxia test") is useful for discriminating those with cyanotic heart disease from those with pulmonary disease. The partial pressure of carbon dioxide ($p\text{CO}_2$) is typically mildly decreased in newborns with cardiac disease and mildly elevated in those with pulmonary disease. The arterial oxygen pressure (PaO_2) is often between 25 to 40 mm Hg on room air in both patient groups. In 100% FiO_2 , the PaO_2 will usually rise to more than 100 mm Hg in patients with pulmonary disease, provided that significant pulmonary artery hypertension is not present. The PaO_2 will remain unchanged or only increase slightly in most neonates with cyanotic heart disease. There are limitations to the hyperoxia test. Patients with left sided obstructive lesions (e. g., HLHS, critical coarctation of the aorta, critical aortic valve stenosis, interrupted aortic arch) may have a high PaO_2 (>60 mm Hg) in any extremity or a very high PaO_2 (>150 mm Hg) in the right arm with certain anatomic variants. Pulse oximetry should not be used as a substitute for arterial blood gas analysis when performing the hyperoxia test. For example, a neonate receiving 100% fraction of inspired oxygen (FiO_2) may have a pulse oximetry reading of 100%, with a PaO_2 of 80 mm Hg (suggestive of cyanotic heart disease), or a PaO_2 more than 100 mm Hg (suggestive of pulmonary disease). Potential complications exist when performing the hyperoxia test. For example, if the test is continued for a prolonged period of time in neonates with left sided obstructive lesions, pulmonary vascular resistance may drop further, and the ductus arteriosus may begin to close, leading to clinical deterioration.

Interpretation of a chest radiograph (CXR) and 12-lead electrocardiogram (ECG) may provide insight to the underlying cardiac diagnosis in cyanotic newborns. For example, cyanotic newborns with normal heart size, normal to increased pulmonary arterial markings on CXR, and a normal ECG may have TGA. Cyanotic newborns with normal heart size and decreased pulmonary blood flow on CXR are stratified by the ECG findings: those with right axis deviation (90° - 180°) on ECG may have tetralogy of Fallot; those with a normal adult axis (10° - 90°) on ECG may have pulmonary atresia with an intact ventricular septum; and those with an ECG with left axis deviation (0° to -90°) and left ventricular hypertrophy may have tricuspid atresia. Infants with a normal to small heart size and increased pulmonary vascular markings on CXR may have total anomalous pulmonary venous return, and those with a large heart with increased pulmonary vascular markings may have truncus arteriosus, or a complex single ventricle lesion with unobstructed pulmonary blood flow. Neonates with a very large heart and decreased pulmonary arterial markings may have Ebstein's anomaly of the tricuspid valve.

If the aforementioned evaluation is consistent with the presence of critical congenital heart disease, it is reasonable to stabilize the infant, including the initiation of a PGE₁ infusion in some cases, and then arrange transport to a pediatric cardiology center in which the initial echocardiogram can be performed. A PGE₁ infusion should be initiated in neonates who present with shock, cyanosis with a minimal increase in PaO₂ during the hyperoxia test, or a fetal diagnosis of ductal dependent congenital heart disease. An echocardiogram may be performed at the presenting institution if the presence of critical congenital heart disease is in doubt, or to guide initial stabilization if the transport time will be prolonged. The echocardiographer and the sonographer must have experience with congenital heart lesions, otherwise false negative and false positive evaluations may occur (24).

The introduction of prostaglandin infusions to maintain ductal patency in the late 1970s represented a major advance for infants with critical congenital heart disease (25,26). While receiving PGE₁, infants can be safely transported over long distances to congenital heart centers. Cardiac surgery can be postponed while infections are treated and other major congenital anomalies identified. Patients who present in shock can be medically managed for several days, allowing time for recovery of end-organ function prior to surgery. Detailed cardiac diagnostic information can be obtained using echocardiography, cardiac catheterization, spiral computed tomography (CT), magnetic resonance imaging (MRI), or electron beam tomography (EBT) to allow optimal planning for intervention.

PGE₁ can be administered through a peripheral intravenous line, although many practitioners prefer to use central venous access to ensure uninterrupted medication delivery. A wide range of dosing of PGE₁ is used depending on the clinical state of the patient. Generally a PGE₁ infusion

P.714

of 0.1 mcg/kg/min is used when the ductus arteriosus is severely constricted or functionally closed and a state of shock or severe cyanosis exists. Lower doses (0.01- 0.05 mcg/kg/min) will maintain ductal patency in neonates with presumed ductal dependent systemic or pulmonary circulation who are otherwise stable (27).

The most troublesome side effect of PGE₁ infusion is apnea, which occurs in approximately one-third of neonates (27,28). Tracheal intubation and mechanical ventilation are usually indicated when PGE₁ is started for neonates who present with severe cyanosis or shock and/or require transfer to another institution. Lower doses of PGE₁ are associated with fewer side effects, particularly apnea (27,29). Patients who are stable upon presentation and are started on a low dose of PGE₁ may be less likely to develop apnea, and their respiratory status may be observed without mechanical ventilation. This strategy may be used in patients who require transfer to another institution, provided that members of the transport team are experienced and prepared to intubate the patient's trachea should the need arise. Preliminary data suggest that aminophylline may be prescribed to minimize the occurrence of apnea in neonates requiring PGE₁ infusion (30). PGE₁ is a potent vasodilator, and hypotension may occur following the initiation of the drug, particularly if narcotics are also administered to facilitate procedures. This problem should be anticipated, and the hypotension usually resolves with a dose reduction of PGE₁ and volume administration. Other common side effects are listed in Table 34-2 (27,28). Although unusual, clinical deterioration may occur following the initiation of a PGE₁ infusion, and in these instances, obstruction to pulmonary venous return (e.g., obstructed total anomalous pulmonary venous return) or left atrial egress (e.g., TGA with intact ventricular septum and a restrictive atrial communication) may be present. These infants require emergent surgical or catheter intervention. Some neonates have congenital absence of the ductus arteriosus (such as those with tetralogy of Fallot with absent pulmonary valve syndrome) or some infants with pulmonary atresia, ventricular septal defect, and major aortopulmonary collateral arteries. A PGE₁ infusion in these patients may worsen cyanosis by lowering systemic vascular resistance and thereby decreasing pulmonary blood flow.

When endotracheal intubation is indicated for a neonate with critical congenital heart disease, the use of medications should be considered to blunt the stress and vagal responses to laryngoscopy, decrease oxygen consumption and thus improve oxygen delivery, and provide pharmacologic paralysis to facilitate the procedure. The choice of specific medications depends on the clinical scenario and the airway skills of the clinician. As mechanical ventilation is initiated, care must be taken in many instances to avoid excessive use of supplemental oxygen and hyperventilation. These maneuvers may lower pulmonary vascular resistance, thereby increasing the ratio of pulmonary to systemic blood flow (Q_p/Q_s), and "stealing" blood flow from the systemic circulation. This is discussed in greater detail in the HLHS section below.

TABLE 34-2 SIDE EFFECTS OF PROSTAGLANDIN E₁ INFUSION

Respiratory	respiratory depression, apnea
Cardiovascular	hypotension, tachycardia
Central nervous system	fever, seizures
Endocrine/metabolic	hypocalcemia, hypoglycemia, cortical hyperostosis*
Gastrointestinal	diarrhea, gastric outlet obstruction*
Hematologic	inhibition of platelet aggregation
Dermatologic	flushing, harlequin rash

* Seen with long-term use.

Stable intravenous access is required for all infants with critical congenital heart disease. The need for arterial and central venous access should be determined on a case-by case basis, based upon the heart defect, clinical presentation and anticipated preoperative course. Central access may be needed to allow for medication delivery, frequent blood sampling, and the administration of parenteral nutrition. The most accessible vessels in the newborn are the umbilical arteries and veins. The use of umbilical vessels for preoperative stabilization leaves other vessels available for future cardiac catheterizations and surgical procedures. If umbilical lines cannot be placed, the radial or femoral arteries and the femoral veins may be accessed. Some clinicians prefer to avoid placing central venous catheters in the internal jugular or subclavian veins in patients with single ventricle physiology to prevent scarring and clot formation, which may impede venous return following the bi-directional Glenn/hemi-Fontan and Fontan operations.

Adequate cardiac output and oxygen delivery usually exist in infants with critical congenital heart disease following initial stabilization and infusion of PGE₁. Infants who demonstrate signs of inadequate cardiac output may benefit from inotropic infusions, but should be critically reassessed to ensure that the PGE₁ is being delivered correctly, that appropriate oxygenation and ventilation strategies are being employed to prevent pulmonary over-circulation, and that noncardiac etiologies for shock are not present, such as pneumothorax or sepsis. Fetal-maternal hemorrhage, twin-twin transfusion, and blood loss at delivery from delayed cord clamping are examples of perinatal causes of anemia that may necessitate transfusion of packed red blood cells soon after delivery. Most patients with ductal dependent congenital heart disease require a hemoglobin level of 13 to

P.715

15 gm/dL. Attention also needs to be given to acid-base status, and blood glucose and calcium levels.

Bacterial pneumonia and sepsis are often considered when an infant presents with cyanosis and shock, and empiric antibiotics may be prescribed before a diagnosis of critical congenital heart disease is confirmed. If no source of bacterial infection is identified, the antibiotics may be discontinued after a 48-hour period. Although it has been suggested that the use of PGE₁ increases the risk of bacterial infection, there is no published evidence to support this concept.

Neonates with critical congenital heart disease require transport to congenital heart centers for further evaluation and intervention. Experienced pediatric transport teams are used when available, and close communication is required with the intensivist and pediatric cardiologist at the congenital heart center throughout the transport process. During transport, care must be taken to maintain a normal patient temperature as hypothermia will increase systemic vascular resistance and may be poorly tolerated. The transport team members must understand that normal ventilation and the avoidance of excessive supplemental oxygen are important to maintain a balanced circulation in many infants with ductal dependent systemic or pulmonary blood flow.

Evaluation at the Congenital Heart Center

Upon arrival to the tertiary care center, the intensivist and nursing staff should obtain a detailed report from the transport team. Historical features that are useful to direct the diagnostic evaluation and initial management include the results of fetal echocardiogram(s), complications of the pregnancy, family history, estimated

gestational age of the fetus, severity of cyanosis or shock prior to initial resuscitation, presence of risk factors for infection, and suspected noncardiac congenital anomalies.

A detailed physical examination includes a review of recent and current vital signs. Heart rates are usually within the normal range for age. Four-extremity blood measurements should be obtained. Pulse oximetry results are interpreted in the context of the patient's physiology. The presence of dysmorphic facial features may suggest a specific genetic syndrome. The cardiac examination begins with inspection and palpation of the precordium. An increased right ventricular impulse is often present with significant left ventricular outflow tract obstruction and/or pulmonary hypertension. Auscultation is performed with attention to splitting and quality of the second heart sound, systolic ejection clicks, and the presence of pathologic systolic or diastolic murmurs. The span of the liver is determined, and the quality of the peripheral pulses and perfusion are noted.

The ECG and CXR are reviewed with attention to features that may suggest an underlying cardiac diagnosis as described above. The CXR should also be reviewed to ensure that any tubes or lines placed prior to transport have not migrated. Cardiopulmonary instability in the infant with critical congenital heart disease is often as a result of noncardiac issues, such as respiratory distress syndrome, tension pneumothorax, or endotracheal tube plugging or malposition.

Even if an echocardiogram has been performed at the referring institution, a complete echocardiogram is obtained upon arrival to the congenital heart center to confirm the diagnosis and clarify anatomic and physiologic details. Complete diagnostic information is obtained in the vast majority of patients with critical congenital heart disease using transthoracic echocardiogram, eliminating the need for diagnostic cardiac catheterization (31,32). Occasionally a critically ill infant with congenital heart disease will not tolerate a prolonged echocardiogram, as a result of temperature instability related to exposure, or hypotension related to abdominal compression during subcostal imaging.

Limited indications exist for diagnostic cardiac catheterization in the current era. For example, infants with pulmonary atresia, VSD and major aortopulmonary collateral arteries (MAPCAs) usually require catheterization to define all sources of pulmonary arterial blood flow. Coronary anatomy can usually be clarified by echocardiography, but occasionally angiography is required, as is the case in some infants with tetralogy of Fallot, pulmonary atresia with intact ventricular septum, or TGA (33). Hemodynamic data, such as pulmonary vascular resistance, may need to be obtained by cardiac catheterization in selected older infants prior to a definitive procedure. Cardiac catheterization is more commonly indicated to perform interventional procedures. For example, neonates with TGA and intact ventricular septum may require enlargement of the atrial communication, and those with HLHS and intact atrial septum require emergent creation of an adequate atrial septal defect (ASD) to allow egress of pulmonary venous blood from the left atrium into the right atrium (34,35). Balloon valvuloplasty of critical aortic or pulmonary valve stenosis is commonly performed in many centers. Cardiac MRI, spiral CT, and electron beam tomography are evolving tools that are currently available in selected centers and are most useful for clarifying anatomy of extracardiac vessels (36,37).

Evaluation of other organ systems is indicated in infants with critical congenital heart disease prior to intervention. Basic laboratory studies are obtained to evaluate acid-base status, oxygenation and ventilation, and the hepatic, renal and hematologic systems. Recovery of end-organ function in infants who present in shock is to be expected in nearly all cases following appropriate resuscitation and stabilization. Infants who are premature or who present with severe cyanosis or shock should have a head ultrasound performed to evaluate for intracranial hemorrhage. If not clear by echocardiography, an abdominal ultrasound is indicated in patients with heart disease associated with heterotaxy syndrome to determine the sidedness of the liver and spleen. An upper gastrointestinal series may be needed in such infants to evaluate for malrotation. Any suspected hematologic issues, such as thrombocytopenia or a bleeding diathesis, should be thoroughly evaluated prior to intervention. Other major birth defects may be seen in up

P.716

to 25% of patients with significant congenital heart disease. For example, infants with conotruncal heart defects, such as tetralogy of Fallot, pulmonary atresia with VSD, interrupted aortic arch, and truncus arteriosus have an increased risk compared with the general population of having an associated oral cleft, omphalocele, trachoesophageal fistula, or imperforate anus (38). There is an increased incidence of renal anomalies in infants with congenital heart disease who have other major congenital anomalies, and a screening renal ultrasound may be indicated in this subset of patients (39).

A chromosomal abnormality or easily definable genetic syndrome may be identified in approximately 20% of infants with congenital heart disease. Table 34-3 lists selected common chromosomal abnormalities and genetic syndromes, and the congenital heart lesions with which they are associated (40,41,42).

Preoperative Supportive Care: General Principles

Cardiopulmonary Management

Infants with ductal dependent congenital heart disease require a “balanced” circulation to achieve adequate systemic and pulmonary blood flow. Those who present with severe cyanosis or shock, or require prolonged interhospital transport are tracheally intubated and mechanical ventilation is provided. Great care must be taken throughout the preoperative period to ensure that appropriate ventilation and oxygenation strategies are used to prevent an iatrogenic imbalance between systemic and pulmonary blood flow. In particular, in patients with ductal dependent systemic blood flow (e.g., HLHS or interrupted aortic arch), hyperventilation and provision of supplemental oxygen will decrease pulmonary vascular resistance, thereby promoting increased pulmonary to systemic flow ratio (Q_p/Q_s), and “steal” from the systemic and coronary circulations. Such patients will have inappropriately high systemic oxygen saturations (greater than 90%), poor systemic perfusion and are at risk of developing myocardial dysfunction as a result of volume overload and coronary ischemia, renal insufficiency, and/or NEC. Interventions that may be employed to increase pulmonary vascular resistance and improve the balance between systemic and pulmonary circulations, including subambient FiO_2 and hypoventilation, are discussed below in the section on preoperative management of HLHS. Neonates with left ventricular outflow tract obstruction who are stable at presentation may be allowed to spontaneously breathe while awaiting surgical intervention, with close monitoring of their cardiopulmonary status. These neonates will typically have relatively high systemic oxygen saturations (greater than 90%) and “quiet tachypnea,” but will maintain adequate peripheral pulses, urine output, and low

P.717

lactate levels. Diuretics and low dose inotropic support are occasionally needed to alleviate pulmonary edema and to support the volume-loaded ventricular myocardium. In neonates with right ventricular outflow tract obstruction, the ductus arteriosus is often somewhat stenotic and takes a tortuous course from the aorta to the pulmonary artery, related to the in utero blood flow pattern, which typically will prevent torrential pulmonary blood flow. Thus marked pulmonary overcirculation is less of a clinical concern in ductal-dependent neonates with right ventricular outflow tract obstruction.

TABLE 34-3 SELECTED COMMON CHROMOSOMAL ABNORMALITIES AND GENETIC SYNDROMES ASSOCIATED WITH CONGENITAL HEART DISEASE (SEE ALSO TABLE 33-5)

Patient Group	Incidence of CHD	Most Common Lesions		
		1	2	3
Trisomy 21 (Down S.)	40-50%	AVSD	VSD	ASD
Trisomy 18 (Edwards S.)	90%	VSD	PDA	ASD
Trisomy 13	80%	VSD	PDA	ASD
4p- (Wolf-Hirschhorn S.)	50%	VSD	PDA	ASD
5p- (Cri-du-Chat S.)	30%	variable		
Monosomy X (Turner S.)	20%	CoA	BAV	AS

AR, aortic regurgitation; AS, aortic valve stenosis; AAO, ascending aorta; ASD, atrial septal defect; AVSD, atrioventricular septal defect; BAV, bicuspid aortic valve; CHARGE, acronym for coloboma, heart defects, atresia of the posterior choanae, retarded growth/development, genital hypoplasia, ear anomalies/deafness; CoA, coarctation of aorta; HCM, hypertrophic cardiomyopathy; IAA, interrupted aortic arch; MVP, mitral valve prolapse; MR, mitral regurgitation; PDA, patent ductus arteriosus; PPS, peripheral pulmonary stenosis; PS, pulmonary valve stenosis; S, syndrome; TOF, tetralogy of Fallot; VATER/VACTERL, acronyms for vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula, esophageal atresia, renal defects, limb defects; VSD, ventricular septal defect.

