Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

Contributors

Thomas E. Adrian Ph.D., F.R.C.Path.

Professor

Department of Biomedical Sciences Creighton University School of Medicine, Omaha, Nebraska.

Chapter 40: Gastrointestinal Disease

Ruben E. Alvaro M.D., F.A.A.P.

Associate Professor

Department of Pediatrics University of Manitoba; Acting Head of Neonatology, Department of Pediatrics, St. Boniface General Hospital, Winnipeg, Manitoba, Canada.

Chapter 17: Cardiorespiratory Adjustments at Birth

Marianne S. Anderson

Associate Professor of Pediatrics and Neonatology

Perinatal Research Center, University of Colorado HSC, Denver, Colorado.

Chapter 26: Intrauterine Growth Restriction and the Small-For-Gestational-Age Infant

Robert J. Arceci M.D., Ph.D.

Director and King Fahd Professor of Pediatric Oncology; Professor of Pediatrics and Oncology

Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Baltimore, Maryland.

Chapter 53: Neoplasia

John H. Arnold M.D.

Assistant Professor

Department of Anaesthesia (Pediatrics), Harvard Medical School; and Senior Associate, Anesthesia and Critical Care, Children's Hospital, Boston, Massachusetts.

Chapter 57: Anesthesia and Analgesia in the Neonate

Gordon B. Avery M.D., Ph.D.

Emeritus Professor of Pediatrics; Retired Chair

Department of Pediatrics, The George Washington University School of Medicine and Health Sciences; and Chief Academic Officer, Emeritus, Department of Pediatrics and Neonatology, Children's National Medical Center, Washington, D.C.

Chapter 1: Neonatology: Past, Present and Future

Stephen Baumgart M.D.

Professor of Pediatrics Elect

George Washington University School of Medicine; Senior Staff Physician, Department of Neonatology, Children's Hospital National Medical Center, Washington, D.C.

Chapter 24: Thermal Regulation

David A. Beckman Ph.D.

Associate Professor

Department of Pediatrics, Thomas Jefferson University; and Nemours Research Programs, Alfred I. duPont Hospital for Children, Wilmington, Delaware.

Chapter 15: The Effects of Maternal Drugs on the Developing Fetus

Edward F. Bell M.D.

Professor

Department of Pediatrics, University of Iowa; and Director, Division of Neonatology, Children's Hospital of Iowa, Iowa City, Iowa.

Chapter 21: Fluid and Electrolyte Management

Joseph A. Bellanti M.D.

Professor

Department of Pediatrics and Microbiology-Immunology, Georgetown University Medical Center, Washington, D.C.

Chapter 45: Immunology of the Fetus and Newborn

Corinne Benchimol D.O.

Clinical Assistant Professor

Department of Pediatrics, Mount Sinai School of Medicine; Clinical Assistant Professor, Department of Pediatrics, Mount Sinai Hospital, New York, New York.

Chapter 42: Renal Disease

Forrest C. Bennett M.D.

Professor

Department of Pediatrics, University of Washington School of Medicine, Seattle, Washington.

Chapter 60: Developmental Outcome

Judy Bernbaum M.D.

Professor

Department of Pediatrics, University of Pennsylvania School of Medicine; and Director, Neonatal Follow-Up Program, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania.

Chapter 59: Medical Care After Discharge

Victor Blanchette M.D., B.Ch., F.R.C.P.

Professor

Department of Pediatrics, University of Toronto; and Chief, Division of Hematology/Oncology, The Hospital for Sick Children, Toronto, Ontario, Canada.

Chapter 46: Hematology

Carl L. Bose M.D.

Professor

Department of Pediatrics, University of North Carolina at Chapel Hill; and Chief Division of Neonatal-Perinatal Medicine, UNC Hospitals, Chapel Hill, North Carolina.

Chapter 4: Neonatal Transport

Michael J. Boyajian

Program director plastic and reconstructive surgery; Director craniofacial surgery program

Division: plastic and reconstructive surgery, Children's National Medical Center, Washington, D.C.

Chapter 44: Surgical Care of Conditions Presenting in the Newborn

Robert J. Boyle M.D.

Professor of Pediatrics

University of Virginia Health System, Charlottesville, Virginia.

Chapter 2: Current Moral Priorities and Decision Making in Neonatal-Perinatal Medicine

Robert L. Brent M.D., Ph.D., D.Sc.

Distinguished Professor of Pediatrics, Radiology, and Pathology

Department of Pediatrics, Jefferson Medical College, Philadelphia,

Pennsylvania; and Head, Clinical and Environmental Teratology

Laboratory, Nemours Research Programs, Alfred I. duPont Hospital for Children, Wilmington, Delaware.

Chapter 15: The Effects of Maternal Drugs on the Developing Fetus

Luc P. Brion M.D.

Professor

Department of Pediatrics, Albert Einstein College of Medicine; and

Attending Neonatologist, Department of Pediatrics, Children's Hospital at Montefiore, Bronx, New York.

Chapter 42: Renal Disease

Richard L. Bucciarelli M.D.

Associate Vice President for Health Affairs and Professor of Pediatrics

Department of Pediatrics, University of Florida; Neonatologist, Depart-

ment of Pediatrics and Neonatology, Shands at University of Florida, Gainesville, Florida.

Chapter 3: Neonatology in the United States: Scope and Organization

Dorothy I. Bulas M.D.

Professor of Pediatrics and Radiology

Departments of Radiology and Pediatrics, The George Washington

University Medical Center; and Director, Program in Diagnostic Imaging, Division of Diagnostic Imaging, Children's National Medical Center, Washington, D.C.

Chapter 12: Fetal Imaging: Ultrasound and Magnetic Resonance Imaging

Barbara K. Burton M.D.

Professor and Head

Division of Genetics and Metabolism, Department of Pediatrics, University of Illinois College of Medicine; and Director, Center for Medical and Reproductive Genetics, Michael Reese Hospital, Chicago, Illinois.

Chapter 41: Inherited Metabolic Disorders

Anthony J. Camerota M.D.

Department of Critical Care Medicine, Naval Regional Center, Portsmouth, Virginia.

Chapter 57: Anesthesia and Analgesia in the Neonate

Joyce Campbell R.N., M.S.

Service Director

Emergency Department Infection Control Practitioner, Children's National Medical Center, Washington, D.C.

Chapter 49: Healthcare-Associated Infections

Anthony Chan M.B.B.S., F.R.C.P.C.

Professor of Pediatrics

McMaster University, Hamilton, Canada; and Consultant, Coagulation Laboratory, Department of Pediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Canada.

Chapter 46: Hematology

Sukgi S. Choi M.D.

Associate Professor

Department of Otolaryngology and Pediatrics, The George Washington University School of Medicine; and Vice Chairman, Department of

Otolaryngology, Children's National Medical Center, Washington, D.C.

Chapter 44: Surgical Care of Conditions Presenting in the Newborn

John M. Costello M.D.

Instructor

Department of Pediatrics, Harvard Medical School, Division of Cardiac Intensive Care, Department of Cardiology, Children's Hospital Boston, Boston, Massachusetts.

Chapter 34: Preoperative and Postoperative Care of the Infant with Critical Congenital Heart Disease

Gary L. Darmstadt M.D.

Assistant Director

Department of International Health, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, Maryland; and Senior Research Advisor, Saving Newborn Lives Initiative, Office of Health, Save the Children Federation-USA, Washington, D.C.

Chapter 55: Dermatologic Conditions

Jonathan M. Davis M.D.

Professor

Department of Pediatrics, State University of New York at Stony Brook School of Medicine, Stony Brook; and Director, Neonatology; Director, Cardiopulmonary Research Institute, Department of Pediatrics, Winthrop-University Hospital, Mineola, New York.

Chapter 30: Bronchopulmonary Dysplasia

James G. H. Dinulos M.D.

Assistant Professor of Medicine and Pediatrics (Dermatology)

Children's Hospital at Dartmouth, Dartmouth Medical School, Lebanon, New Hampshire.

Chapter 55: Dermatologic Conditions

Yigal Dror M.D.

Division of Hematology/Oncology and Bone Marrow Transplantation;

Director, Marrow Failure and Myelodysplasia Program, Scientist Track, Research Institute, The Hospital for Sick Children, University of Toronto, Canada.

Chapter 46: Hematology

Arie Drugan M.D.

Associate Professor

Department of Obstetrics and Gynecology, Wayne State University, Hutzel Hospital, Detroit, Michigan; and Vice-Chairman, Department of Obstetrics and Gynecology, Rambam Medical Center, Haifa, Israel.

Chapter 10: Prenatal Diagnosis in the Molecular Age— Indications, Procedures, and Laboratory Techniques

Chester M. Edelman Jr. M.D.

Professor

Department of Pediatrics, Albert Einstein College of Medicine; Attending Physician, Department of Pediatrics, Montefiore Medical Center, Bronx, New York.

Chapter 42: Renal Disease

Martin R. Eichelberger M.D.

Professor

Department of Surgery and Pediatrics, The George Washington University School of Medicine; and Director, Emergency Trauma Services, Children's National Medical Center, Washington, D.C.

Chapter 44: Surgical Care of Conditions Presenting in the Newborn

Mark I. Evans M.D.

Professor

Department of Obstetrics and Gynecology, Mount Sinai School of Medicine; Director, Institute for Genetics, New York, New York.

Chapter 10: Prenatal Diagnosis in the Molecular Age— Indications, Procedures, and Laboratory Techniques

Lynda B. Fawcett Ph.D.

Assistant Professor of Pediatrics

Department of Pediatrics, Jefferson Medical College, Philadelphia, Pennsylvania; and Assistant Professor, Nemours Biomedical Research, Alfred I. duPont Hospital for Children, Wilmington, Delaware.

Chapter 15: The Effects of Maternal Drugs on the Developing Fetus

Michael F. Flanagan M.D.

Department of Pediatrics, Section of Pediatrics Cardiology, Dartmouth Medical School; and Dartmouth–Hitchcock Medical Center, Lebanon, New Hampshire.

Chapter 33: Cardiac Disease

Alan W. Flake M.D.

Department of Pediatric Surgery, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania.

Chapter 13: Fetal Therapy

John C. Fletcher Ph.D.

Deceased; Prior Professor Emeritus of Biomedical Ethics, Department of Internal Medicine, University of Virginia School of Medicine, Charlottesville, Virginia.

Chapter 2: Current Moral Priorities and Decision Making in Neonatal-Perinatal Medicine

Mary Ann Fletcher M.D.

Clinical Professor of Pediatrics

The George Washington University School of Medicine and Health Sciences, Washington, D.C.

Chapter 19: Physical Assessment and Classification

Joseph T. Flynn M.D., M.Sc.

Associate Professor of Clinical Pediatrics

Department of Pediatrics, Albert Einstein College of Medicine; and Director, Pediatric Hypertension Program, Department of Pediatric Nephrology, Montefiore Medical Center, New York, New York.

Chapter 42: Renal Disease

Wayne H. Franklin M.D., M.P.H.

Associate Professor

Department of Pediatrics, Feinberg School of Medicine at Northwestern University, Division of Pediatric Cardiology, Children's Memorial Hospital, Chicago, Illinois.

Chapter 34: Preoperative and Postoperative Care of the Infant with Critical Congenital Heart Disease

Bishara J. Freij M.D.

Clinical Professor of Pediatrics

Department of Pediatrics, Wayne State University School of Medicine; and Chief, Division of Infectious Diseases, Department of Pediatrics, William Beaumont Hospital, Royal Oak, Detroit, Michigan.

Chapter 47: Bacterial and Fungal Infections

Michael Friedman M.D.

Assistant Professor of Pediatrics

Division of Neonatology, Stonybrook University; and Senior Staff Physician, Department of Neonatology, Stonybrook University Hospital, Stonybrook, New York.

Chapter 24: Thermal Regulation

David M. Frim M.D., Ph.D.

Assistant Professor

Department of Surgery and Pediatrics, The University of Chicago; and Chief, Section of Pediatric Neurosurgery, The University of Chicago Children's Hospital, Chicago, Illinois.

Chapter 51: Neurosurgery of the Newborn

Michael K. Georgieff M.D.

Professor

Department of Pediatrics, University of Minnesota; and Staff Neonatologist, Department of Pediatrics, Fairview-University Medical

Center, Minneapolis, Minnesota.

Chapter 22: Nutrition

Harold M. Ginzburg M.D., J.D., M.P.H.

Clinical Professor

Departments of Psychiatry and Neurology, Tulane Medical Center; and Clinical Professor, Department of Psychiatry, Louisiana State University, New Orleans, Louisiana.

Chapter 8: Law, Quality Assurance and Risk Management in the Practice of Neonatology

Penny Glass Ph.D.

Associate Professor of Pediatrics

Department of Pediatrics, George Washington University School of Medicine and Health Sciences; and Director, Child Development Program, Department of Psychology, Children's National Medical Center, Washington, D.C.

Chapter 9: The Vulnerable Neonate and the Neonatal Intensive Care Environment

Sergio G. Golombek M.D.

Associate Professor of Pediatrics

Department of Pediatrics, Division of Neonatology, Westchester Medical Center, New York Medical College, Valhalla, New York.

Chapter 31: Principles of Management of Respiratory Problems

Stanley N. Graven M.D.

Professor

Community and Family Health, Department of Pediatrics, University of South Florida; and Staff Physician, Department of Pediatrics, Tampa General Hospital, Tampa, Florida.

Chapter 6: Newborn Intensive Care Unit Design: Scientific and Practical Considerations

Kathy Hamelin R.N. B.A, M.N., I.B.C.L.C.

Clinical Nurse Specialist; Lactation Consultant

Women's Health Program, Health Sciences Centre; Adjunct Professor, Faculty of Nursing, University of Manitoba, Winnipeg, Manitoba, Canada.

Chapter 23: Breastfeeding and the Use of Human Milk in the Neonatal Intensive Care Unit

Anne R. Hansen M.D.

Assistant Professor

Department of Pediatrics, Harvard Medical School; and Medical Director Neonatal Intensive Care Unit, Department of Medicine, Children's Hospital Boston, Boston, Massachusetts.

Chapter 51: Neurosurgery of the Newborn

Michael R. Harrison M.D.

Department of Pediatric Surgery, University of California, San Francisco, San Francisco, California.

Chapter 13: Fetal Therapy

Gary E. Hartman M.D.

Professor of Surgery and Pediatrics

Department of Surgery, The George Washington University School of Medicine; and Chairman, Department of Pediatric Surgery, Children's National Medical Center, Washington, D.C.

Chapter 44: Surgical Care of Conditions Presenting in the Newborn

William W. Hay Jr. M.D.

Professor

Department of Pediatrics, University of Colorado Health Sciences Center, Aurora, Colorado.

Chapter 26: Intrauterine Growth Restriction and the Small-For-Gestational-Age Infant

Alan Hill M.D., Ph.D.

Professor

Department of Pediatrics, University of British Columbia; and Head, Division of Neurology, Department of Pediatrics, British Columbia's Children's Hospital, Vancouver, British Columbia, Canada.

Chapter 50: Neurological and Neuromuscular Disorders

Carl E. Hunt M.D.

Department of Pediatrics, Medical College of Ohio, Toledo, Ohio; and Director, National Center on Sleep Disorders Research, National Heart, Lung, and Blood Institute, Bethesda, Maryland.

Chapter 28: Control of Breathing: Development, Apnea of Prematurity, Apparent Life-Threatening Events, Sudden Infant Death Syndrome

Nelson B. Isada M.D.

Alaska Perinatology Associates, Anchorage, Alaska.

Chapter 10: Prenatal Diagnosis in the Molecular Age— Indications, Procedures, and Laboratory Techniques

Sherwin J. Isenberg M.D.

Lantz Professor of Pediatric Ophthalmology and Vice-Chairman
Department of Ophthalmology, Jules Stein Eye Institute, Harbor–UCLA School of Medicine, Los Angeles, California.

Chapter 54: Eye Disorders

Mark P. Johnson M.D.

Associate Professor

Departments of Obstetrics/Gynecology, Pathology, Molecular Medicine, and Genetics, Wayne State University; and Associate Director, Reproductive Genetics, Department of Obstetrics and Gynecology, Hutzel Hospital/The Detroit Medical Center, Detroit, Michigan.

Chapter 13: Fetal Therapy

Lauren A. Johnson-Robbins M.D.

Assistant Professor

Department of Pediatrics, Albany Medical College; and Attending Neonatologist, Albany Medical Center, Albany, New York.

Chapter 27: Multiple Gestations

George W. Kaplan M.D., M.S., F.A.A.P., F.A.C.S.

Clinical Professor

Department of Surgery and Pediatrics, School of Medicine, University of California, San Diego; and Chairman, Division of Urology, Children's Hospital, San Diego, California.

Chapter 43: Structural Abnormalities of the Genitourinary Tract

Winston W. K. Koo M.B.B.S.

Professor

Department of Pediatrics, Wayne State University; and Neonatologist, Department of Pediatrics, Hutzel Hospital, Detroit, Michigan.

Chapter 36: Calcium and Magnesium Homeostasis

Lajos Kovacs M.D.C.M., F.R.C.P.C., F.A.A.P.

Associate Professor

Department of Pediatrics; Faculty of Medicine, McGill University; and Staff Neonatologist, Department of Neonatology, Sir Mortimer B. Davis Jewish General Hospital, Montreal, Quebec, Canada.

Chapter 25: The Extremely Low-Birth-Weight Infant

Jukka K. Korpela M.D., Ph.D.

Adjunct Professor of Pediatrics

Department of Infectious Diseases, The George Washington University Medical Center; and Faculty, Department of Infectious Diseases, Children's National Medical Center, Washington, D.C.

Chapter 49: Healthcare-Associated Infections

Ian Laing M.D., F.R.C.P.C.H., F.R.C.P.E.

Clinical Director

Neonatal Unit, Simpson Centre for Reproductive Health, Royal Infirmary, Edinburgh, Great Britain.

Chapter 20: General Care

Helal J. Landy M.D.

Professor and Chair

*Department of Obstetrics and Gynecology, Georgetown University; and
Chief, Department of Obstetrics and Gynecology, Georgetown University
Hospital, Washington, D.C.*

Chapter 14: The Impact of Maternal Illness on the Neonate

Mary M. Lee M.D.

Associate Professor of Pediatrics

*Department of Pediatrics, Duke University Medical Center, Durham, North
Carolina.*

Chapter 39: Endocrine Disorders of the Newborn

Judith Littleford M.D., B.Sc., F.R.C.P.C.

Associate Professor

*Department of Anesthesia, University of Manitoba; and Section Head,
Women's Hospital of Anesthesia, Department of Anesthesia, Winnipeg,
Manitoba, Canada.*

Chapter 16: Obstetric Anesthesia and Analgesia: Effects on the Fetus and
Newborn

Liz Loewen R.N., B.F.A., M.N.

Lecturer; Faculty of Nursing

*University of Manitoba; and Network Researcher, MB Telehealth,
Winnipeg, Regional Health Authority, Winnipeg, Manitoba, Canada.*

Chapter 5: Telehealth in Neonatology

Ralph A. Lugo M.D.

Associate Professor

*Department of Pharmacotherapy, University of Utah College of Pharmacy,
Salt Lake City, Utah.*

Chapter 56: Drug Therapy in the Newborn

Carolyn Houska Lund R.N., M.S.N, F.A.A.N.

Intensive Care Nursery, Children's Hospital, Oakland, California.

Chapter 7: Organization of Care and Quality in the NICU

George H. McCracken Jr. M.D.

Professor; The Sarah M. and Charles E. Seay Chair in Pediatric Infectious Diseases

Department of Pediatrics, University of Texas, Southwestern Medical Center; and Attending Physician, Children's Medical Center, Dallas, Texas.

Chapter 47: Bacterial and Fungal Infections

Mhairi G. MacDonald M.B.Ch.B., F.R.C.P.(E.), F.R.C.P.C.H., D.C.H.

Professor of Pediatrics

The George Washington University School of Medicine and Health Sciences, Washington, D.C.

Chapter 8: Law, Quality Assurance and Risk Management in the Practice of Neonatology

Joseph R. Madsen M.D.

Assistant Professor

Department of Surgery, Harvard Medical School; and Associate Professor, Department of Neurosurgery, Children's Hospital, Boston, Massachusetts.

Chapter 51: Neurosurgery of the Newborn

M. Jeffrey Maisels M.B., B.Ch.

Clinical Professor of Pediatrics

Wayne State University School of Medicine, University of Michigan Medical Center; and Chairman, Department of Pediatrics, William Beaumont Hospital, Royal Oak, Michigan.

Chapter 35: Jaundice

Kathleen A. Marinelli M.D., T.R.C.L.C., F.A.B.M.

Associate Professor of Pediatrics

Department of Pediatrics, University of Connecticut School of Medicine, Hartford, Connecticut.

Chapter 23: Breastfeeding and the Use of Human Milk in the Neonatal Intensive Care Unit

Gilbert I. Martin M.D.

Clinical Professor

Department of Pediatrics, University of California, Irvine, Irvine; and Director, Neonatal Intensive Care Unit, Citrus Valley Medical Center, West Covina, California.

Chapter 6: Newborn Intensive Care Unit Design: Scientific and Practical Considerations

Irene M. McAleer M.D.

Department of Surgery, School of Medicine, University of California, San Diego; and Division of Urology, Children's Hospital, San Diego, California.

Chapter 43: Structural Abnormalities of the Genitourinary Tract

Scott Douglas McLean M.D.

Assistant Professor

Department of Pediatrics, Uniformed Services University of the Health Sciences, Bethesda, Maryland; and Chief, Medical Genetics, San Antonio Military Pediatrics Center, Brooke Army Medical Center, Ft. Sam Houston, Texas.

Chapter 38: Congenital Anomalies

Thomas Moshang Jr. M.D.

Professor

Department of Pediatrics, University of Pennsylvania; and Chief, Department of Pediatrics, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania.

Chapter 39: Endocrine Disorders of the Newborn

Martha D. Mullett M.D.

Professor of Pediatrics

Robert C. Byrd Health Sciences Center, West Virginia University, Department of Pediatrics, Morgantown, West Virginia.

Sarah C. Muttitt M.D., F.R.C.P.C., F.A.A.P., M.B.A.

Assistant Professor

*Department of Pediatrics and Child Health, University of Manitoba; and
Director, MB Telehealth, Winnipeg RHA, Winnipeg, Manitoba, Canada.*

Chapter 5: Telehealth in Neonatology

Suhas M. Nafday M.D., M.r.C.P.I., F.A.A.P.

Assistant Professor

*Department of Pediatrics, Albert Einstein College of Medicine; and
Attending Neonatologist, Section of Neonatology, Children's Hospital at
Montefiore, Bronx, New York.*

Chapter 42: Renal Disease

Michael Narvey M.D., F.R.C.P.C.

Neonatal Fellow

*Department of Pediatrics, University of Alberta, Edmonton, Alberta,
Canada.*

Chapter 19: Physical Assessment and Classification

Kurt D. Newman M.D.

*Departments of Surgery and Pediatrics, The George Washington
University School of Medicine, Department of Pediatric Surgery, Children's
National Medical Center, Washington, D.C.*

Chapter 44: Surgical Care of Conditions Presenting in the Newborn

Edward S. Ogata M.D., M.M.

Professor

*Department of Pediatrics, Northwestern University Medical School; and
Chief Medical Officer, Children's Memorial Hospital, Chicago, Illinois.*

Chapter 37: Carbohydrate Homeostasis

William Oh M.D.

Professor

Department of Pediatrics, Brown Medical School; Attending Neonatologist,

Department of Pediatrics, Women and Infants' Hospital, Providence, Rhode Island.

Chapter 21: Fluid and Electrolyte Management

Enrique M. Ostrea Jr. M.D.

Professor

Department of Pediatrics, Wayne State University School of Medicine; and Neonatologist, Department of Neonatology, Hutzel Women's Hospital, Detroit, Michigan.

Chapter 58: The Infant of the Drug-Dependent Mother

Apostolos Papageorgiou M.D., F.R.C.P.C., F.A.A.P.

Professor

Departments of Pediatrics and Obstetrics and Gynecology, McGill University; and Chief, Department of Pediatrics and Neonatology, Sir Mortimer B. Davis Jewish General Hospital, Montreal, Quebec, Canada.

Chapter 25: The Extremely Low-Birth-Weight Infant

Ermelinda Pelausa M.D., F.R.C.P.C.

Assistant Professor of Pediatrics (Neonatology)

McGill University Faculty of Medicine; and Staff Neonatologist; Medical Director (Neonatal Follow-up), Department of Neonatology, Sir Mortimer B. Davis Jewish General Hospital, Montreal, Quebec, Canada.

Chapter 25: The Extremely Low-Birth-Weight Infant

Roderic H. Phibbs M.D.

Department of Pediatrics, University of California, San Francisco, San Francisco, California.

Chapter 18: Delivery Room Management

J. Edgar Winston Cruz Posecion M.D.

Division of Neonatal–Perinatal Medicine, Department of Pediatrics, Wayne State University School of Medicine, Hutzel Hospital; and Children's Hospital of Michigan, Detroit, Michigan.

Chapter 58: The Infant of the Drug-Dependent Mother

David M. Powell M.D.

Assistant Professor

Department of Surgery, The George Washington University School of Medicine; and Attending Surgeon, Department of Pediatric Surgery, Children's National Medical Center, Washington, D.C.

Chapter 44: Surgical Care of Conditions Presenting in the Newborn

Richard Powers M.D.

Associate Neonatologist

Division of Neonatology, Children's Hospital and Research Center at Oakland, Oakland, California.

Chapter 7: Organization of Care and Quality in the NICU

Gabriella Pridjian M.D.

Professor and Chairman; The Ernest A. and Elizabeth Miller-Robin Chair in Obstetrics and Gynecology

Tulane University School of Medicine; and Assistant Dean, Lakeside Hospital and Clinic; Adjunct Professor of Pediatrics, Clinical Geneticist in Human Genetics Program, New Orleans, Louisiana.

Chapter 11: Feto-Maternal Interactions: Placental Physiology, the In Utero Environment, and Fetal Determinants of Adult Disease

Gloria S. Pryhuber M.D.

Associate Professor of Pediatrics (Neonatology) and Environmental Medicine Associate; and Director

Neonatal-Perinatal Fellowship Program, Golisano Children's Hospital at Strong, Rochester, New York.

Chapter 29: Acute Respiratory Disorders

Yung-Hao Pung M.D., M.P.H.

Assistant Professor

Department of Pediatrics, Georgetown University School of Medicine, Washington, D.C.

Chapter 45: Immunology of the Fetus and Newborn

Virender K. Rehan M.D., M.R.C.P. (UK), M.R.C.P.I. (Dublin)

Associate Professor

Department of Pediatrics, David Geffen School of Medicine at UCLA; and Director, Neonatal Intensive Care, Department of Pediatrics, Harbor UCLA Medical Center, Torrance, California.

Chapter 18: Delivery Room Management

Mary E. Revenis M.D.

Assistant Professor of Pediatrics

Department of Neonatology, The George Washington University School of Medicine and Health Sciences, and Children's National Medical Center, Washington, D.C.

Chapter 27: Multiple Gestations

Ward R. Rice M.D, Ph.D.

Associate Professor of Pediatrics

University of Cincinnati College of Medicine, Children's Hospital Medical Center, Cincinnati, Ohio.

Chapter 29: Acute Respiratory Disorders

Henrique Rigatto M.D.

Professor

Department of Pediatrics, Physiology and Reproductive Medicine, University of Manitoba–Winnipeg; and Director of Neonatal Research, Health Sciences Centre, Winnipeg, Manitoba, Canada.

Chapter 17: Cardiorespiratory Adjustments at Birth

William W. Robertson Jr. M.D.

Professor

Departments of Orthopaedic Surgery and Pediatrics, The George Washington University School of Medicine, Washington, D.C.

Chapter 52: Orthopedics

Warren N. Rosenfeld M.D.

Professor

Department of Pediatrics, State University of New York at Stony Brook School of Medicine, Stony Brook; and Chairman, Department of Pediatrics, Winthrop-University Hospital, Mineola, New York.

Chapter 30: Bronchopulmonary Dysplasia

Lisa M. Satlin M.D.

Professor

Department of Pediatrics, Mount Sinai School of Medicine; Chief, Division of Pediatric Nephrology, Department of Pediatrics, Mount Sinai Medical Center, New York, New York.

Chapter 42: Renal Disease

Robert L. Schelonka M.D.

Assistant Professor

Department of Pediatrics, University of Alabama at Birmingham; and Associate Medical Director, Regional Newborn Intensive Care Unit, Division of Neonatology, University of Alabama at Birmingham, Birmingham, Alabama.

Chapter 47: Bacterial and Fungal Infections

Mary M. K. Seshia M.b.Ch.B., F.R.C.P.

Department of Pediatrics, University of Cincinnati College of Medicine; and Director, Division of Pulmonary Biology, Children's Hospital Medical Center, Cincinnati, Ohio.

Chapter 5: Telehealth in Neonatology

Karen S. Wood M.D.

Assistant Professor

Department of Pediatrics, University of North Carolina at Chapel Hill; Medical Director, Pediatric Transport, Carolina Air Care, UNC Hospitals, Chapel Hill, North Carolina.

Chapter 4: Neonatal Transport

Yuval Yaron M.D.

Sourasly Medical Center, Tel Aviv, Israel.

Chapter 13: Fetal Therapy

Scott B. Yeager M.D.

Associate Professor

Department of Pediatrics, University of Vermont; and Chief, Division of Pediatric Cardiology, Medical Center Hospital of Vermont, Burlington, Vermont.

Chapter 33: Cardiac Disease

Terence L. Zach M.D.

Associate Professor

Department of Pediatrics, Creighton University, Omaha, Nebraska.

Chapter 40: Gastrointestinal Disease

Barbara J. Zeligs

Research Associate

Department of Pediatrics, Georgetown University School of Medicine; and International Center for Interdisciplinary Studies of Immunology, Washington, D.C.

Chapter 45: Immunology of the Fetus and Newborn

Foreword

It was in 1972 that I began planning the first edition of *Neonatology: Pathophysiology and Management of the Newborn*. In the preface of the first edition, I wrote that "Knowledge in this area has so expanded that it now seems important to collect this material in a multi-author reference work.... The newborn is heir to so many problems, and his or her physiology is so unique and rapidly changing, that all conditions in the newborn should come within the concern of the new and expanding discipline of neonatology." This thinking still guides the sixth edition, which you hold in your hands.

In the meantime, science and practice in neonatology have grown so rapidly that it is impossible for anyone to retain all the information that this text contains. It is more an anthology, a collection of major state-of-the-art papers, than a single book. We just do not have enough personal disk space and RAM to encompass it all. Many neonatologists have become sub-sub-specialists, while still retaining a broad view of the field. We also have become adept at using remote information, via electronic searches and consultation. Perhaps one of our all-too-frequent weaknesses rests in failing to fulfill the role of the general practitioner who puts it all together for individual families. In this respect, the chapter on ethical considerations has been an important aspect of each edition. As we go to publication, we mourn the death of John C. Fletcher, a pioneer and leader in medical ethics and co-author of the current *Ethical Considerations* chapter, who died May 27, 2004, at the age of 72. Dr. Fletcher was an Episcopal priest a man of deep personal convictions who was chief ethics officer at the NIH Clinical Center and a member of the faculty of the Virginia Theological Seminary. He served on many NIH committees as an ethicist, and he was a frequent consultant, author, and lecturer on ethics. We have learned much from his wisdom and compassion, and we offer him our admiration and respect.

There are 60 chapters in the current edition. All of those previously published have been extensively rewritten. Eight chapters have new authors, and there are three entirely new chapters regarding breast feeding, infection control in the NICU, and telehealth. "Something old, something new, something borrowed, something blue," as the saying

goes. Concerns about thermoregulation, delivery room resuscitation, nutrition, and infection have been there since the beginning. New contributions regarding molecular genetics, imaging and monitoring technology, and respiratory support are now important. Borrowed information comes from experts in perinatal obstetrics, radiology and imaging technology, pharmacology, laboratory medicine, cardiology, surgery, and outcomes research. And something blue is still with us: the critical problems of oxygenation attending delivery, lung immaturity, cardiac malformations, and pulmonary hypertension.

This is my last hurrah with this textbook. I have long been out of the nursery, even longer out of the laboratory, and I find life as an Emeritus Professor pleasant indeed. But I still delight in the wonderful interplay of science and art in the now-robust field of neonatology. Permit me, then, a few predictions. We will devote more energy to understanding and preventing preterm birth. We will find ways to deal with adverse behaviors that result in poor outcomes for the neonate: smoking, alcohol, drugs, poor prenatal care, inadequate nutrition, excess stress, prenatal infections, and others not yet described. We will apply health outcomes research to provide efficient feedback loops so that our best practices will be more quickly adopted, and variation among NICUs will be reduced. We will understand how to use our new molecular biology tools to modify growth and aid healing and repair. We will become more adept at neuroprotection and will intervene in destructive spirals such as reperfusion injury to the brain. And most importantly, we will learn wonderful and unexpected things about the plasticity of the brain and nervous system. Geoffrey Raisman, a founder of the concept of neuroplasticity, has said that current theory is the enemy of new scientific discovery. We need to marvel at the feats of regeneration achieved by salamanders, for one, and not rest until we understand which factors turn on, and which inhibit, regrowth of neural tissue. If newts can do it, we can do it. Enjoy!!

Gordon B. Avery M.D., Ph.D.

Preface

Early in the 1970s, the major medical postgraduate examining bodies in the United Kingdom, the Royal College of Physicians and the Royal College of Surgeons, recognized two specialties: adult medicine and general surgery. Pediatrics could be practiced only after completion of training and examination in adult medicine. The subspecialty of neonatology did not yet exist, and newborns weighing less than 1500 grams at birth were considered unlikely to survive. In the United States, subspecialty apprenticeships (fellowships) were available in neonatology; however, the treatment provided to sick newborn infants was largely extrapolated by miniaturization of that provided to adults and larger children. Earlier misadventures with “benign” therapeutic agents, such as oxygen, had resulted in calamitous complications, leading to the concept that premature infants stood a greater chance of intact survival if interventions were limited to the minimum.

In 1972, when the founding editor of *Neonatology: Pathophysiology and Management of the Newborn*, Gordon B. Avery, M.D. Ph.D., was planning the first edition, Dr. Mhairi MacDonald was in residency training in Edinburgh, Scotland; Dr. Martha Mullett in Morgantown, West Virginia, USA; Dr. Molly Seshia was practicing pediatrics in India. By the time that Drs. MacDonald and Mary Ann Fletcher joined Dr. Avery as co-editors for the fourth edition in the early 1990s, neonatology was an established pediatric subspecialty in both the United Kingdom and the United States, with a track record at once admirable for the pace of advancement of knowledge and technology and cautionary for the significant incidence of long-term morbidity in NICU survivors.

As the sixth edition goes to press, with two new editors, Drs. Mullett and Seshia, it is clear that the optimal practice of neonatology continues to require a careful balance between the aggressive use of modern therapeutic technology and the prevention of unintended damage to a fragile organism. The prefaces to previous editions reflect an ongoing concern with ethical issues surrounding the increasing ability to treat newborns previously considered nonviable.

The Accreditation Council for Graduate Medicine (ACGME) in the United States has defined 6 general medical competencies that must be achieved

by trainees in any branch of clinical medicine and surgery; namely: patient care (appropriate, effective, and compassionate), clinical science (application of evolving biomedical and clinical science to patient care), practice-based learning and improvement (ongoing investigation, evaluation, and improvement of patient care practices), interpersonal skills and communication (with patients, patients' families, and other members of the healthcare team), professionalism (vocation, ethical practice, self-evaluation, demeanor), and systems-based medicine (having the awareness that all healthcare is provided in the context of a larger system and the ability to effectively utilize system resources to support the care of patients). We hope that the sixth edition of this text will substantially assist those in training to acquire all six competencies. ACGME emphasis on communication skills and systems-based medicine, in particular, provides a timely reminder that the NICU team cannot exist in a vacuum; sound decisions must be made with the assistance of consultants in the community, and follow-up care for NICU graduates must be planned and monitored as carefully as acute intensive care.

In this edition of Neonatology there are three new chapters and eight new first authors. The addition of the chapter on telemedicine is based on advances in knowledge and technology. The addition of the chapters on breast feeding and infection control in the NICU are long overdue.

Mhairi G. MacDonald M.B.Ch.B., F.R.C.P.(E.), F.R.C.P.C.H., F.A.A.P., D.C.H.

Martha D. Mullett M.D., M.P.H.

Mary M. K. Seshia M.B.Ch.B., F.R.C.P.(E.), F.R.C.P.C.H., D.C.H.

Preface to the First Edition

Neonatology means knowledge of the human newborn. The term was coined by Alexander Schaffer, whose book on the subject, *Diseases of the Newborn*, was first published in 1960. This book, together with Clement Smith's *Physiology of the Newborn Infant*, formed cornerstones of the developing field. In the past fifteen years, neonatology has grown from the preoccupation of a handful of pioneers to a major subspecialty of pediatrics. Knowledge in this area has so expanded that it now seems important to collect this material into a multiauthor reference work.

Although the perinatal mortality rate has declined over the past fifty years, the best presently attainable survival rates have not been achieved throughout the world, and indeed the United States lags behind fifteen other countries, despite its vast resources. New knowledge and improvement in the coordination of services for mother and child are needed to drive down perinatal mortality further. And finally, far greater emphasis must be placed on morbidity, so that surviving infants can lead full and productive lives. One hopes that in the future the yardstick of success will be the quality of life and not the mere fact of life itself.

In this past decade, neonatology, as a recognized subspecialty of pediatrics, has come into being around the intensive care-premature nursery. Needless to say, the problems of prematurity are far from solved. But neonatology is ripe for a broadening-out from its prematurity-hyaline membrane disease beginnings. The newborn is heir to so many problems, and his or her physiology is so unique and rapidly changing that all conditions of the newborn should come within the concern of the new and expanding discipline of neonatology. It has long since become standard practice to admit to premature nurseries other high-risk infants such as those of diabetic or toxemic mothers. Here the criterion is the need for intensive care. However, the neonatologist's specialized knowledge should give him a significant role in the care of other infants in the first two to three months of life, whether they require intensive care and whether they are readmitted for problems unrelated to prematurity and birth itself. Detailed knowledge of newborn physiology can assist in the management of congenital anomalies, surgical conditions of the neonate, failure to thrive, nutritional problems, genetic, neurologic, and

biochemical diseases, and a host of conditions involving delayed maturation. Thus one can conceive of a subspecialty sharply limited in age to early infancy but broad in its study of the interaction of normal physiology and disease processes.

Neonatology must also grow in its relationship to obstetrics and fetal biology. In the best centers, an active partnership has developed between obstetrics and pediatrics around the management of high-risk pregnancies and newborns. Sometimes training has been cooperative, but in only a few instances have basic scientists concerned with fetal biology been brought into this effort. Important beginnings have been made in studying the fetomaternal unit, such as the endocrine studies of Egon Diczfalusy, the cardiopulmonary studies of Geoffrey Dawes, and the immunologic studies of Arther Silverstein. But fundamental processes such as the controls of fetal growth and the onset of labor are not understood at this time. Centers or institutes bringing together workers of diverse points of view are needed to wrestle with the profound problems of fetal biology. At the clinical level, the interdependence of obstetrics and neonatology is obvious. As an ultimate development, these two specialties may one day be joined as a new entity-perinatology-at least at the level of training and certification. In the meantime, far greater mutual understanding and daily interaction are needed for the optimal care of mothers and their infants.

This book is organized around problems as they occur, as well as by organ systems. It hopes to achieve a balance between presentation of the basic science on which rational management must rest, and the advice concerning patient care which experts in each subarea are qualified to give. Individual chapter authors have approached their subjects in various ways, and no attempt has been made to achieve a completely uniform format. In some instances, there is overlap of subject material, but the somewhat different viewpoints presented, and the desire to spare the reader from hopscotching through the book after cross references, have persuaded me to leave small overlaps undisturbed.

It is appreciated that no volume such as this can have more than a finite useful lifetime. Yet while its currency lasts, I hope it will serve as a practical guide to therapy and an aid in the understanding of pathophysiology for those active in the care of newborns.

Gordon B. Avery M.D., Ph.D.

Table of Contents

Part I - General Considerations

Chapter 1 - Neonatology: Past, Present and Future

- PAST: THE ROOTS
- PRESENT: THE TRUNK
- THE BRANCHES
- THE PRESENT
- THE FUTURE
- REFERENCES

Chapter 2 - Current Moral Priorities and Decision Making in Neonatal-Perinatal Medicine

- GOALS OF NEONATAL-PERINATAL MEDICINE
- SOCIETAL AND PROFESSIONAL ISSUES
- ETHICS AND MORAL DELIBERATION
- CULTURAL AND RELIGIOUS DIVERSITY
- HIV SCREENING OF PREGNANT WOMEN AND NEWBORN INFANTS
- SUBSTANCE ABUSE IN PREGNANCY
- GENETIC TESTING
- MAKING DECISIONS REGARDING THE APPROPRIATENESS OF INTER-INSTITUTIONAL TRANSFER
- REFERENCES

Chapter 3 - Neonatology in the United States: Scope and Organization

- THE CAPACITY TO DELIVER IN-HOSPITAL NEONATAL CARE
- COSTS OF DELIVERING NEONATAL CARE
- MAJOR MEASURES OF OUTCOME
- MAJOR MORBIDITIES
- REGIONALIZATION TODAY
- REFERENCES

Chapter 4 - Neonatal Transport

- HISTORY
- ORGANIZATION AND ADMINISTRATION
- TECHNICAL ASPECTS
- DOCUMENTATION

- QUALITY ASSURANCE
- PSYCHOSOCIAL CONSIDERATIONS
- LEGAL CONSIDERATIONS
- BACK TRANSPORT
- REFERENCES

Chapter 5 - Telehealth in Neonatology

- THE HISTORY OF TELEHEALTH
- TECHNOLOGY
- MEDICO-LEGAL AND REGULATORY ISSUES
- THE ECONOMICS AND EVALUATION OF TELEHEALTH
- TELEHEALTH APPLICATIONS IN NEONATOLOGY
- PRACTICAL STEPS IN GETTING STARTED
- IMPLICATIONS FOR THE FUTURE
- REFERENCES

Chapter 6 - Newborn Intensive Care Unit Design: Scientific and Practical Considerations

- DEVELOPING A MISSION STATEMENT
- CREATING THE TEAMS
- SITE VISITS
- SPECIFIC DESIGN ISSUES
- EQUIPMENT SELECTION
- REVIEW AND APPROVAL PROCESS
- HUMAN DYNAMICS CRUCIAL TO A SUCCESSFUL MOVE
- CHANGE-IN-PLACE
- REFERENCES

Chapter 7 - Organization of Care and Quality in the NICU

- ORGANIZATION OF CARE
- QUALITY IN THE NEONATAL INTENSIVE CARE UNIT
- CONCLUSION
- REFERENCES

Chapter 8 - Law, Quality Assurance and Risk Management in the Practice of Neonatology

- BASIC LEGAL AND REGULATORY CONCEPTS
- QUALITY ASSURANCE, PERFORMANCE IMPROVEMENT, AND RISK MANAGEMENT

- CONCLUSIONS
- REFERENCES

Chapter 9 - The Vulnerable Neonate and the Neonatal Intensive Care Environment

- NEONATAL SENSORY SYSTEMS: DEVELOPMENT, DISORDERS, ENVIRONMENT, AND INTERVENTION
- GENERAL PRINCIPLES
- ACKNOWLEDGMENTS
- REFERENCES

Part II - The Fetal Patient

Chapter 10 - Prenatal Diagnosis in the Molecular Age— Indications, Procedures, and Laboratory Techniques

- GENE ORGANIZATION
- ELEMENTS OF MOLECULAR GENETICS
- PRENATAL DIAGNOSIS
- REFERENCES

Chapter 11 - Feto-Maternal Interactions: Placental Physiology, the In Utero Environment, and Fetal Determinants of Adult Disease

- HUMAN PLACENTATION
- PLACENTAL TRANSFER
- PLACENTAL METABOLISM
- PLACENTA AS AN ENDOCRINE ORGAN
- AMNIOTIC FLUID
- FETAL MEMBRANES
- UMBILICAL CORD
- PLACENTAL PHYSIOLOGY IN DISEASE STATES
- THE IN UTERO ENVIRONMENT AND FETAL DETERMINANTS OF ADULT DISEASE
- BIRTH-WEIGHT AND CORONARY HEART DISEASE
- BIRTH-WEIGHT AND HYPERTENSION
- BIRTH-WEIGHT AND DIABETES
- REFERENCES

Chapter 12 - Fetal Imaging: Ultrasound and Magnetic Resonance Imaging

- ASSESSMENT OF FETAL AGE, GROWTH, AND MATURITY
- DETERMINING FETAL AGE

- FETAL WEIGHT ESTIMATES
- ASSESSMENT OF FETAL GROWTH
- FETAL ANATOMY
- DETECTION OF FETAL ASPHYXIA
- DOPPLER ASSESSMENT OF BLOOD VELOCITIES IN UMBILICAL AND FETAL VESSELS
- SUMMARY
- REFERENCES

Chapter 13 - Fetal Therapy

- SURGICAL THERAPY
- ENDOCRINE DISORDERS
- INBORN ERRORS OF METABOLISM
- PRENATAL HEMATOPOIETIC STEM CELL TRANSPLANTATION
- CONCLUSION
- References

Chapter 14 - The Impact of Maternal Illness on the Neonate

- PRETERM DELIVERY
- MATERNAL NUTRITION
- MATERNAL ILLNESSES
- SUMMARY
- REFERENCES

Chapter 15 - The Effects of Maternal Drugs on the Developing Fetus

- CHARACTERIZATION OF ADVERSE REPRODUCTIVE OUTCOMES
- FACTORS THAT AFFECT SUSCEPTIBILITY TO THE DELETERIOUS EFFECTS OF DRUGS
- ACKNOWLEDGMENTS
- REFERENCES

Chapter 16 - Obstetric Anesthesia and Analgesia: Effects on the Fetus and Newborn

- EVALUATION OF WELL-BEING
- PAIN MANAGEMENT
- ANALGESIC TECHNIQUES FOR LABOR: EFFECTS ON THE FETUS AND NEWBORN
- SURGERY DURING PREGNANCY
- RESUSCITATION ISSUES DURING PREGNANCY

- ANESTHETIC TECHNIQUES FOR CESAREAN SECTION: EFFECTS ON THE FETUS AND NEWBORN
- POSTPARTUM PAIN MANAGEMENT
- CONCLUSION
- ACKNOWLEDGEMENT
- REFERENCES

Part III - Transition and Stabilization

Chapter 17 - Cardiorespiratory Adjustments at Birth

- PULMONARY ADAPTATION
- RESPIRATORY ADAPTATION
- CIRCULATORY ADAPTATION
- CONCLUSION
- REFERENCES

Chapter 18 - Delivery Room Management

- RESPIRATORY ADAPTATION
- CIRCULATORY ADAPTATION
- PATHOPHYSIOLOGY OF INTRAPARTUM ASPHYXIA AND RESUSCITATION
- HIGH-RISK PREGNANCIES
- RESUSCITATION OF THE ASPHYXIATED INFANT
- DISCONTINUATION OF RESUSCITATION
- SPECIAL PROBLEMS
- ACKNOWLEDGMENTS
- REFERENCES

Chapter 19 - Physical Assessment and Classification

- NEWBORN HISTORY
- GESTATIONAL AGE ASSESSMENT
- GROWTH
- EXAMINATION
- REFERENCES

Chapter 20 - General Care

- ANTENATAL
- INTRAPARTUM
- NEONATAL

- SPECIFIC CONGENITAL INFECTIONS
- POST-DISCHARGE
- REFERENCES

Chapter 21 - Fluid and Electrolyte Management

- BODY COMPOSITION OF THE FETUS AND NEWBORN INFANT
- INSENSIBLE WATER LOSS
- NEUROENDOCRINE CONTROL OF FLUID AND ELECTROLYTE BALANCE
- RENAL FUNCTION IN RELATION TO FLUID AND ELECTROLYTE THERAPY
- PRINCIPLES OF FLUID AND ELECTROLYTE THERAPY
- ACID-BASE BALANCE
- FLUID AND ELECTROLYTE PROBLEMS ASSOCIATED WITH SPECIFIC CLINICAL CONDITIONS
- TECHNICAL ASPECTS OF PARENTERAL FLUID THERAPY
- REFERENCES

Chapter 22 - Nutrition

- NUTRITIONAL CAPABILITIES OF THE NEWBORN INFANT
- NUTRIENT REQUIREMENTS FOR TERM AND PRETERM INFANTS
- NUTRIENT DELIVERY
- WHAT TO FEED NEWBORN INFANTS
- NUTRITIONAL MONITORING
- REFERENCES

Chapter 23 - Breastfeeding and the Use of Human Milk in the Neonatal Intensive Care Unit

- OVERVIEW
- BACKGROUND
- INCIDENCE OF BREASTFEEDING OR PROVISION OF HUMAN MILK
- ADVANTAGES OF HUMAN MILK FOR PREMATURE AND COMPROMISED BABIES
- CHALLENGES TO THE PROVISION OF HUMAN MILK
- THE USE OF MOTHER'S MILK IN NEONATAL INTENSIVE CARE
- FORTIFICATION OF HUMAN MILK FOR VERY LOW BIRTH WEIGHT BABIES
- THE DEVELOPMENTAL PROGRESSION TOWARD BREASTFEEDING
- ONGOING BREASTFEEDING SESSIONS
- DISCHARGE PLANNING
- SUPPORTING BREASTFEEDING IN THE NEONATAL INTENSIVE CARE UNIT AND AFTER DISCHARGE

- SPECIAL CIRCUMSTANCES
- CONTRAINDICATIONS TO BREAST FEEDING
- MEDICATIONS AND DRUGS
- CONCLUSION
- REFERENCES

Chapter 24 - Thermal Regulation

- A HISTORICAL PERSPECTIVE
- THERMAL BALANCE AT THE BEGINNING OF LIFE
- CONVECTION-WARMED INCUBATORS
- THE RADIANT WARMER BED
- HEAT SHIELDING
- EPIDERMAL BARRIER PROTECTION
- HYBRID INCUBATOR/RADIANT WARMER DESIGN
- FEVER
- PHYSIOLOGIC CONTROL OF BODY TEMPERATURE
- MECHANISMS PRODUCING NEONATAL FEVER
- REFERENCES

Part IV - The Low-Birth-Weight Infant

Chapter 25 - The Extremely Low-Birth-Weight Infant

- EPIDEMIOLOGY
- PERINATAL MANAGEMENT
- FLUIDS AND ELECTROLYTES
- MAJOR MORBIDITIES OF THE EXTREMELY LOW-BIRTH-WEIGHT INFANT
- FOLLOW-UP OF THE EXTREMELY LOW BIRTH WEIGHT INFANT
- FUTURE DIRECTIONS AND ETHICAL ISSUES
- ACKNOWLEDGMENTS
- REFERENCES

Chapter 26 - Intrauterine Growth Restriction and the Small-For-Gestational-Age Infant

- INTRODUCTION
- DEFINITIONS
- INTERPRETATION OF FETAL GROWTH CURVES
- INTRAUTERINE GROWTH RESTRICTION AND PRETERM BIRTH
- FETAL GROWTH

- GROWTH OF BODY COMPONENTS IN THE FETUS
- REGULATION OF FETAL GROWTH
- FETAL NUTRIENT UPTAKE AND METABOLISM AND REGULATION OF FETAL GROWTH
- ANTENATAL CARE OF THE INTRAUTERINE GROWTH-RESTRICTED FETUS
- CLINICAL EVALUATION AND TREATMENT OF THE SMALL-FOR-GESTATIONAL AGE INFANT
- CLINICAL PROBLEMS OF THE SMALL-FOR-GESTATIONAL-AGE NEONATE (
- OUTCOMES AND LONG-TERM CONSEQUENCES OF SMALL-FOR-GESTATIONAL-AGE INFANTS
- REFERENCES

Chapter 27 - Multiple Gestations

- EPIDEMIOLOGY
- IMPACT OF REPRODUCTIVE TECHNOLOGY
- ZYGOSITY
- PLACENTATION
- ANTEPARTUM COMPLICATIONS
- ANTENATAL MANAGEMENT
- LABOR AND DELIVERY
- MORTALITY
- TWIN-TO-TWIN TRANSFUSION SYNDROME
- STUCK TWIN
- ASPHYXIA
- GROWTH
- CONGENITAL ANOMALIES
- NEONATAL DISORDERS
- POSTNEONATAL CARE AND FOLLOW-UP
- REFERENCES

Part V - The Newborn Infant

Chapter 28 - Control of Breathing: Development, Apnea of Prematurity, Apparent Life-Threatening Events, Sudden Infant Death Syndrome

- NORMAL CONTROL OF BREATHING
- CLINICAL DISORDERS IN CONTROL OF BREATHING
- IDIOPATHIC APPARENT LIFE-THREATENING EVENTS
- SUDDEN INFANT DEATH SYNDROME
- REFERENCES

Chapter 29 - Acute Respiratory Disorders

- HUMAN LUNG DEVELOPMENT
- DEVELOPMENTAL ANOMALIES
- THE SURFACTANT SYSTEM
- RESPIRATORY DISTRESS SYNDROME
- MECONIUM ASPIRATION SYNDROME
- PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN
- AIR LEAKS
- REFERENCES

Chapter 30 - Bronchopulmonary Dysplasia

- DEFINITION AND INCIDENCE
- PATHOGENESIS
- PATHOPHYSIOLOGIC CHANGES
- MANAGEMENT
- OUTCOME
- PREVENTION STRATEGIES
- REFERENCES

Chapter 31 - Principles of Management of Respiratory Problems

- OXYGEN THERAPY
- ASSESSMENT OF GAS EXCHANGE
- STRATEGIES FOR RESPIRATORY SUPPORT
- MANAGEMENT IN THE INTENSIVE CARE SETTING
- REFERENCES

Chapter 32 - Extracorporeal Membrane Oxygenation

- INDICATIONS
- PROCEDURE
- EQUIPMENT AND SYSTEMS
- PATIENT MANAGEMENT
- SUMMARY
- REFERENCES

Chapter 33 - Cardiac Disease

- Incidence
- Infant Mortality

- Long-Term Survival
- Etiology
- Fetal Cardiology
- Fetal Cardiac Intervention
- Prematurity
- Recognition of Clinical Features
- Diagnostic Tools
- Diagnostic Cardiac Catheterization and Angiography
- Management Procedures for Severe Cardiac Disease
- Cyanotic Lesions
- Acyanotic Lesions
- Acyanotic Anomalies with Abnormal Cardiac Function or Structure
- Arrhythmias
- Sinus Arrhythmia
- Accelerated Ventricular Rhythm
- Junctional Ectopic Tachycardia
- Atrioventricular Block
- Second-Degree Atrioventricular Block

Chapter 1

Neonatology: Past, Present and Future

Gordon B. Avery

Rapid change has characterized neonatology since the name was coined in 1960 by Alexander Schaffer. Structurally, it can be compared with a tree (Fig. 1-1). Its *roots*—obstetrics, pediatrics, and physiology—began at the turn of the century. A sturdy *trunk* has developed in the intensive care nurseries (ICNs) scattered across the United States and around the world. The *branches* have spread so widely that it is difficult for a single person to be expert in all the areas of activity required for a tertiary neonatology service. Important interactions have gone beyond allied disciplines such as obstetrics, anesthesiology, cardiology, radiology, and surgery. Neonatologists today struggle with hospital administrators, pediatric training program directors, legislatures, Congress, the courts, the federal government, malpractice lawyers, right-to-life groups, and ethicists in an effort to determine their proper roles and limits. Caught in a cross-fire between strenuous cost-containment measures and regulations mandating the vigorous treatment of all newborns regardless of prognosis, many neonatologists wonder when a stable situation will be reached. Yet stimulating growth has occurred, mainly since 1960.