Inotropic support is occasionally necessary for neonates with congenital heart disease, particularly those with volume loaded single ventricles, but escalating inotropic or vasopressor requirements often signify a noncardiac problem or inadequate systemic cardiac output as a result of Qp/Qs imbalance. Inotropic agents are discussed in the postoperative section on low cardiac output.

Prematurity

The premature infant with critical congenital heart disease presents a significant challenge. Problems inherent to prematurity, including temperature instability, decreased nutritional reserve, intraventricular hemorrhage, respiratory distress syndrome, infection, and NEC, may develop during the pre- and postoperative course. In preterm infants with critical congenital heart disease, a management strategy of prolonged medical therapy to achieve weight gain prior to surgery is fraught with complications related to infection, heart failure and feeding intolerance (43,44). Advances in cardiopulmonary bypass techniques and miniaturization of surgical equipment allow for the safe conduct of open-heart surgery in these patients. Several reports depict the recent experience with palliative or definitive surgical intervention in premature infants with critical congenital heart disease. Reddy and associates reported the University of California at San Francisco experience with complete (two-ventricle) repair in 102 infants with significant congenital heart disease weighing less than 2,500 grams. These investigators found higher preoperative morbidity in the group of patients having delayed repair. The early and late mortalities were 10 and 8%, respectively, and no patient had postbypass intracranial hemorrhage (44). Investigators from the same center reported a series of 20 very low birth weight (LBW) (< 1,500 gm) infants with symptomatic congenital heart disease who underwent complete repair with only two deaths (10%) (45). Rossi and associates reported a series of infants weighing less than 2 kg, 73% of which were born prematurely. Hospital survival was 83%, and 24% of the patients had neurologic complications (46). Bacha and associates, in a study of 18 infants weighing less than 2 kg with coarctation of the aorta, found that repair can be accomplished with low operative mortality, but the residual or recurrent coarctation rate was 44% (47). Results for single ventricle palliation are less encouraging. The reported mortality for infants weighing less than 2.5 kg at the time of Norwood operation for HLHS or other single ventricle variants is 45% to 51% (48,49). Thus, although prematurity and LBW complicate the care of infants with significant heart disease, early intervention, including corrective surgery, can be performed with acceptable morbidity and mortality.

Nutrition

Although the enteral route is the preferred method for providing nutrition to infants in the intensive care unit, those with critical congenital heart disease awaiting intervention often have several pathophysiologic features that must be considered prior to initiation of enteral feedings. The combination of myocardial dysfunction, cyanosis and falling pulmonary vascular resistance, the later allowing increased diastolic runoff through the ductus arteriosus, may result in inadequate mesenteric oxygen delivery. In one large, retrospective study, approximately 3% of neonates admitted to a busy cardiac intensive care unit developed NEC (50). Independent risk factors for developing NEC were prematurity, a history of resuscitation from severe cyanosis or shock, HLHS, or the presence of diastolic runoff through the ductus arteriosus or other aorto-pulmonary connections (50). In part as a result of the absence of randomized studies, the use of enteral nutrition in infants with ductal-dependent congenital heart disease remains controversial and clinical practice varies widely. The risk-benefit ratio for providing enteral nutrition must be individually determined for each patient. One approach is to avoid

enteral feeding in those infants who have one or more of the aforementioned risk factors. It is also reasonable to consider enteral feedings in those infants with an acceptable diastolic blood pressure despite the presence of a patent ductus arteriosus, provided that additional risk factors are not present.

Congenital Complete Heart Block

Congenital complete heart block may be associated with structural heart disease including atrioventricular canal defects and complex lesions with ventricular inversion. In neonates with normal intracardiac anatomy, there is a high incidence of maternal autoimmune disease, particularly systemic lupus erythematosus (51). Congenital complete heart block is diagnosed electrocardiographically when atrioventricular dissociation is present with an atrial rate that is appropriate for age and a slow ventricular rate. The diagnosis may be made in utero by fetal echocardiography and may be associated with hydrops fetalis. Dual chamber epicardial pacemaker placement is indicated when third degree congenital atrioventricular heart block is associated with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction. A pacemaker is also indicated in an infant with a ventricular rate less than 50 to 55 beats per minute, or with congenital heart disease and a ventricular rate less than 70 beats per minute (52).

P.718

PREOPERATIVE PHYSIOLOGY AND MANAGEMENT: SPECIFIC LESIONS

Right Ventricular Outflow Tract Obstruction

Critical Pulmonary Valve Stenosis

In neonates with critical pulmonary valve stenosis, the pulmonary valve leaflets are thickened and fused to a variable extent, and their mobility is decreased (Fig. 34-1, see also color plate). The pulmonary valve annulus is hypoplastic in severe cases. The pulmonary arteries are usually of normal size, but may be stenotic or dilated. The right ventricle is often hypertrophied and mildly hypoplastic. Significant tricuspid regurgitation, and a right to left atrial shunt are present (53). Infants with isolated critical pulmonary valve stenosis will develop significant cyanosis (See Color Plate) upon closure of the ductus arteriosus. Such infants are dependent on a PGE₁ infusion to maintain ductal patency for adequate pulmonary blood flow. Although open surgical valvotomy was routinely performed in the past to relieve right ventricular outflow tract obstruction, most of these infants are candidates for a balloon valvuloplasty in the cardiac catheterization laboratory. Balloon valvuloplasty is successful in approximately 60% to 80% of cases (53,54,55,56,57,58). Neonates who fail an attempted balloon valvuloplasty may have smaller right heart structures, and are referred for a surgical valvotomy +/- a systemic to pulmonary artery shunt (59,60).

Tetralogy of Fallot

Tetralogy of Fallot, the most common cyanotic congenital heart lesion, is comprised of an anterior malalignment VSD in a heart with two ventricles and aortic to mitral fibrous continuity. Anatomic details that need to be clarified at the time of diagnosis include the severity and location of right ventricular outflow tract obstruction, the pulmonary artery anatomy, the presence of additional VSDs, the sidedness of the aortic arch (rightward in 25%), and the coronary artery anatomy. The left coronary artery may arise from the right coronary artery and cross the right ventricular outflow tract in 5% of cases. Complete anatomic information is usually obtainable by transthoracic echocardiogram (33). If uncertainty exists about the coronary artery anatomy, some surgeons may request a cardiac catheterization, as great care must be taken not to injure the coronary vessels during right ventricular outflow tract reconstruction. Chromosome 22q11 deletion is present in 15% of patients with tetralogy of Fallot, and those with a right aortic arch are at higher risk (41).

Figure 34-1 Critical pulmonary valve stenosis. **A.** Two-dimensional echocardiogram from the parasternal long axis view demonstrating thickened and doming pulmonary valve leaflets. Note the poststenotic dilation of the main pulmonary artery. **B.** Application of color Doppler during ventricular systole demonstrates a turbulent flow jet originating at the pulmonary valve leaflets and extending into the main pulmonary artery. MPA, main pulmonary artery; PV, pulmonary valve; RVOT, right ventricular outflow tract. (See color plate)

In neonates with tetralogy of Fallot, a wide spectrum of presentation exists, depending in large part upon the degree of malalignment of the conal septum into the right ventricular outflow tract. Infants with a minimal degree of obstruction to pulmonary blood flow, commonly referred to as “pink tets,” are usually asymptomatic and fairly well oxygenated (systemic saturations > 85%) soon after birth. They are commonly observed in the hospital until the ductus arteriosus closes and then sent home to await surgical repair within the first 6 months of life. Occasionally a “pink tet” will mimic the pathophysiology of an infant with a large VSD and develop congestive heart failure within the first few months of life as pulmonary vascular resistance falls. More commonly these patients develop progressive right ventricular outflow tract obstruction and cyanosis. The exact timing of repair varies depending

P.719

upon several variables including the development of increasing cyanosis, hypercyanotic spells (“TET spells”), and institutional preference (2,61). Infants with tetralogy of Fallot and more severe right ventricular outflow tract obstruction or pulmonary atresia will develop excessive cyanosis (oxygen saturation < 75%-80%) upon closure of the ductus arteriosus. Such patients will require surgical intervention during the initial hospitalization. Either a complete repair or a systemic to pulmonary shunt is performed, depending on the details of the anatomy and surgeon preference (62).

Hypercyanotic episodes, or “TET spells,” are potentially life-threatening events notable for significant desaturation and irritability as a result of an acute decrease in pulmonary blood flow. The precise etiology of these spells is unclear but has been attributed to spasm of the infundibular conus, an imbalance between the systemic and pulmonary vascular resistances, increased systemic venous return, and/or tachycardia, all of which may lead to a progressive cycle of decreased pulmonary blood flow, increased cyanosis, and eventually metabolic acidosis. Although TOF spells can occur at any age, the incidence seems to increase after 4 to 6 months of age, which is one of the reasons that early complete repair before this age is commonly recommended. TET spells can be triggered by medical procedures including placement of intravenous catheters and cardiac catheterization. Infants with tetralogy of Fallot have a fixed component of obstruction to pulmonary blood flow, and thus will normally develop transient desaturation with agitation and feeding as a result of increased oxygen consumption and cardiac output. Clinical judgment is required to differentiate a true TET spell from these common and benign desaturation episodes. The absence of a murmur during a true TET spell, signifying a substantial reduction of blood flow across the right ventricular outflow tract, may be useful in this regard. Treatment strategies are implemented with the goal of decreasing patient agitation and heart rate, increasing systemic vascular resistance and pulmonary blood flow, and correcting metabolic acidosis (Table 34-4). Prompt surgical intervention is indicated once an infant has had a TET spell.

Absent pulmonary valve syndrome, identified by the presence of rudimentary pulmonary valve leaflets and free pulmonary insufficiency, is a relatively rare lesion, present in approximately 3% of all patients with tetralogy of Fallot. This lesion is most notable for *in utero* development of aneurysmal dilation of the pulmonary arteries, which may occur as a result of the lack of a ductus arteriosus or as a result of the pulsatile blood flow pattern across the right ventricular outflow tract. When compared with infants with typical tetralogy of Fallot, there may

be a higher incidence of chromosome 22q11 deletion in those with absent pulmonary valve (63). A nearly pathognomonic to-and-fro ("sawing wood") murmur is heard as a result of pulmonary annulus stenosis and free pulmonary insufficiency (Fig. 34-2, see also color plate). Such patients may have minimal if any respiratory symptoms and behave much like a "pink tet," or present with severe problems with oxygenation and ventilation soon after birth as a result of compression of the bronchi by the dilated pulmonary arteries (64). Intubation, mechanical ventilation (with judicious use of positive end-expiratory pressure), and deep sedation may be life saving in neonates with symptomatic airway obstruction. Prone positioning may be advantageous as gravity will allow the pulmonary arteries to fall off the mainstem bronchi, thus permitting adequate gas exchange (65). Prompt surgical repair is indicated in symptomatic neonates.

TABLE 34-4 TREATMENT FOR HYPERCYANOTIC EPISODES ("TOF SPELLS")

Intervention	Effect on Pathophysiology
Knee-chest position	↑ systemic vascular resistance
Oxygen	↓ pulmonary vascular resistance
Morphine	↓ agitation
Ketamine	↓ agitation, ↑ systemic vascular resistance
Propranolol	↓ infundibular spasm, ↓ heart rate
Sodium bicarbonate	↓ metabolic acidosis
Phenylephrine	↑ systemic vascular resistance
Cardiopulmonary bypass	rescue therapy when above measures fail

Pulmonary Atresia, Ventricular Septal Defect, Major Aortopulmonary Collateral Arteries

Infants with pulmonary atresia, VSD and MAPCAs represent a challenging subset of infants with pulmonary atresia. This lesion is also referred to as tetralogy of Fallot, pulmonary atresia and MAPCAs. In addition to the anatomic features of tetralogy of Fallot as described above, the true pulmonary arteries are often diminutive or absent, and a variable number of aortopulmonary collaterals arise from the aorta or brachiocephalic vessels to supply pulmonary blood flow. Infants with this lesion will present with either cyanosis or congestive heart failure, depending upon the cardiac anatomy (66). The physical examination may be notable for the presence of a widely radiating continuous murmur produced by the aortopulmonary collateral blood flow. These infants are generally not dependent upon prostaglandin infusion unless a major aortopulmonary

P.720

collateral vessel arises from the ductus arteriosus. Cardiac catheterization is required to identify all sources of pulmonary blood flow. Surgical strategy must then be individualized depending upon the pulmonary artery and collateral vessel anatomy. True pulmonary arteries, MAPCAs, or both may supply blood to individual segments of the lungs. The ultimate goal is to encourage true pulmonary artery growth and incorporate as many arterial blood vessels and lung segments into the repair as possible to maximize the effective pulmonary arterial vascular bed, and thus minimize right ventricular hypertension following VSD closure. In situations in which dual blood supply to a lung segment exists, the MAPCAs are coil occluded in the cardiac catheterization laboratory or ligated at the time of surgery to eliminate left to right shunting. As with other conotruncal defects, these infants should undergo genetic testing for chromosome 22q11 deletion.

Figure 34-2 Tetralogy of Fallot with absent pulmonary valve. **A.** Two-dimensional echocardiogram from the parasternal long axis view demonstrating rudimentary pulmonary valve leaflets and aneurysmal dilation of the main pulmonary artery. **B.** Application of color Doppler during ventricular diastole revealing free regurgitation from the main pulmonary artery into the right ventricular outflow tract. MPA, main pulmonary artery; PV, pulmonary valve; RVOT, right ventricular outflow tract. (See color plate)

Pulmonary Atresia with Intact Ventricular Septum

Pulmonary atresia is characterized by a membranous or plate-like obstruction of the right ventricular outflow tract at the level of the pulmonary valve, with variable degrees of hypoplasia of the tricuspid valve and right ventricle, and occasional coronary artery fistulous connections to the right ventricle. Systemic venous return to the right atrium flows through an obligatory atrial communication to the left atrium. Infants with pulmonary atresia and intact ventricular septum will manifest with significant cyanosis upon closure of the ductus arteriosus, and are thus dependent on prostaglandin infusion. Intervention in these patients depends on two key issues: the adequacy of the right ventricular size to support a two-ventricular circulation, and on the presence of "right ventricle dependent coronary circulation." The right ventricle must have adequate size to support the entire right heart circulation if these patients are to be considered for a two-ventricle repair. The size of the tricuspid valve annulus plays an important role in the decision making process (67). Infants with pulmonary atresia and intact ventricular septum, particularly those with small tricuspid valve annulus size, may have significant fistula communications between the right ventricle and the coronary circulation, known as coronary-cameral fistulae, which may be identified by echocardiogram and further characterized by cardiac catheterization (68,69). If coronary stenoses exist such that a significant amount of coronary blood flow to the myocardium is derived from and dependent upon the coronary cameral fistulae, then "right ventricular dependent coronary circulation" is present. If the right ventricular outflow tract obstruction is relieved in an infant with "right ventricular dependent coronary circulation," coronary perfusion pressure falls and the patient may develop a myocardial infarction. Thus, if the right ventricle is not of adequate size, or if "right ventricle dependent coronary circulation" exists, these patients are referred for a systemic to pulmonary artery shunt in anticipation of an eventual Fontan operation. If a complete two-ventricle repair is deemed appropriate, this may be performed as a primary operation in the neonatal period, although more commonly a systemic to pulmonary artery shunt and right ventricular outflow tract decompression is initially performed to encourage right ventricular growth, with complete repair in later infancy (70). Some infants with membranous pulmonary atresia and intact ventricular septum who meet criteria for a two ventricular repair may undergo perforation of the pulmonary valve using a stiff wire, a radiofrequency ablation catheter, or a laser catheter, followed by balloon valvuloplasty (54,58,71). In well-selected patients, the use of transcatheter intervention

P.721

may eliminate the need for surgical intervention. The decision to attempt transcatheter intervention is made considering patient size, co-morbidities, anatomic details, and institutional experience.

Ebstein's Anomaly of the Tricuspid Valve

Ebstein's anomaly of the tricuspid valve is a malformation in which the septal and posterior leaflets of the tricuspid valve are displaced to a variable extent into the anatomic right ventricle, and the anterior leaflet, although not inferiorly displaced, is redundant. Tricuspid regurgitation of variable severity occurs (Fig. 34-3, see

also Color Plate). One or more accessory connections may be present at the tricuspid valve annulus, creating the necessary substrate for atrio-ventricular reentrant tachycardia. The clinical presentation is usually one of right-sided congestive heart failure and arrhythmias in adolescence or early adulthood. A small subset of infants with Ebstein's anomaly, those with severe tricuspid regurgitation, a large "atrialized" portion of the right ventricle, severe cardiomegaly, and pulmonary hypoplasia are critically ill soon after birth and have a high mortality (72). These neonates will present with severe cyanosis as a result of functional right ventricular outflow tract obstruction, and right to left shunting at the atrial level. Infants with significant cyanosis should be started on PGE₁, and judicious use of positive end-expiratory pressure is required to re-expand the lungs, which are compressed by the generous heart size (73). Additionally, standard measures including inhaled nitric oxide should be employed to decrease pulmonary vascular resistance and cyanosis. In many of these patients, as pulmonary vascular resistance falls over time, forward flow increases across the right ventricular outflow tract, cyanosis decreases, and surgery can be deferred. For those neonates with refractory cyanosis, referral is made for either a primary complete repair, consisting of a reduction atrioplasty, fenestrated closure of the atrial septum and tricuspid valvuloplasty, or palliation toward the Fontan pathway starting with a systemic to pulmonary artery shunt (73,74,75).