PAST: THE ROOTS

One of the main roots from which neonatology grew was supplied by obstetricians such as Pierre Budin and Sir Dugald Baird, who were interested in the babies they delivered and not merely in the immediate welfare of the mother. It may be a serious oversimplification to imply that, in former times, obstetricians were content if the baby was born alive. Childbirth, however, was the cause of a significant number of maternal deaths and for many was a fearful experience. Premature infants were expected to die, as were most neonates with malformations. There was a feeling that natural selection should be allowed to discard the “runt of the litter,” as suggested by the designation of premature babies as *weaklings*. It was Budin and his pupil Couney who pioneered incubator care of premature infants and thus helped change some of the early, pessimistic attitudes toward these babies.

Another significant root of neonatology can be found in the “quiet premature nursery,” such as that operated by Julius Hess and Evelyn Lundeen in Chicago in the early 1900s (1). Only premature infants were admitted to these nurseries, and gentleness with minimal intervention was the policy. To prevent infection, staff wore gowns, caps, and masks and set up a scrub routine that excluded parents and minimized traffic in the area. Feedings of breast milk by eyedropper were delayed for up to 72 hours, and the infants were handled as little as possible. Yet the supportive conditions needed to allow the body to recover, as described by Florence Nightingale, were present: “warmth, rest, diet, quiet, sanitation, space, and others” (2). Perhaps some of the high-tech nurseries of today could benefit from an infusion of this superb nurturing orientation.

Physiology is a taproot of neonatology. Advances in neonatal care rest directly on descriptions of the changing body processes of the newborn infant. Men such as Barcroft and Dawes began delineation of fetal circulation and placental function. These studies in turn led to the establishment of the fetal lamb model, which subsequently was widely exploited. Neonatal metabolic, gastrointestinal, respiratory, and central nervous system functions were studied by Levine, Smith, Peiper, and others. The 1945 publication of the first edition of Clement Smith's

textbook, *The Physiology of the Newborn Infant*, was a signal event in our evolving ability to care for sick newborns in a rational manner (3).

A final anchoring root of neonatology is the therapeutic trial. Innumerable traditional teachings about premature infants eventually have been proved false. Without scientific testing as a guide, neonatologists would constantly be off course. As it is, several dangerous misadventures have been averted by clinical trials. An example is prophylactic sulfonamide treatment of premature infants, which was

P.3

found to cause increased kernicterus (4). Silverman, Gordon, and Day were pioneers who insisted on rigor in such trials.

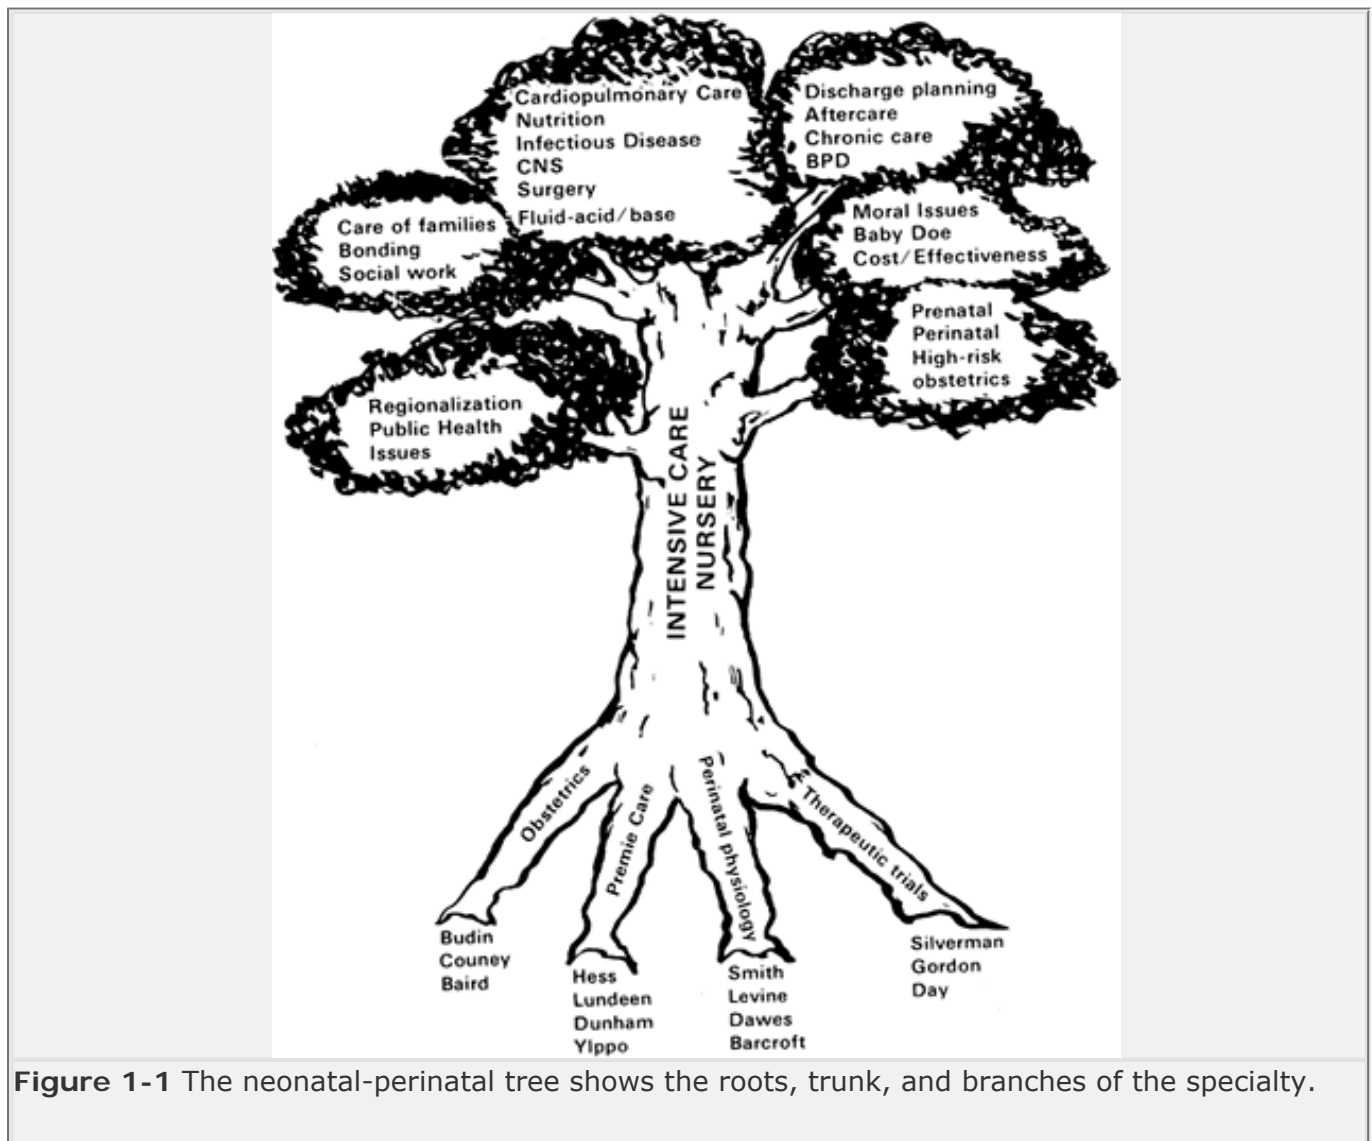

Figure 1-1 The neonatal-perinatal tree shows the roots, trunk, and branches of the specialty.

PRESENT: THE TRUNK

The ICN is the institution that forms the sturdy trunk of endeavors in neonatology. The ICN is a therapeutic environment, a collection of equipment, and a multidisciplinary team that is guided by dedicated leadership, by a group of specific protocols, and by a body of relevant scientific knowledge. It is the ICN as an integrated organism, rather than any single person or collection of people, that takes care of the sick neonate—in a sense, this is holistic medicine turned inside out. The ICN is very effective in the care of desperately ill babies, but its rationale remains difficult to explain to hospital administrators, insurance companies, and the U.S. Congress.

Over the years, there has been a steady increase in the intensity of illness observed in the ICN.

With this rise has come an increase in the number and variety of personnel and the amount of technically sophisticated equipment. In the 1950s, premature care was a major concern. The principal interventions were resuscitation, thermoregulation, careful feeding, simple and exchange transfusion, and supportive care of respiratory distress. By the 1960s, electronic monitors came into use, and blood gases began to be measured. Feedings were aided by nasogastric tubes, and increased laboratory monitoring became possible. Antibiotics became available for treatment of neonatal sepsis.

By the 1970s, the use of umbilical catheters and arterial pressure transducers was routine, and respirator therapy for hyaline membrane disease began to succeed. Nutritional support for sick infants was aided by transpyloric feeding tubes and finally by complete intravenous alimentation. Microchemistry tests for most necessary parameters became widely available. Neonatal surgery was shown to be feasible for many congenital abnormalities, including serious cardiac defects. With the 1980s came the advent of computed tomography and ultrasonography. Significant concern centered around ventricular hemorrhages and consequent post hemorrhagic hydrocephalus in small premature infants. Transcutaneous electrodes became available first for measurement of oxygen and then for carbon dioxide. Pulse oximetry was used increasingly for continuous physiologic monitoring. Nutritional and metabolic supports were significantly refined. Surfactant replacement has reduced the severity of lung disease in premature infants. Extracorporeal membrane oxygenation permitted the survival of some previously unsalvageable infants. In the 1990s, magnetic resonance imaging improved visualization of lesions, and positron emission tomography and magnetic resonance spectroscopy promise to reveal the physiology of the intact brain. As survival has become common for infants who weigh as little as 600 g (1.3 lb) at birth, increased attention has swung to assuring intact survival, and the 1990s have been dubbed the decade of the brain.

THE BRANCHES

Perinatology

A body of specialized knowledge, a group of subspecialized professionals, the advent of technically advanced equipment, and the formation of special care units all contributed to the development of neonatology. In obstetrics, these same elements came together approximately 10 years later and resulted in the specialty of maternofetal medicine. Perinatologists developed high-risk prenatal clinics and special delivery facilities for unstable patients. A steadily growing body of literature from animal and clinical investigations allowed improved management of pregnancy complications and monitoring of fetal status. Ultrasonography detected fetal abnormalities and determined fetal size, anatomy, activity, breathing, and response to stress. For the first time, mothers were given drugs designed to treat fetal conditions, and intrauterine transfusions were performed in cases of threatened hydrops. Fetal surgery has yet to find its proper place, but prenatal shunts have been inserted for hydrocephalus, obstructed urinary tracts have been drained, and diaphragmatic hernia repair has been attempted.

In many major teaching hospitals, perinatal obstetric and neonatal services have joined forces to form perinatal centers. Often with codirectors from the two disciplines,

P.4

these centers foster cooperation in the best interests of the high-risk patient. Integrated planning and management in optimal cases consist of a high-risk prenatal clinic, timing and management of labor and delivery, resuscitation, and intensive care in the nursery. Statistics on morbidity and mortality, reviewed in periodic joint conferences, permit constant refinement of policy and technique. These centers facilitate training programs in both perinatology and neonatology and

are important sources for research. They demonstrate the best survival rates for small premature and other categories of infants at highest risk, and they provide the standard by which perinatal care is judged.

The natural alliance between perinatal obstetrics and neonatology is so great that some have suggested it receive department status within the medical complex. In some ways, the perinatal center accomplishes this on an ad hoc basis. However, perinatologists and neonatologists are parts of traditional departments of obstetrics and pediatrics, with surgical and medical orientations, respectively. Allocation of resources and ranking of faculty occur predominantly through the parent departments, where the priorities of the chairpersons are paramount.

Regional Connections

The medical community found that to optimize function of the perinatal center, it was necessary to form complex relationships among hospitals and community resources (see Chapter 3). First, neonatal and then maternal transport services were developed to move patients safely and efficiently to the center and back. Hot lines were established to provide consultation and bed allocation, which could be coordinated through a single phone number. Affiliations for continuing education were formed, and standard protocols for referral were worked out. In some instances, exchange of personnel and joint review of statistics helped cement the connection.

Government agencies extended a helping hand in this networking. Some state legislatures were convinced early of the public health advantage of regional systems. The government began to award grants to perinatal centers to underwrite some of the cost of outreach and system activities. Training and research grants from the federal government often were given to the same perinatal centers and served to buttress the resources of these centers. With passage of the National Health Planning and Resources Development Act (Public Law 93-641) in 1974, the federal government mandated regional planning of expensive resources in the interest of efficiency and economy. Designation of care levels I, II, and III was adopted, and publication of regional plans for perinatal care became widespread.

Unfortunately, during the 1980s regionalization suffered striking reversals. The mandated state health planning mechanisms were emasculated. Hospitals became increasingly competitive and wished to offer full services to prepaid health plans. Large numbers of neonatologists moved into suburban hospitals and set up level II nurseries. The result was a decentralization of perinatal high-risk care, with loss of efficiency and economy of scale.

Finally, I wish to call attention to the involvement of neonatologists in a mixture of educational, administrative, and political activities that have been very taxing and time-consuming. Although neonatology training has emphasized bedside care, a business school or public health degree would be directly useful to today's neonatologist. A thorough training in counseling, group dynamics, and law also would be invaluable.

THE PRESENT

Ethics

During the newborn period, babies with congenital malformations, asphyxia, and extreme immaturity are seen. Modern, powerful life-support systems provide the technology for relatively prolonged continuation of futile care. These circumstances have thrust neonatologists into the center of a national debate on medical ethics. In the midst of all this, neonatologists must keep their heads and care for babies and their families as best they can. Chapter 2 deals extensively

with the moral issues raised by neonatal intensive care.

Care of the Family

In general, there has been striking improvement in care of the distressed families of critically ill newborn infants. Formerly excluded from the ICN because of fear of infection, parents are brought to the bedside and encouraged to touch their babies. Limited sibling visitation often is permitted. Nurses help parents get used to intrusive medical equipment, and, as soon as possible, parents perform simple caretaking procedures with their child. Social workers, parent support groups, chaplains, and literature for parents have become increasingly available. Starting with the work of Klaus and Kennell, a growing body of publications has appeared that suggests that bonding of parents to the newborn infant is important to later functioning of the family unit. The change of the title of Klaus and Kennell's monograph from *Maternal-Infant Bonding* (5) in 1976 to *Parent-Infant Bonding* (6) in 1982 reflects recognition of the role of fathers in the parenting of neonates.

Home Care

The aftercare of discharged high-risk newborns has become an increasingly important area of concern for neonatologists. Although many problems are resolved quickly and require only routine follow-up, a significant number of babies with chronic problems are taken home from the ICN. As a small premature infant approaches discharge, it becomes clear that parent instruction; sleep apnea testing; cardiopulmonary resuscitation training; concern with feeding and growth; schedules for testing sight, hearing, and speech; physical medicine; and developmental psychology

P.5

foreshadow a first year of life crowded with clinic visits and special needs. Infants with chronic lung disease often go home on oxygen therapy, multiple medications, and special feeding regimens. During the first year or two of life, intercurrent infections may require several readmissions. The best outcomes have been achieved with early diagnosis of developmental difficulties and the mobilization of community resources. All this necessitates input from a physician with appreciation of the stormy neonatal period and an understanding of the continuing problems of infants born prematurely with other perinatal insults. Often, a multidisciplinary team at the tertiary center collaborates with the family's pediatrician to provide this special care. Although oriented to neonatal intensive care, neonatologists have begun to assume responsibility in this aftercare.

The Intensive Care Nursery as a Space Station

The quiet, simple, gentle premature nursery of 50 years ago has been transformed into a bustling space station. Suspended halfway up a tall building, too often it is drenched in bright light and alive with activity throughout the night. The tiny baby in the incubator is dwarfed by a procedure light, a respirator, a multichannel monitor, four intravenous pumps, and a transcutaneous oxygen module. The baby's chest is covered with electrodes, and tubes lead into and out of his or her body at several points. Eight to 12 electrical cords, 2 oxygen lines, and a suction catheter attach to the bedside console. Medications and flush solutions are drawn up in syringes close at hand. A resuscitation bag is at the head of the baby's bed in case he or she should stop breathing. Alarms sound, knots of people move busily about, and large machines are pushed among the incubators. Ultrasonography elements are touched to the infant's head, chest, and abdomen. Images flash on a screen and are recorded on tape for later analysis. House

officers speak rapidly in an acronymic code barely intelligible to residents who graduated 2 years previously. Hess and Lundeen, coming some morning for a visit, might wonder if they had missed the address and arrived on the wrong planet!

At such a bedside, today's neonatologist must cope with a constantly enlarging body of new literature on cardiopulmonary physiology; nutritional and metabolic support; new antibiotics and infectious disease conditions; ventricular hemorrhage and asphyxial syndromes; and surgical, genetic, and cardiac problems. It is no longer possible for a physician to read all the new publications, even when restricted to the area of neonatology. New therapeutic approaches are proposed much faster than they can be tested in an orderly way; many such theories never will be tested.

THE FUTURE

In the future, I believe neonatology will move in two divergent directions. In the realm of neonatal intensive care, the contributions of basic science, and particularly genetics, will produce powerful diagnostic and therapeutic tools, which will significantly improve results. However, the global and public health dimensions of dealing with distressed newborns will require simpler, less expensive interventions that can be applied in developing nations. Clearly, the *bang for the buck* in neonatology is greatest where care is the least developed, and is least where the standard of care is already high. The challenge will be to keep the locomotive moving forward without leaving the caboose too far behind.

Of course, I cannot report to you with any precision what new developments in neonatology will occur in the next 20 years. Nevertheless, Table 1-1 is offered to illustrate, side by side, several areas of practice: past, present, and future. A few themes are highlighted. The past was characterized by minimum intervention and a nurturing sort of care dominated by gentle bedside nursing. The present era seizes on maintenance of normal physiologic and biochemical parameters. The baby—beset with indwelling lines, ventilators, and monitors, who “dies in balance”—is in line with this approach. The future will include accepting or deliberately producing some abnormal values in recognition of the baby's unique disease state. Examples include cooling for neuroprotection, hyperthermia for tumor inhibition, permissive hypercapnia to minimize pulmonary barotrauma, and cardiovascular unloading to treat neonatal lung failure. We will develop gene products and receptor blockers as medications, and use gene promoters and inhibitors to manipulate the cell's own genetic apparatus to treat diseases. Examples are the use of vascular endothelial growth factor (VEGF) and elastase inhibitors for reducing chronic lung disease (7,8,9).

Worldwide, measures to combat perinatal and neonatal infections, lower the incidence of prematurity, and reduce maternal malnutrition will benefit outcomes without the need for new technology. The impact of basic public health measures is so dramatic that one World Health Organization (WHO) official described infant mortality as “a public health problem with medical aspects, not a medical problem with public health aspects” (10,11).

Finally, the way we learn will evolve in the years ahead. Our scientific method emphasizes comparisons of groups differing by a single variable, ideally in a single disease state. Studies using tissue culture or the laboratory mouse are the models we try to approximate in the intensive care nursery. But our babies typically have many abnormal states simultaneously, and many therapies running at the same time. The staff is caring for many infants at the same time, and sometimes several investigative protocols are running alongside one another. The research study is never the first priority where life-and-death illness is involved. While all this is going on, there are changes in policy and equipment that affect care in the whole neonatal intensive care unit (NICU), across all diseases and birth weights.

We will need new types of statistics to aid in benchmarking interventions and studies of the impact of benchmarking practices. Large, computer-supported databases will help with hypothesis generation. We will become more adept at recognizing secular trends in NICU care

P.6

P.7

versus the specific interventions we intend to study. And some of our interventions will be outside the nursery, in programs of education and/or pre- and post-NICU care. The years ahead will be as fast paced and challenging as those that have gone before.

TABLE 1-1 NEONATOLOGY—PAST, PRESENT, AND FUTURE. THE AUTHOR'S THOUGHTS AND REPRESENTATIVE EXAMPLES

	PAST	PRESENT	FUTURE
Temperature	Physical bundling Laissez-Faire	Thermoneutral maintenance Servocontrols	Cooling for brain protection Hyperthermia for tumor inhibition

Chapter 2

Current Moral Priorities and Decision Making in Neonatal-Perinatal Medicine

Robert J. Boyle

John C. Fletcher

(deceased)

GOALS OF NEONATAL-PERINATAL MEDICINE

The first part of this chapter discusses broad goals and moral priorities of neonatal-perinatal medicine (NPM) in relation to patients, American society, and developing nations. The second part reviews some specific ethical issues that frequently arise in clinical decision making in the neonatal period.

Medicine is a goal-oriented profession. One approach might argue that healing is the sole and overriding goal of medicine. This view is unconvincing, because some valid goals of medicine (e.g., prevention) cannot be collapsed into healing. The practice of NPM illustrates that medicine has multiple, complex, and sometimes conflicting goals:

- To save life and cure disease
- To relieve pain, suffering, and disability
- To rehabilitate and restore function
- To prevent disease
- To improve the quality of living and dying
- To seek new knowledge

The highest moral priority of these subspecialties is to implement medicine's goals in the perinatal period. In a recent review, Carter and Stahlman broadly discuss the successes (and limits) of neonatal intensive care in the United States over the past 40 years (1).

SOCIETAL AND PROFESSIONAL ISSUES

Medicine is also accountable to society and to the international community. Critics may validly argue that American medicine and public policy have neglected primary prevention and fostered the technological imperative. To counter these criticisms, the moral priorities of NPM specialists need to include advocacy for comprehensive prenatal care, improved nutrition, prevention of premature delivery and appropriate family support and services for the infant after discharge. NPM in the United States is also part of a global community of science, medicine, and humanitarian outreach. The moral priorities of the field ought to include commitment to global infant health. An editorial by Sidney Brenner, a leading figure in genetics, also applies to neonatal medicine. He wrote: "Somehow, in our abstruse discussions about the high technology of the developed world, we need to balance the equation by thinking about the rest of the world as well" (2). Nations where newborns are in greatest danger of death or lifelong disability could benefit from transferable knowledge and technology, for example, maternal folic acid supplementation, prevention of HIV transmission, vitamin K prophylaxis, eye prophylaxis for gonorrhoea, and prevention of neonatal tetanus.

Preterm delivery—live birth prior to 37 completed weeks' gestation—grew in the United States from 8.9% in 1980 to 11.9% in 2001, more than 476,000 annual preterm births (3,4). The increase is caused by an 11% rise in moderately preterm births (32 to 36 weeks' gestation) in the 1990's. In 2001; charges for hospital stays for prematurity-related illness reached \$13.6 billion. There are large differences in preterm births by race and ethnicity, although non-Hispanic white women give birth to the majority of the 4 million annual live births.

Paradoxically, both poverty and economic success are harmful to many infants. Poverty, race, class, and substance abuse are linked to a large percentage of prematurity, extremely low-birth-weight, and brain injury. However,

P.9

multifetal pregnancies after assisted reproductive technologies (ART) and non-ART procedures have reached epidemic proportions (5,6,7,8). Epidemiologic studies also suggest an increased risk of major birth defects after assisted reproduction (9). Neonatologists see first hand the human damage and costs of these polar social determinants of gestational harm. Infertile individuals who want their own genetic child suffer psychologically and spiritually. Fertility treatments have allowed literally millions of women to have children who otherwise would not have been able to conceive. The primary responsibility to reduce these harms falls on reproductive medicine and policy makers. NPM specialists can facilitate research and remedies for the problem. To date, reliance on professional self-regulation has not been effective in reducing multifetal pregnancy in the United States. There is currently a debate about whether social controls of infertility treatment and research are fitting for a pluralistic society that highly values reproductive liberty. The President's Council on Bioethics is now considering a set of very strong federal controls to protect human embryos and constrain infertility treatment (8). At this point, all could agree that

women undergoing ART should be informed about the risks of multiple gestation and preterm delivery.

What perspective ought to be taken on the social ethics of the medical profession and its mission? Many in the United States believe that the *'answer'* is simply to let markets work in the interests of liberty (10). In this model, health care is a two-tiered marketplace. The costs for those who can pay include a pool of money and charity care for those who cannot pay. When the overriding value is justice, medicine ought to be a largely subsidized service in a society that guarantees security in health care for all to increase solidarity among its people. However, even when health policy guarantees universal access, disparities persist in disease and health care that reflect class, race, and sex.

Following Buchanan, we propose that in a pluralistic democracy, the relation between society and medicine ought to be understood as a self-correcting contract or bargain (11). Instead of resting on one supreme value easily captured by ideology, the contract reflects a commonwealth of values. These values govern the complex goals of medicine and interests of society in health. A commonwealth has a primary locus of loyalty. In this society, the preeminent value is fidelity to patients or loyalty to the patient at hand. Using the right procedural principles, patient-centered medicine is not inconsistent with viewing the patient in a population with needs for a finite supply of expensive community health care resources. (12) Within constraints of fidelity to patients and their rights, physicians ought to promote the welfare of the many, to practice fairness in access and distribution of resources, and to be efficient and effective in their practices. Physicians in this society are also members of a scientific community with a high standard of evidence in practicing medicine. Guided by these values, society grants the profession a privileged place, permits its members to earn high incomes, and subsidizes their training. In return, society expects the net health benefits of pursuit of the goals of medicine to outweigh the net costs.

In the United States, the increasing investment in perinatal-neonatal care has not produced proportional improvements in crude infant survival and low-birth-weight. Thompson and associates (13) compared the neonatal intensive care (NICU) resources of the United States with those of Australia, Canada, and the United Kingdom. Compared to the other three nations, the United States has far greater resources but higher rates of low-birth-weight and death among newborns. The United States has 6.1 neonatologists per 10,000 live births compared with 3.7, 3.3, and 2.7 in the other nations, respectively. NICU beds in the United States are 3.3 per 10,000 live births, compared with 2.6 in the first two nations and 0.67 in the UK. Resources are not linked with low-birth-weight. In the United States, 1.45% of all neonates have a very low-birth-weight (<1500 g) compared with approximately 1% in the other nations. Newborns weighing less than 2500 g are born more frequently in the United States. Low-birth-weight is the single most accurate predictor of neonatal death. The crude neonatal mortality rate is 4.7% deaths per 1000 births in the United States, compared with 3.0% in Australia, 3.7% in Canada, and 3.8% in England and Wales.

Why does success not follow from greater resources? Thompson and associates (13) point to cultural and political differences between the nations. Australia, Canada, and the United Kingdom provide health insurance for all children under 18 years of age and all women ages 18 to 44 years. In the United States only 86% of children and 78% of women had health insurance at the time of the study. These three nations provide free family planning advice and prenatal and perinatal care, and the United States does not. The influence of race, poverty, and poor nutrition must also be factored into the answers. Longstanding recommendations of the Committee on Perinatal Health to address the root problems have not been implemented (14). The current March of Dimes campaign on prematurity is a valuable step but does not replace missing federal support (3).

ETHICS AND MORAL DELIBERATION

Ethics is a body of practical knowledge comprised of principles and values, judgments about cases and policies, and beliefs and theories about the world and persons (15). John Dewey's view of the main purpose of ethics is integration of beliefs about the world with beliefs about the values and purposes that should direct human conduct (16). Decision making for infants and children should follow the same general approaches taken for all patients who are unable to make decisions for themselves.

John Dewey wrote, "life is a moving affair in which old truth ceases to apply" (16). Making judgments in novel situations can lead to change of background beliefs and practices. Since the advent of modern neonatal care in the 1960's, rapid advances in technology and aggressive care of smaller and sicker neonates have focused philosophical, theological, professional, legal, consumer, and media attention (both

P.10

positive and negative) on the use of technology and the processes for decision making in life or death choices for newborns. One can trace changes in background beliefs and values in the history of ethics in neonatal decision making using the "landmark" cases in which medical decisions for infants have been scrutinized by the United States government or the legal system. Table 2-1 gives samples of important cases, events, articles, and studies in that history. In addition, several recent reviews trace this evolution and multinational differences in approach (1,17,18,19).

TABLE 2-1 LANDMARK CASES IN NEONATAL ETHICS

TABLE 2-1 LANDMARK CASES IN NEONATAL ETHICS

Year	Name of Case, Event	Clinical Issues	Outcome
1963	Hopkins Baby ^a	Trisomy 21, duodenal atresia; parental refusal of surgery.	Died after 15 days of no feeding/ hydration.
1974	Baby Houle ^{b,c}	Multiple malformations; parental refusal.	Court orders surgery; infant died.
1973	Duff & Campbell ^d	Selective nontreatment of multiple infants with variety of medical conditions.	Controversial report from a NICU.
1981	The Danville Twins ^e	Siamese twins, joined at the abdomen, with three legs and a common pelvis. The parents and physicians were criminally charged with ordering that the infants not be fed.	The parents and physicians were found not guilty.
1981	Stinson baby ^f	Premature infant; 800 g, 26 wks; parents object to unwanted treatment.	Infant dies at 6 mo.
1982	Bloomington Baby (Baby Doe) ^g	Trisomy 21, tracheal esophageal fistula; parental refusal of surgery.	Indiana Supreme Court rules for parents.
1983	Baby Jane Doe ^h	Spina bifida, hydrocephalus, and <i>microcephaly</i> ; parental refusal of surgery.	NY Court of Appeals rules for parents.
1983	Baby Doe regulations ⁱ	U.S. Dept. of HHS issues regulations.	Requires life-sustaining treatment for every infant.
1983	President's Commission ^j	Clarifies decisions to forgo treatment in newborns.	More moderate than U. S. Dept. of HHS regulations.
1984	Child Abuse Protection Act ^k	Federal law.	To receive federal funds for child protection, states must have procedures for such cases.

1990	Baby K ^{l,m,n}	Anencephaly.	Mother demands life supports and federal courts rule for her.
1994	Messenger ^{o,p,q}	Premature infant; 780 g, 25 wk. Parents request no resuscitation.	Father disconnects respirator and jury finds not guilty of manslaughter.
2000	HCA v. Miller ^{r,s}	Premature (629 g, 23 wk) infant resuscitated against parents wishes.	Court of Appeals reverses prior judgment awarding parents \$60 million.

Neonatologists, nurses, and parents of newborns today stand on the cumulative moral experience of the past. The

P.11

process for decision making in NPM is more transparent and shared between clinicians and parents than in the past. However, it is never immune from confusion, especially when cultural beliefs about medicine collide. Practitioners are arguably better trained to identify ethical issues, participate in shared decision making, and seek help with ethical problems. For example, most try to be empathetic, nonbiased, and honest in disclosing a poor or uncertain prognosis to anxious parents.

Neonatologists, nurses, and their colleagues are fallible. They have made serious mistakes in excluding parents from decisions and imputing guilt to them for wanting to withdraw treatment (20). Some events and cases test the limits of moral concepts, for example, the best interests of the infant, parental autonomy, professional integrity, futility, and fairness in use of resources, or quality of life. These cases brew storms that can throw experienced neonatologists, nurses, other staff, parents, and administrators off balance and into conflict with one another. In these situations, Martin Buber's metaphor of a "narrow rocky ridge between the gulfs" (21) can ring true. Ethics helps human beings to keep enough balance, when taking hazardous, puzzling, or new paths in social and personal life, to maintain moral insight and equilibrium. It is a self-correcting, constantly evolving body of practical knowledge about human problems—conflicts of moral principles, duties, or loyalties in relationships.

CULTURAL AND RELIGIOUS DIVERSITY

Because ethics is a self-correcting body of knowledge, open societies require a public process of debate about continuity and change in the moral aspects of social and professional practices. The United States is now the world's most diverse religious and cultural society. These differences are very difficult to sort out in debate about ethics. To change public policy in this society, faith-based reasons standing alone are

insufficient. Secular and presumably rational reasons are required to persuade a court, legislature, or commission. In debatable health care decisions, we see cases involving newborns that break down the limits of rationality. For example, should physicians continue to respect parents' faith-based rejection of futility of treatment when the baby has total intestinal necrosis or renal agenesis and pulmonary hypoplasia? In our view, the case of Baby K (22) shows that the federal courts can approve parental faith-based demands as a legally justified reason to continue futile treatment of an anencephalic newborn, because the society has been unwilling to ration resources for this category of newborns.

Cross-cultural issues deeply complicate debate on ethics. For example, should any moral weight be given to a request to withdraw life support if the parents of a neonate are immigrants from a society with very different moral beliefs about medicine and what constitutes a seriously impaired newborn? What if the parents' culture requires that a traditional healer participate in the care of the infant? Should weight be given to parents' religious views when the infant is in pain and not benefiting from additional procedures and the parents flatly reject the concept of futility? What is best, all things considered, for the infant? Does concern for the infant absolutely override competing concerns?

The authors take a broadly pragmatic approach to ethics and to cross-cultural issues in ethical debates. Moral norms and ways of life are, in fact, relative to culture and personality. However, cultural and psychological relativity does not drain ethics of content or moral force. Although ethics is a phenomenon within and not independent of human experience, it has objectivity in two senses. First, ethics is objective as a growing and evolving body of knowledge about practices in society and the professions. Secondly, the basic imperatives of ethics are "no less objective than law or medicine" (23) when it comes to destructive acts like murder, torture, genocide, rape, cruelty for its own sake, and so forth. Such acts "violate our most basic convictions" about the intrinsic value of human life and community. As Benjamin writes, "If these things aren't wrong, nothing is" (24). Some argue that moral judgments are not binding across cultural boundaries or that ethics is "merely" a matter of personal taste. If ethics is merely subjective or relative, there is no basis for a moral judgment about any horrific act that occurs in subcultures or beyond one's own culture, such as forcing children to wage war against their own people or to suffer loss of limb or life. The case of Baby K ought not be judged as "horrific acts" because the parents' intentions are loving and not destructive. The moral failure in these cases is societal in its failure to assume responsibility for setting democratically debated limits on health care resources. Societal failures can result in horrific consequences, but the parents and staff involved in these cases do not deserve moral blame.

Working Through Ethical Problems

Although important moral values and principles are binding, there is no prefabricated way to work through ethical problems in cases or events when principles collide.

Different methods of moral deliberation compete for selection. When compared with highly theoretical or case-by-case approaches, the method of “wide reflective equilibrium” (25) has proven useful in bioethics. In this approach, one weighs ethical problems in cases by creating a dialogue (internally or externally) that moves between three interactive elements: the values and principles at stake, the problem at hand, and relevant background beliefs and theories.

“*Principlism*” is a dialectical method that analyzes ethical problems in a framework of *prima facie* principles of biomedical ethics (10). This approach is widely used in ethics courses and in the literature of neonatal ethics. In our view, a method that moves only between values or principles and the problem at hand lacks larger constraints and correctives. Cultural influences and personal bias are at work in selecting principles and putting them to work in cases. Judgments made in past cases, such as Baby K (22)

P.12

and Baby Doe (26), are fallible and need evaluation. Background beliefs and theories are sources of critical distance and constraint—beliefs and theories about the nature of personhood, community, the world as revealed by science and metaphysics, human psychology, sociology, and political and economic behavior; the nature of nonhuman animals, and so forth. In short, our uses of principles and judgments in cases ought to make sense in terms of intelligible background beliefs and in-depth knowledge of the issues at hand.

When parents and clinicians are unable to reach agreement on an approach to care, additional resources should be available to assist the process. Many “ethical conflicts” are actually problems in communication and misunderstanding. Involvement of social workers, chaplains, parent support groups, or other clinical staff often improves the interaction and leads to a resolution of the conflict. One of the outcomes of the Baby Doe controversy (27) in the early 1980's was the recommendation that infant bioethics review committees be established to prospectively and retrospectively review cases where life-sustaining therapy was withheld or withdrawn. While the function of these committees was short-lived, they were the forerunners of the current ethics committees in most institutions. Ethics committees serve multiple functions including policy development and review, staff education, and review of difficult cases brought to them. In many institutions, both medical staff and families may bring cases to the committee. Committee process varies widely from institution to institution in terms of membership, involvement of family, and decision-making models (28,29,30). Other institutions use a less intimidating model of an ethics consultation service, where an individual consultant, or, more often, a team of consultants (who usually have multidisciplinary backgrounds), will review the situation with those involved, provide background or policy information, facilitate communication, and, when necessary, bring the parties together to work toward a consensus. In most institutions the committee or consultation service recommendations are advisory rather than binding. Finally, when consensus is cannot be reached and the clinician, family or institution feels the issues are sufficiently serious, the court system can be petitioned to intervene. While

the court system is seen as the voice of society weighing in on a difficult issue, this is often a time-consuming, not necessarily objective process that by its nature is adversarial and may negatively impact the relationship between the clinician and parents. A court decision may be appealed and overturned or may result in an outcome that with greater societal scrutiny may be seen as questionable. Most would argue that approaching the court should be a last resort.

Moral Status of the Newborn

Part of the evolution in clinical ethics in neonatal-perinatal medicine has involved ascribing greater moral status and protection at birth to seriously ill newborns. There has been a dramatic transition from frequent nontreatment of trisomy 21 (31) to the Baby Doe Rules (22) and support for appropriate assessment of extremely low-birth-weight (ELBW) infants.(32) However, there remains a philosophical impression that decisions to withhold or withdraw treatment for newborns, especially the extremely premature newborn, may be less troublesome than decisions for older children and adults, because the newborn does not have the same moral worth or is not fully a person. Tooley (33) argued that because a newborn lacks advanced brain function, has no self-consciousness, ability to suffer, or sense of the future, it should not be considered a person. Engelhardt (34) agrees that neonates are not persons in the strict sense at the time but affirms that they are persons in a social and cultural sense. Others have further defined this view, identifying the bonding, affection, and care given newborns by parents and other adults (35).

While detailed plans for conception, antenatal ultrasound, and fetal movement may support parental attachment early in and progressing through gestation, it cannot be denied these emotions are not as strong in the perinatal period, especially when the infant is extremely preterm, as they are at several months or years of age. In addition, many preterm infants are the result of unplanned, often unwanted, or sometimes unknown pregnancies. Blustein describes the neonate as “not born into the family circle so much as outside it, awaiting inclusion or exclusion. The moral problem the family must confront is whether the child should become part of the family unit” (36). Ross notes that respect for the person is “owed to all individuals on the basis of the individual's personhood (and developing personhood)... proportionate to the actualized capacities of the individual and his or her potential to attain full personhood” (37). It is therefore problematic that the infant's moral worth is variable, dependent on acceptance by its family rather than on any innate socially or even legally accepted character. This worth may change over a short period of time, and this change may then affect differences in or difficulties with decision making prior to birth versus at a week or month of life. Decisions made in the labor room regarding a child who has never been seen by the parent and who may have an increased risk of mental retardation become much more difficult when the 6-month-old child has confirmed severe developmental delay.

Decision Making

Sound clinical decision making should be based on sound data, a careful and thorough diagnostic assessment, and, based on that diagnostic assessment, accurate prognostic estimates. Sometimes this is relatively easily accomplished: chromosomal analysis has documented trisomy 13 and the natural history of this disease is well-known. In other situations the diagnosis may not be well-defined or the prognosis is uncertain. For both the ELBW infant about to be born or the premature infant with grade III intraventricular hemorrhage, there is an increased statistical risk of developmental delay, but it is not certain how this particular

P.13

infant will progress. Rhoden (38) has defined strategies that have been or might be used when there is uncertainty about prognosis:

- Wait until certain: Continue until the patient is actually dying or will survive but with definite severe disability. There is an underlying discomfort with infants, admittedly few in number, who are dying but who might survive with aggressive care. There is little attention paid to suffering, burden-benefit ratios, or the number of infants needed to be treated for one additional intact survivor.
- Statistical prognosis: Use statistical cutoffs and aggressively treat all those selected. This might be described as the "evidence-based approach." Selection might be by birth weight or gestational age. This approach may be used when resources are limited. Professional, regional, or national guidelines might exist to define these cutoffs. This approach ignores individual variation and may sacrifice some potentially normal infants who may behave outside of the norm. It relies on data that may or may not accurately reflect the clinical situation at hand. Decision making is psychologically "*easier*," because it is allegedly "*objective*." Most clinicians justifiably use some criteria for limiting treatment for some populations, for example, resuscitation at 21 to 22 weeks gestation.
- Individualized prognosis: Decide for each infant using the available data, the present condition, and a benefit-burden analysis. This approach allows for clinical change, evaluation and reevaluation, and ongoing communication. There is more of a role for the family in decision making. It also can be a source of confusion, uncertainty, error, and agony. However, Rhoden believes that this is justified, given the tragic nature of the situations. Fischer and Stevenson (39), and more recently Kraybill (40), have expanded on this approach beginning with a "nonprobabilistic paradigm" of attempting to save every ELBW infant's life ("provisional intensive care for all") modified by an "individualized prognostic strategy" when prognosis could be better defined. The American Academy of Pediatrics has endorsed this approach (41).

Withholdin/Withdrawing

Most agree that it is ethically superior to withdraw a therapy compared to withholding it (42,43). If therapy is begun and is effective, the patient benefits. If the therapy is begun but is not effective, it can be stopped. If the therapy is never initiated, the patient can never benefit. Initiation of therapy also provides the clinician with additional time to collect data, which may lead to a more accurate diagnosis and therefore more reliable prognosis and allows the family more time to understand the situation. While a preference to withdrawing rather than withholding is sound philosophically, in actual clinical settings there are often emotional responses and in some settings religious restrictions to withdrawal of a therapy. It is much easier emotionally to be passive than to make an active decision to withdraw aggressive care. "Pulling the plug" and "killing my baby" are not infrequently heard. "Letting God decide" and "waiting for a miracle" are examples of the same phenomenon. Doron and associates (44) document the relatively frequent disagreement of parents when clinicians recommend withholding aggressive care. There is a potential for weeks or months of care, and possible pain and suffering, before the infant's death or an eventual decision to withdraw. The clinical situation may reach the point that there is no aggressive care to withdraw, and the outcome is poor. Some clinicians are reluctant, based on this experience, to initiate care as freely. If a clinician is less willing to withdraw care than not to initiate it because of uncertainty or philosophical reasons, this should influence their decision process and be made clear during discussions with parents.

Clinically the withdrawal of life-sustaining therapy does not require that the patient have multiorgan system failure or meet criteria for brain death. If the organ that has failed or been irreversibly injured is a vital one, decision making should be based on the infant's prognosis for recovery, long-term survival, quality of life, and so forth. Technology would be withdrawn, and the infant would be allowed to die. "Brain death" or "death by neurological criteria" is a clinical and legal definition of a type of death. Criteria for brain death in the newborn are somewhat different than for older children and adults (45,46,47). Some jurisdictions allow for a religious exemption. However, in most circumstances, once the criteria have been met, the patient is pronounced dead. These families need to be compassionately informed about what this means ethically and legally and appropriately prepared for withdrawal of the ventilator. There should be no discussion of removing "life-sustaining treatment" or "keeping the baby alive" because the patient is legally dead.

The term "*euthanasia*" generates a great deal of confusion and debate in legal, legislative, media, and clinical spheres. Active versus passive euthanasia, voluntary versus involuntary euthanasia, physician-assisted suicide, and other descriptors have created unfortunate ambiguity about the actual issue at hand. If one defines euthanasia or active euthanasia as directly and actively causing the death of a patient who may not be imminently dying or is dependent on life-sustaining technology, usually by administering a lethal dose of a drug, most state law and

policies of the American Medical Association and the American Academy of Pediatrics would prohibit that action (48,49). How often active euthanasia of neonates actually occurs in the United States is not known. However, there is a significantly different approach in Europe. Recent studies suggest that while active euthanasia is illegal and rarely occurs in most countries, it appears to be acceptable practice in the Netherlands and France. Approximately 70% of neonatal physicians in France and 45% in the Netherlands have been involved in a decision of active euthanasia (50). Confusion arises when the term "passive euthanasia" is used for decisions to withdraw life-sustaining therapy with the expectation that the patient will die (51). The use of medication to treat symptoms of pain or dyspnea or other suffering in the context of comfort or palliative care further compounds the confusion,

P.14

in spite of an ethical duty to provide this type of care. Some would argue that the overall intention may be the same as or may certainly blur into "active euthanasia." However, others would suggest that intention is an important determinant (52). Describing what actually is being considered as a plan of care and avoiding the terminology may prevent the confusion and the associated emotion.

The Role of Parents

Parents are the decision makers for their children. This role is understood to have social, legal, and ethical facets; some are better defined than others, some are potentially in conflict with others. Parents should be in the best position to judge what is in their child's best interest. They will be the ones who will continue to raise the child after the newborn period. Numerous studies and commentaries have reflected on the difficulties families may have to face following the birth of an infant who will have long-term medical and educational needs and how they perceive their situations (53,54,55,56). They will be the ones who will have to deal with the consequences of the decisions. Ethically, this right and responsibility of parents has been the focus of considerable analysis and commentary since the Baby Doe era. The extremes of "no one, including parents, should make these decisions" and "absolute right of parents to make medical decisions" are simplistic and unrealistic (57). Parents should be seen as guardians of their child's welfare, not owners.

Batholome (58) suggests using the language of "permission," a term somewhat less rigid than "consent." He sees the parents' role as a duty rather than a right, a duty to ensure the provision of necessary medical care. "Parental permission for interventions into children's lives must not be seen as the unconditional right to demand or refuse a particular intervention because it is a proper exercise of parental authority over the lives of children. That children are largely dependent, at least for a time, on their parents is to be affirmed, but that dependency does not warrant the second-class social standing implied by a parental right of 'consent' in decisions affecting the health care of their children." Child abuse and neglect statutes frequently result in challenges to parental decision and control. Finally, decision making for another individual is not identical to making decisions for oneself. While

the legal system and ethical consensus give an adult patient's personal decisions wide leeway, surrogate decision making for the adult patient requires that decisions be solely in the patient's best interests or what the patient would have wanted. Surrogates are often questioned, especially when life-sustaining therapies are at issue. The infant and child should be afforded this same protection.

Weir (59) proposes that the parents as decision makers should:

- Have relevant knowledge and information about medical facts, prognosis, and family setting
- Be impartial
- Be emotionally stable
- Be consistent

This final quality should assure that the process ends with the same result in similar cases. However, what information the parents receive and from whom may clearly impact their decision. The clinician has an obligation to present accurate, up-to-date information. The story of Baby Doe resulted, in part, from outdated impressions about Down syndrome (26). The large number of studies, many now outdated, with small sample sizes or preselected samples, clouds prognostication about extremely premature infants. Several studies document the different prognoses presented by obstetricians versus pediatricians/neonatologists for the extremely premature infant (60). Others reflect major differences in clinical approach and parental counsel between intensivists and rehabilitation physicians for children who are or might become ventilator dependent (61).

Other issues complicate the process relative to the parents' emotional stability and consistency. Especially in the immediate newborn period, the infant and parents—especially the mother—may have been separated, sometimes by hundreds of miles. In some cases the parents may not even have seen the baby before it was transferred to a neonatal unit. The mother may at times be ill herself or recovering from anesthesia. The parents may have varying degrees of support from other family members. The father of the baby may or may not be involved. The birth of a critically ill or severely malformed infant is often seen as a loss (of the normal-term infant they expected); the family may actually be grieving or dealing with anger, depression, denial, or fear. Often the information presented to the family is complex and difficult to understand, especially at first hearing. Time constraints may further complicate the process, for example, in the delivery suite or for surgical emergencies.

Standards for Decision Making

The usual broad standard for decision making for this population is to decide what is "in the child's "best interests."" However, defining "*best interests*" can be difficult and reflects a basic problem with the use of terms that may carry very different meanings for different individuals.

Weir and Bale (62) suggest eight variables for evaluating "best interest":

- The severity of the patient's medical condition
- The achievability of curative or corrective treatment
- The important medical goals in the case (such as prolongation of life, relief of pain, or amelioration of disabling conditions)
- The presence of serious neurologic impairments
- The extent of the infant's suffering
- The multiplicity of other serious medical problems
- The life expectancy of the infant
- The proportionality of treatment-related benefits and burdens

Is the "best-interests" standard not, in fact, quite subjective; potentially defined differently by clinicians and family? How do we define how much potential pain and suffering

P.15

is acceptable for a given outcome, especially when the outcome may not be precisely predicted? How do we define an "*acceptable*" outcome? Is being alive but vegetative "acceptable"? Is a 20% or 40% or 70% risk of death or developmental disability acceptable? Is it in the best interests of a child with trisomy 21 to have surgery for duodenal atresia, or the child with trisomy 18 to have open heart repair for congenital heart disease? How differently should one consider a 25% risk of a poor outcome (e.g., for the very-low-birth-weight [VLBW] infant) versus a known, defined poor prognosis (e.g., for trisomy 13)? Silverman (63,64) has proposed abandoning the term "*best interests*" and adopting the concept of a "standard of reasonableness" proposed by Veatch. Here the issue is how far the technology is pursued to

“accomplish reasonable ends defined by those most directly affected by the decisions—the parents.” Well-being extends beyond organic and physiologic function into the realms of social, legal, occupational, religious, aesthetic, and other aspects of life.

Are “*best interest*” or “*reasonableness*” standards the same as “*quality of life*” standards? The latter term is often viewed negatively because of the even greater subjective element. How does one define a good or bad quality of life? Does defining a “quality of life that is “poor” reflect potential for discrimination against individuals with disabilities? In response to the death of an infant with trisomy 21 whose parents refused surgery for tracheoesophageal fistula, the federal government in 1982, under pressure from right-to-life advocates and advocacy groups for the handicapped, proposed regulations to prohibit hospitals from withholding care from newborns. “The Baby Doe” rules stated:

- All such disabled infants must, under all circumstances, receive appropriate nutrition, hydration, and medication.
- All such disabled infants must be given medically indicated treatment.
- There are three exceptions to the requirement that all disabled infants must receive treatment, or, stated in other terms, three circumstances in which treatment is not considered “medically indicated.” These circumstances are:
 - The infant is chronically and irreversibly comatose.
 - The provision of such treatment would merely prolong dying, not be effective in ameliorating or correcting all of the infant's life-threatening conditions, or otherwise be futile in terms of the survival of the infant.
 - The provision of such treatment would be virtually futile in terms of the survival of the infant, and the treatment itself under such circumstances would be inhumane.
- The physician's “*reasonable* medical judgment” concerning the medically indicated treatment must be one that would be made by a reasonably prudent physician who is knowledgeable about the case and the treatment possibilities with respect to the medical conditions involved. It is not to be based on subjective “*quality of life*” or other abstract concepts (27).

In the commentary for the rules, certain conditions were identified as not requiring treatment, including anencephaly, trisomy 13, and extremely low-birth-weight.

"Quality-of-life" terminology carries negative connotations from the Baby Doe era. "Quality of life," just as "best interests," can be very subjective; what one clinician sees as a good quality of life may be unacceptable to another professional or a parent. A family may see the life of a child who is profoundly visually handicapped but with normal intelligence as qualitatively poor. Although many families do not feel burdened with a moderately mentally retarded child, others consider learning disability with normal intelligence unacceptable. Clinicians who work with developmentally impaired children often have a very different appraisal than do laypersons of the quality of life in this patient population.

However, it may be possible to use quality of life as a basis for decision making when considering more fundamental issues. Richard McCormick (65) proposes a minimal condition for defining "quality": the capacity for experience or social interrelating. If the condition is not met, as with anencephaly, treatment is not required. Coulter and associates (66) define interests that would constitute a "minimal quality of life" as:

- Freedom from intractable pain and suffering. Mental retardation, paralysis, cerebral palsy would not be considered physical suffering; dyspnea or intractable physical pain would.
- Capacity to experience and enjoy life—the ability to enjoy food, warmth, or the caring touch of another; the ability to give or receive love.
- Expectation of continued life—heroic treatment, when death will likely occur in a few weeks or months, may be cruel.

There has been considerable debate about how much attention should be paid in the decision-making process to interests other than the child's. Parents may be overwhelmed with the prospects of chronic medical care, financial burdens, difficulty in raising a handicapped child, need for special education, and harm to other children in the family. Some parents may focus on their own psychological and financial interests, protecting their lifestyle and other children at home. Fost (67) suggests, "The history of childhood is one that does not support idyllic notions of parents as decision makers for their children. "It is naïve to posit an identity of interest between infant and parent [in all situations]. Parents guard their own interests, those of the family as a unit, and those of current and future siblings—all of which may be gravely threatened by the newborn" (68). Most would argue that the parents should not refuse treatment that would be in the infant's interests in order to avoid burdens to the family (59,69,70). These considerations are rarely allowed to play a role in surrogate decisions for older children and adults. Others suggest that the impact of a decision on the welfare of the family may be taken into account. Silverman (71)

required to pass a sacrifice test to satisfy the moral expectations of those who do not live, day by day, with the consequences of diffuse idealism. It is easy ... to demand prolongation of each...life that requires none of [the clinician's] own resources to maintain that life later." Ross (72), using the concept of the "intimate family," proposes a model of "constrained parental autonomy," where the parent should be guided by the child's well being, but is not obligated to disregard all personal interests of themselves or other children in order to fulfill the child's needs and interests. This is an issue that requires sensitivity to the parents and family situation, but at the same time balancing the short- and long-term needs of the child. A New York Academy of Medicine conference reached the following conclusion:

Although parents may have legitimate concerns about the effect of treatment decisions on themselves and their other children, the desire to avoid emotional, financial or other hardships cannot justify the denial of clearly beneficial medical care to an ill or injured child....If parents are unable or unwilling to provide essential medical treatment, healthcare professionals should first assure that social counseling and supports are made available to the family to assist them. If the parents remain unwilling to consent to the needed medical treatment, then we must utilize legal mechanisms to ensure social support or supervision to provide those treatments which are clearly in the best interests of the child." (73)

What is the clinician's role in decision making for the infant? Do pediatric practitioners have a stronger responsibility for the decisions made for the child than the clinician caring for an adult patient? Bartholome (74) defines a role that imposes "legal and ethical duties and obligations which exist independently of any parental wishes, desires or consentings." The New York Academy of Medicine states the clinician "must maintain an independent obligation to protect the child's interest" (73). The Academy of Pediatrics defines providers' responsibilities as follows:

"Proxy consent poses serious problems for ... providers. [They] have legal and ethical duties to their child patients to render competent medical care based on what the patient needs, not what someone else expresses ... The pediatrician's responsibilities to his or her patient exist independent of parental desires or proxy consent" (75).

Futility

Conflict also may arise when the parents demand care that the clinician feels is inappropriate, futile, and potentially harmful to the child. The clinician should not be required to provide care that he or she considers harmful or unethical. The problem again is one of definition: What is futile care? Who defines futility? What may be futile in the eyes of the clinician may be beneficial for the child from the parents' point of view (76). Being kept alive on the ventilator with no chance of recovery and minimal or no social interaction may be sufficient for the parents to continue. The case of Baby K complicated this question even further when the federal court upheld the mother's demand for resuscitation and aggressive treatment of her anencephalic infant (22). While the application of this case to other futility cases may be limited—because the court's decision was based on the Federal Emergency Treatment and Labor Act, which requires emergency care for life-threatening situations—it has clearly raised the level of sensitivity to parental demands. Again, ethics consultation or ethics committee involvement may facilitate resolution. The clinician may transfer the patient to another clinician (or institution) who is willing to provide the care. Some institutions have developed procedures for case review that may conclude that life-sustaining treatments can be withdrawn, even against the objections of the family (77). As noted earlier, the health care system and society have usually been unwilling to consider the important justice issues of the financial costs to society, both immediate and long-term, and of limitation of resources.

The Extremely Low-birth-weight Infant

Infants who are born at gestational ages of less than 27 weeks or who weigh less than 800 g have been the focus of considerable professional, legal, and media debate about withholding resuscitation in the delivery room, parental requests for aggressive care or no resuscitation, mortality rates, and quality of outcome (both short-term into later infancy and long-term to school age). There are hundreds of outcome studies and reviews regarding this population, several of which highlight the critical issues for this population (78,79,80). The problems of decision making (discussed previously) are painfully apparent. For example, the clinician has an obligation to accurately inform the parents expecting an ELBW infant about the clinical situation, prognosis, anticipated clinical course, and so forth. While there is certainly no lack of outcome data, it is clear that there are wide variations in outcome from one study to another. The studies are also faulted by the sample size of infants at any gestation, by the selection criteria (were all live born infants included or only those admitted to the NICU, inborn or outborn, etc), and by decisions about viability and nonresuscitation that then impact mortality of the sample as a whole. Mortality will, by definition, be higher if most infants were not resuscitated because of clinician or family preference. Drop out and incomplete followup, small numbers, and variation in definitions of morbidity impact the usefulness of long-term outcome studies. With such a wide range of study results, there is a risk or tendency for an individual clinician to choose those that support his

or her philosophical approach (conservative or aggressive). Fortunately, there are several large, collaborative studies now available that lessen the impact of uncontrolled variables and provide more reliable outcome data (81,82,83,84,85,86). El-Metwally and associates (87) report significantly different survival rates when all ELBW infants are aggressively managed. Ideally, clinicians should have mortality and morbidity data for their own institution in addition to national statistics to share with the parents.

P.17

Use of gestational criteria for decision making is reasonable because studies show a very dramatic correlation to survival (81,82,88,89,90,91,92,93,94,95). Each additional gestational week adds a significant increase in survival percentage. However, in many cases both obstetrical estimates using ultrasound and neonatal estimates using physical exam scoring are not accurate enough to define 23 versus 24 or 24 versus 25 weeks gestation (96,97,98). The current practice of quoting gestational age in fractions of a week (e.g., 23 5/7) provides a sense of accuracy that is not justified by the existing data.

Birth weights are accurately measured and have been correlated to outcome (35,88,89,99,100,101,102,103). However, for gestations in the 22- to 25-week range, there is an extremely wide variation in birth weights. Using birth weights also ignores the impact of intrauterine growth restriction. If study populations include growth-restricted infants, outcome data may be overly optimistic. If the decision makers consider only birth weight, the predicted prognosis may be overly pessimistic.

Guidelines for Resuscitation/Care

Several professional groups have developed criteria or guidelines for decision making for this population. In 1994, the Canadian Paediatric Society and the Society of Obstetricians and Gynaecologists of Canada defined relatively specific recommendations:

At 22 completed weeks of gestation, they suggest "treatment should be started only at the request of fully informed parents or if it appears that the gestational age has been underestimated." At 23 to 24 completed weeks of gestation, they emphasize a significant role for parental wishes, the option of resuscitation, and the importance of discussion with parents about the "need for flexibility in deciding to start or withhold resuscitation, depending on the infant's condition at birth." Finally, at 25 weeks gestation they state "resuscitation should be attempted for all infants ... without fatal anomalies" (104).

Discussions by neonatologists in Colorado, in collaboration with the Colorado

Collective for Medical Decisions, developed guidelines that define comfort care as the only appropriate choice for the 22 weeks' gestation infant. At 23 weeks, most would advise comfort care; but, if the parents understood the high risks involved, would be willing to initiate a course of intensive care. At 24 weeks, the neonatologists were able to support either decision, as long as a collaborative process with good information occurred. At 25 weeks, they were uncomfortable with withholding intensive care, and some, but not all, were willing to support a parental request for comfort care, if there had been a good parent education process and an effort to collaborate with the parents (Hulac P. Colorado Collective for Medical Decisions, personal communication, January 2000). Tyson and associates (80) have suggested developing fairly detailed guidelines based on outcome data. Female and/or small-for-gestational-age infants would be resuscitated at lower birth weights than male and/or appropriately grown infants. Antenatal steroids would lower the recommended weight further. They recommend mandatory resuscitation when the data reveal a greater than 50% chance of survival without severe sequelae and optional resuscitation when the chance is 25% to 49%. Resuscitation for infants with a less than 25% chance of survival without severe sequelae would be seen as investigational. Neonatal Resuscitation Program, which is supported by the American Academy of Pediatrics and the American Heart Association, suggests that noninitiation of resuscitation for newborns of less than 23 weeks' gestational age and/or 400 g in birth weight is appropriate (105). Interestingly, clinicians have overinterpreted these criteria as either demanding resuscitation at 23 weeks or 400 g or as stating it is inappropriate to resuscitate at less than 23 weeks or 400 g (80).

Discussions with the family should include the uncertainty of gestational age if that is at issue, the advantage of assessing and then making decisions, the possibility of withdrawal of support if it is apparent that there will be a bad outcome, and the importance of ongoing assessment and ongoing communication. To avoid confusion and conflict, the obstetrician and the pediatrician/neonatologist should coordinate their approaches. For the extremely immature infant, the parents should be aware that there may be nothing that can be done. There may be physical limitations to the resuscitation. In most circumstances, firm decisions about how to proceed should be avoided. Likewise, vague terms such as "no heroic measures" or "do everything" can cause confusion and conflict. Several recent papers have discussed the importance of antenatal and intrapartum discussions (106,107). When possible, the use of educational materials, tours of the NICU, or videos of NICU experiences may further the parents understanding of the situation. The Colorado Collective for Medical Decisions has developed a video especially for the parents of an ELBW infant (108).

Infants with Severe Encephalopathy/Brain Death

Infants with perinatal hypoxic-ischemic injury may have lethal multisystem failure. However, more often they are able to survive despite severe central nervous system (CNS) injury. Prolonged, difficult-to-control seizures, hypotonia; poor feeding; apnea; and inability to maintain body temperature are poor prognostic signs for developmental outcome. Imaging studies (computed tomography [CT], magnetic

resonance imaging [MRI]) as well as an electroencephalogram (EEG) may add additional prognostic data. Some may be ventilator dependent because of poor respiratory drive. Others may require gastrostomy feedings. Prognosticating may be difficult early after the insult, but in some circumstances the clinical data convincingly show that the prognosis is extremely poor. Do not resuscitate orders and/or withdrawal from the ventilator are appropriate decisions at this time.

Infants with Severe Congenital Malformations/ Chromosomal Anomalies

In a series of articles and commentaries beginning in 1973, pediatricians Duff and Campbell (20) reported on a practice

P.18

of selective nontreatment at Yale-New Haven Hospital that resulted in the deaths of 43 infants over a period of 30 months. Physicians and parents decided together, with the physicians sometimes yielding to parental wishes. Surveys at that time confirmed that many pediatricians and pediatric surgeons accepted selective nontreatment of seriously impaired newborns. In a survey of New England pediatricians, 54% did not recommend surgery for an infant with Down syndrome and duodenal atresia, and 66% would not recommend surgery for an infant with a severe case of spina bifida (109). Twenty-two percent of surveyed pediatricians in the San Francisco area favored nontreatment for infants with trisomy 21 who had no complications, and more than 50% recommended nontreatment for Down syndrome with duodenal atresia (110). With the Baby Doe case, advocates for the handicapped, developmental pediatricians, and family support groups promoted a change in approach for infants with trisomy 21 and meningomyelocele. Treatment and approaches to rehabilitation and special education have improved; the current standard of care in the United States is that infants with trisomy 21 receive the same treatment that is indicated for a child with a similar medical or surgical condition who does not have trisomy 21.

There are other conditions associated with extremely poor prognoses for survival or for reasonable "quality of life", including anencephaly and other severe CNS developmental anomalies, trisomy 13, and trisomy 18 (111). Most of these infants will not survive beyond the first few months of life. Those who do survive have severe neurodevelopmental delays. Many have life-threatening conditions in the immediate newborn period and require life-sustaining treatment to prolong survival. Most would agree that a recommendation to withdraw or withhold aggressive therapy and provide comfort care is appropriate. The Neonatal Resuscitation Program guidelines suggest that noninitiation of resuscitation is appropriate for confirmed diagnoses of anencephaly or trisomies 13 or 18 (105). Hopefully, every parent of such an infant would have appropriate counseling about the diagnosis; and in this circumstance, a definite plan for care in the delivery room (including no cesarean section for fetal distress) and during the newborn period can be very

helpful and comforting to the parent. Again, the guideline does not state that it is inappropriate to resuscitate. When a condition is not diagnosed until after birth, there is the usual obligation for the clinician to provide the parents with appropriate, accurate information in a timely fashion. Some families wish to pursue aggressive treatment, and their wishes should be considered. Internet sites and parent support groups have expanded the options available to families for treatment (112). While cardiac surgery for infants with trisomy 18 was formerly quite uncommon, there are now increasing requests for such procedures. The parents should be well informed, and a plan should be developed for the care, including how to proceed if the infant does not tolerate the procedure, becomes ventilator dependent, and so forth. If the clinician is not willing to offer this level of care, efforts should be made to transfer care to another physician or facility.

Artificial Nutrition and Hydration

While most agree that withdrawing artificial nutrition and hydration from hopelessly ill, persistently vegetative or dying patients may be appropriate (113,114), this issue becomes less well-defined in the newborn population, who are all dependent on others for feeding and where tube feeding is the standard of care for many until they develop the ability to feed. There are circumstances, however, where discontinuing intravenous nutrition or tube feedings may be appropriate (115,116,117,118). If the infant is actively dying, there is no benefit to feeding or hydration, and experience would suggest that there may be less suffering from excess secretions if the patient is somewhat dehydrated (113). Coma and persistent vegetative state are rarely defined in the newborn, but severe neurologic impairment is, unfortunately, not rare. However, exact prognostication about recovery is difficult, and some infants who need feeding support initially may develop the ability to feed normally after a period of recovery. When clinical evaluation strongly suggests an extremely poor neurologic outcome, it may be reasonable to withhold feedings (118). Factors to consider include whether the infant is able to feed at all or whether the infant demonstrates hunger or satiety. Infants may have medical conditions that preclude enteral feeding (e.g., short gut syndrome), and, therefore, they are dependent on total parenteral nutrition (TPN). TPN has many potential complications including loss of venous access, infection, and liver toxicity. If the possibility of slow recovery of absorptive ability or successful bowel transplant is poor, withdrawal of TPN may be an option after consideration of the criteria discussed earlier. Withdrawal of feeding often presents more psychological and emotional angst than withdrawal of other life-sustaining technology because of the cultural connotations of "feeding" and "starving" (119). While the "Baby Doe" regulations specifically list hydration and nutrition as "required," the term "appropriate" is also used and therefore open to interpretation.

Palliative/Comfort Care and Pain Control

When aggressive care or life-sustaining technology is withheld or withdrawn, care

does not stop. The clinician has an obligation to the patient and the parents to provide comfort care, warmth, feedings, if desired, and emotional support. The clinical staff must attend to relief of symptoms and pain control (120). Care may in fact become more “intensive” in terms of time spent with the family. Catlin and Carter (121) have developed a protocol for neonatal end-of-life palliative care. Clinicians and, more recently, regulators have highlighted the importance clinically and ethically of identification and treatment of pain in the neonate (122,123,124).

High-Technology Home Care

With technological advances in the hospital has come the use of this same technology in the home—tube feedings,

P.19

oxygen, and mechanical ventilators. This development has raised numerous ethical issues both on an individual patient basis and related to the general issues of resource allocation, funding, and health planning (125, 126). How a family and the clinician reach the conclusion to proceed or not proceed with long-term home care, especially mechanical ventilation, requires careful attention to the details of adequate information, parent education and training, planning for professional assistance in the home, adequate support and funding, opportunity for respite care, and so forth. Studies suggest that there is wide variation in physician practice regarding offering home ventilation, with families then receiving unbalanced information (61). With the growing incidence of ventilator use in the home, parent support groups and the Internet offer a very positive bias. Physicians may feel that this is fiscally inappropriate, or that the child's quality of life may be poor, or that the family will be unable to manage at home. Home ventilation for older children and adults with a variety of diseases provides a great deal of satisfaction for many of them (127). Every child and family is unique in their clinical situation, prognosis, family goals and stamina, and resources. On the other hand, just because the technology for home ventilation is now available does not require its use in every circumstance. If the family is unable or unwilling to provide less intensive care in the home (e.g., tube feeding or oxygen), other options must be identified. It is inappropriate to discharge an infant with heavy ongoing health care needs home to a family that is ill prepared and does not have adequate support from outside services.

HIV SCREENING OF PREGNANT WOMEN AND NEWBORN INFANTS

The diagnosis and treatment of HIV infection has changed dramatically in a short time period. A decade ago, diagnosis often involved a screening test with confirmation testing to follow; diagnosis can now be quite accurately made in an hour or less. Antibody testing of the newborn is, in reality, antibody testing of the mother; it is now possible to test the newborn for viral DNA. The critical treatment element relates to the ability to prevent transmission of infection from mother to

baby, by treatment of the mother during the pregnancy and labor and of the newborn in the first several weeks after birth. There is also evidence that treatment limited to labor and the postnatal period only, or even to the infant postnatally, may significantly decrease the risk of transmission. It has therefore become significantly more important to know the mother's HIV status early in the gestation and certainly during labor. Public Health recommendations promote universal, voluntary, routine testing of the mother, using an "opt-out" strategy for consent—"we will test you for HIV unless you specifically say you refuse" (128,129,130,131). Mandatory testing potentially violates the mother's rights to privacy and self-determination and, even today, may expose her to social consequences and discrimination. Being pregnant should not require an individual to forgo rights. Once the infant has been born, some would argue that the advantages of early diagnosis and treatment outweigh the risks to the mother. Some jurisdictions have mandated newborn screening if the mother's status is not known. However, most professionals would recommend routine, but voluntary, testing. The mother's status will be defined, but the benefits to the baby would outweigh the risks to the mother (131).

SUBSTANCE ABUSE IN PREGNANCY

Substance abuse during pregnancy has incited a great deal of media and legal attention. Prosecutors and governmental agencies have charged mothers with homicide and child abuse, imprisoned them for the duration of their pregnancies, and removed their children from their custody (132,133,134). Complicating the ethical and legal issues is a wide range of scientific opinion about the short- and long-term effects of drug exposure in utero on the child (135,136). Recent studies suggest that the rearing environment is much more critical for the child's development (135). Routine drug screening of pregnant women without their consent has been ruled unconstitutional (137). Punitive approaches in general are counterproductive, potentially keeping women away from prenatal care (132). Routine screening of newborns should be limited to situations in which there is a clinical history or signs or symptoms compatible with drug exposure or withdrawal. Testing infants solely to identify substance-abusing mothers should be avoided. The approach to mothers and babies should be supportive, voluntary, and nonpunitive (138).

GENETIC TESTING

In the past two decades, there has been a dramatic increase in knowledge about the human genome and the ability to screen for the presence of certain genetic diseases, carrier states, traits, or predispositions to disease. Genetic testing of a newborn raises different issues than routine medical testing performed as part of clinical care. The genetic information relates not only to the individual tested but also to other members of the family. Results of testing may have psychological (guilt, anxiety), social (stigmatization, discrimination), and financial impact (insurability, employment considerations) with long-term consequences. Some genetic information defines

risks only and does not predict with any certitude a specific condition or outcome. Finally, many defined conditions do not necessarily have effective therapy. For these reasons, concerned professional organizations have developed policies and guidelines related to these issues. Testing should involve effective counseling, informed consent, and attention to confidentiality. Genetic testing to confirm a medical diagnosis would be an appropriate component of medical care, for example, DNA analysis for cystic fibrosis in an infant with meconium ileus or chromosomal analysis for a newborn with clinical

P.20

features of Down syndrome. Testing for conditions that may benefit from monitoring, prophylaxis, or treatment in an otherwise healthy individual (e.g., familial hyperlipidemia) may also be in the child's best interest. However, carrier screening for diseases with no risk to the pediatric patient should be avoided. Likewise, screening for adult-onset conditions should be deferred until adulthood or until the mature adolescent is able to consent (139,140).

MAKING DECISIONS REGARDING THE APPROPRIATENESS OF INTER-INSTITUTIONAL TRANSFER

The transfer of neonates from referring to referral hospitals potentially adds an additional layer of ambiguity to the process of ethical decision making, particularly if there is uncertainty on the part of the NPM team at the referral hospital regarding the level of treatment received by the infant since birth. For example, a 25-week gestation premature infant who has been '*set aside*' as nonviable but is found gasping 1 hour later and resuscitated is unlikely to benefit from transfer to another institution for aggressive support.

A regional network of hospitals can reduce this problem by having a common set of criteria for delivery room practices and inter-institutional referral. Fletcher and Paris (141) suggested the following mnemonics to assist in formulating these policies:

- **ACUTE (Acute, Critical, Unexpected, Treatable, and Easily diagnosed)**
Infants included in this group are those with prematurity and respiratory distress syndrome; ELBW infants of gestational age known to be 25 weeks or greater; term or preterm infants with sepsis, pneumonia, or meningitis; and infants with surgically correctable malformations.

The authors place these infants in a '*definite*' category for transfer to an NICU capable of providing the level of care required.

- **UNSURE (UNknown disease, SUSpected REsponse).** This group includes

preterms of 23 to 24 weeks gestational age or with very low-birth-weight and uncertain gestational age, infants with severe birth asphyxia, and any infant with an unexplained disease or syndrome that requires further diagnostic efforts. Within this group there will be a significant number of infants for whom the response to treatment will be unpredictable. These infants should be given full medical care until the diagnosis has been made or the response to treatment is clear; decisions to omit care or not to transfer should not be made precipitously.

- **KNOT (Known, NOT Treatable).** Although only a small number of infants fit into this category, treatment decisions for this group frequently take a disproportionate amount of time. This group includes neonates with anencephaly and those with lethal genetic disorders such as trisomy 13 and trisomy 18.

Transfer of neonates with anencephaly for aggressive support is not indicated; transfer of those with lethal genetic defects is not indicated if there are facilities for accurate diagnosis and appropriate care and counseling at the hospital of birth. When diagnostic facilities are not available at the birth hospital, onsite consultation by a specialist from the referral hospital is an appropriate alternative to transferring the infant.

Chapter 3

Neonatology in the United States: Scope and Organization

Richard L. Bucciarelli

The practice of neonatal and perinatal medicine has changed enormously since its recognition as a distinct subspecialty in 1975. The development of technologies as complex as extracorporeal membrane oxygenation and as simple as the administration of exogenous surfactant, has resulted in the survival of many infants who would have succumbed to their illnesses just a few years ago. In addition, an ever-increasing awareness of the benefits of interpregnancy and prenatal care has led to significant behavior modification among many pregnant women, resulting in a reduction in the occurrences of conditions such as fetal alcohol syndrome and neural tube defects (1). Early diagnosis and peripartum therapy has decreased the risk of the vertical transmission of diseases such as hepatitis B and HIV (2). Despite erosions in health insurance coverage for women and the general population, fewer pregnant women are uninsured than nonpregnant women (13% versus 28%), and recent expansions in eligibility for coverage under Medicaid may reduce this number even further (1). In 2000, 83.2% of women received early prenatal care, up from 75.8% in 1990 (Fig. 3-1) (3). Teen birth rate has reached an all time low at 27 per 1,000 females ages 15 to 17 years, compared to 39 per 1,000 in 1991 (Fig. 3-2) (4).

Notwithstanding these positive trends, the rate of preterm, very preterm, low-birth-weight (LBW), and very-low-birth-weight (VLBW) deliveries in the United States has not changed significantly in more than a decade and remains far below the Healthy People 2010 goals (1). In 1998 the United States reported an infant mortality rate of 7.2 per 1,000 live births, resulting in a ranking of 28th in the world behind Cuba and just ahead of Slovakia (Table 3-1) (5). Even more troubling is the existence of significant racial and ethnic disparities in every indicator of perinatal health outcome, with neonatal and infant mortality for African Americans exceeding twice that of whites and three times the year 2010 goal (1).

This poor performance of the United States is not because of an unwillingness to commit significant resources to the delivery of perinatal care. In 1985, expenditures for obstetric and neonatal care approached \$15 billion. Today this figure exceeds \$40 billion, with the incremental costs for hospitalization for preterm labor reaching \$820 million (6).

The stark contrast between the enormous economic investment in perinatal care and the relatively static outcome statistics suggests that while the United States has concentrated on developing the world's most sophisticated high-tech care, we have done little to understand the biological and societal issues responsible for producing high-risk infants. Perhaps this is a statement of our health care system's superb ability to care for the individual patient, in this case a high-risk infant after delivery, while failing to develop systems that integrate resources to provide efficient, cost-effective preventive care that could reduce human suffering and conserve vast resources.

In this chapter, the current size and scope of the practice of neonatology in the United States is reviewed, emphasizing how resources are currently used to deliver neonatal care. Issues are presented in an attempt to identify potential areas of focus for those involved in developing future perinatal public policy.

Figure 3-1 Early prenatal care among mothers: United States, 1970-2000. Early prenatal care begins during the first trimester of pregnancy. This figure is related to the *Healthy People 2010* leading health indicators on access to health care. (From *Chartbook on trends in the health of Americans 2002*. Centers for Disease Control and Prevention, National Center for Health Statistics, National Vital Statistics System. Redrawn from table 6, with permission.)

THE CAPACITY TO DELIVER IN-HOSPITAL NEONATAL CARE

Neonatal Hospital Bed Capacity

Because there is no national database defining or inventorying special-care neonatal beds, the exact capacity for providing neonatal intensive care unit (NICU) services in the United States is unknown. The estimates of capacity are further complicated by the fact that the definition for levels of inpatient NICU services varies greatly from state to state. Although clearly outlined by the Committee on Perinatal Health (COPH) of the March of Dimes Birth Defects Foundation in 1970 (revised in 1980 and 1993), financial, marketing, medical-legal, and community demands have encouraged many hospitals to elevate the level of select perinatal services, focusing on the provision of services locally with little regard to regional needs (7,8). As a result, there has been a significant increase in the number of hospitals providing NICU care, as well as blending neonatal services available primarily at basic care (level I) and specialty care (level II) centers (8).

Figure 3-2 Teen birth rate (births per 1,000 females ages 15 to 17 years), 1975-2000. Note: Teenage childbearing has declined steadily since rising to 39 births per 1,000 teen girls in 1991. At 27 births per 1,000 in 2000, the teen birth rate has reached its lowest level ever. (From *The Annie E. Casey Foundation, Kids count data book, 2003 apocket guide*. Baltimore, MD: The Annie E. Casey Foundation, 2003:7, with permission.)

TABLE 3-1 INFANT MORTALITY RATES, BY COUNTRY, 1998

Rank	Country	Rate
1	Hong Kong	3.2
2	Sweden	3.5
3	Japan	3.6
4	Norway	4.0
5	Finland	4.1
6	Singapore	4.2
7	France	4.6
7	Germany	4.6
9	Denmark	4.7
10	Switzerland	4.8
11	Austria	4.9
12	Australia	5.0
13	Czech Republic	5.2
13	Netherlands	5.2
15	Canada	5.3
15	Italy	5.3
17	New Zealand	5.5
17	Scotland	5.5
19	Belgium	5.6
19	Northern Ireland	5.6
21	England and Wales	5.7
21	Greece	5.7
21	Israel	5.7
21	Spain	5.7
25	Portugal	5.9
26	Ireland	6.2
27	Cuba	7.1
28	United States	7.2
29	Slovakia	8.8
30	Kuwait	9.4

Note: Differences in data and definitions limit international comparisons. For more information, see National Center for Health Statistics, 2002. Table 26, p. 114.

From Pastor PN, Makuc DM, Reuben C, et al. *Chartbook on trends in the health of Americans 2002*. Hyattsville, MD: National Center for Health Statistics, 2002, with permission.

March of Dimes. *March of Dimes data book for policy makers*, Washington, DC: March of Dimes Office of Government Affairs 2003, with permission.

In 1996, the National Perinatal Information Center reported an extensive survey of the supply and distribution of obstetric and neonatal services. While the number of hospitals offering obstetric services had declined, the numbers offering NICU services had increased dramatically by 64% such that one third of all hospitals with obstetric services were also operating an NICU. When the investigators adjusted for the number of live births, they discovered that the number of neonatal special care beds had increased significantly from 3.0 per 1,000 live births to 4.3 per 1,000 live births over the 10-year period of the study (9). More recent information suggests that this ratio has climbed

P.26

even further to 5.1 per 1,000 live births, exceeding the calculated demand by a factor of between 2 and 3 (10,11). In 2002, Thompson and associates (11) compared the capacity for in-hospital neonatal intensive care in the United States with that of the United Kingdom, Australia, and Canada (countries with similar neonatal practices). It is no surprise that the United States leads the way with an NICU bed capacity equal to five times that of the United Kingdom and twice that of Australia and Canada. Further, this difference remains even if the capacity is adjusted for the incidence of LBW infants (Table 3-2). The authors also point out that despite this huge capital investment, the United States trails all three countries in reported neonatal and infant mortality

rates.

TABLE 3-2 NEONATAL CARE: PHYSICIAN AND HOSPITAL CAPACITY

	United States	Australia	Canada	United Kingdom
Annual deliveries (in thousands)	3942	256	349	636
Physicians* (per 10,000 live births):				
Pediatricians	144.7	34.2	59.7	20.0
Neonatologists	6.1	3.7	3.3	2.7
Neonatologists per 1,000 low-birth-weight infants	8.0	5.7	5.5	3.7
Obstetricians/gynecologists	100.2	42.2	45.3	24.3
Maternal/fetal specialists	3.2	0.4	NA	NA
Family practitioners	169.7	813.9	816.7	597.7
Number level III units* (per 10,000 live births)	1.21	0.90	0.72	2.92
Neonatal hospital beds* (per 1,000 live births)	3.3	NA	NA	0.67
Intensive care beds				
Intensive beds per 1,000 low birth weight	43.4	NA	NA	9.3
Intensive + intermediate care beds	5.1	2.6	2.6	NA
Intensive + intermediate care beds per 1,000 low-birth-weight infants	67.1	39.4	44.8	NA

From Thompson LA, Goodman DC, Little GA. Is more neonatal intensive care always better? Insights from across-national comparison of reproductive care. *Pediatrics* 2002; 109:1036–1043, with permission.

Although the United States has an in-hospital neonatal bed capacity that exceeds that of any other nation, its distribution across our nation is not homogenous and does not seem to follow any identifiable pattern, ranging from a low of 14 per 10,000 live births to a high of 59 per 10,000 live births (from 71 to 1,319 total births per NICU bed). Once again there was no correlation between the number of beds in a region with the incidence of LBW or neonatal mortality (12).

Size and Effectiveness of the Neonatologist Workforce

In an attempt to address the capacity issue more accurately, investigation recently has focused on the size and distribution of the neonatal work force as a potentially more accurate proxy for our capacity to deliver in-hospital neonatal care in the United States. Clearly, neonatologists are the catalysts that create a hospital environment, resulting in the creation of NICU beds and ultimately in the desire to provide higher risk obstetrical and neonatal care within that institution. Because a neonatologist can utilize a broad array of neonatal health care specialists to provide services at several institutions simultaneously, the ratio of neonatologists to both high- and low-risk deliveries and their distribution within the region may more accurately define the capacity for in-hospital neonatal care.

In 1975, the American Board of Pediatrics' sub-Board of Neonatal and Perinatal Medicine certified 355 physicians as the first neonatologists in the United States. Since then, the American Board of Pediatrics has certified an additional 3,531 candidates. Currently there are 3,886 neonatologists certified by the Board, including the results of the latest certifying examination in 2001 (Fig. 3-3) (13). It is of interest to note that between 1987 and 1999, an average of 300 candidates was certified with each examination. In 2001, the number dropped to 182, the lowest number ever certified during a single examination. The average age at certification is 32 years, while the average age of all certified neonatologists is 51 years. During the early years of certification, males dominated by almost 3:1. In more recent years, the gender distribution approached 1:1, with

more females certified during the 2001 certification (97 females, 85 males). Although the attrition rate for neonatologists was once believed to be quite high, it has remained low at 1% to 2% over a 10-year period. Additionally, it appears that almost 1,000 physicians actively engaged in the practice of neonatology are

physicians who have not completed sub-Board certification or are pediatricians with special training in neonatology who concentrate their efforts on caring for neonates with special needs (14,15). Thus, the total neonatal physician workforce approaches 5,500, having doubled in the last decade and more than tripled since 1985 (13,14 and 15).

Figure 3-3 Cumulative total of specialists in neonatal and perinatal medicine certified by the American Board of Pediatrics, 1991-2001. (From American Board of Pediatrics. American Board of Pediatrics Neonatal-Perinatal Medicine qualifying examination statistics. Chapel Hill, NC: American Board of Pediatrics. Available online at <http://www.abp.org/stats/WRKFRC/neostat.htm>.)

TABLE 3-3 BIRTHS PER EACH CLINICALLY ACTIVE NEONATOLOGIST AND PEDITRICIAN IN UNITED STATES, 1981-1996

	Number of Birth (millions) *	Number of Neonatologists†	All Births	Births per Neonatologist		
				Low-Birth-Weight (<2500 g)	Very-Low-Birth-Weight (<1500 g)	Extremely Low-Birth-Weight (1000 g)
1981	3.63	504	7201	490	83	39
1985	3.76	952	3951	266	48	24
1989	4.04	1507	2681	189	34	17
1992	4.07	1866	2178	154	28	14
1996	3.90	2311	1687	123	23	11

* Birth from U.S. Vital Statistics; 1995 births substituted for 1996.

† Physician numbers used for calculation exclude residents and fellows (N = 304), and those predominantly engaged in teaching (N = 106), administration (N = 97), and research (N = 232). From AMA Physician Masterfile (December 31 of calendar year). For comparison, the *United States Directory of Neonatologists 1996* listed 2,635 board-certified, 652 board admissible, and 230 others practicing in neonatology; the professional activities (clinical care, teaching, etc) of the neonatologists are not available.

From Goodman DC, Little GA. General pediatrics, neonatology and the law of diminishing returns. *Pediatrics* 1998;102:396-399, with permission.

Concerns about a physician workforce devoted to neonatology, its distribution, its affect on regionalization, and, most importantly, its affect on outcome measures have been raised several times (16). In 1981, there were 83 very-low-birth-weight (less than 1,500 g) and 39 additional extremely low-birth-weight (ELBW [less than 1,000 g]) infants for every neonatologist. By 1996 these numbers dropped to 23 VLBW infants and 11 ELBW infants for every active neonatologist (Table 3-3) (17). In its statement on the neonatal workforce, the American Academy of Pediatrics Committee on the Fetus and Newborn (COFN) recommended that the neonatologist:live birth ratio be 1:2,569 live births—which is 3.9 neonatologists per 10,000 live births (16). In 1996, the ratio was calculated to be 1:1,687 live births—which is 5.9 neonatologists per 10,000 live births, 1.5 times the original target. In addition, 50% of the neonatologists surveyed in this study reported that a very significant portion of their practice was devoted to the care of normal newborn infants (18).

Similar to the in-hospital bed capacity analysis, Goodman and associates (18) report wide variations in the availability of neonatologists, ranging from 1.2 per 10,000 live births to a high of 25.6 per 10,000 live births (a range of 390-8,197 births per neonatologist) (Figs. 3-4a,b). Regional variations were unexplained by differences in LBW, number of high-risk pregnancies, or use of mid-level providers. Regions with an average of 2.7 neonatologists per 10,000 live births or less experienced a slight, but significant increase in mortality only for infants with birth weights of 500 to 999 g. Once birth weight exceeds 999 g or the number of neonatologists exceeds 4.3 per 10,000 live births, there are no additional improvements seen in neonatal mortality (19).

Lessons Learned

The attempt to correlate outcome with either NICU in-hospital bed capacity or the number and distribution of neonatologists presents several dilemmas. First, gross outcome of neonatal care, such as the incidence of LBW or neonatal and infant mortality, may be insensitive to regional changes in resource availability. It is entirely possible that there exists a yet-to-be-defined threshold above which the impact of additional available resources is no longer obvious. Alternatively, it is well established that birth weight is a reflection of socioeconomic status and quality of care before delivery and is not directly influenced by postnatal medical interventions (12,20). As the COPH stated in 1993, appropriate preconception and prenatal care may contribute significantly to increasing birth weight and decreasing neonatal mortality (7).

COSTS OF DELIVERING NEONATAL CARE

Acute Care In-Hospital Costs

Estimates suggest that the total expenditures for perinatal care in the United States exceed \$6,850 per mother-infant pair (7). This represents 4.5% of personal health care

P.28

spending by all Americans and 7% of health care spending by the population younger than 65 years of age. Most of these resources are spent on acute, high-tech care of the critically ill neonate, with daily charges easily reaching \$1,000 to \$2,500 for hospital services and an additional \$300 to \$450 each day for physician services (21). Of the four million births predicted in 2003, 280,000 will be premature, with an estimated cost of \$12 billion for acute in-hospital neonatal care. Approximately one third of these expenditures, \$4 billion, would be used to provide care for infants weighing between 500 and 700 g (22). An additional \$1 billion would be spent on hospitalizations for preterm labor in an attempt to delay delivery as long as possible. Because the costs for complicated births (ranging from \$20,000 to \$400,000) are many fold greater than the costs of an uncomplicated delivery (averaging \$6,400), the investment in delaying delivery as long as possible is entirely justified (6).

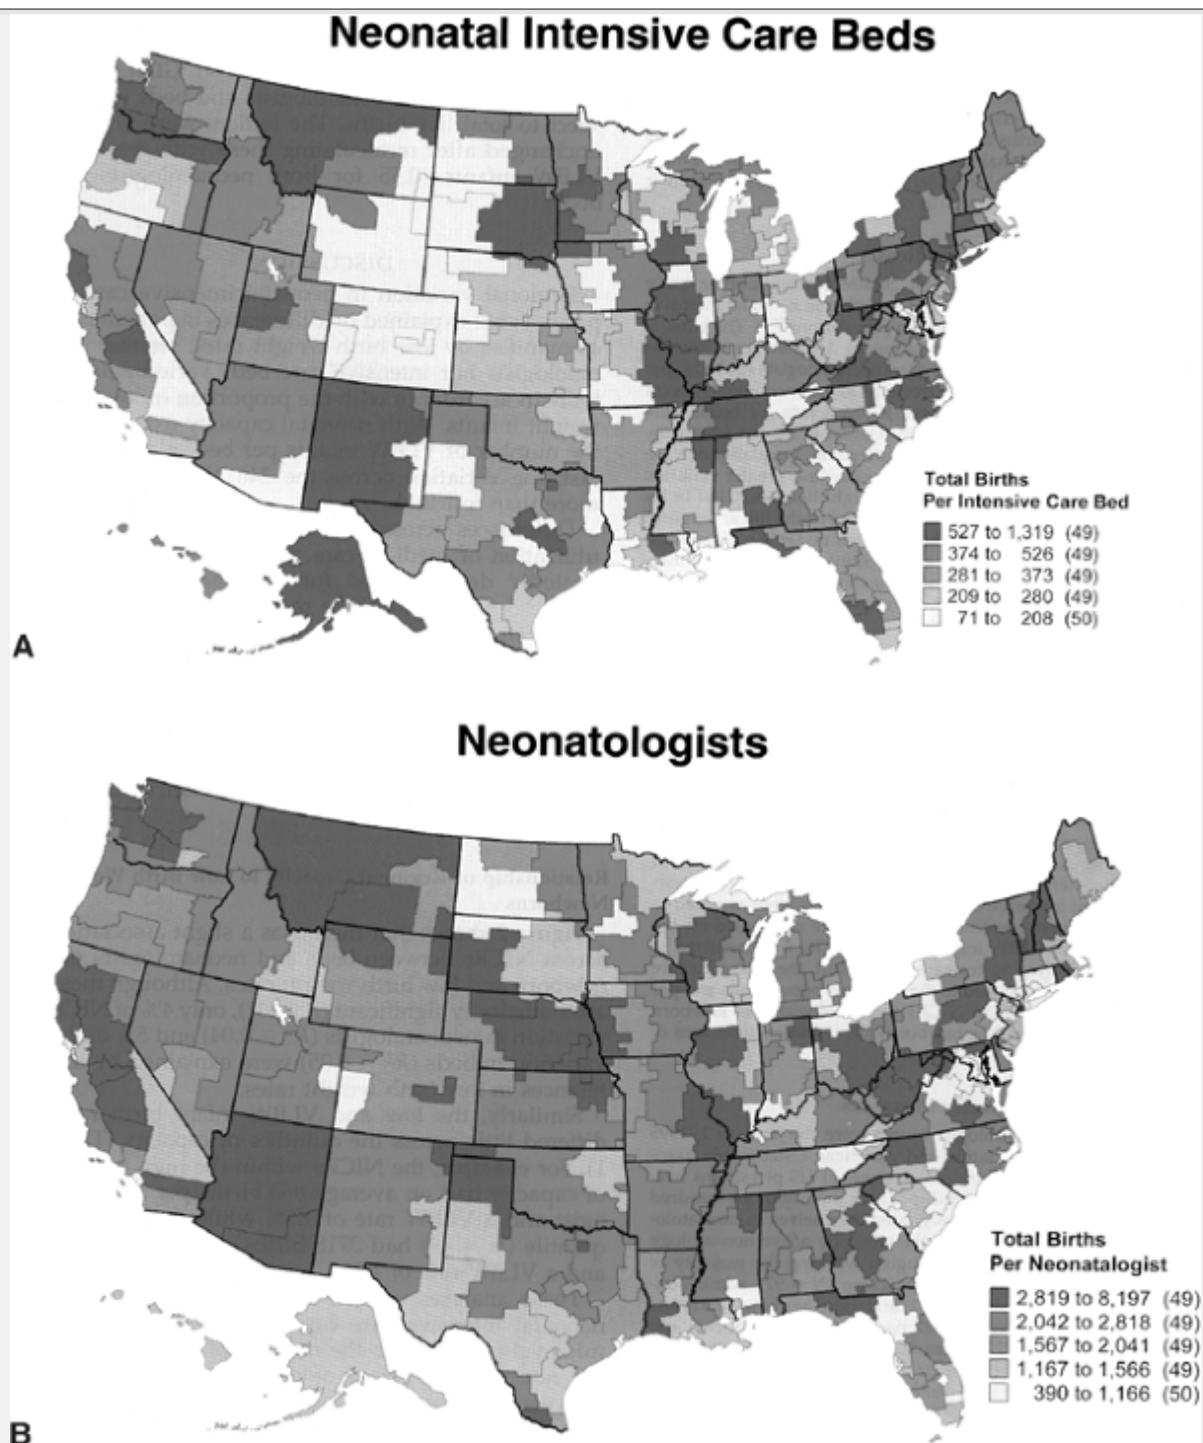

Figure 3-4 Total birth figures. **A:** Total births per intensive care bed. **B:** Total births per neonatologist. (From Goodman DC Fisher ES, Little GA. Are neonatal intensive care resources located according to need? Regional variations in neonatologists, beds, and low birth weight newborns. *Pediatrics*: 2001;108:426, with permission.)