Figure 34-3 Ebstein's anomaly of the tricuspid valve. **A.** Two-dimensional echocardiogram from the apical four-chamber view demonstrating significant displacement of the tricuspid valve leaflets into the right ventricle. **B.** During ventricular diastole, color Doppler demonstrating free retrograde flow across the tricuspid valve annulus. ARV, atrialized right ventricle; LA, left atrium; LV, left ventricle; RA, right atrium; TV, tricuspid valve. (See color plate)

Left Ventricular Outflow Tract Obstruction

Critical Aortic Valve Stenosis

Isolated congenital aortic valve disease may present in a variety of ways, depending primarily upon the severity of stenosis. A bicuspid aortic valve without stenosis or insufficiency may be an incidental finding in an otherwise healthy patient. At the other extreme, newborns with critical aortic valve stenosis develop shock upon closure of the ductus arteriosus. The murmur is typically softer than expected as a result of the low cardiac output state, and the gradient estimated by echocardiography may not correlate with the severity of the stenosis. Initiation of PGE₁ infusion allows blood from the right ventricle to provide systemic perfusion until an intervention can be performed (76). Once the infant is stabilized, echocardiographic information must be carefully reviewed to predict whether the left ventricle is of adequate size to sustain the systemic circulation following a two-ventricle repair (77). Infants thought to be suitable for a two-ventricle repair usually will be referred for a balloon aortic valvuloplasty; although a surgical aortic valvotomy is an acceptable option (78,79,80). If hypoplasia of multiple left sided structures suggests that the left ventricle will not be able to support the circulation, then a Norwood operation or heart transplantation may be considered.

Critical Coarctation of the Aorta

A coarctation of the aorta is present when a significant narrowing exists in the thoracic aorta just distal to the left

subclavian artery. A "posterior shelf" is present opposite the insertion site of the patent ductus arteriosus. Coarctation of the aorta may exist in isolation or can be associated with aortic arch hypoplasia, a VSD, or other complex intracardiac lesions. When present in isolation, coarctation of the aorta is "critical" when ductal dependent systemic blood flow exists, which represents only about 10% of cases. Neonates with isolated critical coarctation of the aorta also will present with shock if the diagnosis is not made before significant constriction of the ductus arteriosus occurs (Fig. 34-4). Prior to the development of shock, the diagnosis should be suspected by the detection of a brachial-femoral pulse discrepancy, which can be confirmed by measuring an arm-leg blood systolic pressure gradient. A systolic blood pressure gradient between the upper and lower extremities of greater than 10 mm Hg is clinically significant. In approximately 5% of infants with isolated coarctation of the aorta, the right subclavian artery will arise aberrantly from the descending thoracic aorta, distal to the coarctation. Thus it is important to palpate pulses and measure blood pressure in both upper extremities in all infants with suspected coarctation. Occasionally differential cyanosis will be present as the lower body is being perfused by deoxygenated blood from the ductus arteriosus. PGE₁ infusion will almost always reopen the ductus arteriosus and allow recovery of end-organ function prior to surgical repair (76). In the absence of data from randomized clinical trials, the method of nutritional support for these patients should be individualized and deserves comment. Those neonates with critical coarctation who present in shock with metabolic acidosis and laboratory evidence of end-organ dysfunction should be maintained on bowel rest prior to surgery, and nutritional support is provided with total parenteral nutrition. However, enteral feeds may be considered in the subset of infants who are diagnosed prior to the development of shock, started on PGE₁, and subsequently have reasonable femoral pulses and diastolic blood pressure distal to the coarctation.

Figure 34-4 Schematic diagram of hemodynamic data and oxygen saturation levels in a neonate with critical coarctation of the aorta. **A:** Hemodynamic data and oxygen saturation levels prior to ductal closure. **B:** Hemodynamic data and oxygen saturation levels following ductal closure. Note the development of systemic hypertension and left atrial hypertension, the persistence of pulmonary hypertension, and the decrease in cardiac output as demonstrated by the lower oxygen saturation level in the inferior vena cava (a, atrial; v, ventricle; m, mean). Reprinted from Rudolph AM. Aortic arch obstruction. In: *Congenital diseases of the heart: clinical-physiological considerations*, 2nd ed. Armonk, NY: Futura, 2001:382-383, with permission.

Hypoplastic Left Heart Syndrome

HLHS exists when there is severe mitral and aortic valve stenosis or atresia, a diminutive left ventricle, ascending aorta, and aortic arch, and often a juxtaductal coarctation of the aorta. Following birth there are two key communications that need to remain open to permit cardiopulmonary stability. A patent ductus arteriosus (PDA) is necessary to allow blood flow from the pulmonary artery to reach the systemic circulation, and shock

blood flow from the left atrium to the right atrium. The 5% of infants with HLHS who have a severely restrictive or intact atrial septum will develop profound cyanosis, pulmonary edema, and shock almost immediately following delivery.

Initially, most patients with HLHS (assuming an unrestrictive or mildly restrictive atrial communication) will be hemodynamically stable following the initiation of a PGE₁ infusion. Over several days, however, as pulmonary vascular resistance falls, the ratio of pulmonary to systemic blood flow (Q_p/Q_s) will increase, leading to an increase in arterial oxygen saturation. Poor systemic circulation may manifest, and the neonate may develop right ventricular volume overload, and coronary and end-organ ischemia. The Q_p/Q_s may be calculated by the following equation which is derived from the Fick principle: $Q_p/Q_s = (SaO_2 - SvO_2) / (PvO_2 - PaO_2)$, in which SaO_2 = aortic saturation; SvO_2 = mixed venous saturation (estimated by the superior vena cava oxygen saturation); PvO_2 = pulmonary venous oxygen saturation (assumed to be > 95% if not directly measured); and PaO_2 = pulmonary artery oxygen saturation (assumed equal to the aortic saturation). Most preoperative neonates will not have a catheter positioned in the superior vena cava to measure SvO_2 , and thus the Q_p/Q_s cannot be precisely calculated. Determination of an absolute value for Q_p/Q_s is of less importance than having an appreciation for the physiologic disturbance that develops as these neonates become progressively over circulated. Theoretical computer models of newborns with HLHS demonstrate that, beyond a certain point, slight increases in arterial oxygen saturation are associated with significant decreases in oxygen delivery, and that maximal oxygen delivery occurs at a Q_p/Q_s less than 1 (Fig. 34-5 and 34.6) (81,82). This model also demonstrates that a SvO_2 less than 40%, or a $SaO_2 - SvO_2$ difference of more than 40%, is likely associated with a severe derangement in systemic oxygen delivery, related to either a high Q_p/Q_s or low cardiac output (82).

Figure 34-5 Systemic arterial oxygen saturation vs. systemic oxygen (O_2) delivery in the theoretical newborn with hypoplastic left heart syndrome. A computer model was used to generate the curves by setting the cardiac output (CO) at 300 or 450 mL/kg/min and varying Q_p/Q_s from 0.2 to 10. The short line on each curve represents the point at which $Q_p/Q_s = 1$. As SaO_2 increases, oxygen delivery increases and reaches a peak, and then decreases rapidly. Peak oxygen delivery occurs at a $Q_p/Q_s = 1$. Reprinted from Barnea O, Santamore WP, Rossi A, et al. Estimation of oxygen delivery in newborns with a univentricular circulation. *Circulation* 1998;98:1407-13, with permission.

In the typical neonate with HLHS, interventions that lower the pulmonary vascular resistance, such as

supplemental oxygen and hyperventilation, may increase Q_p/Q_s and should be avoided. Patients with pulmonary over-circulation (high Q_p/Q_s) and evidence of poor end-organ perfusion (e.g., poor urine output, rising lactate levels, diminished peripheral pulses) may be treated with sub-ambient FiO_2 , obtained using supplemental inhaled nitrogen to increase pulmonary vascular resistance and thus restore the balance between systemic and pulmonary blood flow (83,84). The supplemental nitrogen may be delivered through the endotracheal tube or through a nasal cannula in neonates who are spontaneously breathing. Pulmonary vascular resistance may also be increased in such patients using supplemental inspired carbon dioxide (CO_2) (85). In a prospective, randomized, crossover study, the impact of hypoxia (17% FiO_2) vs. hypercarbia (2.7% $FiCO_2$) on systemic oxygen delivery in preoperative neonates with HLHS was evaluated (86). All patients were receiving mechanical ventilation, deep sedation or anesthesia, and

P.724

neuromuscular blockade. The study found that both hypoxia and hypercarbia were effective in reducing Q_p/Q_s ratio (Fig. 34-7). Hypercarbia increased cerebral oxygen saturation, mean arterial blood pressure, oxygen delivery and, although not directly measured, cardiac output, whereas hypoxia did not change these variables, suggesting that hypercarbia may be the preferred therapy (Fig. 34-8) (86,87). However, administration of supplemental CO_2 requires the concurrent use of sedation and paralysis, thus limiting its applicability for most neonates with HLHS prior to surgery.

Figure 34-6 Systemic oxygen (O_2) delivery vs. Q_p/Q_s in the theoretical newborn with hypoplastic left heart syndrome. A computer model was used to generate the curves by setting the cardiac output (CO) at 300 or 450 mL/kg/min. Note that increasing cardiac output can increase oxygen delivery, and that oxygen delivery decreases significantly once Q_p/Q_s exceeds 1. Reprinted from Barnea O, Santamore WP, Rossi A, et al. Estimation of oxygen delivery in newborns with a univentricular circulation. *Circulation* 1998;98:1407-1413, with permission.

Neonates with HLHS and myocardial dysfunction should receive inotropic support to improve cardiac output and systemic oxygen delivery. However, care should be taken to avoid inotropic agents that increase systemic vascular resistance because this will favor pulmonary blood flow over systemic blood flow. Low-dose dopamine or milrinone are good inotropic agents for neonates with HLHS and myocardial dysfunction.

The neonate with HLHS and a severely restrictive or intact atrial septum will present with profound cyanosis and shock immediately after birth as a result of obstruction of blood egress from the left atrium. The short- and long-term outlook for such infants has historically been poor, regardless of whether they undergo the Norwood operation or are listed for heart transplantation, due in large part to the in utero development of pulmonary

venous hypertension and lymphatic abnormalities that persist following birth (88,89,90). The immediate management of these critically ill neonates involves prompt intervention to decompress the left atrium. Emergent surgical intervention, involving either open atrial septectomy or a Norwood procedure, has usually resulted in early death. A Brockenbrough atrial septoplasty (transcatheter, trans-septal needle puncture followed by serial balloon dilation of the new ASD and possibly stent placement) will serve to decompress the left atrium, increase pulmonary venous return and pulmonary blood flow, and alleviate cyanosis (35). Following this procedure, the patient may be medically managed for a few days with a PGE₁ infusion and diuretics to allow pulmonary vascular resistance to fall and pulmonary edema to improve prior to the Norwood operation. This multidisciplinary approach to the neonate with HLHS and severely restrictive or intact atrial septum has resulted in a contemporary 53% survival rate following the Norwood operation, which is better than results obtained with other management strategies for this lesion, but remains poor when compared with the outcome of neonates without atrial obstruction who undergo the Norwood operation (91). Theoretically, alleviation of the left atrial hypertension *in utero* may improve outcome in patients with HLHS and a severely restrictive or intact atrial septum. Fetal intervention to dilate the atrial septum using percutaneous, transcatheter needle puncture of the atrial septum followed by balloon dilation appears to be feasible and is associated with minimal maternal risk, but technical improvements and additional experience will be required before this procedure is widely adopted (92).

Figure 34-7 Difference in Qp/Qs between condition (either hypoxia or hypercarbia) and baseline (mean \pm SEM) in preoperative neonates with hypoplastic left heart syndrome. Reprinted from Tabbutt S, Ramamoorthy C, Montenegro LM, et al. Figure 34-9 Hospital survival following stage 1 palliation in patients with hypoplastic left heart syndrome by year at a single center. Hospital survival improved coincident with the application of new treatment strategies beginning in July of 1996 (arrow). S1P, stage 1 palliation (Norwood operation). Reprinted from Tweddell JS, Hoffman GM, Mussatto KA, et al. Improved survival of patients undergoing palliation of hypoplastic left heart syndrome: lessons learned from 115 consecutive patients. *Circulation* 2002;106: I82-I89, with permission.

Initial reports suggested that severe tricuspid regurgitation was a significant risk factor for infants with HLHS (93,94). However, in the preoperative infant with HLHS, the severity of tricuspid regurgitation may be in part related to a high Q_p/Q_s , with right ventricular volume overload and stretching of the tricuspid valve annulus.

Following the Norwood operation, the Qp/Qs may decrease as a result of the fixed resistance to pulmonary blood flow provided by the shunt, and subsequently the degree of tricuspid regurgitation may diminish. Thus, clinical judgment and an appreciation of tricuspid valve morphology are required in such cases.

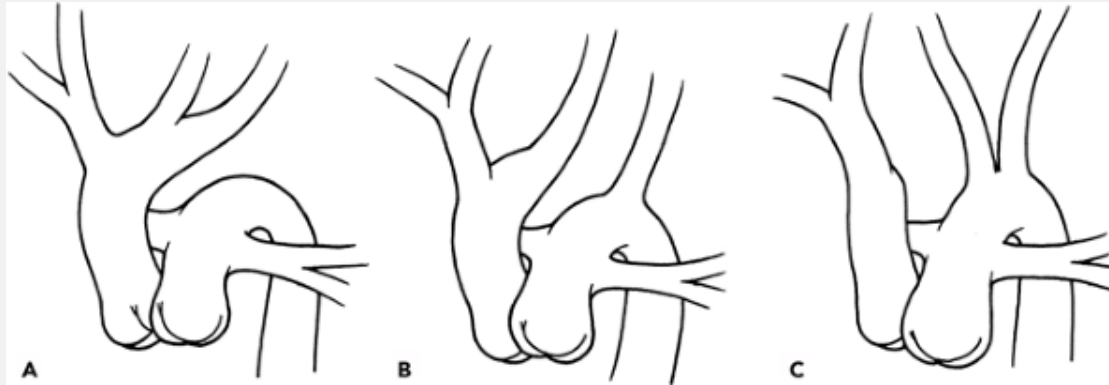

Figure 34-10 The three types of interrupted aortic arch. In type A, the interruption is at the aortic isthmus between the left subclavian artery and the ductus. In type B, the interruption is at the distal aortic arch between the left carotid and left subclavian arteries. In type C, the interruption is at the proximal aortic arch between the innominate and left carotid arteries. Type B is the most common form of this lesion. Type C is rare. Reprinted from Chang AC, Starnes VA. Interrupted aortic arch. In: Chang AC, Hanley FL, Wernovsky G, et al., eds. *Pediatric cardiac intensive care*. Baltimore: Williams and Wilkins, 1998:243-247, with permission.

Several centers have recently reported overall survival rates of more than or equal to 90% following initial surgical palliation for HLHS (Fig. 34-9) (4,95). Contemporary risk factors contributing to higher mortality following the Norwood operation include prematurity, the presence of multiple congenital anomalies, and an intact atrial septum (48,88). Although palliative care is still offered at some centers for neonates with HLHS, fewer clinicians and parents are opting for no intervention given the improving surgical results (96). Some centers offer heart transplantation as a primary option for HLHS (97). Problems with this strategy include the high morbidity and mortality incurred while waiting for a heart to become available from a very limited donor pool, suboptimal neurologic outcome in many patients, and complications inherent to heart transplant (98,99,100). For these reasons, many pediatric cardiology centers recommend the Norwood operation as the initial surgical intervention in neonates with HLHS, and heart transplantation is typically reserved for the small subset that develop subsequent irreversible myocardial failure.

Interrupted Aortic Arch

An interrupted aortic arch (IAA) is most commonly associated with a VSD, but also is seen with a variety of other congenital cardiac malformations, including truncus arteriosus and TGA (101). If a VSD is not present in a patient with an IAA, an aorto-pulmonary window is likely to be found. IAA is classified by the location of the arch interruption in relation to the brachiocephalic vessels (Fig. 34-10) (102). IAA type B is the most common subtype (>50% of cases), and type C is rare. Chromosome 22q11 deletion is present in approximately 60% of neonates with IAA type B (41). The infant with an unrecognized IAA will present with shock, similar to a critical coarctation, upon closure of the ductus arteriosus. Infants with IAA are dependent upon ductal patency to maintain blood flow to the lower body, and

P.727

preoperative management strategies to balance the systemic and pulmonary circulations mimic those used in infants with HLHS. Early surgical intervention is warranted.

Mixing Lesions

Transposition of the Great Arteries

In d-TGA, the aorta arises from the anatomic right ventricle and the pulmonary artery arises from the anatomic left ventricle. Approximately 40% of neonates with TGA have an associated VSD, which occasionally is a malalignment type defect. If anterior malalignment exists, there may be associated right ventricular outflow

tract obstruction, aortic valvar stenosis, coarctation of the aorta or rarely an IAA. A posterior malalignment VSD is associated with left ventricular outflow tract obstruction, pulmonary stenosis or atresia. Coronary artery branching abnormalities are present in approximately 30% of cases.