Charges associated with specific perinatal diagnoses rank among the highest of all hospital diagnoses (Table 3-4). A 1999 report by the Health Care Cost and Utilization Project's Nationwide Inpatient Sample listed neonatal respiratory distress syndrome as the most expensive diagnosis, with a mean charge of \$82,648 and a mean length of stay of 27.8 days. Other diagnoses included in the top 10 categories were:

- Low-birth-weight (mean charge of \$56,942)
- Cardiac anomalies (mean charge of \$49,858)
- Intrauterine hypoxia and birth asphyxia (mean charge of \$36,954) (23)

In analyzing data from 3,288 VLBW infants from 25 NICUs, Rogowski (24) reported that treatment costs vary inversely with birth weight, with a median treatment cost of \$89,546 for infants weighing between 501 g and 750 g and \$32,531 for infants weighing between 1,251 g and 1500 g.

P.29

In this analysis, she included costs of accommodation (room and personnel costs) and ancillary services (respiratory therapy, laboratory, radiology, pharmacy, and medical supplies). While accommodation costs varied by a factor of two when comparing the largest and smallest VLBW infants, ancillary costs varied by almost five fold, with laboratory and respiratory services showing the widest variation. When costs were corrected for length of stay, the costs per day were surprisingly similar, varying by only \$552 per day between infants weighing 1,251 to 1,500 g at birth and those weighing 501 to 750 g at birth (Table 3-5).

Because physician services are billed separately from the hospital, most studies do not include them in the analysis and, as a result, the true picture of the cost of neonatal care is somewhat distorted. This distortion can be significant when one considers that the cost of physician services in the NICU approaches 15% of the total hospital bill (21).

Although these data are valuable and serve as a rough estimate of expenditures, caution must be used when attempting to apply them to actual expenditures for neonatal care at the local or state level. By and large, these data are derived from in-hospital data as reported on state and federal cost reports, which reflect charges and not the true costs of delivering care. Further, many studies report individual hospital, state, or regional experiences that vary greatly based on the accounting principles used by that facility.

TABLE 3-4 MOST COMMON HOSPITAL DISCHARGE DIAGNOSES WITH MEAN CHARGES AND MEAN LENGTH OF STAY

Rank	Principal Diagnosis	Mean Charges*	Mean Length of Stay (days)
1	Respiratory distress syndrome	82,648	27.8
2	Spinal cord injury	58,690	12.4
3	Short gestation, low-birth-weight, and fetal growth retardation	56,942	22.7
4	Leukemias	53,252	13.8
5	Heart valve disorders	51,292	8.8
6	Cardiac and circulatory congenital anomalies	49,858	7.8
7	Other CNS infection and poliomyelitis aneurysms	44,060	12.6
8	Aortic, peripheral, and visceral artery	42,461	8.7
9	Intrauterine hypoxia and birth asphyxia	36,954	12.1
10	Cancer of stomach	35,426	10.8

* Charges are for acute hospital care and do not include physician and other professional fees, rehabilitation expenses, or costs associated with follow-up or home care.

From Rogowski J. Measuring the cost of neonatal and perinatal care. *Pediatrics* 1999;103:329–335, with permission.

In many instances, hospital estimates of disease and patient-specific expenditures are based on small samples, resulting in wide variations within and between studies. Expenditure comparisons are complicated further by regional variations in costs, charges, standards of care, differences in patient population demographics, and intensity of illness. Finally, much of the available information is derived from urban level III NICUs or state-funded perinatal programs, which include a high percentage of publicly funded patients. Because these patients often represent the highest perinatal risks, disease-specific expenditures may be skewed by overrepresentation of the most complex patients in the database, resulting in higher cost estimates when compared to private-sector spending.

In an attempt to control expenditures for neonatal services, both public and private payers have developed

P.30

prospective payment systems, which place providers of neonatal care at risk for managing costs generated by their patients. Payment systems such as the Florida Neonatal Care Groups and the APR-DRGs (all patient refined-diagnostic care groups) have proved to be acceptable ways to provide appropriate reimbursement for services while controlling costs for public and private payers (21,25). With the recent Medicaid expansions and many states enrolling more and more patients in Medicaid managed care plans, fixed rather than cost-based reimbursement is becoming more common, leading many institutions to explore new ways to control NICU costs.

Without a doubt, NICU care is one of the most expensive services available because of the high technology and the prolonged length of stay. If we are going to be able to continue to provide every patient the full range of services, neonatal health care professionals will need to ensure that the available resources are used in the most cost-effective manner to provide the highest quality of care. To achieve this goal, neonatal providers should become aware of the costs and hospital cost structures associated with the care they are providing. Richardson and associates (26) published a detailed analysis of the types of costs generated by an inpatient (Fig. 3-5). Understanding how fixed, variable, direct, and indirect costs are derived will help the neonatal team identify items that can be considered part of cost reduction and those that are unaffected by census or acuity. Although we must strive to be sure that every neonate has access to a full range of therapies, resources used inappropriately on one or a group of patients may deny full access to care to others (27).

Acute Medical Care Post Discharge

Graduation from the NICU does not herald the end of increased capital investment in the surviving infant. In a series from the United Kingdom, Stevenson and associates (28) determined that the mean cost per LBW infant, born at less than 1,500 g and surviving without major disability, was 13 times greater than that of an infant weighing between 1,501 and 2,000 g; and the cost per infant weighing less than 1,000 g at birth was 55 times greater than control. Further, LBW infants continued to utilize hospital and practitioner services at a greater rate than control until age 8 to 9. Similarly, Rogowski (29) reported in 1998 that, on average, the VLBW who is a NICU graduate will require almost \$1,400 in outpatient services and be hospitalized twice with an average length of stay of 11 days at a cost of almost \$12,000. In many instances these outpatient visits and pharmaceuticals are either not covered by traditional payers or they have significant copayments and deductibles, resulting in significant financial hardships for families. Thus, additional acute medical costs after discharge from the NICU are of major concern to private and public payers as well as parents.

Long-Term Costs

Because LBW infants are at high risk for long-term sequelae, the resources dedicated to providing acute care must be supplemented with the continued investment of resources for long-term followup. With the realization that the long-term outcome of LBW infants is enhanced by developmental followup, including multidisciplinary intervention programs, postdischarge costs per NICU graduate have become substantial (30). In a study reported from Helsinki, Finland, the costs for 71 ELBW infants during

P.31

the first 2 years after discharge from an NICU averaged \$34,529 compared to \$1,034 for term, control infants (31). Although this study attempted to identify total postdischarge costs, family out-of-pocket expenses were not estimated. A recent survey indicates that these expenses for children with special health care needs can exceed 15% of annual family income (32).

Figure 3-5 Total hospital costs for newborns greater than 1500 g birth weight, by birth-weight group. (From Richardson DK, Zupancic JA, Escobar GJ, et al. A critical review of cost reduction in the neonatal intensive care unit. I. The structure of costs. *J Perinatol* 2001;21:107, with permission.)

The increased survival of ELBW infants presents several challenges to our educational system. Stevenson and colleagues (28) report that 52% of the long-term expenditures related to LBW are related to special education needs. Lewit and colleagues (33) report that health care, education, and child care for the more than 4 million children ages 0 to 15 born at LBW and VLBW cost between \$5.5 and \$6.0 billion more than they would have if these children had been born at a normal birth weight.

Beyond the Costs of Acute Neonatal Care

When long-term cost-benefit ratios were calculated in each of the past 3 decades, the provision of neonatal care appeared extremely cost-effective. This is still true, because high-quality neonatal care decreases the incidence of significant morbidity in almost all weight groups. However, the increased number of surviving ELBW infants with their financial, social, and educational impacts has led several researchers to raise significant ethical and moral questions about future therapeutic directions as we approach the limits of viability for some of our smallest patients. While the cost-benefit ratio for ELBW infants is of obvious concern, the more fundamental ethical and moral issues deal with whether or not high-tech care should be provided to infants whose very survival is extremely unlikely, and the long-term consequences for those who survive are significant. How should we approach these infants? Who should decide what therapies should and should not be given? What is the role of the neonatal team, the family, the payers in the decision-making process? There appear to be few, if any, consensus answers to these critical questions because the ethical, legal, and moral considerations involving the extremely premature infant have not kept pace with the advancement of technology. Our nation has only recently been willing to admit that even the richest country in the world cannot afford to buy all that science has to offer. Prioritizing therapies and making very difficult decisions about the use of resources must be discussed more in years to come (34).

Missed Opportunities

One cannot consider the magnitude of these costs and the amount of human suffering involved in the delivery of a high-risk infant without wondering why the United States continues to expend enormous resources on postnatal care when half of the ELBW deliveries could be avoided with early prenatal care (1). The benefit of \$1,000 of prenatal care instead of \$150,000 for each surviving LBW infant is obvious. Almost 2 decades ago, the Institute of Medicine reported that for every \$1 spent on prenatal care, \$3 were saved in the first year of life, and \$10 more were saved over a lifetime (35). This relationship between prenatal care and downstream costs appears to be true today as well. A recent report by Lu and associates (36) shows that for every \$1 reduction in prenatal care provided by public programs there was an increase of \$3.33 in postnatal care costs and a \$4.63 increase in long-term morbidity costs. The average cost of long-term care (medical, child care, and special education) for women without prenatal care is \$4,839 compared to \$1,592 for women with prenatal care.

Fortunately, today 83% of women receive prenatal care and begin that care within the first trimester (3). Financial access to care combined with comprehensive prepregnancy and prenatal programs, including good nutrition and avoidance of high-risk lifestyles, have been identified as key in reducing LBW with its attendant costs and human loss (7). Of major concern, however, is the remaining economic and noneconomic barriers confronting minority populations, resulting in late or no prenatal care rates, which are three to four times that of whites (1).

Major Payers of Perinatal Care

There are four major payers for perinatal care in the United States:

- Private health insurance, purchased through employers or directly by individuals
- Public programs including Medicaid and other federal, state, and local programs

- Special perinatal demonstration projects, both public and private
- Self-pay or uninsured

None of the major payers completely cover the costs of high-risk obstetric and neonatal care, especially for the complicated ELBW infant. A significant portion of the uncompensated care created by underpayment by public payers and the uninsured is often shifted to other subscribers in the form of increased charges. One study suggests that as much as 27% of total costs of NICU care were shifted to paying patients who are responsible for generating 60% of total revenues while accounting for only 33% of costs (37). In recent years, payments under fee-for-service plans have been replaced by capitated managed care and discounted plans, reducing the ability of NICUs to shift cost and placing many in financial jeopardy.

Private Health Insurance

Only 72% of women of childbearing age are covered by employer or privately purchased insurance (Fig. 3-6A). Women are less likely than men to have employer-based coverage because they are more likely to be employed less than full time, to work for small employers who do not offer insurance, or have spouses who work for employers who do not offer dependent coverage (1). Even for those with health insurance, 7% of plans offered in 2000 by

P.32

small employers (10 to 24 workers) did not cover prenatal care or delivery expenses. Plans providing maternity benefits often impose substantial cost-sharing arrangements, which can become a significant barrier to care, resulting in limited prenatal care and increasing the chance of a high-risk delivery. Similar limitations are often seen in coverage of high-risk neonates after delivery (38). Cost-sharing arrangements with lifetime caps on policy benefits can be financially devastating to families. For example, a 20% copayment responsibility on a combined hospital and physician bill of \$250,000 for an LBW infant results in a family out-of-pocket expense of \$50,000, an amount that would be impossible for most families to pay. Many policies carry a \$250,000 to \$500,000 lifetime cap. In this case the infant would use all or half of the entire lifetime benefit at discharge from the NICU.

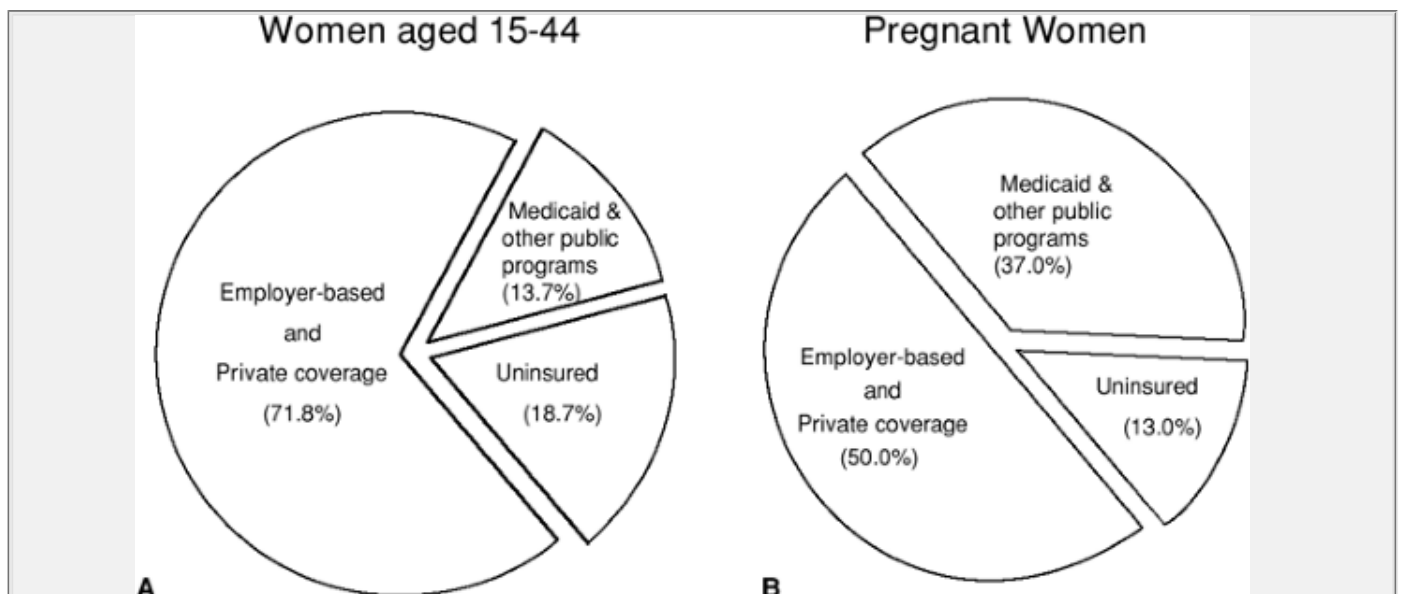

Figure 3-6 Insurance status of (A) women ages 15 to 44 years and (B) pregnant women in the United States, 2002. (From U.S. Department of Health and Human Services. Retrieved July 1, 2003, from <http://www.hhs.gov/budget/docbudget.htm>.)

Medicaid

Medicaid is the largest public program for the financing of prenatal and neonatal care. Authorized as Title XIX of the Social Security Act in 1965, Medicaid is a federal-state partnership that finances care for 51 million low-income pregnant women, children, the elderly, the blind, and the disabled. In 2002, it surpassed Medicare to

become the nation's largest health insurance program in numbers of people served and in expenditures, totaling \$259 billion and outspending Medicare by \$2 billion (39). During the past several years, the federal-state match has remained relatively constant, with federal funds accounting for an average of 56.9% of total fiscal-year program expenditures. The exact level of federal funding is determined from a formula reflecting the state's per capita income and varies between 50% and 80% of the state's total Medicaid expenditures.

Today, 51% of the targeted population consists of pregnant women and children; however, only 15% of total program expenditures are directed toward them (40). With the exception of the matching requirements for federal funds and the required compliance with specific federal mandates, each state has the responsibility for developing and administering its own Medicaid program. This includes setting eligibility and coverage standards within broad federal guidelines. As a result, there is considerable variation among states in eligibility, range of services offered, limitations on services, and reimbursement policies.

Over the past several years, Congress has been successful in extending Medicaid eligibility to more pregnant women and children. Beginning in 1989, all states were required to cover pregnant women and children younger than 6 years of age with family incomes below 133% of the federal poverty level (FPL) and had the option of extending benefits to pregnant women and infants younger than 1 year of age with family incomes below 185% of the FPL. The State Children's Health Insurance Program, under Title XXI of the Social Security Act, enacted in 1997, gave states new latitude in identifying eligible patients and allows states to expand coverage for children and pregnant women up to 200% of the FPL, with some states using additional funds to reach 300% of the FPL (37,40).

In 2001, Medicaid was the source of payment for 1.6 million births, 37% of the nation's deliveries, ranging from a low of 9% in Hawaii (the only state with universal health coverage) to a high of 56% of all births in New Mexico (1,40,41). As a result of this expanded eligibility, many women drop more expensive employer-based and private coverage and enroll in Medicaid. Thus, employer-based and private coverage among pregnant women has dropped to 50% with 13.0% remaining uninsured (Fig. 3-6B) (37).

Title V Maternal and Child Health Block Grant Program

Located within the Health Resources and Services Administration (HRSA) of the Department of Health and

P.33

Human Services (HHS), the Maternal and Child Health (MCH) Block Grant Program was authorized by Title V of the Social Security Act to provide grants to states for a variety of preventive and primary care services to women and children, including prenatal care, immunizations, and rehabilitative services for children with special needs. Although fiscal year 2002 funding for this program exceeded \$930 million, it accounts for less than 1% of the HHS budget (42). Current funding levels allow less than half of eligible women access to prenatal care under the program.

Community Health Centers, Migrant Health Centers, and the National Health Service Corps

As part of HRSA, \$1.4 billion for community health centers, migrant health centers, and programs of the National Health Service Corps are directed toward providing primary preventive care, including prenatal and well-child care, for those served in urban community health centers and in rural areas of the United States (42).

Special Demonstration Projects

Because prevention of low-birth-weight infants can positively affect perinatal outcome, many public (e.g., state, county, and municipal governments) and private (e.g., March of Dimes, Robert Wood Johnson, Pew Foundation) organizations have dedicated significant resources to study how to reach high-risk populations more effectively to reduce the mortality and morbidity related to premature deliveries. Although most of these projects are small and contribute little to covering the total costs of perinatal care, many are highly successful, improve outcomes for individual patients, and add significantly to our understanding of the perinatal health care system and the delivery of health care to special populations. A major problem with these projects is that targeted patients are highly selected, making it difficult to apply program results to larger populations. Many programs are funded for a limited time, creating the problem of how to continue to provide services after funding has expired.

Uninsured, Self-Paying Patients

Many of the uninsured are in young families working for small business or are in the service industry and are not provided employer-based health insurance. Sixty percent of young families of childbearing age are two-parent families, and 85% of them have at least one member employed full- or part-time. Most uninsured families have limited resources, with incomes between \$30,000 and \$32,000 annually. Sixty-one percent of uninsured women have family incomes below 200% of the FPL, making it very difficult to pay out of pocket for medical expenses or even for prenatal care (37).

More than a decade ago, the National Commission on Children found that being uninsured during pregnancy is the greatest barrier to receiving prenatal care, and it results in the highest risk for delivering an LBW infant, approximately three to five times the rate for women with even minimal prenatal care (43). Fortunately, this barrier to access to prenatal care seems to have been significantly reduced. As a result of enhanced eligibility under Medicaid, only 13% of pregnant women (422,000) are uninsured during pregnancy and up to 1 year following delivery (Fig. 3-6B) (1).

Although enhanced coverage for pregnant women ensures access to prenatal care, the loss of eligibility 1 year after delivery presents major problems for continued care between pregnancies and makes preparation for subsequent healthy pregnancies problematic. As many as 20 million women have their insurance interrupted for at least 2 months over a 24-month period, and data indicate that 26% of women are uninsured when they conceive (44).

MAJOR MEASURES OF OUTCOME

Infant Mortality Rate

The infant mortality rate (IMR) is defined by the National Center for Health Statistics and by the World Health Organization as the number of deaths occurring within the first year of life per 1,000 live births. Infant mortality can be divided further into neonatal mortality (i.e., death before 29 days of age) and postneonatal mortality (i.e., death between 29 days and 1 year of age). Neonatal mortality generally is the result of factors related to pregnancy and birth, while postneonatal mortality generally is the result of environmental factors (e.g., trauma, infection, nutrition, sudden infant death syndrome) (41).

Infant mortality in the United States has declined substantially since 1975. Initially, the largest declines were seen in the neonatal mortality rate (NMR), but more recently these advances have been matched by similar declines in the postneonatal mortality rate (PNMR). Between 1980 and 2001, the IMR dropped from 12.5 deaths per 1,000 live births to 6.9 deaths per 1,000 live births as a result of a 45% decline in the NMR (Fig. 3-7) (41). Despite these achievements the current IMR exceeds the Healthy People 2010 goal of 4.5 by 35% (1,3).

Of major concern is the persistent disparity in the IMR between white and African American infants. Although all race groups have experienced a decrease in IMR, the rate for African American infants fell by only 36.5%, which is 12.1% less than that of whites. Recently published 2000 rates show an IMR for white infants at 5.7 per 1,000 live births, whereas that of African American infants is reported to be 14.1 deaths per 1,000 live births, a ratio of 2.5:1 (Fig. 3-8). The infant mortality rate for Hispanics is slightly better than that for whites at 5.6 per 1,000 live births (41,44).

Neonatal Mortality Rate

Although the IMR reflects the general health of a community, separate examination of early and late infant deaths

P.34

can further pinpoint problems. The NMR equals the number of deaths occurring at less than 29 days after birth per 1,000 live births (39). These account for approximately 67% of all infant deaths. Half of all neonatal deaths can be attributed to four leading causes:

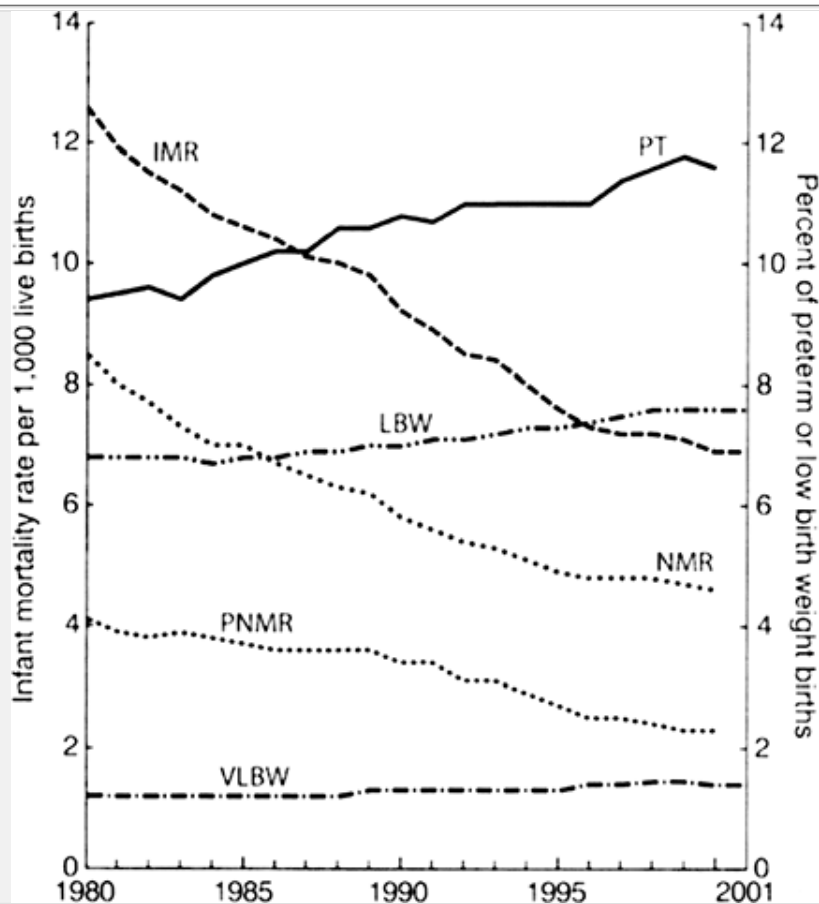

Figure 3-7 Infant, neonatal, and postneonatal mortality for low-birth-weight (LBW), very-low-birth-weight (VLBW), and preterm (PT) delivery in the United States from 1980-2001. Infant mortality rate (IMR) indicates infant deaths per 1,000 live births; neonatal mortality rate (NMR) indicates neonatal deaths per 1,000 live births; postneonatal mortality rate (PNMR) indicates postneonatal deaths per 1,000 live births; LBW indicates percent low-birth-weight (<2500 g); VLBW indicates percent very-low-birth-weight (<1500 g); PT indicates percent preterm (<37 weeks of gestation). (From MacDorman MF, Minino AM, Strobino DM, et al. Annual summary of vital statistics 2001. *Pediatrics* 2002;110:1037, with permission.)

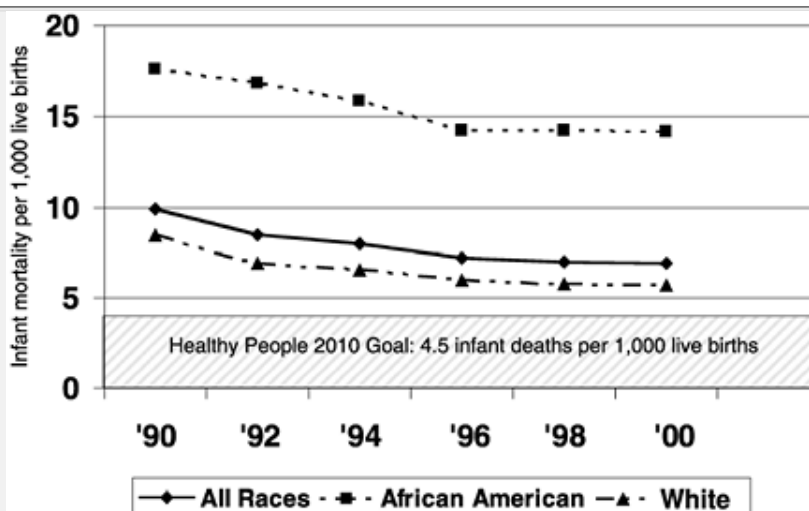

Figure 3-8 Infant mortality in the United States from 1990 to 2000 by race. Infant mortality constitutes deaths that occur before 1 year of age. (From U.S. Department of Health and Human Services. Retrieved July 1, 2003, from <http://www.hhs.gov/budget/dccbudget.htm>)

Figure 3-9 Neonatal mortality in the United States from 1990 to 2000 by race. Neonatal mortality constitutes deaths that occur before 28 days of age. (From U.S. Department of Health and Human Services. Retrieved July 1, 2003, from <http://www.hhs.gov/budget/dccbudget.htm>)

- LBW
- Acute perinatal asphyxia
- Congenital anomalies
- Perinatal infections

Between 1980 and 2001, the NMR declined by 45%. The 2000 rate of 4.6 deaths per 1,000 live births is thought to be a reflection of the marked improvement in the treatment of respiratory illnesses in term and preterm infants. Once again the rate for African Americans (9.4 deaths per 1,000 live births) parallels the IMR and is considerably higher than the white NMR, with an NMR ratio of African Americans to whites of 2.5:1 (Fig. 3-9). These differences appear to be primarily because of the higher incidence of LBW (less than 2,500 g) and VLBW (less than 1,500 g) infants born to African American women and a higher NMR for African American infants weighing more than 2,500 g (1.2 deaths per 1,000 live births for African Americans compared to 0.9 deaths per 1,000 live births for whites). NMR for Hispanics is slightly better than for whites at 3.7 deaths per 1,000 live births (41).

Perinatal Mortality Rate

The perinatal mortality rate (PMR) is defined by the National Center for Health Statistics as the number of late fetal deaths (i.e., fetal deaths of 28 weeks or more gestation) plus early neonatal deaths (i.e., deaths of infants 0 to 6 days of age) per 1,000 live births (41).

Most fetal deaths are a result of chronic asphyxia (60% to 70%); congenital malformations (20% to 25%); superimposed complications of pregnancy, such as placental abruption, diabetes mellitus, intrauterine infection (5% to 10%); and unexplained deaths (5% to 10%) (43). Although the incidence of congenital malformations has remained relatively constant over the last few years, improvements in the management of pregnancy-related complications, combined with improved early neonatal survival, has resulted in

a significant decrease in PMR to 7.0 deaths per 1,000 live births for 2000. Race variations in PMR are slightly better than those seen in IMR and NMR (Fig. 3-10). PMR in African American women is less than twice that of whites (12.7 deaths per 1,000 live births compared to 6.7 deaths per 1,000 live births). The reported PMR for Hispanics for 2000 is 6.0 deaths per 1,000 live births and is considerably less than the 6.7 deaths per 1,000 live births reported for whites (41).

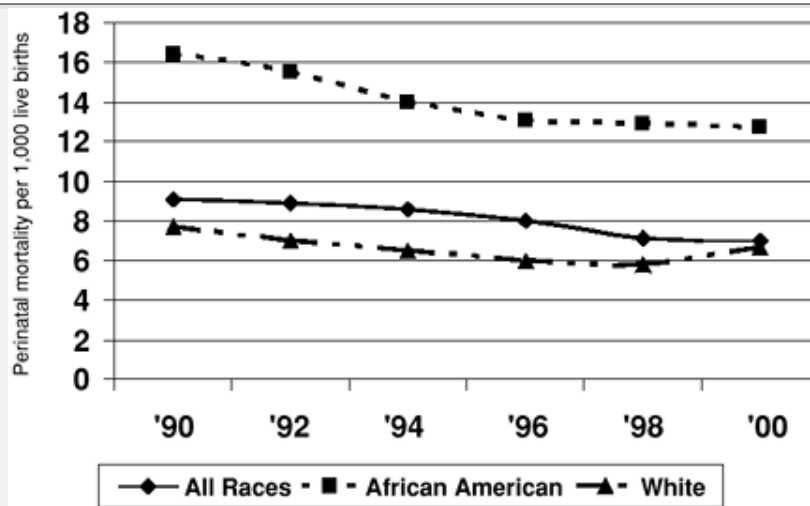

Figure 3-10 Perinatal mortality in the United States from 1990 to 2000 by race. Perinatal mortality constitutes fetal death before 28 weeks of gestation plus infant deaths at 0 to 6 days of age. MAJOR MORBIDITIES

Preterm Birth

The preterm birth rate is defined as births from pregnancies that have completed less than 37 weeks of gestation. In 2000 there were 467,201 (11.6% of live births) preterm births recorded, only 40% of which were also low-birth-weight (Fig. 3-11). This is the first time there has been a decline in the rate of preterm births in the United States since 1992, declining from 11.8% of live births in 1999 to 11.6% of live births in 2000 (1). Although recent trends are encouraging, the 2000 preterm rate still exceeds that of the Healthy People 2010 goal of 7.6% of live births by 50%. The decrease in preterm births from 10.5% to 10.4% of live births among non-Hispanic whites is the first decrease in a decade, during which rates steadily rose from 8.5% of live births. The preterm birth rate in African Americans remains high at 17.3% of live births, but has trended downward since peaking at 18.9% of live births in 1991. The very preterm rate (less than 32 completed weeks of gestation) remains unchanged from the 1981 rate of 1.93% of live births, and is more than twice the Healthy People 2010 goal of 0.9 % of live births (3).

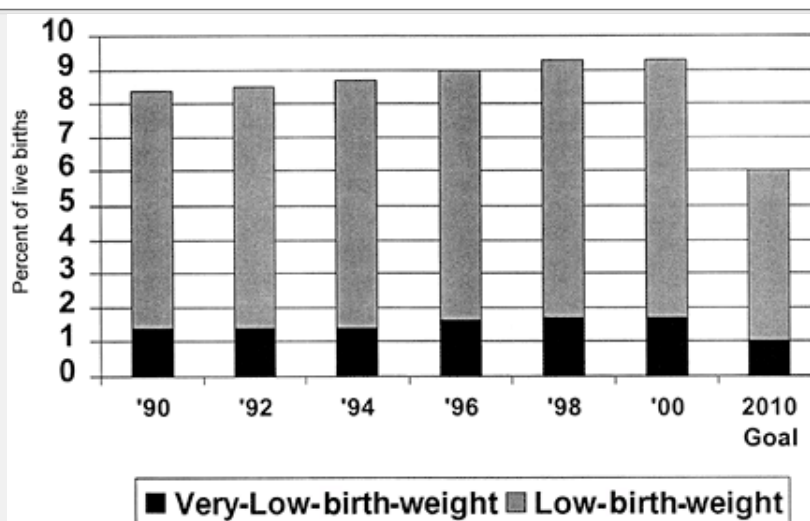

Figure 3-11 Incidence of preterm and low-birth-weight births in 2000. (From March of Dimes. *March of Dimes data book for policy makers*, Washington, DC: March of Dimes Office of Government Affairs, 2003, with permission.)

Figure 3-12 Incidence of low-birth-weight and very-low-birth-weight births as a percent of all live births in the United States from 1990 to 2000. (From March of Dimes. *March of Dimes data book for policy makers*, Washington, DC: March of Dimes Office of Government Affairs, 2003, with permission.)

Low-Birth-Weight

LBW is responsible for 66% of the U.S. IMR and carries a six-fold increased risk of death for infants weighing between 1,500 and 2,499 g, a 98-fold increased risk of death for infants weighing less than 1,500 g, and a two- to three-fold increase in the chance of long-term disability (41). Considering these realities, the prevention of LBW has been one of the nation's top priorities in its effort to reduce infant mortality and morbidity. Despite this focus, no progress has been made in reducing the incidence of LBW over the last decade. In 2000, more than 300,000 infants (7.6% of live births) were born at LBW, which is the highest recorded in the previous 20 years and exceeds the Healthy People 2010 goal by 52% (Fig. 3-12) (1). Currently, the LBW rate among African Americans, at 13.0 % of live births, is 1.7 times that of whites. Examination of annual LBW statistics reveals a slow but continued increase in the overall number of infants born at LBW since 1990 (Fig. 3-13) (41,45). However, the greatest rise in LBW occurred between 1990 and 1995, coincident to a dramatic increase in the number of births to teens (Fig. 3-2). This association is not surprising when one realizes that teen pregnancy carries a very significant increase in the risk of having an LBW infant.

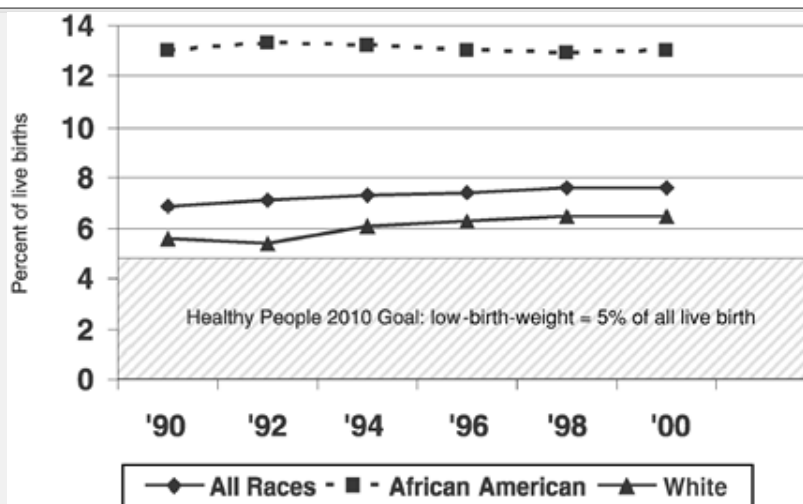

Figure 3-13 Trends in low-birth-weight births (less than 2500 g) by race as a percentage of all births, United States 1990-2000. (From U.S. Department of Health and Human Services. Retrieved July 1, 2003, from <http://www.hhs.gov/budget/dccbudget.htm>)

The twin birth rate has risen by 55% since 1980. This is of major health significance because half of all twin gestations and the great majority of triplet births are high risk. In fact, twins are 5 times as likely to be premature and 9.5 times as likely to be of VLBW than singleton deliveries. As such, they are responsible for some of the continued trends in U.S. perinatal statistics and consume significant resources (41). However, this increase in use of perinatal resources is directly related to prematurity and low-birth-weight rather than the twin gestation *per se* (46). It appears that this increase in multiple births is related to two trends in American society. First, more and more women are delivering later in life. In 2000, birth rates for women in their thirties reached their highest levels in 30 years. Birth rates for women 40 to 44 years of age also rose in 2000 and have more than doubled since 1981 (41). These increases are related to the growing tendency for many women to postpone childbearing. Secondly, the use of assisted reproductive technology, ovulation-inducing drugs, and *in vitro* fertilization, have long been associated with a higher risk of multiple births (47,48). The real potential for multiple births and their attendant increased risk for LBW (with its increased mortality and morbidity) should be considered when either delay in childbearing and/or assisted reproduction are being considered.

Lifestyle Choices

Some of the perinatal risk factors associated with LBW and poor perinatal outcome are not within a pregnant woman's immediate control. However, many of the factors associated with lifestyle choices are (49).

Cigarette Smoking

Cigarette smoking during pregnancy is the single largest modifiable risk factor for LBW (up to 20%) and infant mortality. Babies born to mothers who smoke are, on average, 200 g lighter than those born to mothers who do not smoke. In a recent review, Eyer and Behnke (48) reported that infants exposed to tobacco *in utero* demonstrated abnormal behavior up to 14 days after delivery. Abnormalities included poor auditory habituation, and disorders of orientation and autonomic regulation. Although implications of these findings are unclear, they do suggest that smoking during pregnancy carries significant long-term behavioral risks in addition to those associated with a low-birth-weight.

Despite these and other well-publicized risks of smoking during pregnancy, a March of Dimes survey reports that 20% of pregnant women 15 to 44 years of age stated that they had been smoking cigarettes regularly, and smoking during pregnancy was common with women under 20 years of age. Of the 10% to 15% of smoking women who stop smoking during pregnancy, two thirds resume smoking within 1 year of delivery, exposing the infant to second-hand smoke (1). Because most of these infants are term and near-term LBW infants, their prognosis is good and their medical costs are only moderate. Nonetheless, reduction of smoking during pregnancy can decrease the incidence of LBW and reduce the risk of long-term development delays (1,49,50).

Alcohol

The use of alcohol during pregnancy has been associated with both short- and long-term morbidity. Fetal alcohol syndrome is a well-recognized consequence of excessive consumption of alcohol during pregnancy, occurring in 1 per 1,000 live births. However, several studies report an increase in LBW babies born to women who consume between one and three drinks per day, resulting in an average decrease in birth weight of between 28 and 141 g. Almost 5% of pregnant women report "binge" alcohol use (five or more drinks on the same occasion or the same day) (1,49). Recent studies performed in older alcohol-exposed infants show an increase in the number of speech and language delays, which seem to be directly related to the amount of alcohol consumed during pregnancy. In this study, the decreased mental developmental index in these infants also appears to be dose dependent (50). These data and that of others strongly suggest that the avoidance of alcohol during pregnancy can significantly improve perinatal outcome.

Illicit Drug Use

The exact incidence of illicit drug use during pregnancy is unknown, but several researchers report perinatal cocaine exposure rates of between 0.4% and 27%, depending on the region of the country and the population demographics (49,50 and 51). A myriad of neonatal complications have been reported as a result of cocaine exposure, ranging from none to antenatal cerebral infarction. The estimated short-term costs of perinatal cocaine exposure are between \$33 million and \$650 million (51). The long-term neurodevelopmental effects of perinatal illicit drug exposure are just now

being studied carefully. Many studies in newborns have shown irritability and lability of state, decreases in alertness and orientation, and abnormal muscle tone and reflexes. However, one third of newborn behavioral studies have found no demonstrable effect of perinatal exposure. Further, studies performed in older infants have failed to show significant effects of perinatal cocaine exposure on either the mental developmental index or the physical developmental index (50).

Although perinatal exposure to any drug cannot accurately predict long-term outcome, such exposure often exposes a child to multiple risks—physical, developmental, and psychosocial. If we can eliminate these risks, we have every reason to believe that perinatal outcome will be enhanced.

Neurodevelopmental Sequelae

With survival rates approaching 95% for premature infants weighing between 1,200 and 2,500 g and 60% for those between 500 and 750 g, the incidence and magnitude of the neurodevelopmental sequelae related to the treatment of premature and critically ill neonates has become increasingly important (52). Long-term outcome of infants treated in the NICU has an enormous impact on many aspects of society. Even though the vast majority of children treated in the NICU survive intact, those who experience significant sequelae will need considerable additional resources from the family, state, and federal government in order for them to achieve their full potential. This impact is felt in the form of financial pressures placed on the family and public programs to provide necessary medical services and on schools as they attempt to provide an appropriate learning environment (53). The greatest risks of sequelae occur in the ELBW infants (less than 1,000 g birth weight) and in large infants experiencing perinatal hypoxic-ischemic encephalopathy. These issues are discussed in detail in other chapters; however, it is important to realize that after discharge from the NICU, infants with significant neurodevelopmental sequelae need a system that not only provides long-term support for specialty medical care, but also provides a lifetime of financial, social, and educational support for such children and their families (54). Clearly, the best way to deal with these problems is to prevent them from occurring in the future.

REGIONALIZATION TODAY

Regionalization of perinatal care has been lauded by many as the single most important factor influencing the birth-weight-specific neonatal mortality. Outlined in 1977 by the Committee on Perinatal Health of the National Foundation of the March of Dimes in its landmark report, *Toward Improving the Outcome of Pregnancy: Recommendations for the Regional Development of Maternal and Perinatal Health Services*, this concept served as the guide for the development of perinatal services for the last 2 decades (7). The Committee's concept of regionalization was based on the geographic concentration of neonatal intensive care services supported by cooperative arrangements among hospitals within a region to provide, as a network, the necessary levels of care defined in the document as level I, II, and III services. Although quite intuitive and logical, this concept of cooperation is rather foreign to the American health care system, which is built on the philosophy of free market, free enterprise, and competition. The level of planning and cooperation necessary to make regionalization work is often resisted by all levels of health care providers. How then did regionalization take hold? Many observers think that it came at the right time, when knowledge of high-risk mothers and neonates was advancing rapidly. It came when the transfer of technology was confined to larger urban teaching hospitals and academic centers. It came at a time when other hospital services were running at near capacity.

Under the plan, regions were not defined strictly by geography, but by tradition and the organizational skills of a small number of highly respected early leaders in neonatology. This informal approach to the organization of perinatal care worked well as long as cooperation was seen as mutually beneficial to all involved. In the late 1970s and early 1980s, the health care environment began to change significantly. Driven by dramatic changes in the public financing of health care, the fragile alliance built on cooperation was being replaced by a drive for competition (55).

Medicare's replacement of fee-for-service reimbursement with a prospective payment system caused hospital inpatient census to drop as adult care was shifted to the outpatient clinics and ambulatory surgical centers. Declining hospital margins with excess capacity in the form of empty beds began to drive competition. The diffusion of technology into the community in conjunction with increased numbers of available neonatologists made competition for neonatal patients a possibility. Managed care plans captured an increasing share of the traditional indemnity plan markets and required hospitals to be full-service providers, making competition even more of a reality. Obstetric and newborn services, once seen as avoidable losses, became a requirement of participation in health plans. In some parts of the country, other factors hastened the move to competition. The

medical liability crisis of the 1980s and 1990s, with the huge legal awards for poor neonatal outcome, particularly in the southern United States, increased the desire to have a neonatologist present at almost every delivery. At the same time, the presence of a hospital-based neonatologist presented the opportunity and the necessity to expand neonatal services beyond the delivery room into newly acquired NICU beds in an attempt to cover the costs of the neonatologist and to present appropriate clinical challenges to him or her and the nursery staff. In other regions, the overcrowding of level III units and the need to back transport convalescing neonates provided additional opportunity for community hospitals to begin neonatal programs. The differences in the levels of care, as defined by the CPH and by the American

P.38

Academy of Pediatrics, became blurred. A comprehensive study of regionalization revealed a general weakening of structures and relationships, with many hospitals and physicians working outside the designed networks (55). As a result, the CPH was reconvened in 1990 to respond to the changing health care environment and to make recommendations for the regionalization of perinatal care in the 1990s and beyond. The CPH's report reinforced the concept of regionalization of perinatal services, emphasizing the need for developing systems that integrate all levels of care within the region into a matrix with specific mechanisms for quality review and accountability between and among the various components. To facilitate this integration, the CPH suggested the formation of state and regional perinatal boards, with the authority and responsibility for providing or coordinating regional planning, monitoring access and data collection, and providing education (7). The plan's foundation appeared to be very regulatory in nature at a time when competition and the market were still very strong. As a result, very little progress has been made on the implementation of its recommendations.

So where are we today? It appears that regionalization of perinatal care still exists; however, its focus has evolved from level III units to the level II units, which have expanded their roles. Many neonatologists at level II units are providing labor room resuscitation and stabilization, as well as normal newborn and low-risk neonatal care at level I hospitals in their community. If these infants need more acute care, they are often transported to the local level II facility instead of the regional level III one. The availability of exogenous surfactant therapy, safer mechanical ventilators, and expanded roles for members of the neonatal provider team have allowed more of the LBW and VLBW infants to remain in level II facilities. Although this is troubling to some, the limited outcome information on LBW and VLBW neonates treated at level II rather than level III facilities fail to show any adverse outcomes as a result (56,57,58). It appears that the level III units have become the regional referral centers for ELBW infants, for larger infants in need of high frequency ventilation—extracorporeal membrane oxygenation (ECMO)—and for those in need of medical and surgical subspecialists. This redefinition of regionalization is not too far from the 1993 recommendations. What's missing is the development of specific relationships outlined in the report and the requirement that the various levels of care enter into formal agreements for referral, data transfer, outcomes review, and followup.

What are the inherent concerns about the evolved system? There is a danger that smaller and smaller infants will receive care at level II units as technology advances further. The guiding principle here should be the need for, and availability of, pediatric specialists as well as the availability of postdischarge specialty care and followup. Few level II units have sufficient numbers of critically ill neonates to justify on-site subspecialty coverage, and very few have enough ELBW or VLBW infants to justify investment in posthospital care; however, both are required to provide quality care for this population. Another concern is the effect that changes in referral patterns have on level III regional referral centers. LBW and VLBW infants tend to be less expensive to care for than ELBW infants, those with birth defects, and those in need of specialty care. As a result, the level III units are experiencing more and more financial pressures as they receive the smallest, most complex patients with the smallest reimbursement-to-cost ratio. Because public programs, which routinely are among the poorest payers, cover so many premature infants, shifting the intensity of the level III units to even higher levels of acuity could result in more financial stress for many. Although the primary goal of regionalization is to provide the best, most cost effective care to today's neonates, we must remember that neonatology has evolved to where we are today because of the discovery of new therapies and the training of the next generation of neonatologists and neonatal specialists. A rational system of regionalized care must recognize that institutions dedicated to the development of future therapies and the future providers of neonatal care cannot always survive in a competitive environment. Our few truly educational and research institutions must continue to have a sufficient resources and a patient population representative of all levels of care in order to develop the workforce and therapies of tomorrow, today.

Chapter 4

Neonatal Transport

Karen S. Wood

Carl L. Bose

HISTORY

Neonatal transport began in 1900 with the development of the first mobile incubator for premature infants by Dr. Joseph DeLee of the Chicago Lying-In Hospital (1). This "hand ambulance" provided warmth while transporting premature infants to the hospital following home birth. The development acknowledged the need to create a controlled environment for the transport of infants that simulated the inpatient setting. In 1934, the first dedicated neonatal transport vehicle in the United States was donated to the Chicago Department of Health by Dr. Martin Couney (2), following the closure of the Chicago World's Fair where the vehicle was used to transport premature babies to the exhibit. The first organized transport program in the United States began in 1948 with the development of the New York Premature Infant Transport Service by the New York Department of Health in conjunction with area hospitals (3,4). This remarkable system, created more than a decade before the evolution of neonatal intensive care units (NICUs), incorporated many of the features of modern neonatal transport programs, including around-the-clock staffing by specially trained nurses, dedicated vehicles, a clerk to receive referral calls, and equipment designed specifically for neonatal transport. During a two-year period, this program transported 1,209 patients, of whom 194 weighed less than 1,000 g (4).

Neonatal transport took to the air in 1958 with the first fixed-wing transport of a newborn infant by the Colorado Air National Guard (2). The 1967 flight of a premature baby to St. Francis Hospital in Peoria, Illinois using the *Peoria Journal Star* helicopter marked the first rotor-wing neonatal transport (2). Routine use of air transportation for neonatal patients began in 1972 with Flight for Life of Denver's St. Anthony Hospital (5).

Proliferation of organized transport programs occurred in the late 1970s, in conjunction with regionalization of perinatal care. Regionalization initially minimized the number of infants requiring transport by promoting maternal-fetal transport. Regionalization also shifted the responsibility for transporting infants born in outside centers to the tertiary care center. Subsequently, the next decade saw improvements in perinatal mortality (6) and neonatal morbidity (7) as the percentage of very-low-birth-weight (VLBW) infants delivered in level III hospitals increased.

Since the late 1980s patterns of referral dictated by schemes of regionalization deteriorated in many areas (8), coincident with an increase in level II hospitals capable of providing some degree of neonatal intensive care. As a result, increasing numbers of infants deliver at centers without subspecialists or the necessary support services demanded by some VLBW infants. Community-based neonatal intensive care creates a need to transport infants at a critical time in their illness, occasionally while receiving therapies such as high-frequency ventilation or inhaled nitric oxide, which are not easily portable. Even in areas where regionalized perinatal care persists and prenatal risk assessment is routine, unpredictable, emergent events may precipitate the delivery of an infant in an unsuitable hospital. Collectively these situations mandate increasingly sophisticated neonatal transport systems.

ORGANIZATION AND ADMINISTRATION

Neonatal transport can be performed by either the community hospital referring the patient (one-way transport) or by the tertiary center receiving the patient (two-way transport). Two-way transport offers an economic advantage, generally more highly skilled and experienced transport personnel (9), and may result in improved survival (10,11). The American Academy of Pediatrics supports two-way transport (12), and in most perinatal regions tertiary centers have assumed this responsibility. Of note the major disadvantage of two-way transport is the time delay in getting the transport crew to the referring hospital. The remainder of this chapter discusses two-way transport exclusively.

Administrative Personnel

The components of a transport program include those related to medical care and the nonmedical components

marketing. The medical components must fall under the direction of a physician who is credentialed to supervise the patients served by the program. Direction of the nonmedical components and ultimate responsibility for the program often rests with a hospital administration staff person (Fig. 4-1). The following is a brief discussion of each of the potential contributors to the administration of a transport program (13).

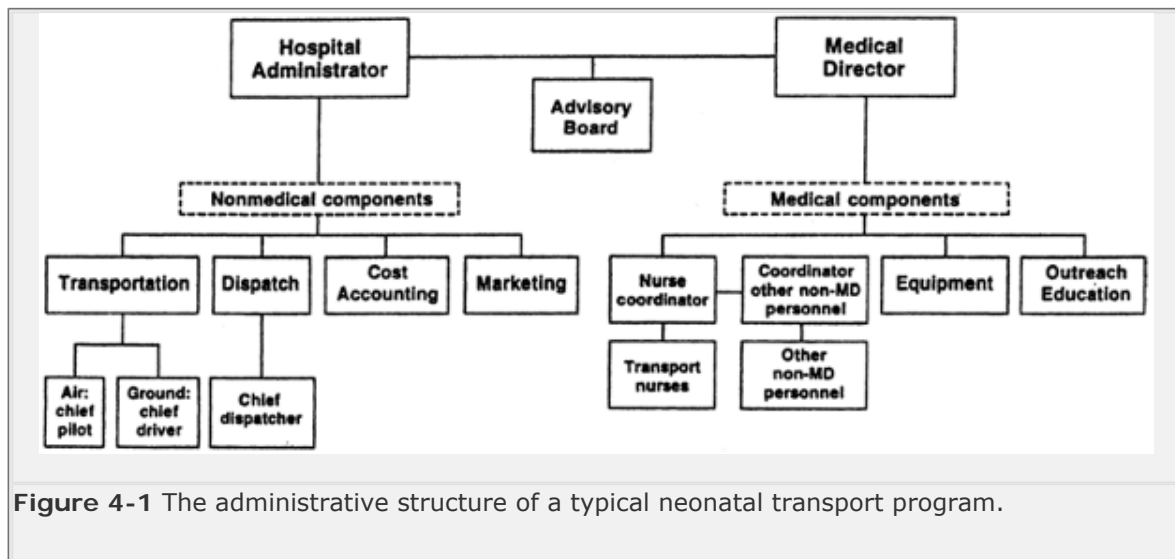

Figure 4-1 The administrative structure of a typical neonatal transport program.

Hospital Administrator

Generally, a hospital administrator manages aspects of the program that are not directly related to patient care. Many decisions regarding program operation require a cost-benefit analysis. While medical personnel are relied on to provide an estimate of benefit, the hospital administrator must assess financial impact. Therefore, the hospital administrator should be prepared to receive advice from medical personnel and develop the nonmedical components of the program in consideration of the financial resources of the institution.

Medical Director

The medical director of a neonatal transport program is usually a neonatologist with expertise or a special interest in transport. The medical director is ultimately responsible for the quality of care provided by the transport team; this is particularly true if physicians do not participate directly in transport. The medical director assumes responsibility for developing and updating training programs, equipment procurement, and treatment protocols. The medical director, in conjunction with the coordinator of nonphysician personnel, must ensure that all personnel have completed training requirements successfully and have satisfied the regulations of the agencies that govern the various professional groups. The director also must develop and maintain a system for reviewing the quality of care provided during transport.

Coordinator of Nonphysician Personnel

Each group of professionals (e.g., nurses, respiratory therapists, paramedics) on the transport team should have a designated coordinator. The coordinator supervises the selection and training of personnel and develops systems of peer review. Additional coordinator responsibilities include scheduling personnel, organizing continuing medical education, ordering supplies and equipment, monitoring documentation standards, promoting effective internal dynamics, and identifying the needs of team members. It is advisable to designate a single person to coordinate team activities who will interface closely with the medical director and, in some programs, the hospital administrator as well.

Consulting Neonatologists and Other Subspecialists

During the transport of a patient, it is important, and often mandated by state law, that a physician provides consultation to the transport team. This physician, known as the medical control officer (MCO), is typically the physician receiving the patient and often has already discussed the patient's care with the referring physician

and made recommendations about interim management. Given this broad consultative role to both the referring physician and to the transport team, the MCO should be a person with extensive training, at a level in excess of that available in the community hospital, such as a neonatologist, a trained pediatric subspecialist, or a postdoctoral fellow. In addition, the MCO must be aware of the handicaps and hazards imposed by the transport environment and must be familiar with the operational aspects of the program.

The Advisory Board

A neonatal transport program should be considered an extension of the inpatient unit to which it delivers patients.

P.42

Therefore, the operation of the program should be reviewed periodically by representatives of all services interfacing with the inpatient unit. These representatives, comprising the advisory board, might include the following:

- Medical Director of the NICU
- Director of the Neonatal Division
- Respiratory Therapy Administrator
- Nursing Administrator
- Outreach Education Coordinator
- Director of Public Relations
- Representatives of community hospitals involved in transport

Advice should be solicited from the advisory board about all major program changes because of the impact these changes may have on their respective services.

The Transport Team

A variety of personnel participate in the inpatient care of infants, and all should be considered candidates for caretakers during neonatal transport. These personnel include the following:

- Neonatologists
- Neonatal fellows
- Pediatric house staff
- Nurse practitioners
- Transport nurses
- Respiratory therapists

- Paramedics

The selection of the type of personnel used by each program is based on the unique aspects of that program; however, some general principles apply that determine the relative desirability of various professionals. As the number of transports increases, it becomes less practical to send physicians on transport. Neonatologists rarely have the time to devote to frequent transports, and reimbursement is not sufficient to justify their presence. Although participation in transport can be very educational, in high-volume programs, time spent on transport by house staff and fellows potentially competes with other aspects of training. In addition, the interest in participation and expertise may vary considerably among trainees. This is a particular problem if participation is mandated. Pediatric residents who participate in transport should be senior-level trainees under close supervision.

Most high-volume programs choose to use nonphysician personnel as attendants during transport. The use of neonatal nurse practitioners offers an attractive alternative to physician attendance (14,15). Nurse practitioners are highly skilled in neonatal stabilization and care and provide a consistency of expertise not usually encountered in other professional groups. They are licensed in most states to perform all the diagnostic and therapeutic procedures required during transport. The greatest disadvantages to the use of neonatal nurse practitioners in some regions are their scarcity and high cost. They are also rarely trained, or willing, to transport patients other than neonates.

As a cost-effective alternative to nurse practitioners, many centers train readily available NICU staff nurses to participate in transport. In addition, most states permit them to perform invasive procedures as an extension of their inpatient nursing role under guidelines and protocols approved by the Boards of Nursing. Therefore, NICU staff nurses can be trained to provide all the care required by a critically ill neonate during transport. This training often is extensive, however, because the cognitive knowledge necessary to diagnose disorders and the experience to perform invasive procedures must be mastered. This extensive training must be considered when estimating the cost of using staff nurses as compared to nurse practitioners. The requirement of training is particularly burdensome when there is a high personnel turnover rate.

Most patients transported to the NICU have either respiratory failure requiring mechanical ventilation or are receiving supplemental oxygen. Respiratory therapists should be considered when selecting transport personnel because of their expertise in the use and maintenance of respiratory care equipment. The therapists' ability to adapt this equipment to the unique environment of transport can be lifesaving, particularly in circumstances when unexpected events occur. The only disadvantage of using therapists is the narrow focus of their usual training. Further education and cross-training allows their scope of practice to be expanded.

Eliminating physicians from attendance during transport can create problems that must be anticipated. For example, leadership of the team is not defined by the usual medical model in which a physician assumes this role. Designating one member of the transport team as the leader—who is accountable for communication, decision making, and documentation—solves this problem.

Advisory personnel at the tertiary center, particularly physicians, often are unwilling to endorse a patient care program that does not mandate initial evaluation by a physician. This resistance usually stems from a concern for the well-being of the patient and can be overcome by the selection and training of competent nonphysician personnel. The support and endorsement of an involved medical director may also be critical. A similar attitude may prevail in community hospitals. Referring physicians may find it unacceptable to relinquish care of a critically ill patient to nonphysician personnel. In an environment in which tertiary centers compete for patients, this may be a motivation for maintaining physician attendance during transport. Most referring physicians, however, are concerned only with transferring their patients in a safe and timely fashion. Anecdotal experience, as well as retrospective and prospective studies, suggests that properly selected and trained nurses provide a level of care during transport that approximates the level provided by physicians (5,16,17 and 18). Once a nonphysician team demonstrates competence and efficiency, the concerns of most referring physicians vanish.

Because the use of specially trained nonphysician personnel represents both a safe and economic alternative to physician participation in neonatal transport, most programs now rely on nonphysician personnel for patient care.

Transport personnel must be proficient in cognitive knowledge of neonatal diseases, management principles of acute problems, and technical skills. The method and extent of training necessary to reach proficiency will

depend on the type of personnel; however, the pattern of preparation will be similar for all professionals (19). Cognitive knowledge is best provided in didactic sessions in conjunction with self-study exercises. Management principles may also be taught in a didactic setting, but refinement of these skills requires repeated experiences in the inpatient setting. Laboratory simulation of technical skills, such as intubation, umbilical vessel catheterization, and thoracostomy tube placement, provides a good introduction to these procedures. These skills can then be refined in the inpatient setting under supervision. Demonstration of proficiency in these areas should be ensured by examination or observation by a qualified supervisor. After initial preparation, a period of training should be provided, during which the trainee accompanies a more experienced team member on transport. Final certification of competence should be awarded by both the medical director and the coordinator for the trainee's professional group.

Communication

The quality of the communication system that supports a transport program may be the key determinant for its success. The communication system serves two basic functions: to provide a point of access for referring physicians, and to coordinate the activities of the transport team (20). A single call by the referring physician should provide access to all of the neonatal services of the tertiary center. The use of a toll-free hot line, often associated with a memorable acronym, is favored by some centers (21). Alternatively, referring physicians can call the NICU directly. If consultation is requested, the referring physician should be connected in a timely fashion with a consultant of appropriate training. If transfer is requested and deemed appropriate, an available bed in the NICU of the tertiary center, or an alternate center if necessary, should be identified. Bed procurement and all subsequent details of the transport should occur without additional calls by the referring physician.

Locating an available and appropriate site of care may be difficult because of a shortage of NICU beds or the lack of availability of subspecialty support in some areas. These regions often benefit from an organized system of identifying available resources. Several such programs exist and are of two varieties. In some areas, sophisticated computerized communication networks link neighboring centers (22). An alternative is an operator-assisted central referral or bed locator system. These systems speed the referral of patients and relieve both the referring physician and the physician at the tertiary center of the burden of placing numerous calls to locate a bed.

Once the decision is made to transport the patient and an admission bed is located, the role of the communications system shifts to dispatching the team and disseminating information about the transport. In this role, the system is best served by a communication center that is staffed and equipped for emergency medical service functions. The referring hospital should be informed of the estimated time of arrival and of any necessary preparations for the arrival of the vehicle. The receiving unit should be notified and be provided with medical information necessary for admission of the patient.

During the conduct of the transport, periodic communication between the dispatch center and the vehicle operator is advisable. Unexpected delays or mishaps are identified promptly and appropriate action taken. Some high-volume transport programs use satellite-tracking systems to monitor the movement of their transport vehicles, which can be exceedingly useful if diversion is necessary. When the transport team does not include a physician, the team should have the capability of communicating directly with the consulting physician at all times. This level of communication is mandated by some states' nurse practice acts. Communication capabilities are usually a trivial problem while in the referring hospital, however they can present a challenge during transit. The gravity of this problem declines each year with the improvement of telecommunications equipment. Cellular phones are typically used during ground transport because of the broad coverage in most areas and the general familiarity of medical personnel with this type of communication. The use of VHF and UHF radios with patching devices to phone lines is an alternative during flight. Typically, air traffic control, medical control, and general communications have separate frequencies.

Many communication centers are equipped with automated devices that record all communications. Although not essential, the recorded transmissions may be valuable educational tools and aids in identifying system errors; in addition, they are often critical if a medicolegal question arises.

Communication should not end with the conclusion of the transport. The transport team should contact both the patient's family and the referring facility to relate the events of the transport. The receiving physician should update the referring physician following admission and give further followup information at regular intervals, including at the patient's discharge. This update should be expedited if an acute event occurs and should occur immediately in the event of death. Even with the ease of communication systems, failure to effectively communicate followup information remains one of the most common criticisms of tertiary care centers.

Financial Considerations

Subjecting a transport program to periodic cost-benefit analyses is a critical aspect of the program's operation. The following elements should be included in the cost of operation:

P.44

- Medical components
 - Nonphysician personnel salaries/benefits
 - Salary support of the medical director
 - Equipment and supplies
 - Medication
 - Expenses related to education of personnel
- Nonmedical components
 - Administrative overhead
 - Vehicle operation, maintenance, insurance
 - Communications
 - Educational and marketing material

Identifying the costs associated with the program may be difficult if its operation is financially integrated into the operation of the NICU. For example, personnel costs often are difficult to quantify because, except in very high-volume programs, transport personnel usually contribute to inpatient services during transport duty time. Therefore, the cost allocated to the transport program should be discounted based on this contribution. The proportion of time devoted by the medical director is even more difficult to quantify and often is ignored in the financial analysis. The cost of equipment most easily separates from the cost of inpatient services as transport equipment rarely is used for other purposes. Included in estimates of equipment costs should be allowances for depreciation and maintenance.

The nonmedical components of a program are often more costly than the medical components because of expenses related to transportation. This is particularly true when air transportation is used. Sharing resources with other hospitals or agencies can minimize these expenses. Ground ambulances can be shared with local emergency medical service agencies or be used for convalescent transport. Aircraft can be used by a consortium of hospitals. The major disadvantage of the shared approach is the possibility of a vehicle being unavailable at the time of a request for transport; however, the potential for this occasional conflict may be far outweighed by the cost reductions.

The revenues of a transport program come from three general sources: reimbursement, support from governmental agencies, and support from other extramural organizations (23). Support from government and charitable organizations is unusual in the United States, and hospitals are increasingly dependent on reimbursement to support transport programs. Most third-party payers will reimburse the majority of the initial transport as long as the care rendered at the receiving hospital was unavailable at the referring hospital. Reimbursement for back transports is less consistent. In general, the cost of a transport program exceeds its

revenues. Subsistence of the program, therefore, depends on financial assistance from the sponsor hospital.

The decision to fund a transport program usually is based on a favorable cost-benefit analysis. Providing a service that is unavailable at the outside hospital is clearly of benefit to the patient. Benefit can be quantified by reductions in mortality, morbidity, and length of hospital stay. Among low-birth-weight (LBW) infants with respiratory disease, one study has demonstrated that the services of a hospital-based neonatal transport team reduce hypothermia and acidosis, the greatest prognostic indicators of mortality (10). However, beyond this study little evidence exists to support the benefits of neonatal transport teams. In an attempt to quantify the benefits of a neonatal transport program, the most prudent approach may be to scrutinize carefully the type of patients being transported to ensure potential benefit from transport. These benefits should be combined with nonmedical benefits to the institution, such as improved public relations and the recruitment of new patients. Ultimately, many institutions in the United States elect to support a neonatal transport program, despite its financial disincentives, in order to increase occupancy of NICU beds.

A potential economy for transport programs may be to combine services, either within a program or between programs. An example of the former would be to cross-train members of specialty transport teams (e.g., pediatric, neonatal, and adult) such that the total number of personnel can be reduced. This strategy invariably results in some loss of expertise but may be necessary to ensure financial viability. Collaboration between programs may include sharing vehicles or teams. Smaller institutions may benefit from outsourcing entirely by contracting with larger medical centers for the provision of all transport services.

TECHNICAL ASPECTS

The Transport Environment

The principles of care provided during transport resemble the principles of inpatient care. Any differences in practice arise from the unique features of the transport environment (24). Many features—including excessive noise, vibration, improper lighting, variable ambient temperature and humidity, changes in barometric pressure, confined space and limited support services—can create problems during transport. The impact of these environmental factors relative to the mode of transportation is summarized in Fig. 4-2.

	GROUND	ROTOR	FIXED WING
Acceleration	–	–	+
Vibration	+	+	+/-
Noise	+	+	+/-
Heat Loss	+/-	+/-	+/-
Hypoxia	–	+/-	+/-
Gas expansion	–	+/-	+/-
EMI	+/-	+	+

EMI = Electromagnetic interference

Figure 4-2 Environmental factors and their impact relative to different modes of transportation.

Noise

High sound levels, in the range of 60 to 70 decibels, are inherent to the NICU (25,26 and 27); but levels recorded on transport are significantly higher, on the order of 90 to 110 decibels (28,29). The effects of exposure to high sound levels on the neonate are not known, but the possibility of physiologic changes is suggested by studies of hospitalized infants (30,31). Brief exposure to high sound levels probably has little long-term effect on transport personnel; however, repeated exposure over time may result in hearing loss. Personnel should protect themselves from exposure by using sound-attenuating devices. Probably the most significant problem resulting from high sound levels is the inability to use auscultation to assess the patient. This handicap

must be recognized before transport, and alternative methods for assessing heart rate and respiratory sufficiency must be available during transport.

Vibration

Vibration exposure is a problem unique to the transport environment (29,32,33). The physiologic consequences in patients of this exposure are not known. Animal studies and investigations using healthy adults suggest that negative effects on the autonomic and central nervous system may occur (34,35 and 36). The vibrational effects on transport personnel are potentially important. For example, a typical helicopter transport results in vibration exposure associated with reduced personnel efficiency (37). The overt symptoms of motion sickness resulting from low-frequency vibration may be incapacitating. A more subtle manifestation of motion sickness, termed the sopite syndrome, also may affect transport team members (38,39). The symptoms associated with this syndrome include drowsiness, inability to concentrate, and disinclination to communicate with others. The sopite syndrome is common among crew members during transport, regardless of the mode of transportation (40). The impact on patient care is poorly understood but may be significant.

The effect of vibration on equipment also poses a major problem. Monitor artifact is a common phenomenon. Personnel should be familiar with monitor artifact and with the use of alternative monitoring techniques. The selection of equipment should be made in consideration of resistance to the effects of vibration. Premature failure of equipment secondary to vibrational damage should be anticipated, and preventive maintenance should be on an accelerated schedule.

Poor Lighting

Improper lighting in transport vehicles is a common problem. The patient care compartment should have illumination to 400 lux (41). In addition, high-intensity directional lighting (1,000-1,500 lux) should be available for procedures. The eyes of the patient, as well as those of the driver or pilot, should be screened from these light sources.

Heat Loss

The difficulties in maintaining a neutral thermal environment are accentuated during transport because of the increased opportunities for heat loss. Hypothermia can be a significant problem during transport and has been linked to increased mortality (10). Heat loss in the transport environment usually occurs by two mechanisms: convection and radiation. Heat loss can be minimized by use of a double-walled isolette, avoiding opening of the isolette, heating the transport vehicle, creating barriers between the isolette and cold surfaces and limiting time in transit.

Variable Humidity

Transport teams often elect not to humidify respiratory gases both for simplicity and to eliminate the negative effects of water vapor pressure on infants in respiratory failure. This is a reasonable approach assuming short transport times; however, long-term effects of poor humidification include dehydration and increased tenacity of secretions. Therefore, gas humidification and close attention to hydration are desirable for longer transports.

Variable Altitude

Changes in altitude that occur during air transport present a potential hazard to an acutely ill neonate because of the phenomena that occur during ascent. As altitude increases the following occur:

- Air temperature decreases
- Partial pressure of gases decreases
- Total atmospheric pressure decreases

For the change in altitude to be clinically important, ascent must be of significant magnitude (in excess of 5,000 feet). At constant temperature, gas volume expands as atmospheric pressure decreases:

$$P_1V_1 = P_2V_2$$

P_1 = initial pressure
 P_2 = final pressure
 V_1 = initial volume
 V_2 = final volume

Therefore, gases contained in spaces not in continuity with the atmosphere—such as those in cuffed endotracheal tubes, sinuses, middle ear canals, pneumothoraces, pneumatoses, intrapulmonary cysts, pulmonary interstitial emphysema, intracranial and intraglobal air, and air spaces distal to obstructed bronchi—can all expand as atmospheric pressure declines. Attempts should be made to ventilate closed-space gas to the atmosphere when significant changes in altitude are expected. Also, the impact of gas expansion during ascent can be minimized by the use of pressurized aircraft if a significant change in altitude during the conduct of a transport is anticipated.

P.46

Confined Space

Space limitations in transport vehicles may impact care. The recommended floor space for the care of a critically ill neonate in an NICU setting is 150 square feet (42); however, the standard ambulance has approximately 47 square feet and aeromedical helicopters have 22 to 36 square feet of workspace. Personnel must remain seated and restrained while the vehicle is in motion; therefore, typically only one provider has any access to the patient in transit.

An appreciation of the problems created by the transport environment and strategies to minimize their impact are essential for safe transport. Some general principles include the following:

- *Prepare the transport vehicle.* The vehicle should be retrofitted to simulate the inpatient environment as much as is possible and practical. This generally requires the addition of supplemental lighting, sound insulation, and a regulated heating-cooling system.
- *Assess and stabilize the patient extensively before transport.* Other than surgical emergencies, neonates have problems that can be managed adequately by the transport team. There is rarely urgency in returning to the tertiary center, and time spent in the community hospital preparing the patient for transport is not time wasted. Stabilization will prepare the patient for the highest risk period, the time in transit between hospitals.
- *Monitor electronically all possible physiologic parameters.* Because of the dynamic nature of the diseases in most transported patients and the inability to assess patients by physical examination in transit, electronic monitoring is critical to the identification of significant changes in physiology.
- *Anticipate deterioration.* All possible forms of deterioration should be anticipated before transport, and strategies to support the patient in the event of deterioration should be planned. Application of this principle can result in the performance of procedures or therapies that may not be necessary in the inpatient setting.

Equipment

Considerable effort has been devoted to the development of devices specifically for neonatal transport, resulting in greater safety and efficacy. The following is a list of the major pieces of equipment used during transport:

Essential equipment

- Portable incubator
- Mechanical ventilator
- Cardiorespiratory monitor
- Blood pressure transducer
- Transcutaneous O₂ monitor or pulse oximeter
- Intravascular infusion pumps
- Air-oxygen blender
- Suction apparatus

Desirable equipment

- Body temperature monitor
- Transcutaneous CO₂ or end-tidal CO₂ monitor
- Noninvasive blood pressure monitor
- Airway humidification system
- Blood gas/glucose analyzer

Although these devices can be purchased individually and either carried separately or attached to the incubator, it usually is advisable, and often more economical, to purchase a modular incubator that includes many of the devices listed. Modular transport incubators have been designed to minimize space and weight. They also use a common battery power supply for most devices. Several transport incubators are commercially available. The logical choice for each program often depends on the size, weight, and heating capability of the unit.

With the increased use of inhaled nitric oxide, many transport teams have acquired the ability to provide this gas during transport. The inhaled nitric oxide delivery system can be cumbersome. Some transport teams use a small, portable, commercially available device, while other teams have constructed their own system for transport (43).

Small accessory equipment and supplies can be divided into respiratory care supplies and nursing supplies. These supplies can be carried in packs or equipment bags (Tables 4-1,4-2,4-3 and 4-4). They should be organized in a recognized and reproducible fashion. This technique will aid in rapidly locating an item during transport and assist in restocking after use.

Transport Vehicles

An essential component of neonatal transport is rapid, safe transportation. The types of vehicles in use include standard ambulances, specially prepared ground ambulances, rotor-wing aircraft, and fixed-wing aircraft. The selection of one or more of these vehicles to support a neonatal transport program usually is based on patient

population, resources, geography, and practical issues, such as the use of the vehicle by other hospital-based services (44,45).

Ambulances are economical, available, and least affected by weather; however, they generally require retrofitting to make them acceptable for neonatal transport. Extensive retrofitting, including the addition of radiant heat and a blood gas analyzer, improves patient care capabilities but dramatically increases costs and decreases usefulness for other services. The major disadvantage of ground ambulance transport is time consumption, which can be prohibitive if frequent long transports are anticipated.

Rotor-wing aircraft minimize transit time and, within a 150-mile radius, usually provide the fastest service. The major disadvantages of helicopter transportation are the constraints of the patient care environment, the high cost of operation, and the inherent safety risks (46,47) of helicopter flight. The cost of rotor-wing transportation usually cannot be justified unless the vehicle can be shared by other emergency medical services.

Fixed-wing aircraft are more economical, spacious, quiet, and efficient as compared to rotor-wing aircraft; however, they must travel between airports and therefore

P.47

additional transfers are required. These shuttles between the hospital and airport often are troublesome and increase the likelihood of mishap. For these reasons, transportation by fixed-wing aircraft usually is advantageous only for distances between hospitals in excess of 150 miles.

TABLE 4-1 NEONATAL NURSING PACK

Equipment	Amount	Equipment	Amount
Chest tube insertion kit	1	Disposable transducer	2
Omphalocele bag, sterile	1	Scissors	1
Sterile lancets	4	Hemostat	1
Blood culture bottle	1	Tape measure	1
Angiocath		Lubricant	2
18 gauge	2	Disposable blood pressure cuffs	1 each
22 gauge	2	sizes 2, 3, 4, and 5	
24 gauge	9	Pacifier	1
Intraosseous needles	2	Bulb syringe	1
IV limb board	2	Sterile gauze	2
Rubber bands	6	Stopcocks	2
Safety pins	6	Extension tubing	1
Tape		Thoracostomy tubes	
Silk	1 roll	10 French	2
Dermaclear	1 roll	12 French	2
Stethoscope	1	Digital thermometer	1
IV fluids		Umbilical catheters	
D ₁₀ W	1 500-mL bag	3.5 French	2
D ₅ W	1 500-mL bag	5.0 French	2
LR	1 1000-ml bag	Heimlich valves	2
NS	1 100-mL bag	Alcohol and Betadine swabs	10 each
Masks	2	IV extension T-connectors	2
Syringes		Butterfly needles	
20-mL Luer Lok	2	19 gauge	2
60-mL Luer Lok	4	23 gauge	2
Transilluminator	1	25 gauge	3
Gloves, sterile		Syringes	
Size 6½	2 pairs	10 mL	3
Size 7½	2 pairs	3 mL	9
Suction catheters, sterile		1 mL	9
Size 6 French	2	60-cc catheter tip syringe	1

Size 8 French	2	60-cc luer lock syringe	4
Stockinette for caps	2	Needles, 19 gauge	10
Cotton balls	4	Tubing adapters (blunt needles)	2
Feeding tubes		Replogle, 10 French	2
8 French	2	Tubing	
5 French	2	Mini-volume extension	1
Gowns	2	Low-volume extension	4
Blood gas syringe	2	Blood component and filter set	1
Tegaderm	1	IV ext. double "T"-connector	1
Protocol Manual	1		

cc, cubic centimeter; D₅W, 5% dextrose in water; D₁₀W, 10% aqueous dextrose solution; IV, intravenous; LR, lactated ringer; NS, normal saline.

DOCUMENTATION

Transport programs typically maintain record-keeping systems that are distinct from the inpatient record. An accurate, thorough record of each transport is essential to provide permanent documentation of the care rendered. The transport record should adhere to the standards of documentation of the sponsor institution. The record also is a valuable tool for quality assurance and education. The critical components of a typical transport record include the following:

- Medical necessity documentation/referral form
- Transport medical record
- Parental consent form
- Billing form

The trend in transport documentation, just as with inpatient charting, has been toward computerized medical records using laptops or personal digital assistants in transport.

TABLE 4-2 NEONATAL RESPIRATORY THERAPY PACK

Equipment	Amount	Equipment	Amount
EXTERIOR POCKETS		Silicone adapter	2
Oxygen tubing	2	O ₂ flowmeter nipple	2
Infant nasal cannula	1	One-way valve	1
Complete ventilation setup with exhalation	1 valve (plus one in isolette)	Set of EKG lead wires	2
		23G, 25G, ½-inch butterfly	3 each
Spare exhalation valve	1	Breath Tracker	1
Face tent	1	Albuterol	1
Treatment setup	1	Racemic epinephrine	1
Space blanket	1	Tape measure	1
		Infant MVB bag, O ₂ tubing, PEEP valve	1 (plus one in isolette)
Thermal hats	2		
Pulse oximeter sensors (N-25 and I-20)	2 each	Infant oral airway	2
Suction catheters 6 Fr, 8 Fr, 10 Fr	3 each	Normal saline	4 vials
		Silk tape	1 roll

NCPAP prongs (#1,#2)	1 each	Oxygen connectors	2
Luekens trap	1	Hemostat	1
INTERIOR OF BAG		Briggs T-adapters	2
Airway supplies		15-mm adapter	2
		O ₂ connectors (NCG, OES, P-	1 each
		B)	
Laerdal masks		Air connectors (NCG, P-B)	1 each
No. 0	2	EKG lead pads	3
No. 1	2	Three-way stopcock	2
No. 2	1	E-Z Heat hot packs	4
Infant McGill forceps	1	Stethoscope	1
Laryngoscope handle	1	1-mL and 3-mL syringe	3 each
Blades, Miller/Shaw #0,#1	1 each	ABG kit	3
Other equipment		Low-volume extension tubing	4
Benzoin applicators	6	Full set Mini-Med Tubing	1
Alcohol preps	4	Endotracheal tubes	
Adjustable wrench	1	2.5 mm	3
E-tank wrench	1	3.0 mm	3
Cable ties	10	3.5 mm	3
Scissors	1	4.0 mm	3
9-volt battery	1	4.5 mm	3
Assorted laryngoscope bulbs	4	Pedi-cap detector	2
Adjustable venturi	2	Istat Pack	1

ABG, arterial blood gas; EKG, electrocardiogram; Fr, French; MVB, manual ventilation bag; NCPAP, nasal continuous positive airway pressure; PEEP, positive end-expiratory pressure.

P.48

QUALITY ASSURANCE

Performance review of the transport program should be a continual process. All activities of the program should be reviewed periodically to ensure that standard operating procedures are being observed. These reviews are best conducted by people directly related to the program activities. Also, the medical care provided by the team should be scrutinized for adherence to protocols and quality assurance. For nonphysician teams, the medical director or a physician designate should conduct this level of review. In addition, to assure that every chart is reviewed and problems discovered in a timely fashion, peer review in the immediate post-transport period is valuable.

Quality assurance activities should be closely linked to education and research. Review of individual transport records can be an extremely valuable method of identifying transport personnel in need of further education and training. The compilation of reviews and the monitoring of patient outcomes provide an assessment of the efficacy of existing protocols and procedures and may identify a need to alter program activities. In addition, new therapies and equipment can be evaluated using existing quality assurance techniques.

General guidelines for developing quality assurance programs have been published (48,49). Guidelines, specific for air transport, have been produced by the Association of Air Medical Services (50). The Commission on Accreditation of Medical Transport Systems (CAMTS) provides external quality assurance reviews for transport programs and allows programs to benchmark themselves against measurable standards (51). A number of states require CAMTS accreditation, and some states use CAMTS certification in lieu of state regulations (52).

TABLE 4-3 NEONATAL MEDICINE PACK

--

Drug	Amount
Isotonic saline vials, 20 mL	4
Heparin	1
Sodium chloride (2%)	1
Phenytoin	2
Naloxone	2
Epinephrine 1:1,000, 1 mL	1
Epinephrine 1:1,000, 30 mL	1
Ampicillin, 500 mg	1
Ampicillin, 250 mg	1
Gentamicin, 20 mg	1
Acyclovir	1
Cefotaxime, 1 g	1
Flumazenil	1
Calcium gluconate	1
Dobutamine	1
D ₅₀ W	1
Calcium chloride Bristoject	1
Atropine Bristoject	1
Survanta	2
Sterile water vials, 20 mL	4
Heparin lock flush	2
Dexamethasone	1
Furosemide	1
Artificial tears	1
Lidocaine 1%	1
Digoxin	1
Adenosine, 6 mg	2
Hydralazine, 20 mg	1
Clindamycin	1
Aminophylline	1
Dopamine	1
Pancuronium	1
Vecuronium	1
Amiodarone	2
Sodium bicarbonate	1
Lidocaine 2% Bristoject	1
Vitamin K, 1 mg/mL	1
Neonatal Narcotic Pack	2
Morphine 2 mg/mL	1
Midazolam 5 mg/mL	1
Phenobarbital 130 mg/mL	1
Fentanyl 50 µg/mL	1
Lorazepam 2 mg/mL	1
D ₅₀ W, 50% dextrose water.	

PSYCHOSOCIAL CONSIDERATIONS

Psychological Impact on the Family

It is impossible to eliminate the parental anxiety associated with neonatal transport; however, a few techniques exist that may help families in coping with this difficult situation. The transport team should provide the family

with as much information as possible about the nature of their child's illness, the therapies and equipment that will be used, the NICU to which the infant will be transported, and the professionals who will provide care. A member of the referring hospital staff should be in attendance during this discussion in preparation for dealing with questions that may arise after the departure of the transport team (53). This information should be provided both verbally and in written form. Many teams use brochures that describe their service, and provide relevant phone numbers and directions to the tertiary care center.

Parents should see their infant before departure from the referring hospital. The benefit of this interaction outweighs any delay in departure (54). This contact should be encouraged prior to the transport of even the most critically ill infant or when parents are reluctant to view their child. When possible, a photograph of the infant should be left with the family. On arrival in the receiving hospital, the transport team should call the family immediately to reassure them that their child has arrived safely. The transport team should alert the tertiary center staff to any unusual problems the parents might have in coping with their child's illness.

Relationships with Referring Hospital Personnel

Transporting a neonate from a community hospital to a tertiary center has the potential to either improve dramatically the relationship between institutions or to cause irreparable damage. Each transport represents an opportunity for success or failure. To ensure success, referring personnel must have easy access to and a quick response time from the transport team. Rapidity of response often is critical from a public relations standpoint, even when the infant's medical condition does not mandate speed.

Even the most responsive service will fail to satisfy personnel in the referring hospital if the team does not conduct itself appropriately. The team must understand the psychological milieu surrounding a transport. The event is often emotionally charged because of the acute nature of the infant's illness and feelings of inadequacy on the part of the referring hospital personnel. These feelings seem to arise even when excellent, comprehensive care is provided. Referring hospital personnel may be very sensitive to criticism, and any critique of care, unless requested, should be deferred until a later time. The team should seek information about the history and condition of the infant before their arrival, and they should ask for assistance from referral hospital personnel when practical. Members of the transport team should clearly state appreciation for the contribution made by the referring staff. The need for performing all procedures should be explained, this being particularly important when referring personnel have made the decision not to perform a procedure because of their lack of understanding of the transport environment. Nonphysician teams must avoid conflicts with referring physicians over the need for therapies or procedures. Any disagreements should be resolved through discussion between the referring physician and the consulting physician in the tertiary center.

TABLE 4-4 BACK TRANSPORT PACK

Equipment or Drug	Amount	Equipment or Drug	Amount
EQUIPMENT		Minimed full set	1
Istat Pack	1	Minimed half set	1
Lancets, sterile	5	Oximeter probes	2
Stethoscope	1	EKG electrodes	6
Syringes		Hot packs	
1 mL	3	Small	1
3 mL	3	Large	1
10 mL	1	Silver thermal hats	
20 mL	1	Small	1
60 mL	3	Large	1
Needles, 19 gauge	10	IV limb board	1
Bulb syringe	1	Intraosseous needle	1
Feeding tubes		BP cuffs (2,3,4,5)	1 each
5 French	1	Scissors	1
8 French	1	Hemostat	1
Butterfly needles		T-connector	2
23 gauge	2	Angiocath, 24 gauge	4
25 gauge	2	Safety pins	6
ET tubes, 2.5 through 5.0	2 each	Tape	2 rolls

Stylets	2	Benzoin	1
Laryngoscope and blades (Miller 0, 1)	1 each	Sterile gloves	
Face masks, assorted sizes	1 each	Size 6½	2
Face tent	1	Size 7½	2
Manual ventilation bag	1	Diapers	3
Nebulizer setup	1	Pacifiers	1
Venturi tubing	2	Oxygen tubing	2
Nasal cannula	2		
Alcohol and Betadine swabs	10 each	MEDICATIONS	
Thermometer	1	Isotonic saline	2
Suction catheters		Heparin flush	2
6 French	2	Sodium bicarbonate	2
8 French	2	Epinephrine 1:10,000 Bristoject	1
10 French	2	Atropine Bristoject	1
Yankauer suction	1	Sterile water	2
Three-way stopcock	2	D ₁₀ W, 500cc	1
IV tubing		D ₅ W, 100 cc	1
Low-volume extension	2	D ₅ /0.2 NaCl, 250 cc	1
Mini-volume extension	1	Normal saline, 250 cc	1

BP, blood pressure; cc, cubic centimeters; D₅/0.2 NaCl dextrose 5% injection in 2% sodium chloride; D₅W, 5% dextrose in water; D₁₀W, 10% aqueous dextrose solution; EKG, electrocardiogram; ET, endotracheal; IV, intravenous.

P.50

LEGAL CONSIDERATIONS

Emergency medical services personnel may be held to a different standard of care while providing care at the scene of an accident or in a transport vehicle compared to performing the same tasks in the inpatient setting (55). Neonatal transport, however, is more closely associated with inpatient intensive care and less likely to be considered an emergency service (providing extraordinary care under adverse conditions). Therefore, neonatal transport personnel should assume that they have the same high risk of litigation as other perinatal caretakers.

Although there are few regulations and little case law defining the legal obligations of transport services, understanding the principles that are likely to govern legal decision making will help guide programs in establishing sound practices and limit risk of litigation (56). The principles of *respondeat superior* define the hospital as the party responsible for governing the protocols and procedures followed by its personnel (57). These principles appear to apply to mobile services as well as inpatient care. Therefore, the hospital that sponsors a transport program is responsible for selecting and training the personnel and defining their scope of practice. Logically, the medical director, as the medical professional delegated to ensure the quality of care, also is liable for the governance of the team. Team members assume personal liability only if they perform outside their enfranchised scope of practice.

Each transport program should construct a manual of operations clearly denoting its standard procedures. The method used for selecting, training, and certifying personnel should be documented. Similarly, protocols and procedures should be recorded and approved by the medical director. Activities of nonphysician personnel that exceed

P.51

their usual scope of practice in the inpatient setting should be listed and approved by the respective governing bodies (e.g., Board of Nursing). All documentation should be kept on permanent file.

During the conduct of a transport, the team should adhere to established protocols and procedures (58) unless the patient's needs dictate an abridgement of usual standards. In this situation, advice from a consulting physician should be sought, and the recommendations of this physician should be carefully noted in the patient record.

Referring hospitals have both ethical and legal responsibilities to patients requiring interhospital transfer, with the latter responsibilities outlined primarily in the Consolidated Omnibus Budget Reconciliation Act (COBRA) of 1985 (59). This federal legislation assigns to the referring hospital the responsibility to adequately stabilize the patient prior to transport. The referring hospital also must establish an agreement with a hospital to receive the patient and must ensure that the receiving hospital is capable of providing for the predicted needs of the patient. Amendment of this act in 1989 added the requirement that referring hospitals make an effort to obtain written consent from parents of a minor patient prior to transport. Failure to comply with these requirements is considered medical abandonment.

Referring and receiving hospitals, and their personnel, have distinct responsibilities to patients at varying points in time during the conduct of a transport. There is no single point at which the responsibility shifts absolutely from referring to receiving hospital. From the time of a referral call to the arrival of the patient in the receiving hospital, there is a stepwise decline in the responsibility of the referring hospital (Fig. 4-3). Critical events that shift responsibility include:

- Arrival of the transport team in the referring hospital
- Assumption of direct patient care by the transport team
- Departure of the team and patient from the referring hospital
- Arrival in the receiving hospital (60)

The scope of nursing practice is usually established by two sets of regulations, the rules and regulations set forth by their employing hospital or agency and the nurse practice acts in the state in which they practice. Transport creates unique problems regarding nursing scope of practice because transport nurses often provide care in a hospital other than their sponsoring institution, and sometimes they may practice in a state other than the one in which they are licensed (60). Nurses in general are not permitted to practice under the supervision of a physician not associated with their employing hospital. Therefore, while providing care in the referral hospital and sharing responsibilities with the referring physician, a transport nurse must follow protocols and procedures established by the sponsoring institution, or receive verbal orders from the receiving hospital's MCO. In anticipation of problems during interstate transport, some adjacent states have established reciprocal relationships for licensure; however, this is not routine. Many transport teams circumvent this problem by "admitting" the patient to their home hospital at the time of first contact with the patient and thus team members are considered to be practicing in their licensed state.

Vendors who provide transportation for medical personnel and patients are governed by either state or federal legislation. The Emergency Medical Services Act of 1973 places the responsibility for the governance of ground transportation under the guidelines of state emergency medical service regulations. Air transportation services must comply with Part 135 of the Federal Aviation Administration regulations, which govern medical air operations.

BACK TRANSPORT

The return transport of convalescing infants to community hospitals before discharge home is referred to as back transport. Benefits of back transport include:

- Reserves tertiary center resources for critically ill patients, decreasing overcrowding in these units (61,62)
- Improves use of level I and level II center resources and helps prepare their personnel for the care of acutely ill patients
- Improves relationships between tertiary centers and their referral hospitals
- Familiarizes primary care physicians with infants before discharge home
- Improves family visitation and promotes family-infant bonding
- Reduces the total cost of medical care (63,64)

There are also potential disadvantages associated with back transport, including the following:

- Parental anxiety and loss of continuity of care caused by the change of caretakers
 - Occasional requirement for readmission to the level III center (65)
 - Lost opportunity by level III personnel to participate in convalescent care
-
- Hazards and cost of transport
 - Lack of reimbursement by third party payers for the transport (64)

P.52

Back transport should be considered an option for all infants who no longer require the unique resources of the level III center and for whom the tertiary center is not the site of subsequent primary care (65).

Chapter 5

Telehealth in Neonatology

Sarah C. Muttitt

Mary M. K. Seshia

Liz Loewen

Health care is facing many challenges and changes with increasing pressure to improve access and quality while reducing the administrative and financial burden of providing care. There is growing expectation that technology has a key role to play in meeting these demands. Telehealth, defined as the use of information and communications technology (ICT) to deliver health services, expertise, and information over barriers of distance, geography, time, and culture, fulfills this role (1). Telehealth can support services within the whole spectrum of health care including diagnosis, treatment, and prevention of disease, continuing education of health professionals and consumers, and research and evaluation. When well-integrated into routine clinical practice, telehealth can improve the efficiency and cost effectiveness of the health care system by moving people and information virtually rather than physically (1). Although not new, telehealth has experienced rapid expansion over the past decade and is being utilized in a growing number of medical specialties including dermatology, oncology, radiology, surgery, cardiology, mental health, and home health care. While telehealth may not have reached the volume and maturity required for large-scale randomized studies, the value of telehealth has been well accepted by consumers and health care providers alike (1).

Telehealth implementation addresses three major issues: access to health care services; retention, recruitment, and support of rural physicians and other health care providers; and potential cost savings to the health care system and/or patients and their families. In order to access specialty care, residents of rural areas are often forced to travel long distances at significant cost, inconvenience and, in some cases, aggravation of underlying medical conditions. Although some tertiary care centers provide itinerant specialty clinics, these services may not be available where and when a patient requires specialist advice. Physician travel for itinerant clinics also has associated risks and costs, including the loss of valuable time while traveling between clinics. Telehealth has the potential to provide access to a broader range of comprehensive primary, secondary, and tertiary health care services, more timely intervention, earlier repatriation, and improved continuity of care for rural patients. Physicians and health care providers in rural areas have limited direct access to peers, specialists, education, and opportunities to participate in health care administration or professional association activities. This sense of professional and social isolation often contributes to clinicians leaving positions prematurely and the inability to recruit skilled practitioners, leaving rural communities largely underserved. Access to education and peer support through telehealth may impact retention and recruitment and allow health care providers in rural settings to work to the full potential of their scope of practice as well as provide more complex care closer to home.

Although telehealth is primarily driven by the demand for more equitable access to health care for rural and remote residents, much attention has been given to the telehealth "business case." Cost avoidance and cost savings are constantly sought to offset the substantial costs of telehealth implementation and operations. Although there are cost savings associated with a reduced number of unnecessary medical transports, earlier patient discharge to community hospitals or home, and decreased education and administrative travel, the longer-term savings associated with more timely access to care resulting in less consumption of health care resources and

improved health outcomes have yet to be measured (1,2,3). The ability of telehealth to contribute to greater efficiencies within the system may offer the opportunity to redirect any savings towards improved patient services. Even if telehealth does not result in a reduction in total health expenditures, improved access to quality health care services should be of high importance to patients, providers, and health care funders (1).

THE HISTORY OF TELEHEALTH

Health care at a distance, or telehealth, has been practiced for decades using less sophisticated communications technologies than we currently associate with telehealth. The National Aeronautics and Space Agency (NASA) played an important role in the early development of telehealth. The remote monitoring of crew, spacecraft, and environmental health has been an integral part of NASA operations. Similarly, the United States (U.S.) military has been actively involved in telehealth research and applications as a means of bringing medical expertise to those injured in battle with less risk of injury to health care personnel. In the 1960s, the Nebraska Psychiatric Institute became one of the first facilities in the United States to develop a two-way link via microwave technology to provide education and consultations between specialists and general practitioners. NASA's efforts at enhancing satellite communications provided the opportunity to pilot telehealth in more remote locations such as Alaska in the early 1970s (4). Satellite technology also facilitated the development of the Telemedicine Centre at Memorial University of Newfoundland (MUN) in 1977. Using simple, low-cost audio-conferencing technology, the MUN program linked hospitals, community colleges, university campuses, high schools, town halls, and education agencies throughout the province for educational programs and transmission of medical data (5). In the 1980s, there was a flurry of telehealth activity in North America as well as around the world, with new projects in Australia, New Zealand, the United Kingdom, France, and Norway. Early projects were largely focused on the technical feasibility of telehealth and often were developed around a single application and single clinical "champion." Because of the high capital costs of these projects, they were also extremely dependent on grant funding. Many came to end when funding expired or the clinical champion moved on to other areas of research interest.

In the late 1980s and early 1990s, telehealth technology became more robust and less expensive, making telehealth a more viable alternative for health care service delivery. The past decade has seen rapid expansion of telehealth sites and applications. The Telemedicine Information Exchange currently lists more than 160 telehealth programs internationally (6). A better understanding of the human factors associated with telehealth success has allowed improved planning, deployment, and management of telehealth programs. However, the majority of telehealth activity worldwide still remains grant funded or hospital supported with consequent vulnerability to annual funding cycles. Today's projects focus on assessing sustainability. It is becoming apparent that telehealth solutions have to be integrated within the traditional healthcare system to be sustainable. With careful attention to cost-effectiveness and quality services, telehealth is destined to become a standard component of health service delivery.

TECHNOLOGY

There are two main types of communications in telehealth. Asynchronous, or store-and-forward, involves the capture and later transmission of data or images for dissemination or interpretation. Teleradiology, the sending of radiographs, computed tomography (CT) scans, or other digital scans, is the most common store-and-forward application of telehealth in use today, and is often integrated into larger picture archiving and communication systems (PACS). Pathology and dermatology are other specialties that typically use store-and-forward technology for remote

diagnosis. Synchronous, or real time, implies the transmission of information instantly and is primarily associated with the use of videoconferencing to support face-to-face consultation between a patient in one location and a provider in another. Almost all medical specialties have found an application for the use of videoconferencing technology and with the addition of appropriate peripheral medical devices, such as stethoscopes, otoscopes, and examination cameras, a comprehensive examination can be conducted remotely. Some telehealth applications use a combination of store-and-forward and videoconferencing technologies to allow both the review of still images and interactive consultation with peers and patients. In all cases, the clinical requirements must drive the technical solution. The price and performance of telehealth technology has improved dramatically over recent years and in many cases, off-the-shelf hardware now provides the necessary functionality at much lower cost than systems specifically designed for telehealth. All equipment should comply with accepted technical standards to ensure quality, flexibility, and compatibility between systems.

In addition to end points, telehealth requires a telecommunications network to facilitate the exchange of information. Although telecommunications infrastructure in urban settings has developed remarkably over the past decade, the primary focus of telehealth has been to serve rural and remote populations where connectivity continues to be a considerable challenge. Requirements for bandwidth (communication channel capacity) vary depending on the application. The higher the bandwidth, the more information can be sent in a measured time period. POTS (plain old telephone system) may be appropriate for transmitting low volumes of nonurgent X-ray images between two destinations for a teleradiology service. Larger volumes of images or a need for urgent interpretation would require a higher bandwidth solution. Similarly, higher bandwidth is required to support quality interactive videoconferencing for clinical applications. Although urban sites may be able to choose between a number of suitable solutions such as ISDN (Integrated Services Digital Network), DSL (digital subscriber lines), or high-speed cable, geographically remote communities may only have access to the necessary bandwidth through satellite or other high-cost wireless solutions. Telecommunications costs for rural education and health care networks in the United States

P.56

are heavily subsidized through the Universal Service Fund, a fund generated through contributions from telecommunications companies. In Canada, the federal government continues to support the deployment of broadband to many rural, northern, and isolated communities through initiatives such as the Broadband for Rural and Northern Development and the National Satellite Initiatives. In some cases, sharing infrastructure costs with other sectors, such as education, justice, or industry, may improve the viability of telehealth in a small, remote community. The availability of low-cost telecommunications solutions is critical to the expansion and sustainability of telehealth in many of the neediest areas, including developing countries.