In this unique parallel circulation, deoxygenated systemic venous blood returns to the right heart and is pumped back to the systemic arterial circulation, and oxygenated pulmonary venous blood passes through the left heart and is pumped back to the lungs. Unless there is adequate mixing between these parallel circulations, severe cyanosis, metabolic acidosis and death will occur. Such intercirculatory mixing represents effective pulmonary and systemic blood flows, and may take place at the atrial, ventricular, or great artery level (Fig. 34-11). Infants with TGA and an intact ventricular septum typically have a patent foramen ovale (PFO) or ASD that allows some mixing at the atrial level. However, a PGE₁ infusion is usually necessary to open or maintain patency of the ductus arteriosus, which will increase effective pulmonary blood flow, provided that the pulmonary vascular resistance is lower than the systemic vascular resistance and that there is an adequate atrial communication.

Occasionally infants with TGA may develop severe cyanosis and shock following the initiation of PGE₁ infusion, as a result of increasing blood volume returning to the left atrium and functional closure of the foramen ovale. If this occurs, or if the PFO is restrictive, as assessed by echocardiography, and excessive cyanosis is present, an emergent balloon atrial septostomy should be performed to enlarge the atrial communication (Fig. 34-12, see also Color Plate) (34). The balloon atrial septostomy may be performed at the bedside using echocardiographic guidance, or in the cardiac catheterization laboratory (103). Excessive cyanosis may persist despite a technically successful balloon atrial septostomy. High pulmonary vascular resistance may limit effective pulmonary blood flow, and measures should be taken to lower pulmonary vascular resistance. Because the majority of systemic blood flow comes from the systemic venous circulation in TGA, neonates who remain excessively cyanotic following a balloon atrial septostomy will also improve following maneuvers that will increase the mixed venous oxygen saturation. These include interventions to decrease oxygen consumption, such as sedation and paralysis, and improve oxygen delivery, such as correcting anemia and administering inotropic agents. To summarize, infants with TGA and intact ventricular septum who remain excessively cyanotic despite the initiation of PGE₁ require a balloon atrial septostomy, and if necessary, interventions to lower pulmonary vascular resistance and increase systemic venous oxygen saturation.

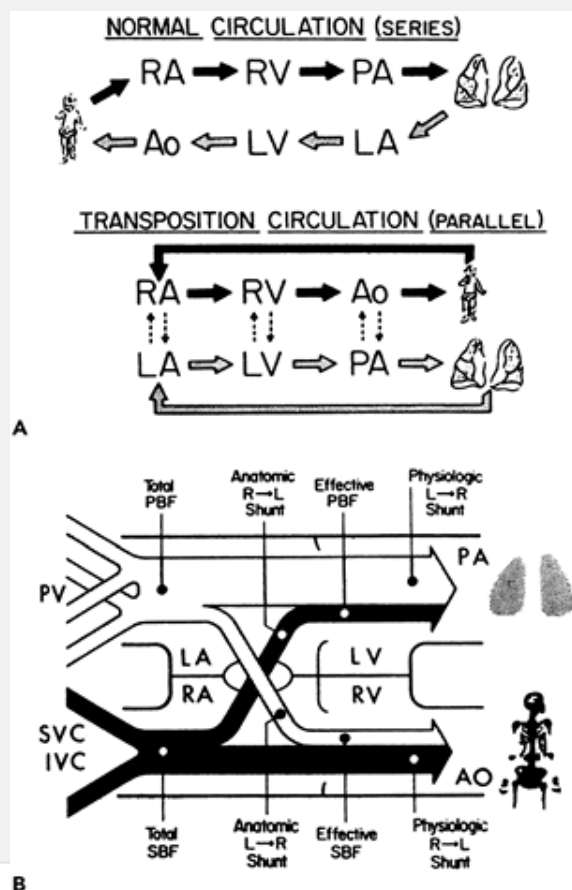

Figure 34-11 The circulation in transposition of the great arteries. **A:** The systemic and pulmonary circulations are in series in the normal circulation, whereas they are in parallel in TGA. Solid arrows, relatively unoxygenated blood; stippled arrows, oxygenated blood; dashed arrows, intercirculatory shunts. **B:** Circulation schema demonstrating flows and shunts in infants with TGA/intact ventricular septum. Note that the anatomic left to right shunt constitutes the effective SBF, and the anatomic right-to-left shunt constitutes the effective PBF. Baltimore: Williams & Wilkins, 1995:1154-1225, with permission.

Many clinicians recommend that a semi-elective balloon atrial septostomy be performed in nearly all patients with TGA and intact ventricular septum, even those without

P.728

excessive cyanosis. Once the atrial septum is enlarged, the PGE₁ can usually be safely discontinued, thus avoiding complications related to that medication and a large ductus arteriosus, such as apnea and NEC. Furthermore, the left atrium is decompressed following a balloon atrial septostomy, which may allow the pulmonary vascular resistance to fall prior to surgery. Finally, the infant may be transferred from the ICU to the general ward to initiate feedings and await surgery. The major risks associated with the performance of a balloon atrial septostomy include myocardial perforation or avulsion of the inferior vena cava from the right atrium during pullback of the balloon, both of which rarely occur. Following initial stabilization of the neonate with TGA and intact ventricular septum, an early arterial switch operation is required before the left ventricle becomes deconditioned.

Figure 34-12 Restrictive atrial septum in a newborn with transposition of the great arteries. **A.** Two-dimensional echocardiogram with color Doppler from the subcostal window demonstrating a tiny patent foramen ovale with left to right flow across the atrial septum. **B.** Following successful balloon atrial septostomy, a wide communication now exists between the left and right atria. Infants with TGA and moderate to large VSD generally are well oxygenated and do not require a PGE₁ infusion provided that the ventricular outflow tracts are unobstructed. Early congestive heart failure typically develops, and surgical repair is indicated within the first few weeks of life. A malalignment-type VSD may be associated with clinically significant left or right ventricular outflow tract obstruction. Patients with sub-aortic obstruction may have an associated coarctation of the aorta or an IAA. Such an infant may present with the very unique finding of reverse differential cyanosis, with low oxygen saturation in the right arm and high oxygen saturation in the leg. A PGE₁ infusion is needed, followed by early surgical intervention. Infants with d-TGA and VSD who are referred for surgery after the first few months of life (typically from underdeveloped nations) are at risk for having developed pulmonary vascular obstructive disease. These patients may require a cardiac catheterization to evaluate their pulmonary vascular resistance prior to surgery.

Tricuspid Atresia

Tricuspid atresia is present when there is agenesis of the tricuspid valve and an absent communication between the right atrium and right ventricle. The presentation of infants with this lesion is variable and depends primarily upon the presence and size of a VSD, whether the great arteries are normally related or transposed, and the degree of ventricular outflow tract obstruction (Table 34-5) (104,105). These factors determine which of these neonates will be dependent on a PGE₁ infusion. All of the systemic venous blood must pass through an obligate atrial communication to the left atrium, in which it mixes with the pulmonary venous blood. In the presence of normally looped ventricles and normally related great arteries, the left ventricle then ejects blood to the aorta, and through the VSD, if present, to the pulmonary artery. If the great arteries are transposed, the left ventricle pumps blood to the pulmonary artery (unless pulmonary atresia is present), and through the VSD to the aorta. Although all infants with tricuspid atresia eventually require a Fontan palliation, the type of initial operation depends upon the extent of cyanosis or systemic outflow obstruction. For example, infants with tricuspid atresia, normally looped ventricles and normally related great vessels, a large VSD and no or minimal right ventricular outflow tract obstruction (type I-C) will be well oxygenated and develop early heart failure. In the neonatal period, they require placement of a pulmonary artery band or transection of the pulmonary artery and placement of a systemic to pulmonary artery shunt. Those with a moderate size VSD and a moderate degree of right ventricular outflow tract obstruction (type I-B) will have a balanced circulation with an acceptable amount of cyanosis. Such infants may be discharged home with the expectation of a bi-directional

P.729

Glenn or hemi-Fontan operation within the first six months of life. Infants with tricuspid atresia and a small or absent VSD (type I-A or I-B) will have significant cyanosis and thus be dependent on a PGE₁ infusion until a systemic to pulmonary artery shunt is performed. Infants with tricuspid atresia and transposed great arteries, a small or absent VSD (type II-A or II-B) will develop shock unless ductal patency is maintained. These infants require a Damus-Kaye-Stansel operation (aortopulmonary anastomosis) or a modified Norwood operation with a systemic to pulmonary artery shunt.

TABLE 34-5 CLASSIFICATION SYSTEM FOR TRICUSPID ATRESIA

Type and Description	Frequency
Type I: Normally related great arteries	70%–80%
A. Intact ventricular septum with pulmonary atresia	
B. Small ventricular septal defect with pulmonary stenosis	
C. Large ventricular septal defect without pulmonary stenosis	
Type II: d-Transposition of the great arteries	12%–25%
A. Ventricular septal defect with pulmonary atresia	
B. Ventricular septal defect with pulmonary stenosis	
C. Ventricular septal defect without pulmonary stenosis	
Type III: I-Transposition of the great arteries	3%–6%

Total Anomalous Pulmonary Venous Return

Total anomalous pulmonary venous return (TAPVR) is a congenital heart defect in which all four pulmonary veins drain to a systemic vein or the right atrium. TAPVR results from a failure of the common pulmonary vein to fuse with the posterior surface of the left atrium early in fetal life. The pulmonary veins then decompress via the coronary sinus or primitive venous structures, which eventually lead to the right atrium, in which mixing occurs with the systemic venous blood. An anatomic classification system divides TAPVR into supracardiac, cardiac, infracardiac, and mixed, depending upon which primitive venous pathways are employed. Supracardiac TAPVR exists when all of the pulmonary veins come to a confluence behind the left atrium and drain via a vertical vein to the innominate vein or superior vena cava. Occasionally the vertical vein is obstructed as it passes between the left mainstem bronchus and left pulmonary artery. Cardiac TAPVR exists when the pulmonary veins drain to the coronary sinus or right atrium. Obstruction is uncommon in cardiac TAPVR. In infracardiac TAPVR, the pulmonary venous confluence drains inferiorly through the diaphragm and into the portal or hepatic veins, in which obstruction is common. Patients with mixed TAPVR have drainage to more than one site. For example, the left sided pulmonary veins may drain through a vertical vein to the innominate vein, although the right

pulmonary veins drain to the right atrium. An obligatory intracardiac (usually atrial) communication exists in neonates with TAPVR to allow some oxygenated blood to reach the left heart and systemic arterial circulation. TAPVR may be associated with significant intracardiac disease as is seen in patients with heterotaxy syndrome, or may exist as an isolated lesion.

The presentation of isolated TAPVR is primarily based upon the presence and degree of obstruction between the pulmonary veins and the right heart. Most patients with infracardiac TAPVR and some with supracardiac TAPVR will have obstructed pulmonary venous pathways that result in pulmonary edema, pulmonary hypertension, cyanosis, and significant respiratory distress soon after birth. The clinical presentation and CXR may mimic those seen with neonatal pneumonia or respiratory distress syndrome, leading to delays in diagnosis. If a venous blood gas is drawn from an umbilical venous catheter positioned just above the liver in a cyanotic newborn, and the oxygen saturation level is in the high 90s, the diagnosis of infracardiac TAPVR should be suspected, as the sample is reflective of pulmonary venous return. The umbilical venous catheter should be removed so that it does not further obstruct pulmonary venous flow and cause clinical decompensation. Stabilization for the neonate with obstructed TAPVR involves mechanical ventilation, sedation and urgent surgical intervention (106). Hypoxemia may be abated somewhat by interventions that increase mixed venous oxygen saturation, including pharmacologic paralysis, correction of anemia, and inotropic support. Although neonates with obstructed TAPVR may be quite cyanotic, measures to lower pulmonary vascular resistance, including the use of hyperventilation and nitric oxide (NO), are usually not beneficial. The use of PGE₁ infusion in such patients is controversial, but generally is discouraged. Some physicians feel that PGE₁ may maintain patency of the ductus venosus in infants with infracardiac obstructed TAPVR, thus allowing for better drainage back to the right heart. Other clinicians believe that maintaining patency of the ductus arteriosus may allow left to right shunting at the arterial level (if the pulmonary vascular resistance is less than the systemic vascular resistance) and thus exacerbate pulmonary edema.

P.730

Infants with unobstructed isolated TAPVR and an adequate atrial communication will be mildly hypoxemic without overt clinical cyanosis at birth but develop congestive heart failure (CHF) within a few weeks to months. Surgical repair is performed within the first few days to weeks of life.

Truncus Arteriosus

Truncus arteriosus is present when a single (common) arterial trunk gives rise to the aorta, at least one coronary artery, and at least one pulmonary artery. A single semilunar ("truncal") valve is always present, and an unrestrictive VSD is almost always present. About one-third of patients with truncus arteriosus have a 22q11.2 microdeletion (DiGeorge syndrome) that can be diagnosed with florescent in-situ hybridization (FISH) (107). Several classification systems exist that may be used to describe the origins of the pulmonary arteries from the arterial trunk and the presence or absence of an IAA (108). Newborns with truncus arteriosus who present with mild cyanosis do not require a PGE₁ infusion unless an IAA (about 10% of cases) or ductal origin of one of the pulmonary arteries is present.

Infants with truncus arteriosus usually develop too much pulmonary blood flow and congestive heart failure within a few weeks after birth as pulmonary vascular resistance falls and systemic vascular resistance increases, unless stenosis is present at the origin of the pulmonary arteries from the aorta. Supplemental oxygen should be avoided to minimize the risk of decreasing pulmonary vascular resistance. Congestive heart failure is exacerbated in the presence of significant truncal valve insufficiency, which occurs in 50% of cases, or significant truncal valve stenosis (less common). For this reason, and to prevent the development of pulmonary vascular obstructive disease before surgery and minimize the incidence of pulmonary hypertension crises postoperatively, complete surgical repair is generally performed prior to discharge from the nursery (8,109,110).

Left to Right Shunts

Atrial Septal Defect

ASDs may be present in isolation or with nearly any other type of congenital heart defect. ASDs are categorized by location and include secundum, ostium primum and sinus venosus types. The most common type is the secundum ASD, which exists when there is a deficiency in the septum primum in the central portion of the atrial septum. Although secundum ASDs may become smaller and close spontaneously, particularly those that are less

than 5 mm in diameter, the ostium primum and sinus venosus defects will always require surgical intervention. The ostium primum defects are located in the inferior region of the atrial septum, and are almost always associated with an additional endocardial cushion abnormality. The sinus venosus defects usually occur at the junction between the superior vena cava and the right atrium, and are almost always associated with partial anomalous pulmonary venous return.

Isolated ASDs only rarely cause symptoms in infants, as significant left to right shunting does not occur until right ventricular compliance falls below left ventricular compliance, and this often takes years to occur. Likewise it is uncommon for patients with large ASDs to require oral medications (digoxin or diuretics). However, clinical judgment regarding the medical management and timing of surgical intervention is required in the neonate with a large ASD and additional medical problems (e.g., chronic lung disease) that complicate the clinical picture. The primary indication for surgery in infancy is the presence of symptoms secondary to left to right shunting. Toddlers require intervention if they have an ostium primum or sinus venosus ASD, or a secundum ASD with evidence for volume overload of the right ventricle. Intervention is indicated in early childhood in asymptomatic patients with significant left to right atrial shunts to prevent late complications including pulmonary vascular obstructive disease, thromboembolic events, arrhythmias, and right heart failure. A variety of devices exist that are used to close secundum ASDs in the catheterization laboratory, but the majority of clinical experience thus far exists with older children (111).

Ventricular Septal Defect

VSDs may be found in a variety of complex congenital heart lesions, or may exist in isolation. VSDs are categorized by location and size. VSDs may be located in the perimembranous, muscular, inlet or conal (outlet, subarterial, supracristal) regions of the ventricular septum, and there may be more than one VSD present. Malalignment of the conal septum may exist, resulting in variable degrees of right or left ventricular outflow tract obstruction. Conal VSDs often develop involvement of the aortic valve over many years (112). The size may be determined by an estimation of the diameter of the VSD in relation to the aortic annulus, and by degree of restriction to blood flow as estimated by Doppler echocardiogram. Perimembranous and muscular VSDs may become smaller or close with time, particularly if the initial diameter of the VSD is less than 5 mm (113). In patients with isolated moderate to large VSDs, congestive heart failure develops over time once an imbalance exists between systemic and pulmonary vascular resistance and a significant left to right shunt develops. Neonates with large VSDs will typically develop pulmonary overcirculation, left ventricular volume overload, and symptoms of congestive heart failure within the first several weeks to months of life as pulmonary vascular resistance falls. Any associated left ventricular outflow tract obstruction, such as coarctation of the aorta, will exacerbate this problem. Premature infants with left to right shunting at the ventricular or great artery level may develop congestive heart failure sooner as a result of decreased musculature in the pulmonary arterioles that allows for a precipitous drop in pulmonary vascular resistance.

A trial of medical management is usually indicated in infants with moderate to large VSDs. Provision of adequate nutrition and administration of medications including

P.731

loop diuretics and sometimes digoxin and/or angiotensin converting enzyme inhibitors (ACE inhibitors) can often allow surgery to be deferred for a few months (114). Supplemental oxygen and hyperventilation should be avoided, as they will cause pulmonary vascular resistance to fall, and Qp/Qs to rise. Infants who continue to have failure to thrive despite these measures are referred for surgical repair, or in selected cases, transcatheter intervention (115).