The advent of IP (Internet Protocol) videoconferencing is impacting the design and operations of telehealth networks everywhere. Traditional copper-based networks required dedicated connections so telehealth was often limited to a single site or "suite" within a health care facility. With line installation, monthly line rentals, and long-distance charges associated with each session, telecommunications costs often accounted for as much as 15% to 25% of total telehealth costs (2). With advances in digital video compression, composite audio and video signals can now be carried over typical IP network circuits either on a LAN (local area network) within a health center, across a broader WAN (wide area network), or private network. With nearly ubiquitous access, telehealth can be available on every physician's desktop, at the patient bedside, and throughout every hospital and primary health care facility—providing access wherever and whenever healthcare services are delivered. Although there is a fixed cost associated with an IP network, there is little or no additional cost associated with actual use. As a result, the actual per session cost for telehealth declines with increasing utilization. In addition to long-term cost

savings, the convergence of voice, video, and data onto a single network will ultimately allow telehealth to interface with other health information, including PACS and electronic health records. Issues surrounding network quality, bandwidth requirements, and security continue to be refined but telehealth over IP networks is becoming an attractive option for many programs.

Choosing the right technology for telehealth is complicated in the face of declining equipment and telecommunications costs, inevitable capital depreciation, and rapid technical innovation. Clinical users of the equipment must be involved in purchasing decisions, as clinical and operational requirements will directly determine technical specifications; such involvement will also foster acceptance by the users. In general, a telehealth program should purchase the highest specification equipment available to meet user expectations at the lowest possible cost. Similarly, decisions regarding telecommunications infrastructure should be based on file size, immediacy, and volume of usage balanced by fiscal realities and whether or not funding or revenue streams can offset the associated capital and operating costs. Telehealth programs must also plan for equipment and network maintenance, support, and upgrading. Vendor relationships are crucial to the success of telehealth programs. In addition to price and technical specifications, appropriate service level agreements should be instituted to ensure high-quality, reliable, and state-of-the-art telehealth operations.

MEDICO-LEGAL AND REGULATORY ISSUES

The clinician's duty of care and clinical case responsibility in the telehealth setting adhere to the same principles found in face-to-face encounters. The ethical and quality standards of practice governing clinicians are not altered by the use of telehealth. Proper documentation, including written consent when applicable, should be maintained for all telehealth encounters. The advantage of telehealth is that it permits health care to be delivered anywhere, with no recognition of borders; however, this inherent distinction from traditional in-person care also raises new issues surrounding regulations and policy related to health care practice (7) (see also Chapter 8).

Licensing of health professionals is typically a jurisdictional responsibility. If physicians and patients are located in different provinces or states, it is important to determine whether the locus of accountability will be the patient site or provider site. If the service is deemed to occur at the patient site, the physician may be required to obtain appropriate licensing and credentialing as if practicing in person at that site. A number of policy options to overcome these licensing issues have been proposed including "universal" licensure, a special-purpose license for telehealth, and mutual agreements, but there is still a significant need to harmonize standards to support cross-jurisdictional telehealth activities (7).

The absence of policies regarding physician reimbursement for telehealth consultations has historically been a significant barrier to the widespread adoption of telehealth. Early telehealth initiatives were often pilot projects or clinical trials located at hospitals or universities, and physician reimbursement was not a major concern as most physicians treated their participation as a research initiative or were compensated through alternative payment arrangements (salary or capitation). However, as more practitioners incorporate telehealth into routine practice, compensation has become a pivotal issue. Although many insurance plans still require patients to be seen in person by a physician in order to bill, others have developed specific fee codes for telehealth services; however, these often have significant limitations related to geographic location, specific facilities, number and types of services, and professional category. Canada's publicly administered system is also inconsistent, with some provinces allowing direct reimbursement for telehealth services and others not. There is slow progress toward expanding telehealth reimbursement, but health care organizations should determine the policies in their jurisdiction regarding payment prior to implementing telehealth services.

All physicians engaging in telehealth consultations should verify with their insurance providers that telehealth is included within their malpractice insurance policies. To date, there has been very little litigation associated with telehealth, but there are some specific issues to be considered. Not all consultations are appropriate for telehealth. Providers must use their best clinical judgment to determine whether services can be safely and effectively provided by telehealth. In addition, a back-up process must be established to ensure that patients receive appropriate and timely care in the event of technical failure. Practitioners may require specialized training and expertise for telehealth and demonstrate acceptable technologic competence prior to providing telehealth services. Specific clinical protocols and guidelines may be necessary to ensure consistent, high-quality telehealth applications in some settings. At all times, telehealth services must adhere to basic quality assurance and professional standards of care (7).

Privacy of personal information related to the use of ICTs in health has been a developing issue over the last decade. Concerns over the use of technology to track everything from health care services to spending habits have spurred the development of policies to regulate the protection of individual privacy. Standards for maintaining the privacy of health information in a telehealth context do not differ from those in a face-to-face encounter; however, the introduction of technology adds privacy and security considerations (7). In addition to maintaining privacy through more traditional measures such as a private physical environment and organizational processes, delivery of telehealth requires attention to security of data during transmission and, in some cases, storage. Ensuring security in an ever-changing technologic environment requires a proactive and evolving approach (8). Ensuring confidentiality in a telehealth setting can be more challenging given the potential risks for interception, potential for a permanent video record, and additional people involved in each care session. This is compounded by the variety of equipment and complexity of transmitting images between two settings (9). As telehealth moves from single-room standalone applications to integration within direct patient care areas, such as the neonatal intensive care unit (NICU), the complexity of ensuring privacy increases.

THE ECONOMICS AND EVALUATION OF TELEHEALTH

The body of scientific literature related to the application of telehealth has been growing steadily over the last 30 years. A search for the keyword *telemedicine* on PubMed found only 24 references for the decade 1970 to 1979; this increased to 2,903 for 2000 to 2003. Several recent literature reviews have examined the current state of research knowledge related to telehealth, and most have determined that while telehealth shows promise, research and evaluation of telehealth is still maturing with few scientifically conclusive studies completed to date. The reviews completed to date have identified small numbers of studies which meet criteria for inclusion ranging from 7 for those requiring a randomized controlled trial to 50 when inclusion criteria were broadened to include any controlled design (10,11). The strongest studies examining clinical impacts have demonstrated support for telehomecare initiatives, management of chronic illness, psychiatry, dermatology, cardiology, teleradiology, transmission of digital images for neurosurgery consultation, and echocardiographic image transmission (10,11,12,13,14).

Most telehealth studies include some element of economic analysis. Whitten and colleagues (3) completed a systematic review of telemedicine cost effectiveness studies from 1966 to 2000 and found 612 articles that included some economic analysis, most of which were recorded as small-scale or short-term evaluations with less than ideal economic analysis and limited transferability. Only 55 included actual cost data, 24 of which met the requirements for a full review. Jennett and associates (1) identify more than 40 telehealth studies that found economic indicators (many of which are repeated from the Whitten study); however, again, most were rated as less than

optimal analyses. Economic indicators for telehealth include costs related to travel and travel time for patients and providers; patient transport; equipment and telecommunications; shift of care from larger centers; and recruitment and retention related to access to continuing education.

While the reviews done to date have demonstrated the feasibility of telehealth, telehealth research has not yet included large-scale randomized studies (10). An additional challenge in the evaluation of telehealth is whether face-to-face care is, in fact, the gold standard against which any new service delivery method should be tested (10). As telehealth moves toward a more integrated model, evaluation approaches must also use an integrated and systemic approach rather than focusing on limited indicators to measure the impact of the technology. The potential for increased access to healthcare resulting from telehealth applications may have long-term systemic benefits not easily captured in a single study. A more recent review examining the socioeconomic impact of a variety of telehealth applications found benefits to patients, clinicians, and the health care system (1).

TELEHEALTH APPLICATIONS IN NEONATOLOGY

In 1970, regionalization of perinatal-neonatal care was advocated following the observation that neonatal mortality was highest in those hospitals delivering small numbers of infants compared with that of larger hospitals with neonatal referral units. Additionally since that time, the care of the sick neonate has become increasingly technologically dependent, providing further justification for regionalization of neonatal care. This has resulted in dislocation of families during complicated pregnancies, limited

P.58

access to specialized resources for sick neonates, and difficulties in ensuring access to follow-up resources.

In this same time period, technologic advances have resulted in the ability to deliver health care effectively over distance. Those practicing neonatal-perinatal medicine need to harness this technology, incorporating it into daily care, to provide consultation (both emergent and elective) over distance, allow for televisitation by families, facilitate discharge from tertiary to secondary levels of care, and provide follow-up of high-risk newborns in their home communities, ideally within their home.

This section demonstrates how telehealth has been used effectively through the perinatal-neonatal continuum, both for the delivery of care and for education of health care providers.

Antepartum

Telehealth has been used successfully for a number of antepartum applications including genetic counseling and teleultrasound. In Queensland, Australia, a weekly connection, developed in 1997, allows maternal fetal medicine specialists to provide direction to a sonographer at the patient site while viewing the fetal ultrasound in real time. At the end of the consultation, the subspecialist counsels the parents on diagnosis, prognosis, and management and prepares a report for the referring physician. In addition to increasing patient access to the subspecialist, communication between the two hospitals is improved and knowledge transfer between health care providers is facilitated. A review of the program found only one missed fetal diagnosis out of 120 cases, and patients were highly satisfied with the consultative process. The real-time interaction is considered a key component of the success of this project (15,16).

Neonatal

Health care professionals caring for neonates know that even a low-risk pregnancy can result in a high-risk situation for the neonate in 2% to 4% of deliveries. Additionally, newborn infants who initially appear well can deteriorate rapidly, particularly from sepsis, respiratory problems, and congenital heart disease. Timely access to specialists in newborn care can be a problem for remote and isolated health facilities. In Manitoba, Canada, the provincial MBTelehealth Network supports a telehealth link between a tertiary NICU and a general hospital 760 kilometers north. Pediatricians at the remote site can consult the receiving NICU on an emergent basis for assistance with management and stabilization. In this integrated system, both the remote and receiving staff operate the equipment and only rely on technical support when problems are encountered. The equipment at the remote end is positioned to allow the NICU staff to see the newborn, cardiorespiratory monitor, and ventilator. The NICU health care professionals at the receiving site take over camera control from the remote site to ensure that the remote staff members are not distracted from the care of the newborn. Image resolution is high—even the numbers on the side of the umbilical catheter can be read. The addition of the visual image of the baby to the usual telephone verbal description allows for improved assessment and advice on management (Fig. 5-1). The interaction between the neonatologist and referring physician provides a conduit for ongoing education in neonatal care; further, the “virtually present” neonatologist can talk the referring physician through procedures such as umbilical catheterization, which the referring physician may not have recently performed, enhancing that physician's confidence; and finally, but importantly, the parents are comforted by the ready availability of a specialist for their newborn. This link has also allowed parents and extended family to “visit” the neonate and participate in management decisions from the remote location in situations when they are unable to travel to the NICU. While technology is not going to replace the need for neonatal units, it does allow for improved access to care. In addition, if appropriate education is provided to those smaller referring facilities, earlier retrotransfer of newborns should occur, reducing family dislocation and costs. As telehealth networks expand and personnel realize both its potential and ease of use, this application will surely become more widespread.

Telecardiology

Digital echocardiography has enabled the transmission of echocardiograms from remote sites to pediatric cardiologists both by store-and-forward and real-time, synchronous transmission. Real-time transmission allows for continuous live contact between the cardiologist, sonographer, and other health professionals, and also family members at the remote site. Although this technology is used for all age groups, Finley (17) found that 51% of urgent examinations were for newborn infants. In addition to diagnosis, the utilization of interactive videoconferencing can support case conferencing and echocardiogram review between referring sites and remote surgical teams for infants being referred to a cardiac surgical center. Families can participate in this process, increasing their confidence in the care of their infant. With appropriate bandwidths, images can be of clinical quality. Ideally the sonographer at the remote end should have pediatric cardiology experience to ensure that more difficult diagnoses, such as total anomalous pulmonary venous return and coarctation of the aorta, are not missed (17,18,19,20). Although in many situations the neonate will still have to be transported to the tertiary center, with telecardiology, some transports can be avoided or undertaken more electively and more appropriate management decisions can be made.

Retinal Telephotoscreening

Retinopathy of prematurity (ROP) is a complication of surviving preterm low-birth-weight infants, with

approximately 65% of infants <1,300g at birth and up to 80% of infants <1,000g developing ROP. These infants require frequent retinal screening once the disease is diagnosed to prevent blindness. The “gold standard” for screening is indirect ophthalmoscopy by a pediatric ophthalmologist with expertise in ROP management. Such subspecialists are few in number and with the geographical diversity of levels II and III NICUs, providing this service is challenging. Telehealth technology, using a digital retinal camera equipped with an ROP lens, is currently being investigated as an alternative method for retinal screening. The camera system provides an immediate wide-angle view of 120 degrees and also produces a real-time image on a computer monitor, which is then stored, uncompressed, on a digital videodisc (Figs. 5-2 and 5-3). Two recent studies concluded that the sensitivity was insufficient for recommendation as a screening tool for ROP (21,22). However Schwartz and associates (23) suggested that this telemedical strategy might be highly accurate when assessing whether a child's eye required the urgent attention of a physician capable of evaluating and managing threshold ROP. Ells (24) subsequently adopted a pragmatic approach; rather than using this technology to differentiate between stages 1 and 2 ROP, she focused on whether this technology could identify those eyes that require treatment. In this approach, digital photography had a sensitivity of 100% and a specificity of 96% in detecting referral-warranted ROP. As the technology improves and more people become trained in its use, the use of digital retinal photography will become a useful adjunct to hospitals providing level II care; and growing premature infants at risk of ROP will be able to return to their home community rather than remaining in a center where there is access to a trained pediatric ophthalmologist.

Figure 5-1 Videoconferencing between the neonatologist in the NICU and remote health care professionals following the delivery of this preterm infant.

Televisitation

Telehealth can promote a connection to the neonate's home setting both before and after neonatal discharge. Interactive videoconferencing can provide a link between the mother and her family. Gray and associates (25) have used a web-based solution designed to reduce the costs of

low-birth-weight infants in the NICU. Via the Internet, families can link to the NICU at any time to obtain information about their infant, as well as obtaining educational information and information on experiences of other families. Also incorporated, and perhaps the most exciting aspect for families, is the interactive videoconferencing that can occur. Parents can see their infant and receive information and support from staff at times when they cannot visit. In a small, randomized study of this technology, hospital stay was shorter and families experienced greater satisfaction with the care received. The system requires the installation of an easy-to-use computer in the home. Given that access to the Internet has been adopted more rapidly than any other technologic advance in history, the use of this technology as a means of delivering care can only expand.

Figure 5-2 Retinal telephotoscreening taking place in the NICU using the RetCamII.

Telehomecare

Telehomecare is a growing application with considerable potential to support neonatology. Telehomecare applications link patients from their home environment to hospital or community-based providers with ongoing monitoring of vital signs, and when indicated, videoconferencing contact on a scheduled or urgent basis. Reviews of these applications in the non-neonatal population have demonstrated improved control of chronic conditions such as diabetes and chronic heart failure, along with high levels of patient satisfaction (1,12). Data such as blood glucose, blood pressure, spirometry, or weight can be collected in the home by digital equipment and transmitted to a health care provider at a distance. Some applications include automated reminders about when to monitor and about opportunities to respond to specific questions to enhance the remote assessment and improve self-management. Access to assessment data on an ongoing basis allows providers to readily identify trends requiring intervention, and patients are motivated and reassured knowing their results are monitored routinely. Within the neonatal

setting, telehomecare can be a support to parents following discharge, a time when families may feel inadequate and may be reluctant or have difficulty accessing care. Telehomecare may include regular vital sign monitoring as well as videoconferencing to assess color or respiratory status in conditions such as congenital heart disease or bronchopulmonary dysplasia.

Figure 5-3 This image of an infant with ROP demonstrates the wide-field imaging capability of the RetCamII. (See color plate)

P.61

Postdischarge telehealth applications can include improved access to a wide range of disciplines and support systems, including follow-up developmental assessments, feeding assessments, speech and language therapy, genetic counseling, and many others. For neonates with ongoing health issues, telehealth can also provide access to patient education and support for families in rural locations, who may not have regular access to other families supporting a newborn with a chronic condition. Telehealth can provide key support for neonates as they transition out of the institutional setting, and it may result in earlier discharge and improved patient outcomes.

Continuing Education

The education of healthcare professionals involved in newborn care is critical to maximizing telehealth's potential to improve neonatal care. Continuing education is challenging, particularly for professionals working at a site removed from a tertiary center. It is now recommended that all hospitals delivering newborns should have an individual certified in the Neonatal Resuscitation Program present at the delivery. In addition to initial certification, recertification is required every two years. Cronin and associates (26) have demonstrated that instruction via interactive videoconferencing, including the testing of practical skills, can be provided satisfactorily. Similarly, Loewen and associates (27) have demonstrated that the neonatal stabilization program, S.T.A.B.L. E.[®] (sugar, temperature, artificial breathing, blood pressure, lab work, and emotional support), can be delivered effectively. In a study of 56 health professionals randomized to receive the program either in person or by videoconferencing, both groups, with similar pretest scores, had a similar, but significant increase in their posttest scores.

In Canada, trans-Canada rounds have been established to allow neonatal fellows from across the country to interact and share information on unusual cases. These sessions are highly interactive and in addition to improving knowledge, have resulted in an element of friendly competitiveness.

PRACTICAL STEPS IN GETTING STARTED

As telehealth moves away from pilot projects to operational telehealth networks, there have been many lessons learned and some consensus on the critical factors for success. This background of experience has provided a framework for developing new telehealth services or programs.

Needs Assessment

Experience has proven that time and resources spent on a needs assessment will result in the ability to design systems that truly meet the user requirements. The needs assessment process includes obtaining information and ideas from many groups involved in the delivery of health services to determine the goals, objectives, and priorities for telehealth. The clinical needs identified will drive the goals of the telehealth program and system design. Engaging clinical staff early and promoting buy-in will ensure that clinical needs remain the primary focus of telehealth programs and will begin the change management process necessary to integrate telehealth into clinical workflow. A well-structured telehealth needs assessment will not only define the clinical direction of a potential telehealth application or network, but will identify strategies to resolve issues that could potentially add long delays and increased costs to telehealth implementation.

Readiness Assessment

Prior to telehealth investment, there is a clear need to determine the “telehealth readiness” of communities and organizations to reduce the risk of failure and losses in time, money, and effort. Although there is a fundamental requirement for sufficient bandwidth to support telehealth, non-technical organizational factors are equally important to successful telehealth implementation. The perception of need and the ability and willingness of users to adapt to the changes associated with the introduction of telehealth can have enormous impact on adoption and utilization. Telehealth success depends upon selecting communities, organizations, and programs that are aware of telehealth and its benefits, have a genuine need for and commitment to telehealth, and can provide or acquire the capacity to support and resource telehealth beyond implementation.

Telehealth Business Plan

To successfully deploy and evolve a telehealth program, it is important to develop a telehealth business plan. The business plan serves as a guide for the organization and as a communications tool for external stakeholders and funders. This plan should be generated in collaboration with a range of staff and be revisited frequently in response to changes in the environment. The plan should fully describe the telehealth opportunity, products, and services to be provided; organizational structure; operational and

P.62

technical requirements; implementation plan; marketing and business development strategy; and financial analysis. There is increased pressure for telehealth programs to become viable commercial enterprises. Even in publicly funded health systems, telehealth is expected to show a return on investment realized through cost savings and improved health outcomes. The goal of the financial analysis is to define potential funding/revenue sources, expenses (capital and operating), and cost recovery, as well as to identify and mitigate financial risk. Projections should contain best-case, expected-case, and worst-case scenarios based upon a mix of alternative assumptions related to growth and use of the telehealth network, cost of operations, cost recovery, and sources of funding/revenue. Careful attention to longer-term sustainability is critical from the outset. Guidelines for developing a telehealth business plan can be found in several of

the listed references (2,28).

Program Management

Successful telehealth initiatives are built upon a robust operational infrastructure that ensures efficient delivery of telehealth services on a daily basis. In addition to the obvious need for technical training and support for users, there are many other functions required for effective telehealth program management including scheduling, policy and standards development, workflow and process design, marketing and communications, research and evaluation, and financial management. Strategic clinical leadership is also essential to ensure buy-in of key clinical providers, validate clinical telehealth applications, and develop clinical policies and risk management strategies. Understanding these functions and the related skills and competencies will allow a telehealth program to implement an appropriate organizational structure and human resource plan to support operations. The optimal organizational model will also be determined by the degree of telehealth integration into existing organizational structures and functions.

Evaluation and Quality Assurance Plan

Evaluation and quality assurance are vital to ensuring quality telehealth activities. To date, telehealth evaluation has focused on technical accuracy and reliability, diagnostic quality and effectiveness, impact on clinical management, user satisfaction, and impact on service or program costs (9,10). There is still great need for standardization of evaluation tools, measures and key indicators to assess the impact of telehealth on cost, quality, and accessibility of care. An effective evaluation plan will provide evidence to funding agencies, health care administrators, providers, and patients and will significantly contribute to the strategic development and sustainability of a telehealth program.

Healthcare organizations, including telehealth programs, are adopting a focus on quality improvement in response to increased demands for accountability, heightened consumer expectations, resource limitations, and fundamental changes in health service delivery models (29). Management tools such as the balanced scorecard are increasingly being adapted to the health care setting to guide ongoing evaluation and quality improvement initiatives and can be tailored to include telehealth and other ICTs (30,31,32,33). Regardless of the approach chosen, telehealth services should be continually monitored through a quality assurance process that allows rapid and responsive improvements to performance and the maintenance of quality practices. When possible, both evaluation and quality assurance processes should be aligned with broader program or organizational initiatives.

IMPLICATIONS FOR THE FUTURE

The introduction of advanced information and communications technology is inherently changing the way that medicine is practiced. With the introduction of health information systems, clinical decision support tools, and online learning, medical professionals are being provided the tools to support high-quality, evidence-based practice. Telehealth and the electronic health record allow access to health care services and information across sites, providers, and the continuum of care, removing the traditional organizational boundaries and building a foundation for integrated service delivery. These technologies are transforming the way that health care professionals and patients interact with the health care system. IP-based technologies will provide a convergence of data with images, video, and voice in a media-rich environment. Wireless network solutions will enable mobile access to the health care system and these supporting technologies.

Telehealth is about the relationships and processes that allow health care services to be delivered

virtually—it is not just about technology. Limits to telehealth expansion have less to do with access to bandwidth and equipment costs than the human factors. Telehealth initiatives must have the necessary time and resources committed to address not only the technical solution but also the process redesign, and change management necessary to encourage more widespread adoption of telehealth. Unless those involved with telehealth programs develop their skill and expertise in these areas, the programs will run the risk of limited user acceptance and poor network use. With the relatively high cost of implementation and operations, low utilization threatens the sustainability of any telehealth program.

Neonatology has been accused of focusing on the “high tech.” Telehealth is also viewed by some as yet another application of technology. Ultimately the fundamental purpose of both remains grounded in patient care and achieving the best possible outcomes for patients. Telehealth improves access to health care, which means access to specialist consultation for the neonate; improves access to education of health care professionals in the care of the neonate; and facilitates family involvement with

P.63

their newborn infant over distance. Telehealth applications in neonatology can range from “low-tech” home care applications to high-end intensive care and wireless transport communications. For both, the ultimate goal of improved patient care remains. To achieve this goal, regardless of the technical solution chosen, the need for building user acceptance and confidence, as well as simplifying the telehealth process to support integration into the workplace, is essential.

Chapter 6

Newborn Intensive Care Unit Design: Scientific and Practical Considerations

Robert D. White

Gilbert I. Martin

Judith Smith

Stanley N. Graven

DEVELOPING A MISSION STATEMENT

The first step in a successful newborn intensive care unit (NICU) design project is the development of a shared vision among NICU, hospital, and community leaders. The construction of a new unit or redesign of an existing facility should successfully address key problems in the region's current system of neonatal care. For an existing, stable unit wishing to modernize its facility, these problems may be primarily internal—the need for more space, current technology, and family support. For an entirely new facility, these issues will be predominantly external—who are the existing providers and what niche will this new unit most appropriately fill? A careful appraisal of medical care trends anticipated within the community over the next 20 years, especially with regard to obstetric and intensive care services, should precede any decision on a mission statement intended to guide NICU construction and operation. Whether a hospital is the only provider of NICU services in its area or one of several, it is crucial that it understand its niche and the responsibilities inherent to that role, so that appropriate physical facilities can be constructed to fulfill its mission.

A mission statement that might provide a framework for many NICUs is as follows:

The Newborn Intensive Care Unit will provide a state-of-the-art, integrated, family-centered approach to neonatal care. This interdisciplinary program will strive to give patients, families, and payers high quality and compassionate care through the provision of:

- Care that honors the racial, ethnic, cultural, religious, and socioeconomic diversity of family and staff
- Education, information, and emotional support
-

Access to the most current effective therapies

- Integrated treatment plans emphasizing coordination throughout the continuum of care
- Encouragement of family support and involvement

When consensus is reached on a mission statement, specific goals and objectives can be defined that apply this mission to the local realities of demographics, care practices, and competition. Defining these goals will be the first step toward decisions on bed capacity, types of equipment needed, and changes in care practices. All of these can then be explored in depth by the teams described below. The goals and objectives should be measurable (e.g., survival and morbidity rates compared to regional and national standards, staff experience and turnover, parental satisfaction ratings, cost per patient day) and realistic, so that the overall value of the project can be ascertained at the time cost projections are available, and on an ongoing basis after construction is complete.

CREATING THE TEAMS

Once a decision has been made to proceed with the development of either a new or a renovated NICU, it is important to form specialized teams with well-defined goals. In many hospitals, several persons will serve on two or more teams. Each team should have access to the several excellent reference materials available to assist in the design of an NICU (1,2,3,4,5,6).

The Strategic Planning Team

The strategic planning team will continue to develop the vision and goals that led to the decision to pursue new

P.65

construction. It should include, at a minimum, an administrator, a neonatologist, and a nursing director. This group will be responsible for reviewing utilization and demographic information (available from state and local planning and health agencies, the insurance industry, and the Census Bureau) in order to define the NICU's service area and appropriate number of beds. Some general guidelines in this area include estimates that 5% to 12% of all newborns will need intensive care at the time of birth, and 1% to 2% will need ventilator care. Total NICU days for a defined region will approximate 1.25 patient-days per live birth—if a region has 10,000 live births per year, it will generate approximately 13,000 NICU patient days, or an average census of 35 babies, with an average length of stay of 20 to 25 days. These numbers will be influenced considerably by the level of care

provided by a particular NICU, referral and back transport patterns, admission and discharge criteria, and competing NICUs serving the same region. Because of fluctuations in census, a unit should have sufficient bed positions to care for 40% to 50% more babies than the average census calculations, so a region with 10,000 deliveries per year will need 50 to 55 NICU beds. Many areas currently exceed this number by a sizable proportion because of serving a particularly high-risk population, or because of inefficiencies inherent in multiple NICUs serving a single region.

The strategic planning team also should make some basic calculations regarding staffing patterns, if this is to be a new service for the hospital. Depending on patient mix, overall staffing patterns may require 4 to 6 nurses and 2 support staff (inclusive of nursing administration, respiratory therapy, developmental therapy, social work, ward clerk, and housekeeping staff) for every 10 babies. A unit with an average census of 20 babies, for example, would require 8 to 12 nurses on each shift, or 40 to 65 full-time equivalents (FTEs), with an additional 20 to 25 FTEs for support staff. One neonatologist is needed for each 6 to 8 babies (average census); this is one area, among several, where units with an average census of less than 20 infants encounter certain inefficiencies because of their size. On the other hand, large units (more than 40 beds or so) can be difficult to design and manage efficiently because of the space requirements. Some hospitals have addressed this issue by dividing their NICU into intensive care and continuing care, or step-down areas. Some units will also need to plan staffing for transport team or nurse practitioner coverage. Six to 7 full-time positions are required for 24-hour coverage of each position for these services. A transport team with 2 nurses and a respiratory therapist, for example, would require at least 12 nurses and 6 therapists to provide full-time, in-house coverage.

Next, the strategic planning team also will need to assess the impact of the new or renovated NICU on other hospital departments, especially obstetric, maintenance, and supply services. When these issues are clear, the team will proceed to interview and engage an architect. The timing of this step is important—the architectural firm should be involved before any design decisions are made, but after the strategic planning team has articulated a clear set of goals for the process. Several architectural firms can be asked to make formal presentations of their general concepts for the project, as well as present examples of other projects that they have designed. The architectural firm chosen should have complete engineering and interior design specialists on staff, as well as an equipment representative and a neonatal nurse planner. The entire architectural team should be familiar with the latest trends in NICU design and the scientific principles behind the design process. Once chosen, the architectural group and the strategic planning team can then develop a timetable for planning and construction of the new facility.

The Financial Planning Team

This group is composed of the hospital's chief financial and operational officers, nursing management, and any other individuals representing areas of the hospital whose budgets will be significantly affected by the new construction. Consultants, such as those helpful in the equipment selection process (see Equipment Selection section), also may be asked to join the team. The one-time costs for the project will include architectural fees, the physical plant, and new equipment. Ongoing costs may include increased staffing for direct patient care, housekeeping, and maintenance functions. These costs should be clearly identified early in the planning sequence, with the assistance of the care practices team (see The Care Practices Team section). This team should continue to meet intermittently throughout the planning process, because some unanticipated expenses often surface as the design takes shape.

The Care Practices Team

This is the largest group, and it represents caregivers in the NICU. At a minimum, the following disciplines should participate: neonatology, nursing management and staff, respiratory therapy, social work, pharmacy, laboratory, radiology, infection control, nutrition, housekeeping, and parents. Depending on local care practices, surgery, obstetrics, and clinical research may be appropriate additions to this list. As each individual provides information on his or her own specialty to enhance care for babies, families, and staff, the team should be encouraged to look beyond existing practices and view the new construction as an opportunity to change the way things are done. In particular, most NICUs will need to reevaluate their care practices with respect to parental access and developmentally supportive care, which may have been severely restricted under their previous NICU design. They should consider environmental design features that will provide the most optimal living conditions for babies, working conditions for staff, and integration of families, and they should begin to address some of the conflicts inherent in these ideals. As a team, this group can then identify general

P.66

space, equipment, staffing, and maintenance and cleaning requirements, which can be reported to the financial and design teams for determination of feasibility.

The Design Team

When the strategic planning, financial planning, and care practice teams have agreed on the general scope of the project, including goals, approximate size and cost, major changes in care practices, and an architectural firm, the design team can begin its work. Members of this team should include the architectural group, the hospital's project manager, neonatology, nursing, respiratory therapy,

parents, and the equipment consultant. After creating a functional plan that addresses all the needs identified by the care practices team, this group should visit new or updated NICUs to get additional ideas, learn how to avoid pitfalls, and solicit suggestions on their functional plan. This team then will meet regularly over several months as blueprints are developed to reconcile all these concepts into a working unit. Detailed minutes should be kept and reviewed at the beginning of each meeting.

SITE VISITS

Touring other NICUs can be a valuable investment for many reasons, whether planning for a renovation or new construction. Visits provide a firsthand look at design features that are and are not working for others. The benefits can include a better plan, fewer change orders, and a smoother transition because the planning team gained new ideas and a clearer understanding of the pros and cons of the proposed changes.

Careful planning will assure that site visits are productive. Start by identifying the objectives of the tours, areas of greatest interest, potential units to visit, and the best timing. The typical purpose of a site visit during the early stages of planning is to trigger ideas. Many NICU teams find it useful to tour other units during the stage when they have identified their vision, defined their care practices, and prepared a preliminary functional program. Others stagger their tours and see different units during various stages of planning. Waiting until the preparation of construction documents is underway is not usually the best timing for initial site visits, unless the objective is to clarify operational issues related to the selected design approach.

Two other essential components to be addressed are selecting the members of the tour group and funding the travel. Selecting tour team members should tie back to the objectives. Most units request a budget for site visits as part of the project funding. Some fortunate units have donors who help with the travel budget, and even include interested donors on the tour team, when appropriate. If a travel budget is not feasible, the next best strategy is virtual tours. In many cases, the NICUs or their architects have photos in hard copy, on Web sites, videos or other material that could be viewed, and several of these are also available on a single Web site (6). A phone interview or written survey would be helpful to provide descriptive information for a virtual tour.

Tips for Planning a Site Visit

Performing the tasks below will enable the planning team to get maximum benefit from a site visit:

-

Interview key people by telephone or in person before touring their unit.

- Obtain permission to photograph, videotape, or receive audiovisuals already available from public relations, architects, and other sources. If assigning photography to a team member, assure that he or she has the proper equipment and competence.
- Design a questionnaire that will be used consistently as a guide for all visits.
- Assign a person or people to key topics to assure all pertinent questions are answered before, during, or after the tour. Categorize questions by area of interest, and create the expectation that the responsible person will report on the findings.
- Determine how the information from the tour will be used and by whom.
- After the visit and in a timely manner, discuss and record general impressions of people who toured the facility.

Sample Questionnaire

A questionnaire should be developed to ensure that all needed information in relation to a site visit is captured and recorded. Segments of the questionnaire could be contact information, general statistics, and specific questions.

Contact Information

The contact information should include:

- Date of Visit
- Organization Name/Location
- Contact Names/Titles
- Phone Numbers/E-mail Addresses/Web Site
-

Who attended from your organization

General Statistics

General statistics should include:

- Annual NICU volume (and birth volume, if relevant)
- Number of beds by level of care or other category
- Annual number of infant transports in and out
- Average length of stay (by level, if appropriate)
- Economic and cultural characteristics of population served
- Acuity of patients served (and information on how acuity is defined)
- Payer mix
- Date opened or renovated

P.67

Examples of Questions

The questions to ask at the site being visited should include, but not be limited to:

- Describe the changes that resulted in the current services and facilities and the reasons driving the changes.
- Were the objectives met? (How is success measured?)
- What types of NICU health professionals practice at this hospital (number of neonatal nurse practitioners (NNPs), neonatologists, residents, etc.)?

- What are the key staffing issues that were or need to be resolved?
- What type of staffing education programs, orientation, budget, and amount of time were required to make changes to the current model?
- How is each type of patient care room or area used?
- Where and how are most procedures handled?
- Describe communication systems among staff, between staff and families and others.
- Describe special features of unit.
- What was the biggest challenge related to this project?
- What would be done differently based on the wisdom learned from the experience?
- What were the benchmarks or other resources that were most helpful during the planning process?

Other Potential Topics for Questionnaire

Other topics that may be included on the site visit questionnaire are:

- Family input
- Visitation practices
- Family space
- Care practices
-

Admission process

- Maintenance
- Monitoring systems
- Lighting
- Sound control
- Interior design
- Storage
- Communication Systems Security
- Flow paths
- Cleaning
- Head walls
- Staffing
- Fundraising
- Total project costs
- Acceptance by staff/administration
- Response by community/competitors
- Ceiling/floor/wall/cabinet finishes patterns
- Coordination with labor and delivery

One of the final planning steps is to determine how the information gained from the site visit will be shared with the stakeholders who could not participate directly in the tour. Good documentation of the visits and effective presentation of the information will provide maximum benefit from the activities.

SPECIFIC DESIGN ISSUES

Floor Space Requirements

NICUs have historically been undersized, with insufficient room for storage, parental access, and offices, even when accurate estimates are made for the number of babies to be cared for. Change has been incremental, as administrators, architects, and NICU staff gradually expand their horizons to accommodate new practices, particularly increased parental access.

Given this historical perspective and extrapolating from floor space requirements in adult and pediatric intensive care units (ICUs), it is likely that an NICU design should allow 600 gross square feet per bed to meet the needs of the babies, staff, and families. This figure includes office, storage, and support space as well as the patient care areas; gross square footage estimates also include space required for hallways, ductwork, restrooms, and the like. This figure is an average; teaching hospitals with active clinical research programs, for example, might require more than 600 gross square feet per bed, whereas a community NICU might require somewhat less. Any design that provides less than 500 gross square feet per bed will inevitably demand compromises and limit flexibility for the future, when parental access desires and lengths of stay (because of increasing survival of extremely low-birth-weight infants) may be even greater than they are today.

Previous estimates of floor space requirements often recommended square footage per bed position (e.g., 120 to 150 square feet per intensive care bed position), and most state codes still use this convention. If this method is used, an additional 30 square feet of storage space must be planned outside of the patient care area, as well as 24 cubic feet of cabinet storage at each bedside, at a minimum.

Location Within the Hospital

The NICU should be immediately adjacent to the high-risk delivery rooms whenever possible. There are few, if any, NICUs that are more than a few hundred feet from a high-risk delivery service that do not consider their location as the source of certain risks to optimal care. In some circumstances, especially very large hospital complexes or freestanding children's hospitals, this ideal may be impossible to achieve. In the former situation, a resuscitation area within the

delivery room complex or in each delivery suite, always valuable, becomes crucial; in the latter case, all infants are accepted as transfers, and proximity to the ambulance entrance and heliport becomes particularly significant. When the NICU is on a different floor from the delivery suites, as often occurs in larger hospitals, controlled elevator access between these two areas is essential.

Many NICUs, particularly in small or medium-sized hospitals, share staff and responsibilities with the well baby nursery or pediatric ICU. When these areas are

P.68

contiguous, much of the support space (e.g., family lounge, staff lockers, equipment storage) can be shared, and the opportunities for staff to assist one another are enhanced.

Traffic patterns for infants who leave the NICU for procedures should be identified and private hallways created wherever possible, so that ill infants and their attendants do not need to use public areas.

Security Considerations

As family access to the NICU has become more prevalent, so have security considerations. Most NICUs now permit continuous access to families, so traffic in and out of the NICU is commonplace. Certain design features are necessary in this setting to protect babies and staff. First, the NICU should be designed with only a single public entrance. Other entrances and exits (e.g., to the delivery suite, the clean utility room, and the staff lockers) may be desirable, but these should be less apparent to the public (except as fire exits) and either within constant observation of the staff or equipped with alarms.

The public entrance to the NICU should be designed with the security of all major parties (babies, families, and staff) in mind. Families and staff need a secure locker area to store personal belongings. This area should be large enough to allow more than one family to enter or leave at a time and should be under constant observation. Electronic detection systems increasingly are being used in newborn nursery areas to prevent kidnapping; these are uncommon in NICU settings, but worthy of consideration if constant visual monitoring of all exits from the NICU is not feasible.

Fire exits should be carefully planned in the initial design, and clearly marked, as should the location of fire extinguishers. The fire marshal should be given the first draft of the design documents so that any problems can be corrected early.

Reception Area

In most NICUs, the reception area is part of or near the public entrance. This area also may encompass the family lounge and the ward clerk's workspace. The size

and layout of this space is highly dependent on the size of the NICU and its *culture*, or typical practices.

The family lounge should always be large enough to accommodate at least two families (6-10 people) comfortably, with seating that is comfortable, but not conducive to overnight sleeping. Lockers for valuables, a coffee pot, a television set, reading material (including informational and educational literature for families of NICU babies), and a toy box for children are items found in many such areas; public restrooms and telephones should be nearby.

Families and the public should be able to immediately reach an NICU staff member from the reception area. In some larger units, the contact person might be a full-time ward clerk; in others, it might be a hot line or direct visual contact into the patient care area. In any case, this function should be carefully thought out so that those who should be encouraged to enter (i.e., families) find themselves feeling welcomed, while others (e.g., curious individuals wandering through the hospital) are discouraged.

Direct Patient Care

As might be expected, the greatest design effort is spent creating the patient care area. The first and major decision to be made is the extent to which individualized environments are desirable. The goal to provide each baby with a space that is not impinged upon by noise, bright lights, and commotion from an adjacent bed position, and that has enough space to accommodate staff, family, and bedside equipment and storage seems intuitive and is certainly the norm for adult ICUs; but this has not historically been the pattern for NICUs, for several reasons.

NICUs in the 1970s and 1980s were routinely designed as large, open wards. These permitted care of the largest number of babies in a given space and allowed direct visibility of each baby by the staff, and of staff members by one another. Babies (and staff) were not thought to be adversely affected by the noise and bright lighting that were the norm for such designs. New practices and equipment (as long as they did not require much additional space) could be incorporated easily into this design, and highly variable census patterns also could be accommodated more easily than in the older premature nursery design of several smaller rooms. Parents were allowed, or expected, to visit for only short periods, so very little space at the bedside was allotted to them.

In recent years, many of these assumptions have changed. Direct, continuous observation of most babies no longer is considered necessary, thanks to improved monitoring systems (especially noninvasive oximetry and blood pressure monitoring), and certainly is no longer practiced except for the sickest babies, even in units where it is still physically possible. Babies clearly are affected by excessive, noxious levels of light and noise, and their response to these environmental hazards varies with their gestational age and medical condition.

Extensive adult studies in workplace settings also have established that staff needs and responses can be quite different from those of babies (7). Perhaps, most dramatically, family expectations have changed. Many families now want continuous access to their babies and want to be able to stay at the bedside—without interfering with the ability of staff to care for their baby—in any but the most extraordinary circumstances.

Designing an NICU that takes these newer realities into consideration requires establishing a local philosophy on individualized environments. In some units, private or semiprivate rooms for at least some of the infants will be considered desirable and feasible; in others, space, staffing, or philosophical considerations will lead the design team in a different direction. Often, a combination of “pods” (one, two, or four beds), with a larger room for recovering

P.69

neonates, has been the design of choice. In any NICU, however, the need for each baby to be protected as much as possible from the noise, light, and activity generated at other bed positions and the differing needs of babies from staff need to be discussed and integrated into the design process at the outset (8).

Certain principles can be established for all direct patient care area plans, regardless of whether a single large room, multiple smaller rooms, or private rooms are chosen as the model. First, each bed position must have sufficient space for families to stay for extended periods without interfering with staff duties. Second, each bed position must have individualized lighting, data entry, and communications systems. Third, traffic patterns must be well planned, with sufficient aisle widths to accommodate diagnostic equipment and personnel; generally, this requires aisles of at least 5 feet in width. Nursing functions should be separated from the bedside whenever possible. For babies, the NICU is perhaps ideally visualized as a bedroom for a sick infant; for staff, it is a workplace, where both work-related and social communication occurs. These concepts are often in conflict, yet the NICU design must accommodate both to the greatest extent possible. Therefore, the design team should (again, within the local culture and practices) separate those nursing functions that do not involve direct patient care (e.g., most charting, giving reports, receiving and making most phone calls) from the bedside to the greatest extent possible, especially if those activities require different lighting levels or create noise that would disturb the baby. This is done by providing adequate space for these functions away from the bedside, yet sufficiently proximate to allow appropriate response to the unpredictable needs of the baby. Finally, in any plan that uses modules or individual rooms, staffing patterns should be considered. In general, enough babies should be clustered together to justify staffing with at least three nurses. Designing smaller clusters creates significant staffing issues during those times when at least one nurse must leave the area.

After these considerations are adequately debated and decided, the general layout

of the patient care area can proceed. Each bed position can be identified, as well as nursing work areas (charting, medication preparation, etc.), sinks, and traffic flow patterns. At this point, an infectious disease specialist also should be consulted, to assure that the design is conducive to good infection control practices. This individual also will be interested in airflow considerations and in floor, wall, and ceiling finishes (discussed below). Proximity to other important support areas also will begin to take shape at this stage (specific design features for each of these areas are discussed in the next section).

The design team then can spend considerable time planning the layout of a typical bed position. Perhaps most important in this regard is the headwall, including monitoring and communication systems. Construction of a full-size mockup of an individual bed position, complete with headwall, monitors, and communications systems is well worth the effort and expense to be sure the ergonomics of the design have been adequately considered. Many members of the design team will be unable to fully visualize the layout from a blueprint, and it would be rare that a new NICU would resemble an existing design closely enough to bypass this step. Most NICUs will want to include one or more special care areas for isolation, treatment rooms, parent rooming in, and breast-feeding. In most units, some of these functions can be combined, and many will choose to eliminate one or more of these because of local practice patterns. The need for each should be carefully considered in new designs, however, and if not served by a dedicated space, at least clearly accommodated at some appropriate location in the NICU.

General Support Space

Clean utility, soiled utility, and general storage are functions that each require a dedicated space; in some units, a satellite pharmacy and clinical laboratory are also given designated areas. The layout of these rooms is straightforward; errors in design usually are made by allowing too little space or placing these rooms in an inconvenient position away from the direct patient care area. Ideally, these areas also should be accessible from an outside corridor so that restocking can take place without unnecessary traffic through the NICU, but this must be designed in accordance with security precautions (discussed previously). Storage areas should have a generous supply of electrical outlets and shelving so that battery-powered devices can be recharged. Additional specific considerations are outlined in each state's code documents and in several published guidelines (1,2,3).

Staff Support Space

As noted previously, some charting space, especially for the nursing and respiratory therapy staff, needs to be allocated within the direct patient care area. Additional space, especially for physician and nurse practitioner charting and

discussion, should be provided adjacent to the patient care area, so that the noise and activity generated there does not impinge on the babies' bedsides. The communications systems (phone, computer terminal, printer) that link the NICU with the hospital laboratory, pharmacy, and central supply generally will be situated in this area as well, which will benefit from being centrally located.

The staff lounge and locker room should be adjacent to the NICU, with restroom facilities integral or nearby. The lounge should be large enough to accommodate at least one third of all NICU staff (nurses, therapists, physicians, and other support staff) at one time and be accessible to the NICU by phone or intercom.

Several disciplines should have office space immediately adjacent to the NICU, including social work, medical and nursing administration, and developmental and respiratory therapy. When parent support or research staff

P.70

are actively involved in a unit's activities, they also will need nearby office space. On-call rooms and a conference room should be situated within this complex, with phone and computer links, including digital x-ray transmission, and restrooms with showers.

Family Support Space

In addition to generous provision of space at the bedside and in the family lounge, parents need space to stay overnight, to meet in private with staff to discuss their baby or to grieve, and to breast-feed. Again, depending on the size of the NICU and its local practices, some of these functions can be combined, but none can be ignored.

Rooming in, even with critically ill patients, is provided (indeed, encouraged) in most areas of a typical hospital, except for the NICU, where this practice usually is limited to those infants close to discharge. We are unaware of any documented factors, other than tradition, that justify the exclusion of parents from rooming in with NICU patients from immediately after birth, however, and suggest that future designs should anticipate that this practice will become more prevalent as families come to request and expect this opportunity. To be sure, many families will not choose or will be unable to room in with their ill newborn, so an ideal design need not anticipate that all babies will need space for rooming in at all times, but it should allow most parents who desire this privilege the opportunity to do so. Experience in NICUs that permit unlimited rooming in indicates that up to 50% of babies may have a family member staying overnight at a given time.

Breast-feeding of premature or ill infants is poorly accommodated in many existing NICUs because of space and privacy considerations. Mothers should be able to breast-feed babies at the bedside without compromising their privacy or being asked to wait until the baby is stable enough to be transferred to an area

where these problems do not exist. Alternatives in this regard include private rooms for those babies whose mothers plan to room in and/or breast-feed, or moveable partitions. Breast-feeding rooms are also a good alternative for babies who are healthy enough to be moved and can be utilized by mothers who need to use a breast pump. These rooms should be designed with most of the capabilities of a headwall (e.g., oxygen, suction, monitor, electrical outlets, and direct communication to the NICU staff), yet be as much like home as possible.

Room for parent education and counseling should be available within the NICU complex. This is particularly important when private discussions need to occur with families of critically ill infants.

The location and content of signs are often overlooked when planning an NICU. Some thought should be given to traffic patterns for families and the public from the hospital entrance(s) and how signage will be used to direct them clearly to the NICU. Information on signs should be phrased warmly, in a way that will make families feel welcome, rather than sternly, in a way that could make them feel like outsiders and intruders.

Lighting

Planning appropriate lighting for the NICU requires consideration of the disparate needs of both the babies and staff. In general, babies need very little light, but exposure to moderate levels of illumination during part of the day may help establish circadian rhythmicity.

Staff need moderate levels of illumination at the bedside to evaluate babies and to perform charting and manual tasks. At times, intense levels of illumination are necessary to perform procedures and for phototherapy of hyperbilirubinemia. It is doubtful that babies need natural lighting, but studies of adult office workers and hospital patients document the benefit of windows for staff and families (9).

Consideration of these disparate needs should lead the design team to plan a multilevel lighting scheme. At the bedside, a low level of indirect ambient lighting (200 to 300 lux [20 to 30 foot-candles]) is desirable, so the baby is not exposed to a continuous or direct bright light source. Task lighting, both for the bed surface and the nursing work surface(s), should be highly focused (framed), and rheostatically controlled, so that only the amount of light needed is provided, and only to the specific location desired. This may require multiple light sources at the bedside. The ideal task light would be adjustable to an infinite variety of positions, yet be able to recess fully into the wall or ceiling. It would have a beam of adjustable width and intensity and be free of shadowing effects.

At nursing work areas and traffic circulation areas elsewhere in the patient care area, moderate lighting levels (300 to 1,000 lux) are suitable. The light sources used should avoid glare, especially on work surfaces and computer terminals, and

should have multiple switches or rheostatic controls to allow flexibility in lighting levels. A single master switch may be useful, however, if a darkened room is desired for transillumination. All fixtures should have filters or shields that block ultraviolet radiation and minimize the risk to babies and staff if a bulb should shatter.