Atrioventricular Canal Defect

The presence or absence of a common atrioventricular valve orifice and the relative size of the physiologic VSD characterizes the different types of atrioventricular septal defects, also known as endocardial cushion defects. In patients with an incomplete atrioventricular canal, an ostium primum ASD exists along with a cleft in the mitral valve. There is no physiologic VSD present. A transitional atrioventricular canal defect has an ostium primum ASD, dense attachments of the atrioventricular valve leaflets to the crest of the ventricular septum such that two functionally separate atrioventricular valves exist, and a small physiologic VSD. A complete atrioventricular canal defect has a primum ASD, a common atrioventricular valve and a large inlet VSD. Associate anomalies include a left superior vena cava to the coronary sinus, additional VSDs, and aortic arch obstruction. Uncommonly, right ventricular outflow tract obstruction is seen, and such patients have features of tetralogy of Fallot and an atrioventricular canal (116). In most cases the ventricles are balanced, such that both are of

adequate size to support the full cardiac output following surgery. Occasionally one of the ventricles is hypoplastic (“unbalanced”), precluding a two ventricular repair. Such patients may be considered for a one and a half ventricular repair, the single ventricle pathway, or heart transplantation.

Infants with complete atrioventricular canal defects typically develop congestive heart failure within the first few weeks to months of life. The congestive heart failure will be exacerbated if significant atrioventricular valve regurgitation or aortic arch hypoplasia is present. There is an increased incidence of Down syndrome (trisomy 21) in patients with endocardial cushion defects, and such patients are predisposed to the early development of pulmonary vascular obstructive disease. A trial of medical management is indicated in symptomatic infants, as discussed above for patients with large VSDs. Surgical repair is required within the first three to six months of life to eliminate the symptoms of congestive heart failure, prevent the development of pulmonary vascular obstructive disease and minimize the incidence of postoperative pulmonary hypertensive crises. Surgical repair is not commonly performed in the newborn period as a result of the difficulty with suturing the paper-thin atrioventricular valve leaflets.

Infants with incomplete or transitional atrioventricular canal defects often follow the clinical course of patients with isolated ASDs, and these lesions are typically repaired sometime between 6 months and 4 years of age.

Patent Ductus Arteriosus

The ductus arteriosus normally is functionally closed within the first hours to days of life. PDAs may exist in isolation or with many other types of congenital heart disease. An isolated, large PDA will cause symptoms of congestive heart failure once the pulmonary vascular resistance falls, allowing a left to right shunt from the aorta to the pulmonary artery. Left atrial and left ventricular volume overload are present and pulmonary edema may occur. Diastolic runoff exists leading to a “steal” from systemic blood flow, which may contribute to mesenteric ischemia and the development of NEC. PDAs are more common and cause more symptoms in premature infants. Small PDAs typically do not cause symptoms but are a long-term risk for bacterial endocarditis. Symptoms of congestive heart failure may be treated with diuretics, digoxin and the provision of adequate nutrition. Approximately two-thirds of PDAs in premature infants will close following a course of indomethacin or ibuprofen (117). Surgical ligation is indicated for PDAs that do not respond to medical therapy in premature infants, and for PDAs in any symptomatic term infant. Older children with a continuous murmur but no symptoms should have the PDA closed surgically or in the cardiac catheterization laboratory to minimize the risk of endocarditis.

Aortopulmonary Window

An aortopulmonary window is an uncommon, usually large communication between the ascending aorta and pulmonary artery in the presence of two semilunar valves. This lesion usually exists in isolation, but may be associated with IAA, VSD, or other congenital heart defects (118,119). Infants with large aortopulmonary windows will usually develop congestive heart failure at several weeks of life. Prompt surgical repair is indicated in most cases to eliminate the symptoms of congestive heart failure, prevent the development of pulmonary vascular obstructive disease and minimize the incidence of postoperative pulmonary hypertension.

Cardiomyopathy and Heart Transplantation

Cardiomyopathy

A multidisciplinary team, lead by the intensivist, a cardiologist with expertise in heart failure and transplantation, and a congenital heart surgeon, is required to answer several key questions for each infant who presents with a severe cardiomyopathy: What is the primary cause for the cardiomyopathy? Is it treatable or reversible? What level of medical or mechanical support is required? Is the infant a candidate for heart transplantation?

Infants may develop a severe cardiomyopathy from a wide variety of causes, including infection, structural heart disease, chronic arrhythmia, metabolic disorders, and primary myopathies. The broad differential diagnosis for infantile

for heart transplantation, yet are readily treatable deserve comment. Infants born with anomalous left coronary artery from the pulmonary artery (ALCAPA) develop coronary ischemia when the pulmonary artery pressures fall after birth. These patients typically present in the first few weeks to months of life with severe left ventricular dysfunction, mitral regurgitation (as a result of papillary muscle ischemia), and pulmonary edema. The diagnosis may be suspected by the presence of characteristic findings on the electrocardiogram, and confirmed by echocardiography with careful examination of the coronary anatomy and blood flow pattern (120,121). Following reimplantation of the left coronary artery in the aorta, the vast majority of infants with ALCAPA recover left ventricular and mitral valve function (122). Infants with incessant arrhythmias, such as automatic atrial tachycardia, may present with severe cardiomyopathy. The initial rhythm may be thought to be sinus tachycardia secondary to the cardiomyopathy, but the correct diagnosis may be made by careful examination of the P wave morphology on the electrocardiogram. Myocardial function will recover once the arrhythmia is controlled with medications or ablation. Severe viral myocarditis is another condition that may be difficult to differentiate from a primary cardiomyopathy. Myocardial biopsy may provide clarity but is not without risk in sick infants. Many infants with viral myocarditis will recover ventricular function over time with supportive care (123).

Infants with cardiomyopathy may present with congestive heart failure or shock. Many of the principles for supporting cardiac output and monitoring of patients with severe cardiomyopathy are discussed below in the "postoperative care" section, and thus will not be reiterated. Mechanical support, typically with venoarterial extracorporeal membrane oxygenation (ECMO) in infants, may be used as a bridge to recovery or transplantation and is discussed further below. Indications for mechanical support in an infant with severe cardiomyopathy include worsening end-organ function and metabolic acidosis despite maximal medical support.

TABLE 34-6 CONGENITAL HEART DEFECTS THAT MAY WARRANT PRIMARY HEART TRANSPLANTATION

Hypoplastic left heart syndrome
 Severe Shone's syndrome
 Severe Ebstein's anomaly of the tricuspid valve
 Atrioventricular septal defects with unbalanced ventricles
 Pulmonary atresia/intact ventricular septum with coronary-cameral fistula and myocardial dysfunction
 Multiple cardiac tumors with myocardial dysfunction

Heart Transplantation

Heart transplantation is a widely accepted option for many infants with severe congenital heart disease and irreversible cardiomyopathies. Approximately 100 infant heart transplants are reported annually to the registry of the International Society for Heart and Lung Transplantation. Seventy-five percent of these transplants are for congenital heart disease, and the majority of the remainder are for cardiomyopathies (124). Heart transplantation is considered a primary option in some institutions for infants with complex congenital heart disease if surgical intervention is believed to result in an unacceptably high mortality rate (Table 34-6). Transplantation is also an option if uncorrectable anatomical issues and/or irreversible myocardial dysfunction are present following initial surgical intervention. The donor pool is very limited, and as a result as many as 25% of infants will die while waiting for a heart to become available. If more institutions adopted a policy of primary transplantation for the lesions listed in Table 34-6, particularly HLHS, the mortality while waiting for a donor heart to become available would certainly increase. Recent experience with ABO incompatible transplantation has shortened the wait times at a few centers (125). Relative contraindications to heart transplantation include high, fixed pulmonary vascular resistance (>6-8 Woods units per m²), recent or recurrent malignancy, serious infection, significant systemic disease, other organ system disease (e.g., hepatic, renal, or neurological), and chromosomal, metabolic or genetic abnormalities with a poor long-term prognosis.

Although the 1-year survival following heart transplantation in infancy is lower than that reported for older children, the long-term survival appears to be better, perhaps related to immune tolerance or better compliance with medications (124). The 10-year survival following infant heart transplantation is approximately 60%. Infants who have a successful heart transplant face potential long-term complications related to

with parents are always required before an infant is listed for transplantation.

Comprehensive supportive care is required to maintain patients who are awaiting transplantation in the ICU. An appropriate level of cardiopulmonary support is required to maintain end-organ function. This often entails the use of inotropic agents, vasodilators, and diuretics. Mechanical support, usually ECMO in infants, is occasionally required (126).

Mechanical ventilation may be beneficial to minimize oxygen consumption, and positive end-expiratory pressure will reduce wall stress and thus provide afterload reduction for a failing systemic ventricle. Close attention must also be given to the prevention of infection and the provision of adequate nutrition. Anticoagulation may be indicated for infants with severe myocardial dysfunction to minimize the chance of luminal clot formation.

Management of the infant with HLHS awaiting transplantation deserves comment. Ductal patency is maintained with a low dose PGE₁ infusion, and occasionally these infants can be discharged to home while awaiting transplantation (127). Infants with HLHS awaiting heart transplantation tend to develop pulmonary overcirculation as pulmonary vascular resistance falls over time, which further volume overloads the right ventricle and may exacerbate tricuspid regurgitation. The extended use of subambient FiO₂, achieved using supplemental inspired nitrogen, to increase pulmonary vascular resistance and limit pulmonary blood flow has been reported in this patient population (84,127). Limitation of pulmonary blood flow by banding of the pulmonary artery, either surgically or using innovative transcatheter techniques, has also been reported (128).

POSTOPERATIVE CARE

Intraoperative and Immediate Postoperative Management

Cardiopulmonary Bypass (CPB)

Selected pediatric cardiac surgical procedures may be performed without the use of CPB such as modified Blalock-Taussig shunt or repair of coarctation of the aorta. However, the majority of cardiac operations performed require CPB. Thus, physicians caring for these patients must be familiar with the equipment and techniques used to perform CPB, its sequelae on end-organ function, and several intraoperative strategies used to minimize the associated morbidities. The primary function of CPB is to temporarily replace the major functions of the heart and lungs while surgical interventions are performed on these organs. A typical CPB circuit used to perform these functions includes venous cannula(s) that drain systemic venous blood from the vena cavae or systemic venous atrium, a reservoir, a heat exchanger, a membrane oxygenator, a roller pump, a filter, and an arterial cannula to return blood to the aorta. Before initiation of CPB, the circulated blood must be modified to provide an appropriate composition of oxygen, carbon dioxide, pH, temperature, hematocrit, oncotic pressure, electrolytes, and glucose (129). The circuit is "primed" with standardized quantities of crystalloid solution, albumin, mannitol, sodium bicarbonate, heparin, calcium, and packed red blood cells. The patient is anticoagulated with heparin for the duration of CPB time, and cooled to a variable extent to minimize metabolic needs and oxygen consumption. Because hypothermia causes increased viscosity and red cell rigidity, hemodilution is used during hypothermic cardiopulmonary bypass.

To obtain a motionless heart for intracardiac repairs, the aorta is cross-clamped and a potassium-rich cardioplegia solution is injected into the proximal ascending aorta. Asystole develops once the cardioplegia solution perfuses the coronary circulation. The combination of cardioplegia and hypothermia provides myocardial protection for several hours. Following placement of the aortic cross clamp, blood from aortopulmonary collaterals will continue to return to the left atrium. To eliminate the left atrial blood return and facilitate certain complex left heart operations, deep hypothermic circulatory arrest (DHCA) may be used. Deep hypothermia refers to cooling of the core temperature to 18°C to 20°C. During circulatory arrest the CPB pump is shut off. In addition to the absence of blood returning to the left atrium, the perfusion cannula may be removed from the surgical field, creating optimal conditions for an accurate repair. Due to concerns about neurologic outcome following DHCA, regional perfusion techniques have recently been designed to minimize or avoid the use of circulatory arrest (130). The neurologic sequelae of CPB and DHCA are discussed in the section on neurologic complications later in this chapter. Following rewarming, weaning and separation from CPB, protamine is

administered to reverse the effect of heparin (129). Additional blood components may be required to control bleeding immediately following CPB.

A number of adverse effects from CPB will impact on the postoperative course. During CPB, formed elements of the blood are exposed to artificial surfaces and shear stress. Ischemia reperfusion injury occurs, as does microembolization of gas bubbles and particulate matter. Hemodilution may cause problems with oxygen delivery and dilution of clotting factors. These events trigger a complex neurohumoral and inflammatory response. CPB is associated with the release of endogenous catecholamines, vasopressin, endothelin, and activation of the renin-angiotensin-aldosterone axis, all of which contribute to elevation of systemic and pulmonary vascular resistances and fluid retention (131,132,133,134,135,136,137,138,139,140,141,142). A generalized inflammatory response occurs following CPB, and the complement, coagulation and fibrinolytic systems are activated (143,144,145,146). Capillary leak also occurs, related to fluid retention, the inflammatory response, and dilution of plasma proteins. White blood cells and platelets are also activated, leading to additional release of inflammatory mediators and proteolytic enzymes (147,148,149). Pulmonary leukosequestration occurs, as does oxygen free radical generation (150,151). Platelet counts

P.734

fall following CPB, and clotting factors are diluted (140,152). Myocardial systolic dysfunction also occurs following CPB in infants and children (153). The end result of these processes is a clinical picture of end-organ dysfunction of variable severity. The cardiovascular, pulmonary, hematologic and renal systems tend to be the most severely affected. Myocardial dysfunction, elevated systemic and pulmonary vascular resistance, abnormal gas exchange and decreased pulmonary compliance, bleeding and fluid retention all may be present in the early postoperative period.

Several pharmacologic agents and management strategies may be employed in the operating room to minimize these adverse effects of CPB. Mannitol is administered to the priming solution to induce an osmotic diuresis and act as an antioxidant (154). Dexamethasone, when administered prior to CPB, has been shown to reduce the inflammatory response to CPB, and is associated with several favorable clinical effects including a reduced need for supplemental fluids, a lower alveolar-arterial oxygen gradient, and decreased duration of mechanical ventilation (155,156). Further studies are needed to determine the optimal timing and dosing of dexamethasone prior to CPB. Aprotinin is a serine protease inhibitor that is used at many centers to attenuate the inflammatory and hemostatic activation related to CPB (157). In a series of pediatric studies, this medication, when used in a high dose regimen, has been demonstrated to safely decrease postoperative bleeding and operative closure time, and improve respiratory function, primarily in infants and in those patients undergoing a repeat sternotomy (158,159,160,161,162,163,164,165). Beneficial effects on the systemic inflammatory response were seen when methylprednisolone was used in addition to aprotinin in adults, but this combination of drugs has not been specifically studied in infants (166). New pharmacologic strategies to further blunt the inflammatory response to CPB are being investigated (167,168).

To aid in the removal of edema and hemoconcentrate the infant's blood, ultrafiltration is typically used during rewarming on CPB. Some surgeons use a technique called modified ultrafiltration (MUF) immediately following CPB, which may be a more efficient method to filter and hemoconcentrate the patient's blood. Following pediatric CPB, MUF has been shown to have favorable effects on hemodynamics, blood product requirements, and total body water balance (169,170,171). In a study of pediatric patients at risk for postoperative pulmonary hypertension, those receiving MUF had a lower pulmonary to systemic pressure ratio following CPB when compared to the group that had conventional ultrafiltration (171). Modified ultrafiltration has also been demonstrated to improve intrinsic left ventricular systolic function, improve diastolic compliance, increase blood pressure, and decrease inotropic medication use in the early postoperative period in children (172,173). Some investigators have found that the use of MUF is associated with a decrease in mechanical ventilation time following pediatric CPB (174).

Stabilization in the Intensive Care Unit Following Surgery

Ideally, the physicians caring for infants following cardiac surgery will attend preoperative multidisciplinary conferences in which data are presented and discussed to gain familiarity with each patient's anatomic and pathophysiologic issues and the surgical plan. When an infant is returned from the operating room following cardiac surgery, the intensivist must obtain a detailed report from the anesthesiologist and the surgeon. A description must be obtained of the anesthetic regimen, the operative findings and surgical procedure performed, and CPB, aortic cross-clamp and circulatory arrest times. Prolonged CPB times are a risk factor for significant postoperative morbidity and mortality in infants and children (15,175). Circulatory arrest times more

than 45 to 50 minutes may be associated with increased postoperative neurologic complications (176). A transesophageal echocardiogram may be performed before and following CPB for complex open heart cases in infants weighing >3 kg, and postoperative findings pertaining to myocardial function and residual lesions should be conveyed to the intensive care unit staff (177,178).

Invasive hemodynamic monitoring is required in nearly all infants following cardiac surgery. Some centers rely heavily on data obtained from invasive hemodynamic monitoring to evaluate myocardial function and detect residual lesions. Other institutions use a combination of minimal invasive monitoring and liberal use of transesophageal echocardiogram to achieve similar information. In any case, it is essential that the clinicians caring for infants following cardiac surgery are familiar with the interpretation and limitations of data obtained from invasive monitoring, and the complications associated with these catheters and pacing wires. A variety of factors may contribute to erroneous data obtained from invasive monitoring, including inappropriate transducer height, and bubbles or clots in the catheters. Information obtained from invasive monitoring cannot be used in isolation, but when placed in the context of the overall clinical picture, can be very useful to guide management in the early postoperative period.

Central venous access is required following CPB in infants, and the anesthesiologist or surgeon will choose a site depending upon the patient's anatomy, anticipated postoperative course and personal preference. For example, physicians may choose to minimize the placement of central venous lines in the subclavian and jugular veins in patients with single ventricle physiology as a result of concerns about thrombosis. Intracardiac lines may be inserted by the surgeon prior to chest closure through the right atrial appendage to the right atrium ("RA line"), or through the right upper pulmonary vein or left atrial appendage to the left atrium ("LA line"). An "OA" line refers to an intracardiac line placed in the common atrium in patients with single ventricle physiology. A pulmonary artery catheter may be placed through the right ventricular

P.735

outflow tract in patients at high risk for postoperative pulmonary hypertension, residual VSDs, or residual right ventricular outflow tract obstruction. Continuous monitoring of pulmonary artery pressure provides precise knowledge of the severity of pulmonary hypertension, and immediate feedback regarding the effectiveness of interventions to lower pulmonary artery pressure. Significant lability in pulmonary artery pressures during suctioning of the endotracheal tube or awakening from sedation may be a sign that the patient is not ready to be weaned. Measurement of a step-up in oxygen saturation from a superior vena cava or right atrial catheter to a pulmonary artery catheter may be helpful for the detection of significant residual left to right shunting (179). A pullback pressure tracing from the pulmonary artery to the right ventricle may be obtained at the time of removal of the pulmonary artery catheter, which quantifies any residual gradient across the right ventricular outflow tract (179). Some pulmonary artery catheters also have a thermistor tip, thus allowing cardiac output to be calculated by the thermodilution technique.

The report to the intensivist should include information about right and left heart filling pressures, and pulmonary artery pressures (if available) measured before the patient left the operating room. Proper interpretation of these loading conditions is beneficial for the detection of residual lesions, titration of volume administration, and the implementation of interventions that modify vascular tone. Appropriate interpretation of the atrial waveforms may provide insight into the presence of significant atrioventricular valve regurgitation or rhythm disturbances.

Complications associated with intracardiac lines are uncommon but include air embolus, thrombus, infection, bleeding, and catheter retention. Care must be taken when using LA lines in patients with two ventricular repairs, and with any intravenous or intracardiac line in those patients with single ventricle physiology, not to inject air into the systemic circulation. Thus LA lines are only used for monitoring whenever possible, and medication infusions and parenteral nutrition are typically administered through lines that are in the right heart. Although the reported risk of thrombosis or infection is very low with intracardiac catheters, LA and pulmonary artery catheters are removed as soon as possible following surgery, often on the first postoperative day or at the time of chest closure (180,181). Complications at the time of catheter removal include retention and bleeding; the latter has been shown to occur more commonly with pulmonary artery catheters (180,181). Institutional protocols designed to minimize the chance of bleeding at the time of removal of intracardiac lines include guidelines for acceptable coagulation times and platelet counts. Packed red blood cells should be readily available, particularly during the removal of pulmonary artery lines.

Arterial access, necessary for continuous blood pressure monitoring and frequent arterial blood gas sampling, is obtained prior to CPB in the radial, umbilical, femoral, dorsalis pedis or posterior tibial arteries (182,183,184). Care should be taken to ensure that blood pressure measurements are accurate. If a radial or pedal artery is

used for continuous blood pressure monitoring, one must take into account the effect of pulse amplification (higher systolic and lower diastolic blood pressure measured peripherally when compared with central recordings) when interpreting blood pressure values. Dampened waveforms or pressures measured distal to stenotic arteries may give the false impression of hypotension. For example, arm blood pressure measurements in a patient who has, or had in the past, an ipsilateral Blalock-Taussig shunt may be diminished as a result of arterial stenosis. Proper interpretation of the waveform and pulse pressure is important during postoperative management. For example, significant diastolic runoff may produce a wide pulse pressure if an oversized systemic to pulmonary shunt is used, or if severe aortic regurgitation is present. A narrow pulse pressure, along with tachycardia and hypotension, suggests cardiac tamponade. Patients who have had a repair of coarctation or aortic arch reconstruction should have four extremity blood pressure measurements taken to document the absence of a residual gradient.

Accurate assessment of the patient's heart rhythm is an important part of the initial evaluation following surgery. The heart rate and rhythm should be continuously monitored. An electrocardiogram should be obtained in the immediate postoperative period to serve as a new baseline should the infant subsequently develop a tachyarrhythmia or myocardial ischemia. Atrioventricular synchrony is important for optimizing cardiac output. Temporary pacing wires are commonly placed on the surface of the atrial and/or ventricular myocardium before chest closure, and are tunneled from the mediastinum through the upper abdominal wall where they are secured with tape. These pacing wires may be interrogated when the underlying rhythm is not apparent using the bedside monitor or a 12-lead electrocardiogram (see section on arrhythmias). These wires are quite safe and are usually removed prior to patient discharge (185).

Temperature should be monitored and regulated closely, as high temperature will place increased metabolic demands on the circulatory system, and low temperature will increase systemic vascular resistance (186). Some centers measure central and peripheral temperatures as an indirect estimate of systemic cardiac output. However, a recent investigation found a poor correlation between the core-peripheral temperature gap and lactate levels or hemodynamic parameters, such as cardiac index derived from a pulmonary artery catheter (187).

A directed physical examination should be performed to assess the cardiopulmonary status and adequacy of the surgical repair. Palpation of the precordium should be performed to assess the location and quality of the ventricular impulses. Any murmurs, rubs or gallops should be noted, although dressings and chest tubes may limit the auscultatory findings. It is common to hear a friction rub in the first few days following cardiac surgery, usually as a result of a small accumulation of fluid in the pericardium. The liver span should be noted. Adequate chest rise should be

P.736

found upon inspiration, and breath sounds should be noted bilaterally. The quality and symmetry of peripheral pulses and warmth of the extremities are useful means of assessing the adequacy of the systemic circulation. Caution must be used when attempting to estimate the adequacy of cardiac output by assessing capillary refill in the postoperative period, as capillary refill time has a poor correlation with cardiac index, systemic vascular resistance index and lactate levels in this setting (187).

Chest tubes should be assessed for location and proper function. Some surgeons will place only a mediastinal chest tube, whereas others will also place pleural tubes. Generally the tubes in infants are removed when drainage falls to less than 20 to 30 cc/day and when there is no evidence for chylothorax or air leak. The stomach should be routinely decompressed postoperatively with a nasogastric tube in all tracheally intubated patients. A CXR should be obtained upon admission to the ICU and daily thereafter, as this practice in infants results in a high percentage of films with an abnormality requiring intervention (188). Particular attention should be given to the location of all tubes and lines, and the heart size and lung fields.

The surgeon will occasionally leave the chest "open" for a few days, with the skin closed either primarily or using a silastic patch, until hemodynamic stability can be achieved, bleeding controlled, and myocardial edema can decrease (189). The sternum is routinely left open in many centers following the Norwood operation (4,190,191). The risk for mediastinitis may be increased when the chest is left open (190). When the chest is eventually closed respiratory compliance may decrease necessitating an increase in ventilatory support (190,192).

Cardiopulmonary interactions play an important role in the physiology of an infant following cardiac surgery (193). Ventilatory manipulations in the early postoperative period of PaCO₂, PaO₂, pH and mean airway pressure may be used in the context of the patient's physiology to improve hemodynamics. Mechanical ventilation is also

useful to minimize oxygen consumption in infants with limited cardiac reserve. Arterial oxygen saturation is monitored continuously by pulse oximetry. An arterial blood gas analysis is obtained frequently and attention should be given to ensure adequate oxygenation and ventilation for the individual patient's physiology. Ventilator settings used in the operating room are often quite different to those needed in the ICU, primarily as a result of the different ventilators and respiratory tubing used in these settings. Respiratory acidosis has been demonstrated to increase pulmonary vascular resistance in infants following CPB and in most cases should be avoided (193,194). Pulmonary overdistension increases pulmonary vascular resistance and decreases cardiac output (195). A low functional residual capacity following the discontinuation of mechanical ventilation has been associated with increased pulmonary vascular resistance following congenital heart surgery (193). Thus ventilator settings are ordered to maintain relatively normal lung volumes in the early postoperative period. Although early extubation policies have been reported for older infants and children, most neonates and young infants require at least 12 to 24 hours of mechanical ventilation following congenital heart surgery (196). Criteria for extubation following cardiac surgery in infants include the presence of adequate cardiac output, appropriate mental status to maintain the airway, muscular strength to support respiratory pump function, acceptable gas exchange, and the absence of significant arrhythmias, bleeding or fever.

Standard laboratory values need to be assessed in the early postoperative period. Electrolytes, including magnesium and ionized calcium levels, are monitored and normalized. The complete blood count is obtained daily, and hemoglobin levels are monitored more frequently. In general, a minimum hemoglobin level of 10 to 12 gm/dL is appropriate for infants following a two ventricular repair, and a hemoglobin level of 13 to 15 gm/dL is appropriate for infants following a palliative operation with ongoing cyanosis (See Color Plate). Anemia may place unnecessary workload on the myocardium in the postoperative period. Transfusion of erythrocytes will improve oxygen delivery following pediatric cardiac surgery (197). An excessively high hemoglobin level may increase ventricular afterload or predispose to shunt thrombosis by increasing viscosity (198). Measurement of prothrombin and partial thromboplastin times are obtained initially, and repeated as clinically indicated.

In addition to the physical examination, several clinical parameters may be used to assess the adequacy of cardiac output and oxygen delivery in the immediate postoperative period. The presence of a metabolic acidosis, as quantified by a base deficit or lactate level, suggests inadequate systemic cardiac output and requires investigation. Lactic acidosis develops when inadequate tissue oxygen delivery leads to anaerobic metabolism. Following congenital heart surgery, elevated lactate levels in infants and children upon admission to the ICU are associated with increased morbidity and mortality (175,199-201). Some centers routinely obtain venous blood gases from the superior vena cava to estimate cardiac output. An oxygen extraction ratio (SaO_2-SvO_2/SaO_2) of more than 0.5 at 6 hours after infant cardiac surgery suggests a severe derangement in oxygen transport that may be predictive of mortality (Fig. 34-13) (202). Urine output provides a good estimate of the systemic cardiac output and ideally should be at least 1 cc/kg/hour. Rising blood urea nitrogen (BUN) and creatinine levels (Cr) may be secondary to low cardiac output. Infants often require some inotropic support following CPB, and low dose dopamine is the initial drug of choice at many centers. Additional inotropic support is discussed further in the section below on low cardiac output.

Infants may develop significant fluid retention following CPB, which may impair myocardial, respiratory, and gastrointestinal function. Strategies used to minimize this problem in the operating room, including the use of steroids and ultrafiltration, are discussed earlier. Despite the presence of total body fluid overload,

P.737

intravascular volume depletion is common in the first few hours following surgery and several fluid boluses may be required. Furosemide is typically initiated 12 to 24 hours after surgery, either as bolus doses or continuous infusion (203). Additional diuretics with alternative mechanisms of action are used as clinically indicated. Low dose ("renal dose") dopamine is commonly used to augment urine output despite a lack of convincing data supporting its effectiveness in infants. Electrolyte disturbances, particularly hypokalemia, hyponatremia, and a hypochloremic metabolic alkalosis, are commonly encountered as diuresis occurs in the first few days following CPB.

Figure 34-13 Changes in mean oxygen extraction ratio (OER) for survivors and nonsurvivors after infant congenital heart surgery over time (circles = survivors, squares = nonsurvivors). Reprinted from Rossi AF, Seiden HS, Gross RP, et al. Oxygen transport in critically ill infants after congenital heart operations. *Ann Thorac Surg* 1999;67:739-744, with permission from the Society of Thoracic Surgeons.

Analgesia is required for all infants following cardiopulmonary bypass. High dose fentanyl is well tolerated and blunts the stress response in neonates following CPB (204,205,206). Morphine is another narcotic commonly used in the early postoperative period. Benzodiazepines may be given for amnesia and sedation. Either intermittent boluses or continuous infusions of these agents may be used in infants depending on the hemodynamics and perceived risk for pulmonary hypertension. The indications for the use of neuromuscular blocking agents vary at different centers, but these medications may be used to eliminate coughing and minimize oxygen consumption in patients with labile hemodynamics.

Gastrointestinal tract motility is decreased following cardiac surgery in infants as a result of the inflammatory effects of CPB, anesthesia, fluid retention, postoperative use of narcotics and possibly low cardiac output. Furthermore, some neonates may have been exposed to a preoperative period of mesenteric hypoperfusion. If these considerations preclude the initiation of enteral nutrition following surgery, the parenteral nutrition is prescribed. Histamine-2 receptor antagonists are typically administered to minimize the risk of upper gastrointestinal bleeding until enteral nutrition is established.

Common Postoperative Complications

Low Cardiac Output

The product of heart rate and stroke volume determines cardiac output. Stroke volume is determined by preload, afterload and contractility. Low cardiac output may thus be caused by abnormalities in one or more of these variables. An alteration in the heart rate or rhythm may impact cardiac output, and this is discussed further in the subsequent section on arrhythmias. Decreased preload may occur from hemorrhage, excessive diuresis, insufficient fluid replacement, or cardiac tamponade. Increased afterload may result from pulmonary hypertension, peripheral vasoconstriction or ventricular outflow obstruction. A decrease in myocardial contractility may result from a combination of factors including acidosis, electrolyte imbalance, hypothermia, or myocardial injury secondary to inflammation, a ventriculotomy, inadequate myocardial protection or ischemia reperfusion. Low cardiac output, when defined as a cardiac index less than 2.0 L/min/m², occurs following approximately 25% of complex two ventricle repairs in infancy (Fig. 34-14) (140). Other signs of low cardiac output include tachycardia, hypotension, poor peripheral perfusion, poor urine output and metabolic acidosis. A detailed assessment must be undertaken to identify the cause of low cardiac output so that proper treatment may be initiated and end-organ failure avoided (207).

A suboptimal surgical repair with significant residual intracardiac shunts, ventricular outflow or aortic obstruction,

systemic or pulmonary venous stenosis, and/or valvular lesions may be the primary etiology for low cardiac

output. The incidence of hemodynamically significant residual lesions following congenital heart surgery has likely decreased in recent years as a result of improving surgical technique and the liberal use of transesophageal echocardiogram immediately following CPB (178). That being said, when an infant develops low cardiac output or follows an atypical clinical course following CPB, a primary responsibility of the intensivist and/or cardiologist is the early detection of residual lesions that require reintervention. Failure to do so will expose the patient to prolonged ICU stays with the associated morbidity and mortality. A combination of factors will lead to the early identification of significant residual lesions, including an appreciation of the anticipated "normal" postoperative course, close attention to data obtained by intracardiac monitoring and physical examination, open communication with the cardiovascular surgeon, and a high index of suspicion (208). Early, focused echocardiography or cardiac catheterization is then required to define the extent of the problem (209,210).

Figure 34-14 Scatterplots showing serial measurements of cardiac index as determined by thermodilution techniques in 122 patients after the arterial switch operation for TGA. Cardiac index fell during the first postoperative night, returning to baseline values by 24 hours after surgery. There was no significant difference between patients randomized to deep hypothermic circulatory arrest (DHCA) and those randomized to low-flow cardiopulmonary bypass (LF). Values are depicted as the mean and one side of each 95% CI. Reprinted from Wernovsky G, Wypij D, Jonas RA, et al. Postoperative course and hemodynamic profile after the arterial switch operation in neonates and infants. A comparison of low-flow cardiopulmonary bypass and circulatory arrest. *Circulation* 1995;92:2226-2235, with permission.

Treatment of low cardiac output in neonates differs from that in older children and adults as a result of differences in cardiovascular physiology. Because neonates have a greater ratio of noncontractile to contractile myocardial mass, ventricular diastolic compliance is diminished, and they have a limited ability to increase their stroke volume, which is fixed at approximately 1.5 cc/kg (211,212,213). Thus the cardiac output is rate-dependent in this patient population. Heart rate may be optimized by pacing, or by using intravenous infusions of chronotropic agents including dopamine, dobutamine or rarely isoproterenol. For infants with complete heart block, atrioventricular sequential pacing at an appropriate rate is indicated to increase the cardiac output. Other postoperative arrhythmias are discussed in detail below.

Optimization of cardiac loading conditions is a key component to the management of the infant with low cardiac output (214). As described by the Frank-Starling mechanism, augmentation of the end-diastolic volume increases the number of interactions between actin and myosin molecules, resulting in a larger stroke volume and thus higher cardiac output. Conversely, hypovolemia may result in decreased ventricular filling and low cardiac output. Certain cardiac operations in infants, such as repair of tetralogy of Fallot or truncus arteriosus, result in particularly poor right ventricular compliance, which will require additional preload in the early postoperative period to maintain cardiac output. Volume replacement therapy should also be guided by close attention to filling pressures, arterial pressures, and physical examination signs including gallops, liver distention and peripheral pulses. The type and amount of fluid replacement is based upon the hematocrit, albumin level, and percentage of volume loss. Boluses of fluid are given in increments of 5 to 10 ml/kg over several minutes. A left atrial pressure above 14 to 16 mm Hg rarely produces an additional increase in cardiac output, and a left atrial pressure above 20 mm Hg can cause pulmonary edema (215). Furthermore, as a result of the large venous capacitance of infants, the right atrial pressures may not necessarily reflect the volume administered and should not be used in isolation to estimate preload.

Afterload, defined as the sum of forces that oppose systolic performance, is best quantified by systolic wall stress and vascular impedance, both of which are difficult to measure at the bedside. Afterload may be clinically estimated by using a pulmonary artery catheter to aid in the calculation of the resistance of the systemic and pulmonary vascular beds. An increase in vascular resistance can significantly reduce both stroke volume and the extent and velocity of wall shortening, resulting in decreased cardiac output and ventricular function. Increased vascular resistance is commonly seen following cardiopulmonary bypass in neonates (140). Physiologic factors such as hypoxia, acidosis, hypothermia, and pain may further increase systemic and pulmonary vascular resistance. Increased afterload may also be secondary to residual right or left ventricular outflow tract obstruction. In the setting of decreased cardiac contractility, increased afterload may be a compensatory response necessary to maintain systemic blood pressure.