Provision of natural lighting is highly dependent on the NICU locale. Ideally, each room where adults spend several hours at a time would have a window with an attractive view, allowing the eye to escape and orient to external conditions. In the northern hemisphere, windows that face north are optimal, because they will not transmit glare or heat gain. Windows facing other directions should be appropriately shaded, either with an external overhang or with internal louvers. If the ability to completely darken the room is desired, internal (within a triple-glazed window unit) electrically operated louvers are essential. Because even well-insulated external windows allow some heat gain or loss, these should be situated several feet away from any baby's bed position.

P.71

Noise Abatement

The initial design issue in making an NICU as quiet as possible is to eliminate or reduce as many sources of background noise as possible. Some NICUs are situated in noisy communities, which requires extra insulation in the external walls to minimize the impingement of outside sounds into the NICU. Airflow through the heating and cooling ducts also can produce considerable background noise in an NICU, but this can be reduced through appropriate sizing and baffling of the ducts. These issues must be addressed in the design process, because it is prohibitively expensive to correct a poor design after construction begins.

Traffic patterns also play a role in determining the level of noise to which babies and staff are exposed. To the greatest extent possible, traffic flow should be designed so that an echocardiogram, ultrasound, x-ray, or electroencephalographic technician can get to each baby's bedside as directly as possible, without wheeling the equipment past several other bed positions. As noted previously, support areas should be designed so that restocking functions can be accomplished without creating unnecessary bedside traffic.

Noise production also should be a prime consideration in design of the monitoring and communication systems and in the selection of equipment. Whenever possible, equipment should be selected with a noise criterion rating of less than 40. Based on available data for sound levels that do not interfere with newborn sleep or adult conversation, overall background noise levels in the NICU should be maintained below 55 decibels on the A-weighted slow response scale, with peak levels not in excess of 70 dB (10).

Once all unnecessary sources of sound are minimized, the next design consideration is the abatement of unavoidable sound such as voices, equipment noise, and anything that might disturb a sleeping baby. Here, there is no substitute for adequate space, and another cogent argument for individualized environments becomes apparent. Increasing the distance between beds will diminish noise transfer from one baby's bedside to another, as will higher ceilings, especially those that are angled to reflect sound laterally rather than back to the bedside. Obviously, floor, wall, and ceiling materials are crucial in this regard (see the next section, Surface Finishes).

Finally, care practices should be evaluated as part of the design process to see whether many sources of noise produced by the staff can be diminished or eliminated. Radios, pagers, rounds, and reports are examples of care practices that may create considerable noise at the bedside, and that can be modified or eliminated.

Surface Finishes

In the past, selection of surface finishes was given little attention in NICU design, which focused primarily on integration of the newest technology. The choice of wall, ceiling, and floor finishes is important, however, for reasons of aesthetics, noise abatement, and infection control.

Perhaps the most controversial design issue in this regard is the choice between carpet and hard flooring. Hard flooring (usually a vinyl composite) is easily cleaned, durable, and provides little resistance to wheeled equipment. Carpeting provides noise abatement and may be more attractive and more comfortable to those who are on their feet for several hours a day. The differences between these two choices have started to blur in recent years, as carpet has become more durable and cleanable, and hard flooring has become more resilient and sound absorbent. It seems clear that vinyl or rubber flooring is the ideal for isolation, procedure, and clean and soiled utility areas and around sinks. Carpeting may be desirable for other areas; the direct patient care area is where this question remains most controversial. Carpet, however, has a significantly higher replacement factor and the hospital administration must demonstrate a commitment to the greater maintenance required to keep it clean.

Wall finishes increasingly include quilts or soft sculpture to provide aesthetic and sound-absorbent qualities. Extensive use of highly durable railings or moldings is necessary throughout the NICU, as walls are easily damaged by portable equipment.

Ceiling materials should be designated with a noise reduction coefficient (NRC) of at least 0.90. Many states are now allowing the use of certain types of nonfriable acoustical ceiling tile that helps with noise abatement. The method of cleaning the ceiling and changing lights should be considered in the design process so that this

can be accomplished with minimal disruption to patient care.

Infection Control Considerations

As noted previously, an infection control practitioner will be an important member of the design team during the discussion of the layout of the NICU and the choice of surface finishes. In addition, they will be helpful in discussing air quality issues in design of the heating and cooling system. They also will be very interested in the location and design of hand washing areas.

Sinks should be readily accessible throughout the NICU, within a few steps of any bedside. They should be large and deep, so that a full surgical scrub can be performed with minimal splatter, and the walls and floor surrounding them should be covered with easily cleanable surfaces. Porcelain sinks generally are more attractive and quieter in use than stainless steel. Faucets should operate hands-free; and soap, hand-drying supplies, and large trash receptacles should be easily accessible. These should be designed to avoid cross-contamination, to be easily cleanable, and to minimize noise production. At least some sinks should be provided for children and individuals with handicaps. Signage above each sink should contain written and pictorial hand-washing instructions. A convenient space for waterless hand-cleaning solutions should also be available at each bedside.

P.72

Headwalls

The area surrounding the baby's bedside, containing service outlets, shelving, and bedside storage, is commonly referred to as the "headwall." It is the focal point for creating a self-contained workstation at each bedside. This area must be easily adaptable to changes in census and acuity and to future changes in care practices. It must support and provide easy access to necessary equipment and supplies, as well as to the baby. The headwall design also should contain a comfortable working area for the staff and provide space for the family to personalize the baby's surroundings. There are several vendors that supply headwall systems, or these can be built on site, using either moveable or fixed-rail systems that can be customized for local equipment and practices.

A complete headwall system might include the following items and capabilities:

- Dimmer (rheostat)-controlled task lighting
- Three oxygen ports
-

Three compressed air ports

- Three vacuum ports
- Twenty to 30 electrical outlets
- Telephone jack
- Computer terminal jack

Consideration also should be given to allowing space for future needs.

All electrical, vacuum, and gas outlets need to be simultaneously and conveniently accessible, that is, usage of one outlet cannot obstruct other outlets, even when equipment contains oversized plugs. Some electrical outlets should provide normal power, whereas others should be on emergency power, because either system could be temporarily incapacitated.

A fixed or moveable shelf to contain monitoring equipment should be located as near to eye level as possible and within easy reach. A countertop should be provided as a work surface, with at least 24 cubic feet of cabinet space below to hold supplies. Raceways within this cabinetry to hold wiring and gas lines can minimize the danger and unattractiveness of a clutter of cords, but should be easily accessible for repairs or modifications. Support beams should be placed to avoid visual obstruction or access problems. A ledge at the base of the headwall will prevent moveable equipment, such as incubators or warmers, from damaging the wall.

Heating and Cooling Systems

Heating, ventilation, and air conditioning (HVAC) is perhaps the most mundane segment of NICU design, and the one in which most members of the design team feel they have the least expertise; yet it is important to consider for several reasons. We have previously discussed the contribution HVAC makes to background noise in the NICU, a problem that is amenable to some design considerations. The number of air changes per hour needs to be specified for the patient care area in general, and for the isolation and procedure areas in particular; minimums usually are dictated by state code. In the case of the isolation area(s) and soiled utility room, a negative air pressure design, with 100% of the air exhausted to the outside, is imperative. In all cases, a high-efficiency filtering system is needed to remove particulate matter from the air.

Control of temperature and humidity is particularly important when designing the

HVAC system for an NICU. The system should be able to maintain ambient temperature in the NICU between 72 and 78 degrees Fahrenheit throughout the year, even at the extremes of outside temperatures for that particular locale. A relative humidity of 30% to 60% should be maintained as well, again, even at local extremes externally. Maintaining temperature and humidity within these guidelines will minimize heat and water loss for the babies and discomfort for the staff.

Delivery of airflow into the unit requires considerable forethought. Return ducts should be situated near the floor so that particulate matter is not carried upward. Supply ducts should be located where drafts will not be a problem and should be generous in number, so that high-velocity air flow is avoided. Placement of supply ducts near external walls and windows should be carefully planned to avoid condensation and to minimize convective heat loss or gain to the babies nearby. The fresh air intake into the hospital HVAC system should be planned carefully to avoid areas that will contain exhaust fumes from vehicles, nearby buildings, or from the hospital itself.

Communication Systems

Communication systems comprise, perhaps, the segment of NICU design that requires the greatest anticipation of future developments. It is likely that communication patterns among NICU staff, and between the NICU and other support areas of the hospital (e.g., laboratory, radiology, and pharmacy), will change dramatically in the next decade. Likewise, information transfer among infant monitoring devices, the staff, and the medical record will accelerate rapidly in the same time frame. Because unit design and construction typically take several years, lack of foresight in this area can be inconvenient at best and often quite expensive.

Those planning an NICU should anticipate digital transfer of virtually all information. It is likely that the entire medical record will be computerized, and work areas within the patient care area should be designed accordingly, with adequate space to add terminals. Ergonomics and lighting should be considered, so that staff can work at these terminals with minimal strain. Monitoring systems will be interfaced with all the equipment supporting the baby, such as the incubator, ventilator, and intravenous pumps, and then with the patient chart. This will allow the obvious benefit of making data acquisition faster and more accurate, and it will provide new alternatives for patient alarm systems. At present, most NICUs depend on audible alarms to alert staff that a baby needs attention; but, in the

future, these alarms can be transmitted digitally to the staff via headsets, pagers, or other devices that will not add to the noise of the unit.

Telephone and intercom systems also will change drastically with newer technology. Much of the noise generated in the NICU is because of these devices, but alternatives already exist, such as wireless headsets, which allow communication to occur very efficiently without adding to noise levels. These systems also will facilitate communication among staff in the multiple room arrangement used in most NICUs currently being constructed. Because using these systems requires a considerable adjustment in the local culture of the NICU, the design process should include discussion with end users so that the system chosen will address their needs and concerns.

Maintenance Issues

Many NICU designs that looked good in the blueprint stage have required major revisions soon after construction because maintenance issues were not considered adequately. The choice of carpeting, lighting systems, HVAC design, computer devices, and bedside equipment should not be finalized until maintenance problems are identified fully with those who will be responsible for their upkeep. Many of these devices or systems cost more to maintain than to buy, so the economic perspective also should be considered carefully over the anticipated 15- to 20-year lifespan of the NICU, as well as the extent to which routine or unanticipated maintenance will interfere with patient care.

Designing for Renovations

Unless the pace of change slows dramatically, all NICUs will be faced with the desire to upgrade their facility every few years. Many of the suggestions (listed previously) are practical to implement without a major building program (e.g., reduced ambient lighting; some noise control measures; better, more welcoming signage). Others can be accomplished through a renovation-in-place project (e.g., adding carpeting, wall hangings, and acoustical tile; providing more rooming-in space for families), but some will be impossible without new construction and significant increases in available floor space. In the course of a new construction project, it will be impossible to anticipate all the changes that might occur in neonatal care and technology over the next 20 years, but a couple of general principles should be kept in mind.

First, there is no substitute for adequate space. The square footage needed for state-of-the-art NICU care has increased relentlessly, yet is still less per patient than that allotted to pediatric or adult ICUs in virtually all hospitals. Most NICU new construction projects completed in the last 20 years have been forced to accept reductions in floor space from the ideal for fiscal considerations, which often proved to be short sighted, as renovations were required only a few years later. It is hard to imagine new developments that would reduce the floor space requirements for NICUs, but it is easy to suggest those that might increase them,

such as increased parental access and continued development of new technology to improve monitoring, diagnosis, and thereby survival and outcome of extremely low-birth-weight infants.

Second, we are in the midst of a dramatic transition from the NICU as a high-tech, sterile (in every sense of the word) environment, to one that resembles a baby's bedroom, with all the implications that carries for parental access. This does not mean technology will disappear, or that many bedsides will not continue to resemble an operating room setup. It does suggest that this latter situation should be the exception, and that NICU design teams will need to consider the norm to be an area where each baby is surrounded by its family and a nurturing environment.

EQUIPMENT SELECTION

Equipment selection is an integral part of the planning process, whether for renovation or new construction. It is important to recognize that equipment features change rapidly and that, with the advance of technology, specific plans for space allocation and cost must be easily modifiable. Categories of equipment that will need to be specified include:

- Environmental (incubators, radiant warmers)
- Life support (ventilators, extracorporeal membrane oxygenation, nitric oxide systems)
- Monitors
- Diagnostic (x-ray, ultrasound, electronic scales)
- Treatment (infusion pumps, phototherapy, suction, chest percussion)
- Communications (telephone, computer terminals, printers)
- General support (breast milk, pharmacy refrigerators)

All users, as well as consultants familiar with the process of equipment inventory, planning, procurement, and installation, and with maintenance of the equipment, should be part of the planning team.

The first step of the equipment selection process involves preparing a list of all fixed and portable equipment that will be needed. Next, existing equipment should be evaluated to determine which items can be used in the newly constructed NICU. At this point, dimensions and general space and equipment-mounting requirements should be transmitted to the design team so that design of the patient care and storage areas can proceed while decisions are being made regarding purchase of new equipment.

The choice and procurement of new equipment is itself a several-step process. After deciding exactly what equipment will be needed and the budget available, the selection team should become familiar with options available in the market. If a considerable amount of new equipment is anticipated, it is wise to organize an exhibitors' day where

P.74

all the major vendors can demonstrate their products to the largest number of staff possible. Alternatively, most large medical and nursing conferences have displays by the major vendors.

When evaluating a new product, considerations should include ease of use, durability, ease of maintenance, the ability to interface easily with computer and monitor systems, hazards such as noise and electromagnetic radiation, size and portability, ability to upgrade, and cost. After all this information is gathered, the equipment consultant should organize it into a report that can be given to all interested parties (users, maintenance, and procurement staff) for comment. Procurement then can proceed with a request for bids, and a final purchasing decision can be made when these are available. A delivery schedule should be developed in coordination with the design and construction teams so that equipment will arrive in sufficient time to be assembled, tested, and installed before the NICU opens, but not so far in advance that upgrades and modifications in the technology occur while the equipment is sitting in storage.

After selecting the equipment, the financial planning team will need to consider decisions regarding purchase versus lease and service contracts on each item. Although many hospitals have standing policies for such decisions, certain factors may still be worth reviewing. If a piece of equipment is a newer model of an item from a manufacturer with which the hospital has had considerable experience, the biomedical maintenance department may feel quite comfortable with assuming the responsibility for repair without the benefit of a service contract, and purchase of the item usually will be less expensive than leasing in the long run (although the chief financial officer should confirm this based on the specific terms offered). However, if the piece of equipment is an entirely new device and only one or two are being acquired, lease or purchase with a service contract has considerable value in that repairs will be made by experienced technicians, and faulty equipment may be replaced more readily. In either case, the hospital should have a very clear understanding of how quickly service will be available, and whether

replacement items will be immediately available if repairs cannot be made promptly, especially if the equipment is crucial to the management of a critically ill child. These commitments should be obtained in writing, and their reliability confirmed by calling other units currently using similar equipment from each manufacturer.

Before installation occurs, the equipment consultant should review architectural, mechanical, electrical, and plumbing drawings to ensure that all specifications are current and compatible with the equipment that has been selected. There is nothing more frustrating than trying to install a piece of equipment that does not fit or has inadequate electrical or plumbing support. There are also many human dynamics that are crucial to this process, and the equipment consultant must be able to work with each of the specialists involved and organize a process that will be well structured and successfully implemented. Again, the construction of a full-sized, functional mockup of a patient care area should be considered as part of this process before final approval of the blueprints.

REVIEW AND APPROVAL PROCESS

After several months of planning, the architects will review the completed plans with the design team for final comment and approval. The hospital administration will be asked to sign off on a series of construction documents before submitting them to contractors for bids. Although it is common knowledge to architects and construction managers, many members of the design team may be unaware that changes after this time usually are expensive and sometimes impossible. A design that has considerable flexibility built in will become an obvious benefit, so that interim changes in care practices or equipment can be accommodated easily. When bids on the project are received, however, some major changes may still be required, because financial projections by the architects are, of necessity in such one-of-a-kind projects, only rough estimates. Sometimes compromises are fairly straightforward, such as:

- If aisles were generously sized, a reduction in all aisle widths by 1 foot might save tens of thousands of dollars.
- Bed positions might be reduced in number or size.
- Offices and conference areas might be reduced in size, shared with adjacent units, or redesigned as flexible-use spaces.

The mission statement developed at the beginning of the planning process

provides an important point of reference here. If compromises appear to be required that would make accomplishing that mission and the accompanying goals and objectives difficult or impossible, it may be more appropriate to revise the budget rather than the design or (particularly in areas that already have high-quality neonatal providers) to reconsider the project's feasibility altogether.

Before finalizing the blueprints, the design team should spend one more session exploring all the possible sources of unanticipated problems. Any device or system that could break or malfunction should be reevaluated to see if a change in the design would minimize the impact of such an event. For example, is there anything in, or attached to, the ceiling that could break or come loose and fall on a baby? Is there any wiring, plumbing, or ductwork hidden in a wall for which access might be very difficult or disruptive? Is there any passageway that might be obstructed by a piece of equipment just when a resuscitation became necessary? Architects cannot anticipate all of these events, which usually are not discussed in the planning process, and staff have difficulty visualizing the impact of such events from looking at blueprints, so this process usually is best done with several members of each discipline committed to brainstorming together for several hours. This is another reason visits to other NICUs can be particularly

P.75

valuable to one who is as interested in the flaws as well as the positive features of the design.

After a bid is accepted (a process that, like the choice of an architect, should be based not only on cost but on the extent and quality of the contractor's previous experience), a meeting should be held with the contractor and members of all the planning teams to be sure the construction team has "caught the vision" so carefully thought out over the previous months. Far from being simply contractors, the construction team can offer many helpful suggestions along the way if they understand the planning teams desires, especially with regard to specifics such as easily accessible wiring, minimizing noise generation from HVAC and plumbing supplies, and so forth. Walkthroughs should be performed regularly throughout the construction process, as multiple fine-tuning issues that were not anticipated in advance undoubtedly will occur. Any resulting changes from the architectural drawings should be documented carefully on "as is" drawings, so that future renovations are not hampered by unpleasant surprises.

HUMAN DYNAMICS CRUCIAL TO A SUCCESSFUL MOVE

In renovation projects, construction often must proceed in stages, while patient care continues to be provided in the existing unit. With either new construction or renovation, the implementation of new equipment and care practices can be both exciting and stressful, and it is not unusual for turnover of staff to increase around

the time of the move. There are two contrasting strategies that have been used to ease the transition to a new unit. One school of thought suggests that introducing new equipment and practices to the greatest extent possible before the move is valuable to minimize the culture shock of transition. An alternative strategy is based on the concept that acceptance of new practices is most successful when undertaken wholesale, especially if some issues that are anxiety provoking (e.g., increased access for families) are balanced by others about which the staff will be excited (more space, better equipment). In practice, the transition period requires belief of both philosophies, because some changes may not be possible until the new unit is built (e.g., rooming in for parents), whereas others will be desirable to implement as soon as possible (e.g., a new ventilator).

Certainly the most important strategy in this regard is to integrate the staff as fully as possible into the planning, design, and construction process. The staff must understand and buy into the conceptual changes intended by the mission statement and around which the design process proceeded. Attendance at committee meetings and posting blueprints are helpful in this regard, especially if comments are encouraged and used. Additionally, working with a full-scale mockup of a patient care area and occasional visits to the construction site are very helpful to those who have difficulty visualizing two-dimensional renderings.

CHANGE-IN-PLACE

The final step of any NICU construction is a commitment to "change-in-place." We are just beginning to understand the biological effects of the environment on premature infants, especially the positive and negative effects of light, sound, touch, movement, and smell at each gestation stage. Likewise, a better recognition of the role of parents and staff in the care and nurture of their babies will lead to improved care practices, and technological improvements are sure to continue. Each of these trends will influence our concept of the optimal NICU design and should be incorporated to the greatest extent possible on an ongoing basis within an existing structure, rather than waiting until new construction again becomes feasible. An agreement by all members of the planning process that the NICU will be considered a work in progress, rather than a finished edifice, will enhance the readiness of all disciplines to implement change when the need becomes apparent and will drive the design teams to build in as much flexibility as possible.

Chapter 7

Organization of Care and Quality in the NICU

Richard Powers

Carolyn Houska Lund

Providing current, research-based care to critically ill new borns requires the collaboration of highly skilled, dedicated, and motivated caregivers from a variety of disciplines. Professional nurses, physicians, respiratory therapists, social workers, developmental care specialists, pharmacists, clinical dietitians, and occupational and physical therapists have roles to play in planning, implementing, and evaluating care for infants and their families in the neonatal intensive care unit (NICU). This chapter includes a brief review of the basic organization and components of the NICU. An in-depth discussion of quality improvement is presented, including the systems to monitor and improve the quality of care in the NICU. These systems involve all professional disciplines and are integral in providing care to high-risk infants.

ORGANIZATION OF CARE

The organization of care in the NICU includes the medical staff working in collaboration with nursing and other departments in the care of patients in the NICU. Decisions about delivery of care, unit philosophy, and future directions are best made through this collaborative process rather than by any one department or discipline.

However, most NICUs are organized structurally and financially around the nursing component. The organization and functioning of a NICU is dependent on nursing leadership that can provide knowledgeable support and nursing input for the following functions: strategic planning, budget development and implementation, staff development, education, quality assurance and improvement, interdepartmental collaboration, and clinical standards development.

Nursing leadership is provided by nurses with advanced education, training, and experience in the following roles: nurse manager, clinical nurse specialist (CNS), neonatal nurse practitioner (NNP), nurse educator, transport or extracorporeal membrane oxygenation (ECMO) coordinator, and case manager. Depending on the size and complexity of the NICU, some of these roles may be combined.

Caregivers who work in the NICU require emotional support because of the high stress and sensitive nature of their work with critically ill infants and families. The

nursing leadership group actively seeks out situations that are stressful to staff and provides support to staff through stress debriefing and staff case conferences. Referrals to hospital ethics committees and appropriate professionals such as psychologists, psychiatric nurse liaisons, chaplains, and employee assistance programs should be made early to assist staff when needed.

Nurse Manager

The nurse manager has overall responsibility for the day-to-day operation of the NICU and for coordinating and collaborating with the medical staff, other department directors, and nursing managers from other units. The manager is usually expected to plan and implement both capital and operations budgets. Further, the manager works with the nursing leadership team to ensure that education, ongoing development, and competency of the nursing staff are attained. The nursing leadership group, in collaboration with the medical team and ancillary disciplines, is also responsible for assuring that the quality of care delivered in the NICU is safe and appropriate, meets regulatory standards, and demonstrates a commitment to ongoing quality improvement.

Although the nurse manager and nursing leadership group are accountable for the care delivered in the NICU, the staff nurses are the keystones of care delivery. Therefore, facilitating staff participation at every level of decision making is critical to the success of any unit operations. In some units, this collaboration may be formalized through a system of shared governance in which staff nurses are empowered to govern many aspects of unit operations. However, even in more traditional organizational

P.77

structures, participation by staff is critical to the successful operation of the unit.

Advanced-practice Nurses

The CNS is an advanced practice nurse at the master's degree level. In a nonline position in the nursing structure, the CNS generally has no direct authority over other staff. The CNS role involves direct clinical care, consultation to nursing staff and other professionals, and education of staff and parents. Research is a component of the CNS role, and this is accomplished by keeping abreast of current research applicable to neonatal care, implementing research-based practices, supporting and facilitating research efforts in the NICU, and participating in research studies as primary investigator or co-investigator. Maintaining quality of care is another aspect of CNS practice; monitoring care practices, identifying problems, and participating in the NICU multidisciplinary practice committee are essential aspects of the CNS role and its effective implementation in the NICU (1).

Many units use the CNS in case management functions. Case management, a

model of care delivery, focuses on multidisciplinary care throughout hospitalization to achieve desired patient outcomes in an expected time frame and with efficient use of resources (2,3). Within this model, the CNS follows a caseload of patients throughout their lengths of stay in the NICU, consulting with nursing staff, physicians, and other team members about the patients' expected courses and any variations that occur. The CNS coordinates the interdisciplinary model through weekly interdisciplinary rounds to discuss medical and social aspects of care for each infant in the NICU and identify needed interventions, procedures, or family communication. The CNS may identify a need for individual patient care conferences during which medical staff, nurses, and specialty consultants discuss a complicated patient and establish reasonable goals with evaluation criteria.

The NNP has formal education and certification in the medical management of high-risk newborns. NNPs generally carry a caseload of neonatal patients with consultation, collaboration, and supervision from a neonatologist. With extensive knowledge of physiology, pathophysiology, and pharmacology, the NNP functions both independently and interdependently with physicians in the assessment, diagnosis, and implementation of specific medical practices and procedures. Other responsibilities may include delivery room resuscitation, stabilization and transport either within the hospital or to other facilities, education, consultation, and research at varying levels (1,4,5). In addition to advanced-practice nurses, other nursing roles include neonatal clinical educators, outreach educators, transport nurses, discharge planners, nursing shift coordinators, and ECMO specialists.

The role of the charge nurse in the NICU is an important leadership position in the daily operations of the unit. Charge nurses may be nurse managers, shift coordinators, or experienced staff nurses responsible for the smooth functioning of the unit during each shift in a 24-hour day. Among their responsibilities are evaluating the number and level of acuity of all infants to determine the number of nursing and support staff required, and communicating the assignments of patients and staff. Charge nurses also arrange incoming and outgoing transports and may, in some settings, attend high-risk deliveries. They are often the "extra pair of hands" needed during emergency situations or special procedures, are consulted by other nurses in problem situations and conflict resolution, and become involved in crisis intervention with families. Astute assessment and problem-solving skills, along with excellent communication abilities, are necessary in the successful implementation of the charge nurse role and the daily running of the NICU.

Staff nurses help families in their adaptation to and resolution of crisis by providing consistency in the delivery of daily nursing care. Infants are regularly assigned to a nurse or a group of nurses on admission or shortly thereafter, and consistent care is delivered by this primary nurse or primary team throughout the hospital course.

Primary nurses provide direct patient care, organize and write individual care

plans, and collaborate with the neonatologist, social worker, and advanced-practice nurse to facilitate the smooth transition of the infant throughout the hospital stay and discharge from the NICU. They have extensive knowledge about the individual responses of patients for whom they care on a daily basis and are invaluable to the neonatologist and other team members. Primary nursing care lends itself well to the developmental care that is specific in both assessment and interventions aimed at the individual needs and unique characteristics of neonatal patients.

Primary nursing is highly valued by families of infants in the NICU. Seeing the same person caring for their infant is comforting and establishes trust during this period of crisis and disequilibrium for families. Families often share their feelings and reactions with someone they have come to know and trust; this is often the primary nurse.

Other essential roles are necessary for the safe and effective functioning of the NICU. Respiratory specialists provide expertise in the NICU in areas of pulmonary care and assisted ventilation. Clinical dietitians consult regularly for both parenteral and enteral nutrition issues. Pharmacists assist regarding the safe and appropriate use of the multitude of medications administered in the NICU, as well as monitoring for adverse drug reactions and side effects. Developmental specialists, along with occupational and physical therapists, are responsible for the integration of developmentally appropriate interventions for specific infants, as well as educating other team members about developmental care and assisting in environmental modifications which can improve patient comfort and possibly even outcomes. Social workers assist in crisis intervention and provide psychosocial assessment and emotional support as they advocate for the wide range of families that encounter the NICU experience. In culturally diverse settings, translators are indispensable in the NICU to ensure that information is accurately provided to families.

Family-centered Care

The initial phase of hospitalization for high-risk infants results in significant disequilibrium for families. The expected outcome of their pregnancy has been changed from a healthy, full-term newborn to a premature newborn or a newborn with significant medical or surgical problems. With prenatal detection of problems, as well as perinatal care for premature labor, the families may have some idea of the situation they are facing. Yet, many have not faced a crisis of such importance and may need help in developing coping skills, understanding complicated medical information, and learning how to be an advocate for their infant. Nurses use therapeutic communication, crisis intervention, and supportive techniques to assist families during this time (6).

Because many families may have additional social risk factors, including language or cultural differences, poverty, chronic illness, or substance abuse, knowledge about the impact of these factors on coping with crises and parenting is needed. The importance of early intervention cannot be emphasized strongly enough, and interventions by neonatal nurses along with NICU social workers and neonatologists can have considerable positive effects for high-risk families during this time of disequilibrium.

Family-centered care is both a philosophy and approach to care that can enhance the potential of families to cope with the crisis and experience a positive outcome. Principles for family-centered neonatal care include open and honest communication in both medical and ethical considerations, providing in-depth medical information in terms that are meaningful, and accessibility to other parents who have had infants in similar circumstances. Information is provided to families early if neonatal problems are diagnosed prenatally. Parents are allowed to make decisions for their infants about aggressive treatments once they are fully informed with adequate medical knowledge. Additional areas addressed in family-centered care are alleviation of pain, ensuring an appropriate environment, providing safe and effective treatments, and policies and programs that promote parenting skills and maximum involvement of families with their infants in the NICU (7,8,9). Key elements of family-centered care are outlined in Table 7-1.

TABLE 7-1 THE KEY ELEMENTS OF FAMILY-CENTERED CARE

Incorporating into policy and practice the recognition that the family is the constant in a child's life while the service systems and support personnel within those systems fluctuate.

Facilitating family/professional collaboration at all levels of hospital, home, and community care:

- Care of an individual child

- Program development, implementation, evaluation, and evolution

- Policy formation

Exchanging complete and unbiased information between families and professionals in a supportive manner at all times.

Incorporating into policy and practice the recognition and honoring of cultural diversity, strengths, and individuality within and across all families, including ethnic, racial, spiritual, social, economic, educational, and geographic diversity.

Recognizing and respecting different methods of coping and implementing comprehensive policies and programs that provide developmental, educational, emotional, environmental, and financial supports to meet the diverse needs of families.

Encouraging and facilitating family-to-family support and networking.

Ensuring that hospital, home, and community service and support systems

for children needing specialized health and developmental care and their families are flexible, accessible, and comprehensive in responding to diverse family-identified needs.

Appreciating families as families and children as children, recognizing that they possess a wide range of strengths, concerns, emotions, and aspirations beyond their need for specialized health and developmental services and support.

(Reprinted from Shelton T, Stepanek JS. Family-centered care for children needing specialized health and development services. Bethesda: Association for the Care of Children's Health, 1994, with permission.)

Parent and family education are necessary throughout the hospitalization in the NICU. Initially parents need information about their infant's medical condition and what the prognosis is, as well as an introduction to the NICU personnel they encounter ("who does what"). Pamphlets and booklets about premature infants or specific disease conditions may be helpful. There are also several books written by parents or NICU professionals that contain detailed information, illustrations, and accounts of other parents' reactions to the experience in the NICU (10,11). The Internet is another source of information for parents. Each unit should wisely evaluate which resources on the Internet contain the most up-to-date, factual, nonbiased information about specific conditions and post these resources for parents to access if they wish. Although written information is valuable, it is not a substitution for conferences and verbal interchange with parents. These conferences are focused on what the professional staff expects that the family needs to hear, what the parents are concerned about, and the parents' feelings and reactions to what is happening to them and their infant. Nurses can help parents become involved in the physical care of their

P.79

infant by showing them the things they can do such as comfort measures, bathing, skin or mouth care, changing diapers, taking the temperature, holding as soon as their infant is stable on the ventilator or oxygen (Fig. 7-1), and providing breast milk.

Figure 7-1 Photo of a mother holding her ventilated preemie skin to skin.

Discharge teaching is an important aspect of family-centered care. This includes well-baby care with knowledge about specific patterns of feeding, sleeping, urination, stooling, breathing, skin care, and appropriate use of infant car seats. Teaching about medication administration, including the purpose, method of administration, side effects, and where to obtain the medications, is essential. Special needs are described and skills taught, including gavage or gastrostomy feeding, oxygen administration, ostomy care, tracheostomy care, cardiorespiratory monitoring, and others. Different disease processes or conditions are identified for parents, such as bronchopulmonary dysplasia, short-bowel syndrome, and hydrocephalus, and symptoms are identified for parents so they can assess and seek medical care appropriately after the infant is home (12,13).

QUALITY IN THE NEONATAL INTENSIVE CARE UNIT

The many disciplines and personnel described above provide the structure around the delivery of care in the NICU. However, to move beyond day-to-day care delivery and improve the quality of care, a sound knowledge base in quality improvement theory and practice is essential.

Background of Quality Improvement

Over the past decades, medicine has witnessed a rapid expansion of knowledge and technology. This expansion has occurred in parallel with financial pressures brought on by inexorable increases in per capita costs of health care and limitations in financial resources available to the health care system. These forces are especially applicable to intensive care subspecialties such as neonatology on

which a significant amount of research and technology is focused and for which delivery of care can be extremely costly.

Research in the form of randomized controlled trials (RCTs) has become the “gold standard” for evaluating the efficacy of health care interventions. In 1966, about 100 articles were published annually in all fields of medicine from RCTs; by 1995, more than 10,000 were published (14). More than 3,000 articles about neonatology RCTs have been published alone (15).

In the face of this avalanche of information on clinical efficacy and rapid infusion of technology driven by the computer and pharmaceutical industries, health care workers and institutions have major challenges before them. Individuals in health care organizations need to efficiently evaluate new interventions and adopt the most compelling ones in a timely manner to provide optimal patient care and avoid preventable complications. It is through the principles of quality improvement, along with organizational adaptability, that continuous integration of research, technology, and improved patient care outcomes is accomplished.

Quality of care is defined by the Institute of Medicine as “the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge” (16). This definition, first proposed in 1990, has become widely accepted and is still considered the best definition of health care quality today. The concept of “health services for individuals and populations” is especially important in neonatology where evaluation is often determined by population data such as infant and neonatal mortality rates or the incidence of neurological deficits among a specific subgroup such as extremely low-birth-weight survivors.

The definition also emphasizes that quality care “increases the likelihood” of beneficial outcomes, a reminder that quality is not merely the achievement of positive outcomes. Poor outcomes occur despite excellent care because diseases vary in severity and can defeat even the best efforts. Conversely, patients may do well despite poor quality of care. Assessing quality thus requires attention to both processes and outcomes of care. The last part of the definition of quality, “consistent with current knowledge” highlights the dynamic and evolving body of knowledge available to health care professionals and the need to revise and update measures of quality as new interventions become standards of care.

Problems in quality of health care can be classified in three categories: underuse, overuse, and misuse (14). Underuse is the failure to provide a health care service when it would have produced a favorable outcome. For example, failure to provide surfactant in a timely manner after the delivery of an extremely low-birth-weight infant with respiratory distress syndrome would indicate underuse. Overuse occurs when a health care service is provided despite the fact that its potential for harm exceeds its possible benefit.

The widespread use of postnatal steroids for chronic lung disease popular in the 1990s is an example of overuse in neonatology. Misuse occurs when a preventable complication arises during administration of an appropriately selected treatment. Misuse includes many of the common medical errors that occur during hospitalization or other health care encounters. Medical errors have been extensively discussed (17,18), driving numerous initiatives by the United States (U.S.) government and regulatory agencies aimed at understanding the human and systems factors that contribute to the errors. External reporting systems that collect information on adverse events and errors are important in the reduction of future errors by alerting practitioners to new hazards, using the experience of individual hospitals using new methods to prevent errors, and revealing trends that require attention (19). In neonatology, medical errors have been collated and classified as part of an anonymous error-reporting project in conjunction with the NIC/Q Quality Improvement Collaborative of the Vermont Oxford Network (Table 7-2) (20).

Regulatory agencies, in conjunction with federal and state governments, have traditionally been charged with the task of motivating health care professionals and organizations to maintain and improve quality. The Joint Commission on Accreditation of Healthcare Organizations, formed in 1951, initially developed standards for hospitals and evaluated compliance to these standards, hypothesizing that compliance with these standards would correlate with quality care and positive outcomes for patients in hospitals. In accreditation, quality is evaluated by monitoring adherence to accepted standards and measuring outcomes. Standards used by accreditation organizations are derived from a variety of sources, including government (via regulatory agencies at both the federal and state levels), as well as professional and community-based, standards of practice.

Regulation is for the most part successful in establishing minimal standards of performance and is an important means of protecting the public from egregiously poor providers. It has, however, numerous limitations. Standards are difficult to enforce uniformly, and regulation tends to be inflexible with difficulty in adapting quickly as knowledge changes. Regulation also fails to stimulate organizations to integrate new technologies or developments and does not motivate them to continuously improve. Continuous quality improvement (CQI) can supplement the deficiencies of regulation alone, while providing an impetus for individuals and organizations to strive for the highest quality of care.

TABLE 7-2 CLASSIFICATION OF MEDICAL ERRORS IN NEONATOLOGY(20)

Error Classification	Percent of Errors
Wrong medication/dose/schedule/infusion rate	53.4%
Error in performance of operation, procedure or test	12%
Patient misidentification	7.8%
Error in administration or method of using a treatment	7%
Error or delay in diagnosis	4.7%
Equipment failure	2.3%
Failure of communication	1.3%
Other system failure	6.7%

Continuous Quality Improvement

CQI emerges from the industrial sector as an effective system to reduce errors in production. It motivates good performers to excel, emphasizes identification of potentially successful change opportunities, and facilitates change implementation throughout all levels of the organization. CQI provides the framework for organizations to keep abreast of current knowledge and innovations, identify appropriate changes, and implement them in a timely manner. There are three components to CQI: measurement, benchmarking, and collaboration.

Measurement

The first and most basic element of CQI is the acquisition of data. Data acquisition drives information, which in turn drives action. Over the past 25 years, numerous systems of quality measurement have been developed, encompassing the areas of outcomes, processes, and patient satisfaction.

Outcome measures represent the most objective and often the most meaningful data for health care organizations. When applied to populations, outcome measures provide essential feedback to leaders charged with resource allocation, managers charged with developing successful and efficient organizations, and individual health care providers.

Due to variability in disease severity among patients from different socioeconomic and cultural backgrounds, as well as differences in the type of patients cared for in highly specialized tertiary centers compared to community health facilities, data based on outcomes alone can be inaccurate or misleading. Process measures are also important in evaluating overall quality. Measures of process are needed to determine that accepted standards of care are being met regardless of good or bad outcomes.

TABLE 7-3 TYPICAL QUALITY IMPROVEMENT MEASURES

Process measures

Intrapartum antibiotics for mothers with positive group B strep cultures
Intrapartum antibiotics for mothers with group B strep risk factors
Antenatal steroid use
Admission temperature
Postnatal steroid use
Surfactant administration
Incidence of hypocarbia ($\text{PaCO}_2 < 30$)

Outcome measures

Mean 1-minute and 5-minute Apgar scores
Survival rate
Length of stay
Incidence of chronic lung disease
Incidence retinopathy of prematurity
Incidence of intraventricular hemorrhage
Nosocomial infection rate

Patient satisfaction measures^a

Comfort of facilities
Appearance of room
Nurses' attitudes toward requests
Facilities for family information provided
Doctor's concern for questions/worries

^a From Press, Ganey Associates, Inc., South Bend, IN. 2002

P.81

A third category of measurement in assessing quality of care is patient and family satisfaction. This is the result of applying traditional marketing techniques to the health care industry, and it has accompanied the adoption of CQI principles from industry to health care. It is also a natural result of a larger movement throughout health care that recognizes the autonomy and accountability of the patient and family. As the health care community expands its expectations that patients and their families take on a larger part of the responsibility to maintain their own health and wellness, the feedback obtained from patients and families regarding their interaction with the health care system is crucial. Table 7-3 shows examples of neonatology quality measures in the three areas of outcomes, processes, and patient satisfaction.

Benchmarking: Use of Comparative Databases

The second step in the process of CQI is benchmarking of outcomes. Opportunities

for benchmarking are numerous, thanks to the recognition in the past 15 years of the contribution it brings to CQI. A number of regional, national, and international databases have been organized in neonatology, providing benchmarking opportunities through voluntary participation and confidential reporting of individual center outcomes.

One of the first neonatology databases, and currently the largest, is the Vermont Oxford Neonatal (VON) Network. Started in 1990 with 36 hospitals, this network has grown to 380 centers (21,22). The network includes data on more than 25,000 very low-birth-weight (<1,500 g; VLBW) infants each year, more than 50% of all VLBW infants born in the United States annually.

In the VON Network, centers report outcomes, including survival and lengths of stay for all VLBW infants admitted to the NICU. They also report incidence of chronic lung disease and complications, including nosocomial infection, pneumothorax, necrotizing enterocolitis, intraventricular hemorrhage, retinopathy of prematurity, and other conditions. All participating centers receive a confidential annual report showing their performance compared with the database as a whole. Each center can see how they rank with all other centers, and with centers that are grouped in similar categories by number and type of NICU admissions. In the VON Network, all of the variables are reported in aggregate form showing the mean incidence rate and highest and lowest quartile of each measure. The mortality rate and length of stay for each center is also adjusted for patient acuity.

Other databases have been formed at regional and national levels. The National Institute of Child Health and Development Neonatal Research Network provides a venue for participating institutions to submit outcome measures; their aggregate data has been published to serve as a reference for other centers to compare their performances. These include general survival and complication rates in VLBW infants (23,24) and rates of neurological abnormalities (25). The Canadian Neonatal Network has published reports tracking overall outcomes and complications in infants of all gestational ages (26,27,28). Other national networks include the Scottish Neonatal Consultants and Nurses Collaborative Study Group, New South Wales Neonatal Intensive Care Unit Study Group, and Paulista Collaborative Group on Neonatal Care in Brazil (29,30,31).

Variability in Neonatal Intensive Care Unit Outcomes

Variability in neonatal outcomes becomes apparent when data from multiple newborn intensive care units is analyzed in comparative databases. The VON data describing the first full year of the collaborative in 1990 showed a number of differences in outcomes among VLBW infants in the 36 reporting centers. These included the incidence of respiratory distress syndrome, pneumothorax, chronic lung disease, patent ductus arteriosus, nosocomial infection, intraventricular

hemorrhage, and retinopathy of prematurity (22). The annual VON reports provide the distribution of outcomes among centers by ranking the data and calculating the 25th and 75th percentiles for mean incidence of the given outcome from each center. Percentile ranking of mean values from individual centers represents a simple and effective means of illustrating one center's ranking among the entire sample of participants. Table 7-4 shows the 2001 data from the VON database, illustrating this methodology for selected outcomes (32).

Investigators also report variation in outcomes as part of multicenter prospective interventional trials or retrospectively as multicenter independent research. Brodie and

P.82

associates (33) studied nosocomial bloodstream infections in VLBW infants in 6 NICUs in the Boston area from 1994 to 1996; mean incidence of infections was 19.1% for the whole group, but varied from 8.5% to 42% among the 6 units. After adjusting for patient- and treatment-related variables, significant variation persisted. Variations in blood transfusions among 6 perinatal centers in Massachusetts and Rhode Island were studied, showing a mean total transfused volume ranging from 95.5 mL/kg (highest) to 35.0 mL/kg (lowest) (34). Avery and associates (35) described the variability in incidence of chronic lung disease among 8 units surveyed. Later, an in-depth review of the practices related to respiratory support for infants with respiratory distress syndrome was undertaken at the 8 centers, triggering the study and dissemination of a number of innovations in respiratory care practices from the unit reporting the best outcome.

TABLE 7-4 OUTCOMES AND INTERVENTIONS (VERMONT OXFORD NETWORK 2001, 32)

Outcome/Intervention	Percent	Interquartile Range (25th, 75th Percentile)
Respiratory distress syndrome	72	63,82
Pneumothorax	6	3,7
Oxygen use	90	86,96
Nasal CPAP use	60	60,73
Ventilation	71	63,80
Chronic lung disease	29	17,36
Patent ductus arteriosus	33	22,40
Necrotizing enterocolitis	6	2,8
Nosocomial infection	21	12,26
Intraventricular hemorrhage		
Grade 3	4	2,6
Grade 4	5	2,7
Retinopathy of prematurity		

Stage 3	10	5,13
Stage 4	1	0,0
CPAP, continuous positive air pressure.		

Wide variation in outcomes among centers is often found when centers participate in comparative outcome studies. Even when the data has been adjusted for confounding risk factors, marked variability still exists in many cases. Explanations for this persistent variation include differences in case mix, data quality, and case finding. However, the final and most important factor is often variation in effectiveness of clinical practice.

It can be extremely useful and important for units to recognize how clinical effectiveness contributes to variability, especially in areas where the outcomes for the unit are in the lowest quartile. One of the major benefits of participating in the comparative analyses of outcome measures lies in the understanding that changing clinical care practices truly can influence their outcomes. In most cases, individual units find outcomes in the lowest quartile for only a few variables of the data set, with the majority falling within the interquartile range (25th-75th percentile) or even exceeding the 75th percentile. The lowest quartile outcomes provide target areas to which focused improvement efforts can be directed. Furthermore, centers in the database that report better outcomes can be used as resources to identify practices that may benefit centers in the lowest quartile.

Identification of benchmark data through concurrent measurement among centers represents only one model for benchmarking. Published data can also be used as a benchmark when concurrent data is not available. It is important to review the methodology and data definitions in the published benchmark paper to allow for consistency in data acquisition before any extrinsic comparison can be made. An example is the nosocomial infection rates published by the National Nosocomial Infection Surveillance project of the Centers for Disease Control which is used by many NICUs to analyze their infection prevalence (36).

Collaboration

The concept of institutions collaborating with each other for the purpose of improving overall quality of care is novel, yet essential, in successfully and efficiently changing health care. Comparative databases with institutions prospectively reporting outcomes to identify opportunities for improvement are an example of how collaboration can benefit organizations. Collaboration is equally important for implementing practices that enable institutions to adopt new technology and bring about improved methods of delivering care.

Collaboration among different and sometimes competing companies is found in industries outside of health care. For example, in the semiconductor manufacturing industry

corporations must maintain the pace of technologic research and development to compete. Yet 10 of the largest U.S. semiconductor manufacturers, including Intel, Motorola, Advanced Micro Devices, and Texas Instruments, joined forces in the mid-1990s to form a company called Sematech to foster mutual information and advancement (Austin, TX) (37).

This motivation to achieve common improvement goals among different organizations has led to the formation of numerous quality improvement collaboratives in health care. A number of factors serve as incentives to collaboration. First is the substantial gap that exists between current knowledge and the actual provision of care. Second, collaboration among institutions can accelerate the infusion of existing knowledge into practice by providing insight into how the centers with the best outcomes were able to implement systems that yielded these results. Despite abundant literature describing practices that should or should not be done, little is written about specific activities that facilitate implementing desired practices (37). Dialogue between units, as well as visits involving a multidisciplinary team from one unit to another, provides an exchange of ideas and solutions to clinical problems.

The Institute of Healthcare Improvement Breakthrough Series is an example of large collaboratives working to accomplish common aims, including reducing cesarean section rates, improving asthma care, reducing adverse drug events and others (38,39,40). The NIC/Q Collaboratives on Quality Improvement in Neonatology, organized by the VON, have identified the goal of improving neonatal outcomes in chronic lung disease, nosocomial infection, nutrition and other areas (22). The California Perinatal Quality Care Collaborative is a regional collaborative with the goal of improving perinatal care in California. It involves more than 100 NICUs throughout the state and brings, in addition to health care providers, representatives from state certification agencies and various business groups into the process. Through this diverse collaboration, goals with a broader definition of quality are identified.

During the collaborative process, the decision to adopt new interventions or evaluate existing practices is often encountered. A critical review of the available evidence supporting new interventions and clinical practices is essential. With the pace of development of new drugs and technology, the consistent and systematic evaluation of evidence supporting new interventions becomes a priority.

Evidence-based Medicine

Evidence-based medicine is defined as “the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients” (41). In the context of continuous quality improvement, the definition is expanded beyond the individual patient to decisions regarding institutional guidelines and policies in the care of multiple patients with similar diagnoses. In

both applications, the principles are the same: an answerable clinical question is formulated, the best evidence is located, and the evidence is critically appraised. These steps are essential whether answering a question regarding treatment for a VLBW infant with a patent ductus arteriosus or creating a policy for management of all VLBW admissions who develop the diagnosis of patent ductus arteriosus.

Randomized Controlled Trials

Randomized controlled trials (RCTs) represent the highest level of evidence and are the foundation for establishing effectiveness of interventions. The methodology of RCTs is geared to minimize selection bias by the random allocation of study subjects at the time of enrollment. This unique characteristic of the RCT establishes it as the basis for traditional statistical comparisons in both clinical and basic science research. Sound scientific methodology must also address other potential biases that can impact validity of the results. These include performance bias, or nonuniform exposure to the intervention; exclusion bias, or incomplete follow-up in obtaining postintervention data; and assessment bias, or inaccurate measurement of outcomes.

Metanalyses

Although RCTs are considered the best single methodology to evaluate an intervention, there are sometimes more than one RCT for a given intervention. RCTs can be combined using the technique of quantitative systematic review, or metaanalysis. Pooling results of similar RCTs can increase the statistical power lacking in multiple small RCTs or provide more support for decision making when conflicting results are reported in separate studies on the same treatment. The techniques used in performing metaanalysis are rigorous. The methodology of metaanalysis has been formally outlined and includes 5 stages: (a) specify the objectives of the review, (b) identify and select studies, (c) assess validity, (d) combine results of independent studies, and (e) make inferences (15).

Objectives of the review must be clearly and succinctly stated at the outset, with a principle objective and often secondary objectives given. The strategy for identifying and selecting studies must also be clearly stated in the review. This addresses one of the most challenging issues in any search and analysis of available literature, publication bias. Publication bias refers to the tendency for investigators to preferentially submit studies with positive results and the tendency for editors to preferentially select studies with positive results for publication. Klassen and associates (42) report that only 59% of abstracts presented at meeting of the Society for Pediatric Research between 1992 and 1995 were subsequently published. Abstracts were more likely to be published as a full study if they reported good news about newer therapies. To document their rigor in minimizing publication bias, authors of metaanalyses must include a prospectively designed search protocol, a comprehensive and explicit search strategy, and strict

Validity of each study in the metaanalysis must be determined independently, based on each study's merits and exclusion of bias in all areas. Results of multiple studies are usually combined based on their principle outcomes or measures of treatment effect. These are typically expressed using relative estimators, the relative risk or odds ratio, and absolute estimators, event rate difference or risk difference. Derived from the estimators are the relative risk reduction, computed as $(1 - \text{relative risk})$, and the number needed to treat, computed as $(1/\text{risk difference})$. For continuous outcome data measurements, the effect of treatment is measured as the mean difference. These outcomes are determined for individual trials in the metaanalysis, and then computed for the entire systematic review using statistical methodology that weights each trial based on its population size. The statistical significance of a treatment effect is determined when the confidence interval of the combined estimate for relative risk or odds ratio does not include 1, or when the confidence interval for the risk difference or weighted mean difference does not include 0.