Vascular resistance, and thus afterload, can be pharmacologically decreased by vasodilatation of the vascular bed (s). Systemic afterload reduction is beneficial for infants with significant aortic or mitral valve regurgitation, left ventricular dysfunction or hypertension. Afterload reduction in the pulmonary circulation is beneficial for infants with tricuspid valve regurgitation, right ventricular dysfunction and pulmonary hypertension. In addition to its inotropic properties, milrinone is a direct vasodilator of the systemic and pulmonary vascular beds (216). The systemic and pulmonary vascular resistances are also effectively lowered by intravenous infusion of sodium nitroprusside or nitroglycerine, which are both NO donors that cause smooth muscle relaxation. With the use of any of these vasodilators, volume augmentation may be necessary to fill the expanded vascular space and maintain adequate preload. Inhaled NO selectively vasodilates the pulmonary vascular bed, thereby decreasing right ventricular afterload and allowing for recovery of right ventricular systolic function (217). Positive pressure ventilation may reduce wall stress and left ventricular afterload in two ventricle hearts provided that preload is maintained (218,219). Occasionally an infant may have vasodilatory shock with inappropriately low systemic vascular resistance following CPB that is refractory to catecholamines. Favorable hemodynamic responses to vasopressin infusions have been described in this setting (220).

Cardiac contractility is the load-independent ability of the myocardium to generate force. Contractility may be chronically impaired preoperatively by pressure and/or volume overload related to the specific cardiac lesion. Contractility may be depressed intraoperatively by medications, anesthesia, myocardial ischemia, an extensive ventriculotomy, or by myocardial resection. Postoperatively,

P.739

hypoxia, acidosis, and pharmacologic agents may affect contractility. In infants and children the cardiac index tends to reach its nadir approximately 4 hours after CPB, and begins to rise to normal values after 9 to 12 hours (221). The fall in cardiac index and rise in systemic and pulmonary vascular resistance occurring between 6 to 18 hours following the arterial switch operation in neonates with TGA has been well described (140). If the infant still shows evidence of low cardiac output after optimizing the heart rate, the preload, and afterload, myocardial contractility should be enhanced with pharmacologic agents. Several inotropic drugs are currently available, and each has its own characteristic effects that may be more suitable for use in various clinical situations.

Dopamine activates dopaminergic, α , and β -receptors, depending on the dosage used. When prescribed at 1 to 5 mcg/kg/min, dopamine preferentially dilates mesenteric and renal vessels, and increases renal blood flow. Dosing at 5 to 10 mcg/kg/min tends to increase cardiac output with a mild increase in heart rate (222). Higher doses of dopamine (10-20 mcg/kg/min) are usually avoided because of an increase in pulmonary vascular resistance related to alpha-receptor stimulation. Low-dose dopamine is the initial drug of choice to increase inotrope at many centers.

Dobutamine, a synthetic catecholamine, acts primarily on myocardial beta-receptors. Contractility increases with infusion of dobutamine, but there is less effect on heart rate or vascular tone than with dopamine (223,224,225).

Milrinone is a phosphodiesterase inhibitor that exerts a positive inotropic effect by increasing intracellular levels of cyclic adenosine monophosphate (cAMP), leading to improving cardiac contractility. It also has lusitropic properties, and acts as a direct vasodilator of the systemic and pulmonary vascular beds (216). Milrinone has been shown to decrease the incidence of low cardiac output syndrome in a prospective, randomized clinical trial of pediatric patients less than 6 years of age undergoing biventricular repair, and to improve hemodynamics in neonates with existing low cardiac output (226,227).

Patients who have marked myocardial dysfunction that does not improve with one or a combination of the first line agents listed above may respond to intravenous epinephrine at 0.01 to 0.05 mcg/kg/min. When administered in this dosage range, epinephrine primarily activates β -1 cardiac receptors causing increased inotrope, and β -2 peripheral receptors causing reduced afterload. High-dose epinephrine (>0.1 mcg/kg/min) is

not frequently used because of marked α -adrenergic action and adverse effect on renal perfusion. High-dose epinephrine has also been shown to cause myocardial necrosis in neonatal pigs (228).

Infants with refractory low cardiac output, myocardial dysfunction and impending cardiovascular collapse may benefit from having their sternotomy incision reopened in the ICU. The combination of edema of the myocardium and other mediastinal structures, and any fluid or blood collections around the heart may contribute to poor ventricular filling and compliance. Reopening the chest will expand the mediastinal space until edema improves, and any fluid collections or blood clots can be easily removed. Should low cardiac output persist, an open chest allows easy access for cannulation for mechanical support.

In patients with excessive or prolonged inotropic or vasopressor needs following CPB, a state of relative adrenocortical insufficiency may exist. Myocardial β -receptor down regulation has been demonstrated to occur in infants and small children with congenital heart disease in the perioperative period (229). Corticosteroids, probably acting by improving vascular tone and up regulating adrenergic receptors, may allow weaning of high dose catecholamine infusions in infants (230).

Thyroid hormone plays a critical role in the regulation of the cardiovascular system, and decreased levels of triiodothyronine (T_3) and thyroxine levels occur in some infants following CPB (231,232,233). Preliminary data suggest that exogenous supplementation with T_3 is well tolerated and may improve mixed venous oxygen saturation and decrease inotropic requirements following neonatal CPB (234). Favorable changes in hemodynamics have also been reported in older infants and children who were given T_3 following CPB (235,236). Patient enrollment has been completed for a prospective, randomized, double-blind, placebo-controlled clinical trial designed to evaluate the effects of a 72-hour infusion of T_3 on early postoperative outcomes in neonates undergoing the Norwood procedure or repair of IAA at Children's Hospital Boston, and the results will be available in early 2005.

Arrhythmias

The development of a postoperative arrhythmia may severely compromise cardiac output in the infant following CPB. Prolonged CPB and aortic cross clamp times, and higher postoperative serum troponin levels, are associated with the development of arrhythmias in infants and children (237). An accurate diagnosis of the arrhythmia may be obtained with a 12-lead electrocardiogram. However, it is often the case in infants with fast heart rates that the relationship of the P waves to the QRS complex is uncertain on the standard 12-lead ECG, and in these instances, interrogation of temporary atrial pacing wires is very helpful (185,238). Several techniques may be used to interrogate the temporary atrial pacing wires. One such method is to connect the two leg leads of the ECG machine to the temporary atrial pacing wires, and the two arm leads are placed on the patient's arms in the usual fashion. A rhythm strip of leads I, II and III is then recorded from the ECG machine. Lead I will be a surface electrogram, and a sharp atrial electrogram (indicating atrial depolarization) is produced in leads II and III, which may be compared to the surface QRS complex in lead I to determine the relationship of P waves to the QRS complexes. The presence of cannon a-waves may give insight into the presence of an arrhythmia and its mechanism. Cannon a-waves, depicted on the bedside monitor as an increase in amplitude of the atrial pressure waveform obtained by intraatrial lines,

P.740

occur when the atria contract against a closed atrioventricular valve during various arrhythmias. Nearly any type of arrhythmia may occur following infant CPB. Commonly encountered arrhythmias are discussed in the following paragraphs, and further information may be found in an excellent book on pediatric arrhythmias (239).

Premature atrial complexes (PACs) are occasionally seen and may be related to central lines, electrolyte disturbances or surgical incisions; they are usually benign. Reentrant forms of supraventricular tachycardia (SVT), such as atrial flutter and atrioventricular reentrant tachycardia, are relatively uncommon following infant cardiac surgery. Although rate-related aberrancy and antegrade conduction over accessory connections may occur, in most cases of SVT the QRS complex in tachycardia is similar in morphology and axis to that seen on the baseline postoperative ECG. The baseline QRS complex may be wide if a bundle branch block developed during surgery, as is common following repair of tetralogy of Fallot, VSDs, and complete atrioventricular canal defects. Atrial flutter is more likely to be seen following complex atrial baffling procedures. Atrial flutter is characterized by a rapid, regular atrial rate with variable atrioventricular conduction. Adenosine is helpful diagnostically as the flutter waves will persist in the presence of atrioventricular block. Atrial flutter may be terminated using rapid atrial pacing, via the temporary pacing wires or a transesophageal electrode, or

synchronized cardioversion starting at 0.5 to 1 J/kg. Atrioventricular reentrant tachycardia may be seen in infants with accessory connections, such as some patients with Ebstein's anomaly, L-looped ventricular inversion. Pre-excitation (Wolfe-Parkinson-White Syndrome) may be present on the electrocardiogram in sinus rhythm. Atrioventricular reciprocating tachycardia is characterized by retrograde P waves following the QRS complex in a one-to-one relationship, and is terminated with adenosine, rapid atrial pacing, or synchronized cardioversion. Atrioventricular node reentrant tachycardia and atrial fibrillation are rare in infants and will not be discussed further.

Ectopic atrial tachycardia is an uncommon form of SVT following congenital heart surgery. It is characterized by an automatic atrial rhythm with "warm up" and "cool down" behavior at its onset and termination. Infants having disruption of the atrial septum (e.g., tricuspid atresia or TGA following balloon atrial septostomy), longer CPB times, higher inotropic needs, and potassium depletion may be at increased risk for developing this arrhythmia (240). Treatment strategies include normalization of electrolytes and temperature, minimizing inotropic infusions, and administration of a variety of antiarrhythmic agents including beta-blockers and amiodarone.

Junctional ectopic tachycardia (JET) is a common type of SVT seen in the postoperative period in infants, particularly following repair of tetralogy of Fallot or VSDs (241,242). JET is an automatic rhythm originating from the bundle of His, and although thought to be caused by some form of trauma to the atrioventricular (AV) node during surgery, may occasionally be seen following cardiac surgical interventions distant from the AV node. The occurrence of postoperative JET has been reported to prolong postoperative mechanical ventilation and ICU times (243). Electrophysiological characteristics of JET are as follows: a QRS morphology similar to that seen in sinus rhythm; atrio-ventricular dissociation with the ventricular rate faster than the atrial rate, or 1:1 retrograde conduction; "warm up" behavior as seen with automatic arrhythmias; and failure to respond to adenosine, overdrive pacing or cardioversion (244). Cannon a-waves will have variable amplitude in patients with JET if ventricular-atrial (V-A) dissociation is present, but constant increased amplitude will be seen with JET if the junctional rhythm is conducted to the atria in a 1:1 retrograde pattern. A 12-lead ECG or interrogation of temporary atrial pacing wires will confirm the diagnosis. Although JET usually resolves spontaneously in the first few days following surgery, this arrhythmia will often cause hemodynamic compromise when the ventricular rate exceeds 170 to 180 beats per minute. Treatment strategies must be individualized to the individual patient's heart rate and hemodynamic status and include fever control, provision of adequate analgesia to minimize endogenous catecholamine release, minimizing the use of exogenous catecholamines, normalization of electrolytes and acid-base status, atrial pacing at a rate faster than the junctional rate, and mild hypothermia (245,246). Medications used to treat JET when the above measures fail include amiodarone, esmolol and procainamide (244, 246,247). As these drugs have negative inotropic and chronotropic properties, close monitoring of hemodynamics and back-up pacing capabilities are necessary.

Premature ventricular contractions (PVCs) may reflect myocardial irritability, electrolyte disturbances or hypoxia. Lidocaine is often administered for frequent PVCs or nonsustained ventricular tachycardia (VT). VT is characterized by a fast, wide QRS complex that differs in morphology and axis compared to the postoperative baseline, and has either 1:1 retrograde V-A conduction, or V-A dissociation. The presence of complex ventricular ectopy or VT is suggestive of myocardial ischemia, and those infants who had coronary manipulation as a component of their operation should have a prompt evaluation of coronary blood flow. Sustained VT with hemodynamic compromise may be terminated by synchronized cardioversion starting at 1 J/kg. Pharmacologic therapy, starting with either lidocaine or procainamide, may be considered for patients with hemodynamically stable VT. Ventricular fibrillation (VF) is characterized by a wide complex, irregular rhythm that requires immediate defibrillation, starting at 2 J/kg. Cardiopulmonary resuscitation is required during VF until a perfusing rhythm is reestablished.

Complete heart block typically is apparent when the patient is rewarmed following CPB, but much less commonly may develop in the first few days following surgery. Atrioventricular sequential temporary pacing is used for treatment (248). The capture threshold of the temporary ventricular pacing wire should be determined frequently in patients who have developed or are at high risk for complete heart block. An alternative method of pacing

may be required for patients with very high or rapidly rising capture thresholds. If atrioventricular conduction does not return within 7 to 14 days, a permanent pacemaker is placed to prevent low cardiac output and sudden death (52).

Pulmonary Hypertension

Although the movement toward early complete neonatal repair has led to a decreased incidence of pulmonary hypertensive crises for patients with many congenital heart defects, this complication continues to impede the recovery of infants following complete surgical repair or palliation in the contemporary era (3,8,142,249,250). Severe pulmonary hypertension, defined as a ratio of pulmonary to systemic arterial pressure greater than or equal to 1.0, was present postoperatively in 2% of infants and children having congenital heart surgery at a single center (median age 4.2 months) (251). In this series, severe pulmonary hypertension was associated with an increase in mortality.

Pulmonary hypertension following infant CPB may be caused by a combination of preoperative, intraoperative, and postoperative factors, the sum effect of which may be additive (Table 34-7). The presence of several preoperative clinical features allows for the identification of infants at increased postoperative risk for pulmonary hypertension. Specific lesions, all characterized by having preoperative large left to right shunts or obstructed pulmonary venous return, are associated with postoperative pulmonary hypertension (8,252). Infants with large communications at the ventricular or arterial level by definition have pulmonary hypertension prior to going to the operating room. Infants with obstructed pulmonary venous return, mitral stenosis or left ventricular outflow obstruction (critical aortic valve stenosis or coarctation of the aorta) may have severe preoperative pulmonary hypertension and increased pulmonary vascular resistance. Down syndrome is also a risk factor for severe postoperative pulmonary hypertension (251).

TABLE 34-7 FACTORS CONTRIBUTING TO PERIOPERATIVE PULMONARY HYPERTENSION IN INFANTS

endothelial injury

Postoperative

mechanical obstruction to pulmonary blood flow

residual left to right shunt

atelectasis

hypoxic pulmonary vasoconstriction

catecholamines (endogenous and exogenous)

CPB is associated with increased pulmonary vascular resistance in infants and children (140,141). CPB causes partial ischemia of the pulmonary vasculature, leading to endothelial cell dysfunction and decreased endogenous production of NO (141,253-256). CPB leads to increased plasma levels of catecholamines, endothelin-1 and other pulmonary vasoconstrictors in infants and children (252,257-259). In infants, prolonged CPB time has been associated with increased pulmonary vascular resistance in the postoperative period (142). The presence of significant pulmonary hypertension soon after weaning from CPB is predictive of subsequent pulmonary hypertension in the ICU and the need for prolonged ventilatory support (142,260).

Postoperatively, large residual left to right shunts or obstruction to pulmonary venous or distal pulmonary arterial blood flow, or left ventricular outflow tract obstruction all may cause pulmonary hypertension. Noxious stimuli, particularly suctioning of the endotracheal tube, may trigger a pulmonary hypertensive crisis (261).

Pulmonary hypertension may manifest as low cardiac output following a two-ventricular repair when both septa are completely intact. In infants with a significant risk for pulmonary hypertensive spells, such as those undergoing complete repair of truncus arteriosus, an atrial communication is often intentionally left open so that right to left shunting may occur to preserve cardiac output in the event that pulmonary artery pressures become significantly elevated. In such infants, and those with palliated single ventricle physiology, excessive cyanosis will be present if postoperative pulmonary hypertension occurs. Pulmonary artery catheters, although not commonly used in infants at many congenital heart centers, provide direct and continuous measurement of pulmonary artery pressure following two

ventricular repairs. The severity of pulmonary hypertension may also be estimated echocardiographically by Doppler interrogation of a tricuspid regurgitation jet in the absence of right ventricular outflow tract obstruction.

TABLE 34-8 CRITICAL CARE STRATEGIES FOR TREATMENT OF PULMONARY HYPERTENSION

Encourage	Avoid
1. Anatomic investigation	1. Residual anatomic disease
2. Right to left atrial pop off	2. Intact atrial septum
3. Sedation/analgesia	3. Agitation/pain
4. Moderate hyperventilation	4. Respiratory acidosis
5. Moderate alkalosis	5. Metabolic acidosis
6. Adequate inspired oxygen	6. Alveolar hypoxia
7. Normal lung volumes	7. Atelectasis or overdistension
8. Optimal hematocrit	8. Excessive hematocrit
9. Inotropic support	9. Low output and coronary perfusion
10. Pulmonary vasodilators	10. Pulmonary vasoconstrictors

Modified from Wessel DL. Managing low cardiac output syndrome after congenital heart surgery. Crit Care Med 2001;29:S220-30, with permission.

A combination of relatively simple postoperative strategies should be sufficient to prevent the development of pulmonary hypertensive crises in many at-risk patients (Table 34-8) (262). Adequate oxygenation and ventilation are important in the early postoperative period to maintain low pulmonary vascular resistance, as is the maintenance of relatively normal lung volumes (193-195,263). Deep sedation and analgesia in the immediate postoperative period are also used to minimize the incidence of pulmonary hypertension crises. High dose fentanyl infusions have been shown to reduce the stress response and postoperative morbidity in infants following CPB (257). In particular, fentanyl has been shown to blunt the elevation in pulmonary artery pressure and pulmonary vascular resistance related to endotracheal suctioning following the repair of congenital heart defects in infants (205). Benzodiazepines are commonly used for additional sedation. Prophylactic alpha-receptor blockade and early definitive repair can reduce the incidence of postoperative pulmonary hypertension (8). Although nitric oxide is well tolerated and decreases the incidence of pulmonary hypertensive crises in high-risk infants, this drug is not commonly used for primary prevention of pulmonary hypertension crises in part related to its high cost (250).

Before assuming that increased pulmonary vascular resistance causes pulmonary hypertension, the intensivist must ensure that an anatomic etiology for elevated pulmonary artery pressures is not present. For example, significant residual pulmonary arterial obstruction distal to the point of pulmonary artery pressure measurement will cause pulmonary hypertension, but the pulmonary artery pressure will not fall with medical management including inhaled NO (208).

All of the management strategies mentioned above regarding the prevention of pulmonary hypertension are used in the event of a pulmonary hypertensive crisis. Hyperventilation has been shown to reduce pulmonary artery pressure and pulmonary vascular resistance in infants and children with pulmonary hypertension in the early postoperative period. Although hyperventilation is a first-line intervention for pulmonary hypertensive crises, the following associated effects must be considered. Systemic vascular resistance increases with hyperventilation, as a result of alkalosis, leading to decreased cardiac output (264,265). Depending on the ventilator strategy used to achieve hyperventilation, the mean airway pressure may increase, which may increase pulmonary vascular resistance. Other concerning side effects of hyperventilation include reduced cerebral and coronary blood flow, and a leftward shift of the oxy-hemoglobin dissociation curve.

In an infant with a two-ventricular repair and intact atrial septum who experiences a pulmonary hypertension crisis and develops refractory hypotension, careful infusion of volume through the left atrial line will bypass the pulmonary vascular bed and may temporarily stabilize the blood pressure until the pulmonary vascular resistance is reduced.

Nonselective vasodilators were used in the past to treat severe pulmonary hypertension, however, current standard therapy centers on the use of NO. NO, when produced by the vascular endothelium, diffuses to adjacent smooth muscle cells, in which relaxation occurs by activation of guanylate cyclase, which increases intracellular guanosine 3', 5'-monophosphate (cyclic GMP) (266). Because NO is rapidly inactivated by hemoglobin, it acts as a selective pulmonary vasodilator when delivered by inhalation (267,268). Side effects associated with NO include a rebound effect upon withdrawal of the drug, and methemoglobinemia

(269,270,271). Preliminary observations suggest that sildenafil may be useful to facilitate the weaning of NO in infants who previously demonstrated significant rebound pulmonary hypertension (272).

One randomized study of high-risk infants and young children found that NO did not lower pulmonary artery pressure or prevent pulmonary hypertensive crises. Most

P.743

patients in the study were receiving nitroprusside, a NO donor, and about one-half were receiving milrinone. Furthermore, this study was not controlled for the use of neuromuscular blockade, and several patients in the study had underlying lung disease (273). However, the vast majority of studies found a beneficial effect of NO in alleviating pulmonary hypertension following CPB in infants and children. In a randomized, double-blind, placebo-controlled clinical trial of infants and children (mostly infants with VSDs or atrioventricular canal defects) who emerged from CPB with a mean pulmonary artery pressure more than 50% of the mean systemic artery pressure, NO was shown to reduce the mean pulmonary artery pressure in the immediate postoperative period (260). Several other nonrandomized reports demonstrate the efficacy and safety of NO for selectively lowering pulmonary artery pressure in infants and young children following CPB (141,274-278). Transient right ventricular dysfunction following repair of congenital heart defects may be exacerbated by pulmonary hypertension. NO improves right ventricular ejection fraction and cardiac output while decreasing pulmonary artery pressure and vascular resistance in infants and young children following a biventricular repair (217). NO also decreases pulmonary artery pressure in infants with single ventricle physiology following the bi-directional Glenn operation (278,279). NO may reduce the need for extracorporeal life support in infants with critical pulmonary hypertension after CPB (280).

The benefits of intravenous prostacycline on pulmonary vascular resistance in children with congenital heart disease are offset by tachycardia and systemic hypotension (281,282,283). However, more recent studies have found that inhaled prostacycline, which causes vasodilation by increasing intracellular concentrations of cAMP, is as effective as NO for lowering pulmonary vascular resistance following repair of congenital heart disease (284,285). Further clinical investigation and clinical experience are required before inhaled prostacycline can be recommended for widespread clinical use following CPB in infants.

Cyanosis

Excessive cyanosis following surgical repair or palliation may be attributed to a variety of anatomic problems depending upon the individual patient's physiology. In the infant with palliated single ventricle physiology, excessive cyanosis may be attributable to inadequate pulmonary blood flow, pulmonary venous desaturation and/or systemic venous desaturation. Decreased pulmonary blood flow may be as a result of stenosis or thrombosis in the systemic to pulmonary artery shunt, or stenosis in the superior vena cava or pulmonary arteries following the bi-directional Glenn or hemi-Fontan operation. If an anatomic problem is suspected with the systemic to pulmonary artery shunt or a bi-directional Glenn, a cardiac catheterization is usually required. Pulmonary hypertension may also cause decreased pulmonary blood flow, which can be attributed to CPB, or impairment of blood egress from the pulmonary veins (e.g., pulmonary venous obstruction or left atrial outlet obstruction). In palliated single ventricle patients with excessive cyanosis, treatment of pulmonary hypertension includes the use of NO if standard measures to lower pulmonary vascular resistance are ineffective (278,279). Pulmonary venous desaturation may be caused by parenchymal lung disease, pleural effusions, or systemic to pulmonary venous collateral vessels. Systemic venous desaturation, secondary to anemia, low cardiac output or increased oxygen consumption, may also contribute to cyanosis following single ventricle palliation. Similar causes for excessive cyanosis may exist following a two-ventricle repair, particularly if an atrial communication exists allowing right to left shunting. For example, following complete repair of truncus arteriosus, excessive cyanosis related to decreased pulmonary blood flow may be present in the postoperative period as a result of poor right ventricular compliance, right ventricular outflow tract obstruction, or pulmonary hypertension with subsequent right to left shunting at the atrial level. Note that excessive systemic venous desaturation will not contribute to cyanosis following a two-ventricle repair unless a residual intracardiac communication or veno-venous collaterals exist that allow right to left shunting.

Ventilatory management of the infant with excessive cyanosis following the bi-directional Glenn/hemi-Fontan operation deserves special consideration. As pulmonary blood flow is passive and heavily influenced by intrathoracic pressure, ventilator settings that minimize mean airway pressure and maximize exhalation time will enhance pulmonary blood flow. As these operations place the cerebral and pulmonary vascular beds in series, pulmonary blood flow is derived in large part from venous return from the brain to the superior vena cava. Working on the principle that increased partial pressure of CO₂ (PaCO₂) results in cerebral arterial vasodilation

and increased cerebral blood flow, investigators have demonstrated that hyperventilation decreases SaO₂ following the bi-directional Glenn/hemi-Fontan operation, and the hypoventilation improves SaO₂ (286,287). In addition to CO₂ induced increased cerebral blood flow, however, other uncontrolled factors that may have resulted in improved SaO₂ in these patients included a decrease in mean airway pressure during hypoventilation, and CO₂ stimulated increase in cardiac output leading to increased oxygen saturation in the inferior vena cava (287).

Bleeding

Excessive bleeding may occur from suture lines and/or abnormalities in the coagulation system following CPB (152). Generally accepted risk factors for postoperative bleeding include repeat sternotomy, cyanosis, and operations involving extensive suture lines in the aorta. Excessive bleeding may be defined as greater than 5cc/kg of blood from the chest tube in any given hour or greater than 3 cc/kg/hour × 3 hours. Intraoperative administration of aprotinin may minimize postoperative bleeding, as

P.744

discussed earlier (164). Aminocaproic acid and tranexamic acid, both antifibrinolytic agents, may be administered intraoperatively to infants at risk for bleeding (288,289,290,291). The platelet count is maintained more than 50,000 to 100,000/mL in the early postoperative period. Fresh frozen plasma is administered for a prothrombin time (PT) more than 25 seconds or for excessive bleeding. Hypertension might exacerbate bleeding and should be controlled. Inadequate neutralization of heparin will be manifested by a prolonged partial thromboplastin time (PTT), and additional protamine is indicated if this diagnosis is suspected.

Bleeding may occur when intracardiac lines are removed. Bleeding is more common following the removal of pulmonary artery catheters and left atrial lines, when compared to right atrial lines (180,181). The pulmonary artery and left atrial lines are generally removed on the first day following surgery if no longer needed clinically, or at the time of chest closure. Coagulation times and platelet counts should be at acceptable levels, and cross-matched blood should be available when these catheters are removed.

Cardiac tamponade may occur when significant bleeding is not evacuated by the chest tube(s). External compression of the heart by blood or blood clots leads to impaired ventricular filling, increased central venous pressure, tachycardia, a narrow pulse pressure and eventually systemic hypotension. The diagnosis can be confirmed by echocardiography, and surgical exploration of the chest is required, either emergently at the bedside, or urgently in the operating room.

Cardiac Arrest

Infants having a cardiac arrest following congenital heart surgery have better survival rate (41% in one series) when compared with other general pediatric intensive care unit patient populations (292). The better survival rate may be attributed to a variety of issues unique to the cardiac population, including the increased incidence of an acute ventricular arrhythmia, the absence of multi-organ system failure in the majority of the cardiac patients, and the common presence of central venous access, arterial access and epicardial pacing wires. Survival to hospital discharge was achieved in 5/22 infants despite resuscitation times >30 minutes in one series of patients, making the use of predetermined resuscitation end points somewhat irrelevant (292). However, the long-term neurologic outcome of these 5 infants was not reported in this study. Algorithms exist for the management of infants experiencing a cardiopulmonary arrest and will not be repeated here (293). If spontaneous circulation has not returned despite a few minutes of resuscitation, the chest may be reopened in infants who have had a recent sternotomy, and open cardiac massage performed. Rapid-deployment extracorporeal membranous oxygenation (ECMO; also see Chapter 32) has been used to salvage some infants receiving ongoing cardiopulmonary resuscitation and is discussed further below (294).

Mechanical Cardiac Support

A recently published textbook includes a detailed discussion of pediatric mechanical cardiac support (295). At most congenital heart centers, postoperative ECMO is used in approximately 3% of infants and children following CPB (296). ECMO is used to provide mechanical cardiopulmonary support in most infants, as aortic balloon pumps and ventricular assist devices currently are not widely available for this patient population as a result of size limitations and other technical issues. Some experience does exist, however, with a centrifugal pump

ventricular assist device in infants, including those with isolated left ventricular failure following repair of anomalous origin of the left coronary artery from the pulmonary artery, a lesion that is characterized by having severe but reversible left ventricular systolic dysfunction (297,298).

Following surgical repair or palliation, infants who cannot be weaned from CPB may be converted to an ECMO circuit before leaving the operating room. Once in the ICU, those infants who develop refractory low cardiac output, severe cyanosis, arrhythmias, or pulmonary hypertension despite maximal medical therapy, or have an unexpected cardiac arrest may be candidates for mechanical cardiopulmonary support. Mechanical support may be used as a bridge to myocardial recovery or cardiac transplantation (126,299,300). Venoarterial ECMO is required in nearly all of infants requiring mechanical support for primary cardiac failure, in contrast to neonates with primary respiratory failure who may be supported with venous-venous ECMO. Relative contraindications to ECMO include multi-organ system failure, an irreversible or inoperable disease process, significant neurologic impairment, uncontrolled bleeding, extremes of size and weight, and inaccessible vessels during cardiopulmonary resuscitation (262). The decision to employ ECMO following infant CPB should be made prior to the development of irreversible end-organ failure, as patients who have been placed on ECMO after extended efforts at medical management have been shown to do poorly (301,302).

Although some investigators have found single ventricle physiology to be a risk factor for mortality with cardiac ECMO, relatively good outcomes (50% survival to hospital discharge) were reported in a recent series of patients requiring ECMO after a Norwood palliation (301,302). Management of the systemic to pulmonary artery shunt in infants with single ventricle physiology who require ECMO deserves special consideration. As is the case prior to initiation of mechanical support, the physiology of these patients is such that high flow through the shunt may lead to coronary ischemia, volume overload of the single ventricle and systemic hypoperfusion, all of which will impede efforts to wean from ECMO. If the shunt is left patent when ECMO is initiated, the flow on the ECMO circuit must be increased to compensate. Pulmonary overcirculation may also occur. Partial or complete ligation of the shunt will eliminate the large left to right shunt, but may lead to pulmonary infarction and shunt thrombosis (301,303).

P.745

The intensive care management of infants on ECMO has been reviewed elsewhere in great detail and is beyond the scope of this chapter (304). However, two critical issues deserve comment. In infants with biventricular physiology on ECMO, it is essential that the left atrium and left ventricle are decompressed to reduce myocardial wall stress and pulmonary edema, thus optimizing the chances for myocardial recovery. Left ventricular distension may be assessed by echocardiogram, and decompression may be accomplished by increasing the ECMO flow rate, using low-dose inotropic agents and afterload reduction to improve myocardial ejection, and/or by decompressing the left atrium by surgically placing a vent. The ventilator strategy used in infants on ECMO for cardiac failure is also important to optimize the probability of myocardial recovery. Even on full venoarterial ECMO flow, the coronary circulation is typically perfused by blood ejected from the left ventricle. Thus a primary goal of ventilator management is to ensure that minimal ventilation-perfusion mismatch occurs in the lungs, so that pulmonary venous blood, which eventually perfuses the myocardium, is adequately oxygenated (304). This is in direct contrast with the typical ventilator strategy used in neonates with primary respiratory failure on ECMO, which focuses on lung rest and avoidance of further lung injury.

Inability to wean from ECMO within 3 to 5 days and the development of renal failure are ominous signs for pediatric cardiac patients (296,302,303,305-307). A high index of suspicion for residual lesions is necessary for infants who fail to wean from ECMO in a timely fashion (306). If transthoracic echocardiographic windows are poor, transesophageal echocardiography may be safely used in infants on ECMO to obtain diagnostic information (308). Cardiac catheterization may also be performed safely with infants on ECMO to evaluate for the presence of residual lesions that may be amenable to transcatheter or surgical intervention, or to decompress the left heart (309).

Rapid-deployment ECMO using a modified circuit and an organized response team may be used to facilitate the resuscitation of infants in full cardiopulmonary arrest following congenital heart surgery. One single center report described a series of 11 infants and children following a mean cardiopulmonary resuscitation time of 55 minutes, with 7 patients (64%) surviving to hospital discharge (294). Other centers have reported similar outcomes for emergent ECMO initiated during a postoperative cardiac arrest (299,303).

Survival to hospital discharge following pediatric cardiac ECMO has been shown to be approximately 40% to 60% in several series (296,299,301,303,307,310,311). Children with viral myocarditis requiring mechanical circulatory support have a higher survival rate (80%) (312). Although the intermediate-term cardiac follow-up is favorable for infants who survive postpericardiotomy ECMO, this patient population may have an increased

incidence of significant neurologic deficits when compared with older children who required mechanical support (313,314). The etiology for these neurological deficits is unclear, but may be related to intraoperative variables such as the use of circulatory arrest, or the complex ECMO circuit that may cause thromboembolic events and requires higher levels of anticoagulation when compared to ventricular assist devices used in older patients.

Pulmonary Complications

Pulmonary dysfunction occurs following CPB as a result of a variety of factors, including the diffuse inflammatory response, increased capillary permeability, fluid overload and microemboli. In an infant animal model of CPB, postpump pulmonary dysfunction includes an increased pulmonary vascular resistance, alveolar-arterial oxygen gradient, and decreased pulmonary compliance (256). Following CPB, infants have decreased lung compliance and increased total lung resistance (315). A variety of strategies designed to counteract these adverse effects of CPB have been discussed earlier, including the use of MUF, steroids, and strategies to prevent and treat pulmonary hypertension.

The infant who cannot be weaned from mechanical ventilation or extubated in a timely fashion may have a residual cardiac lesion and/or a noncardiac etiology as an explanation for the lack of progress. Non-cardiac reasons for difficult weaning are numerous and include abnormalities in respiratory drive (e.g., central nervous system injury, sedation), respiratory pump (e.g., critical illness polyneuropathy, phrenic nerve injury), gas exchange (e.g., parenchymal lung injury) or increased ventilatory load (e.g., overfeeding, increased dead space).

External compression of the central airways occasionally may complicate the pre- or postoperative course in infants with congenital heart disease. For example, aortic enlargement causing central airway compression may occur in lesions with increased fetal aortic blood flow such as pulmonary atresia (316). Some neonates with tetralogy of Fallot and absent pulmonary valve syndrome have significant pulmonary artery dilation that leads to tracheal and mainstem bronchial compression in the preoperative period, and tracheobronchial malacia may persist following surgery (317). Tracheal stenosis or malacia may develop postoperatively as a result of airway mucosal injury related to the endotracheal tube. Upper airway obstruction will make intrathoracic pressure significantly more negative in the spontaneously breathing patient, and the resultant increased ventricular afterload may be poorly tolerated in the infant with limited cardiac reserve.

The phrenic nerves are at risk for paresis or transection during many infant cardiac surgeries, and paralysis of a hemidiaphragm may make it difficult to wean infants from mechanical ventilation (318). The diagnosis may be confirmed by echocardiogram or fluoroscopy while the infant is spontaneously breathing. Diaphragmatic plication may be required to facilitate weaning from the ventilator (319,320). The recurrent laryngeal nerve may be injured during aortic arch surgery or PDA ligation, resulting in unilateral vocal cord paralysis. Postoperatively, such infants

P.746

may have problems with maintenance of functional residual capacity and aspiration.

Tracheobronchial ischemia, leading to obstruction of the lower airways, has been reported to occur following unifocalization procedures in infants with pulmonary atresia, ventricular septal defect, and MAPCAs. The tracheobronchial ischemia is probably related to interruption of peribronchial arterial blood supply during mobilization of MAPCAs (321).