Estimates of treatment effect or lack of effect are much stronger in metaanalyses in which there is less heterogeneity. Heterogeneity refers to the observation of large differences in point estimates among the included studies. The ability to make inferences from a metaanalysis depends on the methodologic quality of the primary trials on which the review was based, degree of consistency of results among the trials contributing to the review, and degree of confidence that the search for all trials relevant to the review was comprehensive (15).

The quality of a metaanalysis is dependent upon the rigor of the methodology applied by its authors. The process of metaanalysis has its critics; attempts at pooling results from various studies not only incorporates the biases of the primary studies, but may add additional bias attributable to study selection and heterogeneity of the selected studies (43). In addition, pooling data from small studies not adequately powered cannot answer questions about the potential side effects of new therapies, as compared to larger RCTs.

TABLE 7-5 EVIDENCE-GRADING SYSTEMS (45)

TABLE 7-5 EVIDENCE-GRADING SYSTEMS (45)

Grade	Description
	Agency for Healthcare Research and Quality (45)
	I. Metanalysis of multiple well-designed controlled studies
	II. At least one well-designed experimental study
	III. Well-designed, quasi-experimental studies, such as nonrandomized controlled, single-group, pro-post cohort, time series, or matched case-controlled studies
	IV. Well-designed, non-experimental studies, such as comparative and correlational descriptive and case studies.
	V. Case reports and clinical examples
	Canadian Task Force on the Periodic Health Examination (46,47)
	I. Metanalysis of multiple well-designed controlled studies
	II-1. Evidence obtained from well designed controlled trials without randomization
	II-2. Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than 1 center or research group
	II-3. Evidence obtained from multiple time series with or without intervention
	III. Opinions of respected authorities, based on clinical experience, descriptive studies or reports of expert committees
(Adapted from The periodic health examination. Canadian Task Force on the Periodic Health Examination. CMAS 1979;121:1193–1254; Strom KL. Quality improvement interventions: what works? <i>J Healthc Qual</i> 2001;23:4–14, with permission.)	

Evidence-Grading Systems

Although RCTs and metanalyses of RCTs represent the best sources of evidence, such high-quality evidence is not always available. Multiple systems for grading the strength of evidence have evolved that account for sources other than RCTs. The majority of grading systems place the most value on inferences from a systematic review of RCTs, with evidence from an individual RCT second, followed by evidence from well-designed trials without randomization, evidence from nonexperimental studies and, finally, opinions of respected authorities or reports of expert committees (44). Sources that may not meet the gold standard of an RCT are nevertheless important when this gold standard is either not yet achieved or is not achievable. Numerous systems have been developed to rate the strength of evidence, targeting evidence from metanalyses down to the opinion of experts (45). Table 7-5 shows a summary of 2 typical evidence-grading systems (46,47).

Despite the obvious value of evidence provided by RCT and metanalyses,

examples of other forms of validation can be found in collaborative processes. The Vermont Oxford Quality Improvement Collaborative for Neonatology reported that one of the most fundamental components in reducing nosocomial infection in the NICU observed

P.85

consistently in “best-performing” units was staff accountability for nosocomial infections (48). Implementation of this valuable insight was critical for collaborative participants desiring to reduce infections in their individual units. Although not meeting the usual criteria for high-grade evidence since it has not been formally studied scientifically, this form of observational data nevertheless represents an important category of evidence, i.e. evidence gained from collaborative benchmarking.

In addition to determining the efficacy of a certain intervention, disease prevalence, complication rates, financial impact of treatment versus the disease itself, and cost of implementation of the policy are all critical issues before implementation of evidence-based treatments. Many of the questions can be answered by a critical systematic review of available studies. Decisions to implement an intervention for a population of patients should be thoroughly researched and analyzed to account for case mix, variation over time, availability of subspecialty resources, and baseline complication rate. Although only somewhat relevant in an individual treatment decision, financial cost-effectiveness and feasibility are vital issues to be addressed in adopting policies on a unit-, institution-, or system-wide basis. Especially when financial and staff resources are limited, the implementation of one costly intervention could preclude the implementation of other interventions with more impact for a greater number of patients.

As critical analysis of research and benchmarking allows an organization to identify specific processes to improve, the actual incorporation of change into the organization requires an approach unique to each separate organization. Implementation of change requires individual commitment and open mindedness, a multidisciplinary group culture that embraces new ideas, and an institutional environment established by the management structure that encourages new ideas.

Organizational Change and Unit Culture

Each organization has a culture that is unique, representing the individuals and relationships that make up that organization. As Baker points out, “teams and organizations that attempt to implement quality improvement often identify organizational culture as an important barrier to or facilitator of success” (49).

Change, and an organization's readiness for change, has been the topic of numerous treatises in the field of industrial psychology. Although the traditional view of change management is that change begins at the top of an organization pyramid, recent views emphasize that change must occur at all levels within the

organization, especially on an individual level (50). O'Connor and Fiol (51) describe 3 elements: energizers or motivators that compel people to take action, impediments to change, and action steps needed for change to occur. Examples of energizers include objectives, benefits, and negative consequences. Barriers to change include apathy, errors, disturbed relationships, lost power, status, and money. Action steps are the steps taken to overcome barriers and resistance to change. It is important in CQI to understand common obstacles and the unique interrelationships that characterize different organizations in their quests for providing the same quality of care (51).

Tools for Quality Improvement

Fundamental to CQI is the use of improvement teams working together to solve problems or improve processes in which they are key players. In this approach, a process needing revision is analyzed using a series of tools, with multiple group discussions among the team, progressing through specific phases of analysis. This "diagnostic journey" progresses through description, cause-effect analysis, elaboration of potential improvements, and prioritization of these improvements based on research and study. The end result is the identification and implementation of 1 or 2 improvements that will have the most constructive impact on the related process.

One of the tools used in this process is flowcharting, which allows teams to depict the sequence of activities that make up the process. As teams chart the sequence of activities in a process, they often identify problem areas that become potential opportunities for improvement. Subsequent analyses using another tool, the cause-effect diagram, allow the team to attribute causes to the problem areas in the process being studied. Causes are classified in generic categories, which include personnel, equipment, supplies, information, methods, measurement, and environment. The determination of causes often requires analysis and chart review, with group discussion and consensus determining the likelihood of a cause-effect relationship. After group consensus and further study using a Pareto analysis (based on the "80-20" rule, ascribing 20% of the causes to account for 80% of the problems), the next step is to elaborate on the relationship between potential problems identified and their relative effect on the global process under review. The goal in this stage is to identify the relationship between factors identified with the adverse outcome of the process under review, as well as to systematically describe those factors which have the most potential to favorably influence the process under review.

Traditional CQI incorporates several tools for data collection and analysis. Data are essential in establishing the baseline activity or outcome of a process, ascertaining the relative role of various potential interventions, and measuring the process to document the desired improvement. Examples of data collection tools include simple check sheets, data sheets, interviews, and surveys. Analysis of the data is

often performed using bar charts, histograms, line graphs, and scatter diagrams. Another important and more sophisticated tool useful in this stage is the process control chart (52,53) in which data is plotted over time; analyzing variation in the data allows the distinction of special-cause variation from common-cause variation. This distinguishes variation caused by the influence of extrinsic factors from normal variation intrinsic to the process itself.

P.86

The sequence described represents traditional CQI, which has evolved over time and led to important improvements in industry and health care. However, due to the demands placed on modern health care organizations to implement numerous changes over much shorter time periods, the traditional model may not be best, as it may be tedious, be unnecessarily time consuming, and tie up precious resources when used every time a change is needed.

Rapid-Cycle Continuous Quality Improvement

Most organizations are looking for results at a pace that meets objectives in a more timely manner than traditional CQI. The impetus for getting results more efficiently has led to the development of a new approach called "rapid-cycle CQI." Rather than merely speeding up the discrete stages of traditional CQI, rapid-cycle CQI represents a completely different approach. Rapid-cycle CQI is a system of parallel processes as compared to traditional CQI, a system composed of multiple sequential processes performed in series. Originally designed by Nolan, Langley, and colleagues (54,55), rapid-cycle CQI involves the identification of changes chosen as goals by an organization; introduction of change concepts in small cycles, or tests of change; and measurement of the effects of the change.

Rapid-cycle CQI has several basic prerequisites. Organizations with smaller, less hierarchical leadership structures are best suited for this methodology. The use of smaller sample size in initial assessment is another important element as it allows for more rapid feedback regarding the success or failure of a test of change. Rapid-cycle CQI also works best when potential solutions or successful change concepts are readily available through prior applications in other settings. For more complex, interdepartmental problems, other problem-solving methods, including traditional CQI teams, may be more effective.

The process of rapid-cycle CQI begins with the question. "What are we trying to accomplish?" The answer to this question constitutes the aim statement, the starting point in applying rapid-cycle CQI. Next is establishment of the measurement necessary to answer the question, "How will we know that a change is an improvement?" Measurement is key to any methodology of CQI, and it is especially key to rapid cycle because each small test of change is evaluated by measurement. The progression toward the final outcome requires successive or simultaneous cycles depending on measurement to provide the appropriate

feedback regarding the value of the change concept being evaluated. Change concepts can be based on evidence in the literature, models of practice identified in benchmark centers, ideas generated during brainstorm sessions by teams within units, or modifications based on the result of previous tests of change.

Although not unique to the rapid-cycle CQI model, Plan-Do-Study-Act (PDSA) cycles are important elements of the process. The small tests of change are set in place with PDSA cycles. This involves the systematic planning of a specific adaptation of the change concept followed by the unit making the adaptation. The unit staff then studies its effects through measurement, and finally acts on the outcome of the cycle, either deciding to continue with a further adaptation in another cycle, or determining that the aim has been achieved and concluding the process. The concept of building knowledge through PDSA cycles has a long history with roots that can be traced to the British philosopher John Dewey (56), and it has been adapted by Shewhart (57) and Deming (58) to the science of quality management. Figure 7-2 shows the flow diagram used in rapid-cycle CQI.

Plsek (56) points out numerous examples of successful applications of rapid-cycle CQI. These include 2 teams in the Breakthrough Series Collaborative sponsored by the Institute for Healthcare Improvement. One team, from the Mayo Family Medicine Clinic, identified the following change concepts: build capacity for routine assessment of patient outcomes, reduce unintended variation in care, streamline the process of care, and build information system capacity. By implementing these concepts through a series of small-scale cycles of change, the Mayo team reduced hospitalization in asthma patients by 47% and reduced emergency visits by 22% (39). In another example from the Breakthrough Series, a second team implemented a series of 3 change concepts and decreased readmission to the intensive care unit from 15.6% to 9.8% (40).

The Vermont Oxford NIC/Q 2000 collaborative for quality improvement in neonatology brought together

P.87

teams from 34 participating centers, and provided education, content experts, and resources to facilitate the identification of change concepts in several clinical areas and the application of rapid-cycle CQI principles. One of the focus groups of the collaborative identified and prioritized 3 change concepts for reducing nosocomial infection in the NICU: improved hand hygiene, attention to the care of deep line connections, and standardized diagnosis of coagulase-negative staphylococcal sepsis. They were able to demonstrate a reduction in coagulase-negative staphylococcal sepsis from 25% to 16% (59).

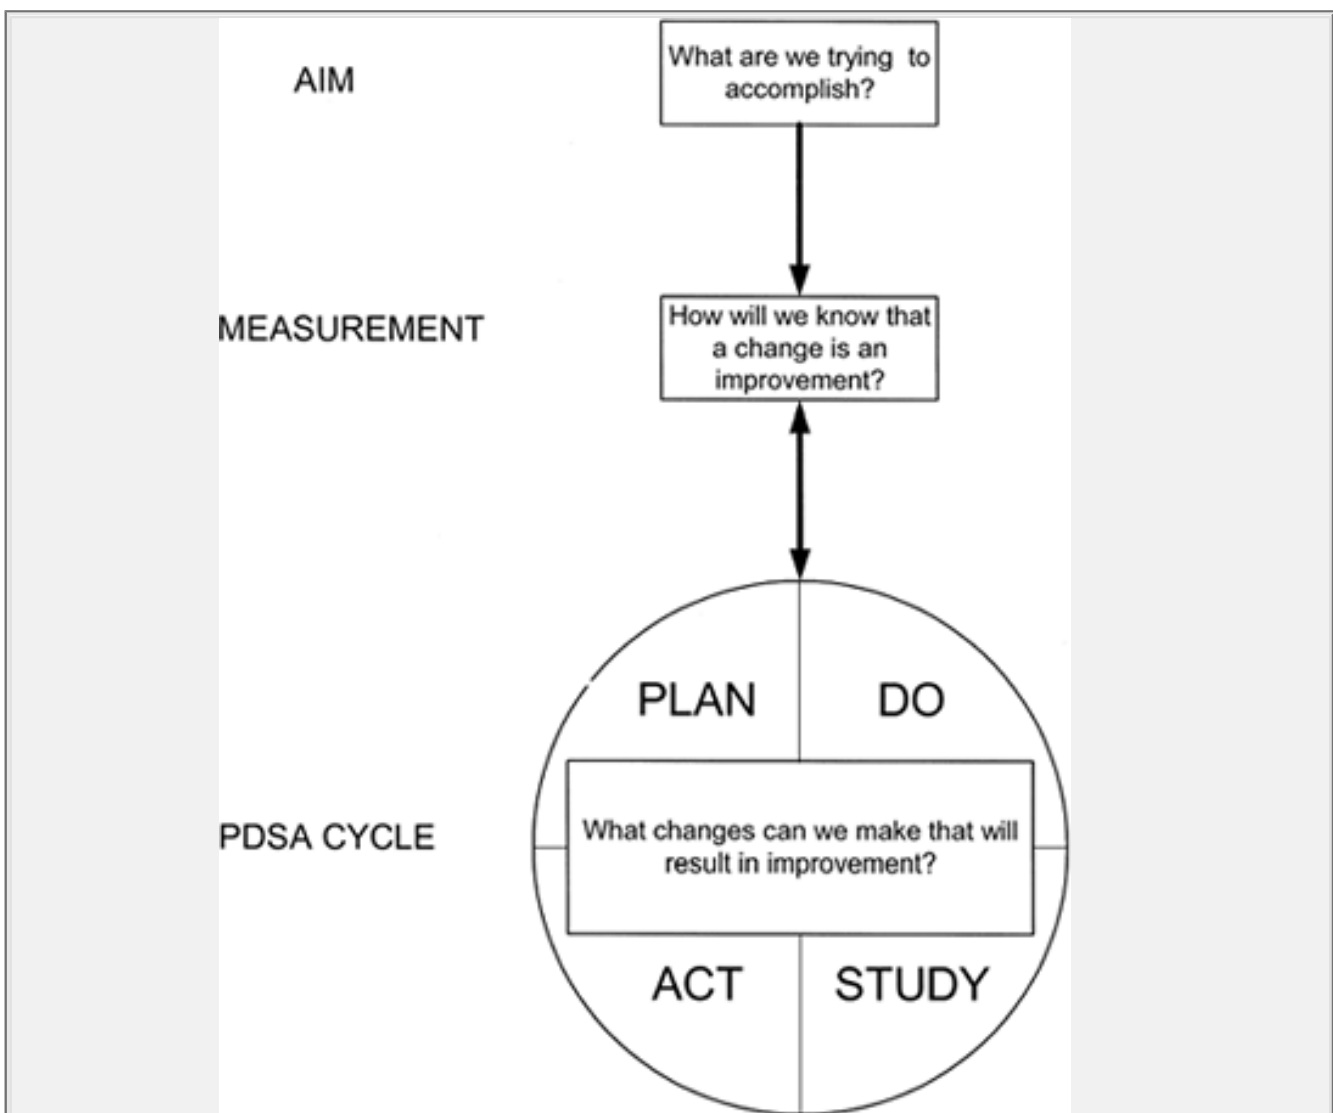

Figure 7-2 Flow diagram of rapid-cycle CQI. (From Plsek PE. Quality improvement methods in clinical medicine. *Pediatrics* 1999;103:203-214, with permission.)

In rapid-cycle quality improvement, pace is important. Successful application has been shown to depend on running small tests of change, short PDSA cycles, rather than running longer ones over an extended period of time. Each cycle provides the feedback forming the bases of learning and giving information on which to base further cycles of change. Efficiency of measurement is also critical for successful application of rapid cycle CQI. Teams have found that measurement within each cycle must be objective and sufficient enough to draw conclusions about the effect of the change concept. This often does not require the use of statistical techniques that would be very difficult given the sample sizes chosen for rapid cycle tests of change. Although not a requirement of many organizations successful at implementing widespread changes, statistical testing may be reserved for comparison of performance measures after large projects are completed, such as the examples of reduced hospitalization rates and nosocomial infection rates cited above.

CONCLUSION

The delivery of care in the NICU is a complex process involving numerous disciplines and personnel. The day-to-day management is important to the overall organization and keeps operations in motion. However, to continually improve practice and reduce medical errors, a system of continuous quality improvement is needed. The integration of comparative databases and benchmarking, evidence-based medicine principles, along with rapid-cycle processes that are compatible with concepts such as unit culture and change cycles, will help an individual unit to maintain quality in the face of technologic advances and organizational change.

Chapter 8

Law, Quality Assurance and Risk Management in the Practice of Neonatology

Harold M. Ginzburg

Mhairi G. MacDonald

BASIC LEGAL AND REGULATORY CONCEPTS

A brief historical overview of the transition from the past to present will help explain some of the current legal and social difficulties within the practice of medicine.

Health care professionals have always been subject to punishment should their medical skills or judgment fall below a community standard. Reports from the Middle Ages in England indicate that compensation was paid when patients were injured. In other nations during the Middle Ages the health care provider, if found responsible for poor medical care, was deformed in the same manner as the injury that he caused. Physicians were not motivated to treat patients with complicated illnesses unless the patient and his or her extended family clearly understood that treatment would be palliative. Although litigation has replaced amputation in modern western societies, health care providers and institutions still practice under the specter of retribution and public criticism.

Prior to the middle of the 20th century members of the healing profession functioned as an integral part of their local community. Since the 1940s there has been a progressive separation of health care providers from the communities they serve; this process has been accelerated by the advent of highly subspecialized and expensive intensive care. Neonatologists function in a crisis environment with little or no prior knowledge of their patients' family unit.

Isolation of patients from health care providers, except in times of crisis, can lead to poor or limited communication and unrealistic expectations. The family expects success.

Litigation may be initiated when negligence has occurred or is perceived to have occurred. A lack of good communication skills and empathy can be as self destructive as a faulty knowledge base, performing unacceptably, or functioning in an impaired manner. Thorough knowledge and understanding of one's medical subspecialty is insufficient to prevent involvement in malpractice litigation. Impersonal institutional and individual behaviors often precipitate a lawsuit. The failure to communicate and document patient and health care system interactions may place a health care system or provider in an untenable position when his or her actions are reviewed in an arbitration, mediation, or courtroom environment.

Health care providers are never able to succeed all the time. Sometimes the nature and extent of the disease is too severe, sometimes the course of treatment is too risky or aggressive to be tolerated by the patient, and sometimes errors of skill and judgment are made. Relatively recently the medical community and their legal advisors have come to the realization that explaining to a patient and family what went wrong in language that they can understand is not only the right thing to do but also appears to decrease the incidence of litigation (1,2). As part of its accreditation process, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) now requires health care organizations to disclose unanticipated injuries to the affected patients, investigate their root causes, and take action to prevent their recurrence (3).

Responsibility and Liability

The mundane aspects of medical care and treatment, such as scheduling of appointments, documentation of procedures, and understanding of the federal, state, and local

P.90

guidelines, procedures, policies, regulations, and laws, are frequently the basis for confrontations between members of the medical and legal professions.

The vast majority of medical education pertains to understanding basic sciences and providing clinical services. Little formal attention is given to the myriad of governmental policies, procedures, and regulations that control all aspects of health care delivery.

Medical care is a contract between the health care professional and the patient. In almost all instances, if the patient is unable, because of age or illness, to render informed educated consent, then others must provide such consent. Thus, as a patient is examined or interviewed, law and medicine become intertwined.

The basic legal considerations relating the care and treatment of any patient, and particularly, a neonate, flow from the following four concepts:

- The duty to act. When does the health care professional-patient or health care facility-patient relationship commence?
- Knowledge and application of hospital policies and local, state, and federal mandates. What resources are available to facilitate information transfer to health care facilities and service providers?
- Responsibility and accountability of the health care provider (individual or organization) to provide adequate care and treatment. Who is responsible for the decisions made in the provision of health care? Who monitors the quality of the services provided? Who ensures that the services provided are consistent with hospital policies and local, state, and federal mandates?
- Information transfer to patients and their families or guardians. Who obtains educated informed consent, in what manner, and with what documentation? Who is responsible for providing ongoing medical information to the families or guardians of neonates and ensuring that the information, and the implications of the information, is understood? State and federal legislation, such as the Health Insurance Portability and Account-ability Act of 1996 (HIPAA) (4), do not set standards for the manner in which a clinician may or should communicate with a patient, family member or significant other.

Defensive Medicine

Defensive medicine has become a medical term of art. However, it can connote a thoughtful systematic approach to health care rather than the excessive ordering of investigatory studies because of anticipatory fear of litigation for malpractice. Medical malpractice lawsuits are based on the principle of negligence. Negligence implies some wrongful act of commission or omission (5). The essence of negligence is unreasonableness.

Due Care

Due care is simply reasonable conduct (6). In order for negligence to be demonstrated in a courtroom, the injured person/plaintiff must demonstrate that (a) there was a legal duty owed to him; (b) there was a breach of that duty (a deviation from the accepted standard of care); (c) as a result of the duty and the breach thereof, damages or an injury occurred; and (d) the damages or injury can be determined to have been caused by, or shown to have flowed from, the care or lack of care provided by the health care provider and/or organization responsible for the environment in which the health care was provided.

Quality assurance and risk management aspects of medical care are relatively recent innovations designed to improve patient care and outcome; they are discussed in greater detail in the second section of this chapter. Quality assurance activities accept the legal and medical position that a health care provider owes a duty to the patient to provide reasonable medical care, consistent with available resources. There are inherent, irreducible risks in the delivery of medical care and treatment, and quality assurance and risk management assessments are designed to identify and limit the risks. There are always risks in a medical intervention, and there are always risks in not rendering a medical intervention. The balance of relative risks needs to be understood by both the health care provider and the patient and/or parent/guardian.

The Duty to Act

The duty to act is determined when the health care professional- or organization-patient relationship commences (7). A "duty" is a legal and ethical responsibility. There is no legal duty under most circumstances for a health care provider or institution to accept a patient for care unless they hold themselves out as providing emergency care or they are required to do so by law, regulation, or contract. If a medical center, hospital, or physician represents itself to the public as a source of emergency medical care and the community has come to expect such care, then a patient cannot be arbitrarily denied such services (8). Once a health care service is initiated, a health care provider/institution-patient relationship exists, a duty is created, and there is then a legal and moral obligation not to abandon the patient. Further, the care that is being provided must be adequate under the circumstances. A moral and legal obligation attaches, which precludes abandonment or "dumping" of the patient (9). A referring hospital transferring an infant to another institution for further care is not perceived as abandoning the patient, as long as the reason for transfer is medical and not financial. The senior medical person responsible for the transport, whether stationed at a hospital or directly providing patient care during transport, is deemed to be supervising the health care until the transport team transfers care to the clinical staff at the receiving referral medical facility. The transport team's legal and ethical duty to the patient exceeds that of other parties, such as the referring or referral hospital.

The complexity of health care responsibility and liability increased rapidly during the 20th century. Public health

care facilities have existed since the Middle Ages. Commencing in the 13th century, the Hotel Dieu in Paris provided indigent care for many centuries. In the United States, city, municipal, state, and federal public hospitals provided care for those unable to obtain it elsewhere, and the physicians and hospitals were not held liable for the outcome of care that was provided free of charge. The doctrine of charitable immunity protected hospitals from legal liability if medical negligence occurred within their boundaries. However, an individual's inability to pay for medical care no longer affects his or her ability to demand and receive services that are commensurate with those provided to patients who pay for their care directly or through third-party payment

systems. Thus, providing care to patients who are unable to pay no longer protects a health care provider or medical institution from liability for negligence or malpractice. Physicians, other health providers, suppliers, and manufacturers of equipment, medical devices, and medicines can now all be sued for negligence and be held individually or jointly liable for their own actions, those that they supervise, and those that are performed by members of their health care team.

Licensure; Interstate-International Practice

In the United States, health care providers (physicians, nurses, emergency medical technicians, etc.) may be licensed in more than one state. They must be licensed in the state in which they maintain their primary office or place of employment. The authorities in most, but not all, states are not concerned about whether a health care provider who enters the state solely to transport a patient to another health care facility is licensed in that state; however, they are concerned that the individuals involved in the transport are competent to perform their job.

An individual who enters a state, regardless of the reason, will be subject to that state's laws. If a driver is involved in an accident, he or she is subject to the laws of the state in which the accident occurred, not to those of the state that issued the driving license; this legal principal also applies to medical transport vehicle operators (10). Failure to obtain informed consent may result in litigation in the state in which it was inadequately obtained or in the state to which the patient was transferred.

Patients and their guardians may initiate medical malpractice litigation in the state in which they reside, the state in which the alleged negligence occurred, the state in which the hospital is located, or the state in which the physician resides. If the patient/plaintiff can show that his or her residence is in a different state from that of the defendant/hospital and defendant/health care provider, then the plaintiff can commence the litigation in a federal court because the matter involves diversity of jurisdiction, i.e., opposing parties are located in two or more states. The defendant can request that the matter be removed to the federal court system for a similar reason (11). Most plaintiffs prefer state courts, especially if the defendant is from a different state. Some state courts are known for their large awards to plaintiffs, whereas others are known to be more sympathetic to defendants/health care providers.

Telemedicine

Recent advances in telephone-linked care (TLC) or "telemedicine" (see also Chapter 5) have initiated new questions regarding the practice of medicine across state lines (12). TLC has been applied as a supplement to direct patient care, to monitor patient progress, and as a service expander for specialized medical expertise and technology (e.g., the interpretation of neonatal radiologic or cardiologic films and tracings). Landwehr and associates (13) demonstrated the feasibility of telesonography for the interpretation of fetal anatomic scans from a remote location. Lewis and Moir (14) in Scotland and Landquist (15) in Finland demonstrated that telemedicine is an international technology.

TLC has been practiced for more than 30 years (in its simplest form, it includes giving advice over the telephone). In 1996 the U.S. Congress passed the Telecommunications Reform Act, which required a study of patient safety, efficacy, and the quality of services (16). The neonatologist has the opportunity to engage in "telehealth," which includes consultation, transportation, and interpretation of radiographic, cardiologic, and other data, as well as professional education, community health education, public health, and administration of health services. The American Medical Association and American Telemedicine Association have urged medical specialty societies to develop appropriate practice standards. Managed care organizations have begun to embrace telemedicine. Louisiana, in 1995, became the first state to enact legislation dealing with

telemedicine reimbursement (17) that specifies a certain reimbursement rate for physicians at the originating site and includes language prohibiting insurance carriers from discriminating against telemedicine as a medium for delivering health care services.

California in 1996 (18), Oklahoma in 1997 (19), Texas in 1997 (20), and Kentucky in 2000 (21) have also passed telemedicine legislation. However, at the present time, issues relating to cross-state licensure are perceived to be potential barriers to the expansion of telemedicine, especially now that reimbursement is possible. States license physicians and other health care providers within their boundaries, but the federal government has the authority to prepare national licensure standards as they relate to national programs such as Medicaid and Medicare. In the future, there may be alternative approaches to licensure (22). Regardless of the end result of the issues surrounding telemedicine, neonatologists increasingly cross state and international boundaries and need to appreciate that the laws of political jurisdictions other than their home state may significantly impact the manner in which they practice.

The U.S. Food and Drug Administration (FDA) has become involved in telehealth activities on the Internet.

P.92

Over the past few years, some Web sites have offered illegal drugs or prescription drugs based on questionnaires rather than a face-to-face examination by a licensed health care practitioner. Some offshore sites offer prescription drugs without any prescription or medical consultation. The FDA works with the U.S. National Association of Boards of Pharmacy, which created a program in 1999 called Verified Internet Pharmacy Practice Sites to provide the consumer with the ability to verify the safety of medications being sold over the Internet (23). A number of U.S. federal and state regulatory agencies are working together to address health-related consumer problems on the Internet. They include state health authorities, FDA, Justice Department, and Federal Trade Commission. The Federal Trade Commission plays a key oversight and enforcement role in Internet commerce.

Medical Torts and Contracts

The legal system is divided into two broad areas. Civil litigation is based on the need to correct or remedy a wrong between one individual (corporation or partnership) and another. Criminal prosecution is instituted to correct a wrong against the community. In a civil litigation matter (or case), the plaintiff is the party bringing the lawsuit and alleging the wrong; the lawsuit is filed against the party (defendant) who is accused of causing the damage. In a criminal prosecution, the plaintiff is the government (local, state, federal) alleging that the community has been harmed by the action or inaction of a party (also known as the defendant).

Civil matters resulting in litigation generally are either contract disputes or torts. A contract dispute occurs when two or more parties have entered into an agreement and one or more parties believe that the terms and conditions of the agreement, either an oral or written contract, have not been met. It is important to appreciate that, in a court; most oral contracts have the same weight as written contracts.

A personal tort is an injury to a person or his or her reputation or feelings that directly results from a violation of a duty owed to the plaintiff (in medical malpractice cases, this is usually the patient) and produces damage. The remedy in any civil matter, after the nature and extent of the damages have been proved to the court (a judge with or without a jury), is determined by a preponderance of the evidence (more than 50.01%). Thus, to a medical degree of certainty means that it is more likely than not, and it is that standard upon which there are usually monetary damages awarded if the matter is found in favor of the plaintiff. In most instances in the United States, each side pays for its own legal services, regardless of the outcome of the case.

Battery

Battery is a tort; it is an intentional and volitional act without consent which results in touching that causes harm (e.g., the touching of a patient's body without consent). A technical battery can occur when there is no actual harm but touching occurred without consent. Patient care, even with a beneficial outcome but without informed consent, may be considered battery.

Plaintiffs may sue for an injury that occurred as a result of negligence or a tort (physical or mental harm), or both. Because the criminal court usually will not award monetary damages to the victim of a crime and because the standard of proof for conviction is "beyond a reasonable doubt" (quantitatively, this can be conceptualized as at least 95% certain), plaintiffs usually prefer to sue for injuries from a tort in civil court. In civil litigation, monetary damages may be awarded, and if the injury was determined to be egregious, punitive damages also can be assessed against the defendant. The standard of proof in civil litigation is the "preponderance of the evidence" or the "more likely than not" standard; it is a "superiority of weight" test that requires that for the plaintiff to be successful, 50.01% of the evidence must weigh in his or her favor (24). Thus, the preponderance of the evidence rule is a threshold test (25). In general, either the plaintiff proves that the damages were more likely to have been caused by the defendant agent than by any other source and is; therefore, entitled to full compensation, or he or she fails to meet the burden of proof and is entitled to nothing (26).

Professional Negligence

Negligence is "conduct, and not a state of mind" (27), "involves an unreasonably great risk of causing damage" (27) and is "conduct which falls below the standard established by the law for the protection of others against unreasonable risk of harm" (28,29).

Professional negligence, or medical malpractice, is a special instance of negligence. The medical profession is held to a specific minimum level of performance based on the possession, or claim of possession, of "special knowledge or skills" that have been accrued through specialized education and training.

Ely and associates (30) found that when family physicians recalled memorable errors, the majority fell into the following categories: physician distracters (hurried or overburdened), process of care factors (premature closure of the diagnostic process), patient-related factors (misleading normal results), and physician factors (lack of knowledge, inadequately aggressive patient management). Understanding the common causes of errors alerts the practitioner to situations when errors are most likely to occur.

The Elements of a Malpractice Case

To establish a *prima facie* medical malpractice case (one that still appears obvious after reviewing the medical evidence), the patient/plaintiff must demonstrate (Fig. 8-1): that (a) there is a duty on the part of the defendant/health care provider and/or defendant/health care facility to the patient/plaintiff, (b) the defendant failed to conform his or her conduct to the requisite standard of care required by the relationship, and (c) an injury to that patient/plaintiff resulted from that failure (31).

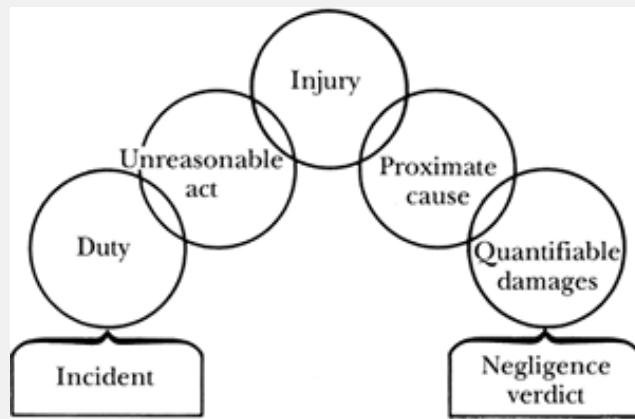

Figure 8-1 The elements of negligence. There must be an unbroken chain for successful litigation. If any link is not proved, the plaintiff will lose the case. (From Ginzburg HM. Legal issues in patient transport. In: MacDonald MG, ed. *Emergency transport of the perinatal patient*. Philadelphia: Little, Brown and Company, 1989:163, with permission.)

Generally, in order for the plaintiff to establish a claim of medical malpractice, the plaintiff must establish by medical expert testimony (a) what the applicable standard of care is, (b) how the defendant breached or violated that standard of care, and (c) that the breach or violation (also referred to as the negligence) was the proximate cause of the injury.

A medical malpractice action can only proceed if the court determines that there is a genuine issue of material fact and if damages are quantifiable (e.g., the future costs of treatment, economic lost value of productive activities, etc.).

The most difficult element to prove is whether or not the standard of care was adequate. The plaintiff usually must provide expert witnesses to establish what a prudent health care provider in similar circumstances might have done. A "conspiracy of silence" may have existed in prior years in the United States, but today there are many "experts" willing to testify anywhere about anything. However, in Japan and other nations, it is difficult to find a local or even national expert to testify in medical malpractice cases (32).

More than 100 years ago in Massachusetts, it was held that a physician in a small town was bound to have only the skill that physicians of ordinary ability and skill in similar localities possessed. The court believed that a small-town physician should not be expected to have the skill of surgeons practicing a specialty in a large city (33). It was also held that a physician was required to use only ordinary skill and diligence, the average of that possessed by the profession as a body, and not by the thoroughly educated (34). However, a physician is now not excused for failing to keep himself or herself informed of medical progress. State requirements for continuing education and the effects of telemedicine consultations and educational programs essentially have removed clinicians' ability to say that they are too busy or so geographically inaccessible as to be precluded from keeping current with new treatments and new understanding of the illnesses that affect their patients.

Courts admit medical evidence based upon rules of evidence. In 1993, the U.S. Supreme Court in *Daubert v Merrill Dow Pharmaceuticals, Inc.* ruled that the Federal Rules of Evidence standards for acceptance of evidence would be used (35). This was an attempt to remove junk science from distracting the jury. The court held that scientific (medical) evidence had to be grounded in relevant scientific principles. The four criteria the court established are: (a) whether the theory or

technique has been tested; (b) whether the theory or technique has been subjected to peer review and publication; (c) the known or potential rate of error of the method used and the existence and maintenance of standards controlling the technique's operation; and (d) whether the theory or method has been generally accepted by the scientific community. Thus, publication in a peer-reviewed or peer-refereed journal was not the only qualification for acceptance of evidence in a courtroom. The district (trial) court judges have the latitude to permit or exclude experts, based on the perceived scientific merit of the information they intend to provide to the court and, thus, to the jury. The fundamental issue for a clinician is not an understanding of the rules of evidence and the workings of the civil justice system but practicing medicine and acting in a professional manner, as documented in a patient's medical record.

Many states have medical peer-review panels in place. In these states, before a medical malpractice case may be heard in a court, the facts of the case are presented to the review panel on behalf of both the plaintiff and defendant. The medical facts often are buttressed by the opinions of retained medical experts for both sides. In some states the medical review panel is comprised of attorneys and physicians; in other states the medical review panel is chaired by an attorney and comprised of physicians in the same or similar medical specialty as the physician being accused of having committed malpractice. Even when there is a finding for the defendant by the medical review panel, the plaintiff may continue litigation in the local court. However, the findings of the medical review panel are admissible on behalf of either the plaintiffs or defendants.

Res ipsa loquitur

There are circumstances in which no expert witness is required to corroborate the findings of negligence. The doctrine of *res ipsa loquitur* essentially means that the thing speaks for itself. Under such circumstances, the negligence is inferred from the act itself, i.e., proof from circumstantial evidence. In the classic case *Ybarra v Spangard*, a patient was well prior to being anesthetized for an appendectomy, and when he woke up he had an injury to his arm (36). Clearly, he could not determine how his arm was injured; the operating room and recovery room staff either could not or would not explain the etiology of the injury. The court found for the injured plaintiff without the introduction of any expert witnesses because (a) the plaintiff had not done anything that in any way could have contributed to the injury, (b) the injury could not have occurred unless someone

P.94

was negligent, and (c) the instrumentalities (hospital staff and physicians) that allegedly caused the injury were at all times under the control of the defendant hospital.

Informed Consent

Informed consent requires that sound, reasonable, comprehensible, and relevant information be provided by a health care professional to a competent individual (patient or guardian) for the purpose of eliciting a voluntary and educated decision by that patient (or guardian) about the advisability of permitting one course of clinical action as opposed to another (28). Physicians and other health care providers are held to have a fiduciary duty to their patients. Such a duty exists when one individual relies on another because of the unequal possession of information. The failure to obtain proper informed consent may result in the defendant/physician or defendant/hospital being sued for battery in some states or for negligence in others.

According to the battery theory, the defendant is to be held liable if any deliberate (not careless or accidental) action resulted in physical contact. The contact must have occurred under circumstances in which the plaintiff/ patient did not provide either express or implied permission and the defendant/health care provider knew or should have known that the action was

unauthorized. If the scope of consent obtained from the patient is exceeded, a claim of battery is proper. The plaintiff in *Mohr v Williams* consented to have surgery performed on her right ear (37). During the procedure, the surgeon determined that the right ear was not sufficiently diseased to require surgery, but the *left* ear required surgery. Because the patient was already anesthetized, the surgeon performed the operation. The operation was a success, but the patient successfully sued for battery. The court held that there was no informed consent for an operation to the left ear. Thus, it is not necessary for injury to occur for damages to be awarded; demonstration that there was unauthorized touching is sufficient. In this instance, the court found that there was no medical emergency that would have threatened the plaintiff/patient if the surgery had not immediately commenced. If there were evidence of a medical emergency, the court's decision might have been significantly different.

Failure to specifically identify the risks that accompany a surgical procedure also can result in a successful claim of battery. In *Canterbury v Spence*, the plaintiff/patient successfully proved that he was not informed of the risks attendant to the surgical procedure and that had he known them he would not have given permission (38). The court held that the physician has a duty to disclose all reasonable risks of a surgical procedure, and because he failed to perform that duty, the court held him liable for damages to the patient. The court noted that the concept of informed consent might be more appropriately replaced with the concept of educated consent. The court also articulated an objective standard that could be used in legal cases involving informed consent. This objective standard is based on what a reasonable person in circumstances similar to that of the patient would have decided if he or she had been provided with an adequate amount of information. Therefore, the central issue in a medical battery is whether an educated, effective, or valid consent was given for the procedure that actually was performed.

A physician is not required to disclose every possible risk to a patient for fear of being guilty of battery (39). The court in *Cooper v Roberts* held that "[t]he physician is bound to disclose only those risks which a reasonable man would consider material to his decision whether or not to undergo treatment" (40). Thus, the court stated that such a standard creates no unreasonable burden for the physician. However, the physician must disclose risks that are material and feasible alternatives that are available. The information should be provided in a language and manner that reflects the emotional and educational status of the patient or, when the patient is a neonate, the parents. In *Davis v Wyeth*, the court held that any medical complication or risk that has a probability of greater than 1:1,000 should be included in the informed consent (41).

When a therapeutic procedure is for the benefit of a minor, the decision to proceed usually belongs to the parent or legal guardian. The failure of the parent to consent to blood transfusions (even if the refusal is based on sincere religious convictions) or other now routine procedures for a small child that are clearly medically indicated and required for the maintenance of life can be overridden by the physician and/or hospital petitioning the court for the appointment of a temporary legal guardian (42).

The unavailability of a parent in a life-threatening circumstance should not preclude therapeutic action. Just as informed consent is imputed to an unconscious accident victim who has a life-threatening condition that requires surgery, such rational behavior can be imputed to the absent parent in the case of a sick neonate. However, in such circumstances if time permits, detailed documentation and consultation with the hospital administration is recommended.

Informed consent in neonatal/perinatal medicine is not an empty gesture to reduce liability, but rather an interaction with the physician that helps parents to become full partners in decision making. Informed consent documents are intended to support decision makers in their choices, rather than to merely have them ratify decisions already made (43). Informed consent documents need to be routinely reviewed to determine that the reading level required to understand them is consistent with the educational and cultural experiences of those being asked to read,

understand, and sign the forms (44).

The informed consent process can be extremely complex, with several legal "gray areas." For example, are maternal rights any more definitive in making critical decisions for a fetus or neonate than paternal rights? Conflicts can arise even when the putative or alleged father is not the legal spouse of the mother. Emergency hearings in front of local judges may be required to resolve conflicting opinions, especially when the decision of one parent may lead,

P.95

to a medical degree of certainty (more likely than not), to the death of the infant.

It is one of the ironies of the law, in most states, that an unwed teenage mother has the ultimate legal responsibility for the care of her child, unless the court is petitioned to appoint an alternative guardian. In many states the live birth of a child, regardless of the age of the mother, results in the mother being declared an emancipated minor. In contrast, a non-pregnant teenager, living at home and attending school, does not have the legal right to make decisions about many aspects of her own medical care.

The disclosure of risks in the informed consent process tends to underscore a parent's sense of helplessness and to portray the physician as somewhat helpless as well. The powerlessness of the parents and their wish that the physician be omnipotent creates unrealistic expectations for the outcomes of procedures and treatment. Gutheil and associates (45) suggest that the physician acknowledge the parent's wish for certainty and substitute the mystical with a physician-parent alliance in which uncertainty is accepted.

Advanced Care Planning

Decision making in life and death situations is not easy. Advanced care planning efforts initially evolved in the care of the elderly (46). Advanced care planning, or contingency medical care planning, is no longer generally reserved for adults. The American Academy of Pediatrics Committee of Bioethics developed a policy statement about parental permission and informed consent (47). A distinction is made in this public policy statement and in case law in the United States between emergency medical treatment, life support efforts, and elective surgical procedures, such as circumcision or removing a kidney from one child to aid a sibling (48,49). Neonates need others to make decisions about their treatment and viability. Their treatment in a neonatal intensive care unit (NICU) is also never a series of leisurely scheduled elective procedures. There must be a designated person to whom the health care providers relate and who is held to render decisions about treatment. When potential conflicts in decision making are recognized, a conference among the concerned individuals, with representation from the hospital administration, may be a worthwhile endeavor to clarify who actually has the final decision-making authority. There may be times in the treatment of a patient when one person has to render an immediate decision, even if that decision is not a consensus. Decision-making issues are often confounded when the mother of the neonate is an adolescent herself and not wed to the father.

While all 50 states in the United States and the District of Columbia have passed legislation on advance directives, reinforcing the fact that adherence to such directives is mandatory rather than optional continues to be problematic (46). The majority of states do place restrictions on proxy decision making. If identification of the responsible party for decision making is not clear or keeps shifting, legal consultation, initiated by the health care providers, is recommended. Most jurisdictions have the ability to hold emergency judicial proceedings when an impasse has been reached and a medical decision must be made before irreversible damage or death to the patient occurs (42).

Medical Records

As evidenced by HIPAA (4) and state regulations, medical records are legal documents. Medical and hospital records are designed to be a contemporaneous record of the available clinical information and medical and other decisions that flow from the clinical information and interactions with the patient's significant others. Records provide an opportunity for adequate documentation. Documentation is the key to management of patients, and it is the key to protecting physicians against malpractice litigation, especially in the instances in which the patients have difficult and complex clinical presentations. The course of treatment and meeting or failing to meet therapeutic goals should be noted in the hospital chart. Treatment options, including the option of no treatment when pertinent, should be explained to the patient's family and, if necessary, others potentially involved in the decision-making process; these interactions should be documented in the patient's chart. The patient's family's understanding, or lack thereof, of the various treatment options also should be noted, especially if there are divergent views among family members. Ultimately one family member or guardian has to be acknowledged by the family and health care providers as the decision maker. Identifying such an individual in the medical record will facilitate treatment decisions and posthospital treatment care and management. Such documentation may preclude the need for judicial intervention.

Adequate medical records will document that the risks of a given procedure have been shared with the patient's decision makers. A record that indicates that specific known adverse side effects, or rare but serious untoward events, were discussed with a patient's family members or guardians helps protect the clinician should one of these untoward events actually occur. No medical procedure is risk free, and although families may be informed of the relative risks of the various procedures and pharmacologic interventions, the stress of the moment may shorten their attention span, concentration, and recall. For example, prescriptions at the time of discharge are often for a limited period of time, with follow-up care being provided in either a hospital outpatient, clinic, or private clinical environment. Prescriptions must be written clearly, identifying the patient, date, dose, dose schedule, and route of administration. The parent or guardian to whom the prescription is provided needs to understand why the medication is being prescribed, adverse side effects, therapeutic effects of the medication, and consequences to the infant if the medication is not provided. Medical record documentation, including discharge instructions and prescriptions, at least provide a contemporaneous record of what information actually was provided.

P.96

Medical records provide the basis for reimbursement of the costs for patient care and treatment. The severity of a condition, justification for laboratory and other investigations, need for consultations, and manner in which the consultative advice is incorporated into patient care should be present within a patient's medical record. In the spring of 1998 the U.S. Justice Department announced the hiring of 250 Federal Bureau of Investigation (FBI) agents for the purpose of investigating Medicare and Medicaid fraud. The U.S. federal government continues to pay increasing attention to the issue of fraudulent billing for health care services whether the care is provided directly or via telemedicine. The FBI estimates that 10% of the money paid out for health care services under the Medicaid program is the result of fraudulent billing (50). Not all the money paid for fraudulent services is recovered. However, in 2002, \$1.6 billion was collected in connection with health care fraud cases and matters (51). The absence of consistent, comprehensive reimbursement policies is frequently cited as one of the most serious obstacles to total integration of telemedicine into health care practice. This lack of an overall telemedicine reimbursement policy reflects the multiplicity of payment sources and policies within the current U. S. health care system.

Adequate documentation facilitates medical audit, permits those who prepare invoices for reimbursement or payment to justify the categories or International Classification of Diseases codes placed on the universal billing forms (sometimes identified as HCFA-1500 forms), and prevents errors that may result in the appearance of fraud (52).

Medical Confidentiality of Oral and Handwritten Communications

The Hippocratic oath states, in part, "Whatever, in connection with my professional practice or not in connection with it, I see or hear, in the life of men, which ought not to be spoken of abroad, I will not divulge, as reckoning that all should be kept secret" (53). This oath, taken by many physicians upon graduating from medical school, has been codified by state and federal law. The confidentiality of the information obtained by the physician is considered to be "privileged" (54). The privilege, however, belongs to the patient or his or her guardian; it does not belong to the physician or other health care provider. A court may order a health care provider to breach medical confidentiality; legislation may require it.

As the delivery of medical care becomes more complex, individuals not generally thought of as direct health care providers are requiring access to confidential medical information. The legitimate needs, for example, of physical therapists, occupational therapists, hospital administrative personnel, and medical insurance personnel may appear to conflict with the principle that medical information is confidential and should be restricted only to physicians. The ethical basis for confidentiality derives from the concept that assurance of confidentiality encourages patients to seek the medical care that they require and to be candid with their health care providers. The legal basis for confidentiality is derived from statutes, which have been enacted in essentially all states within the United States.

There is significant variation among the states as to what classes of health care providers (doctors, nurses, social workers, etc.) can assert that they cannot share medical information provided to them without the patient's express permission or a court order directing them to do so.

Legislatures create state disease-reporting requirements that require medical confidentiality to be breached as historically the courts have found that the state has a compelling need to protect its citizens from certain infectious diseases (55). Certain behaviors, such as dangerousness, also have resulted in reporting requirements that compel a health care professional to notify authorities when a patient has made an explicit threat against a known individual (56) or even an unknown but identifiable group of individuals (57). Dangerous behaviors include spousal and child abuse.

Medical records also are protected by state and federal legislation. The U.S. Public Health Service Act provides for the explicit protection of medical records dealing with treatment for drug (58) and alcohol abuse (59). However, even the contents of substance abuse treatment records may be released "to medical personnel to the extent necessary to meet a *bonafide* medical emergency" (60,61). If release of the medical records is authorized by a court order, then appropriate safeguards need to be put into place to preclude unauthorized disclosure.

The courts recognize that they must balance the public interest and the need for disclosure against injury to the patient, physician-patient relationship, and treatment services (4,62,63).

"A hospital medical record is the property of the hospital, but it is kept for the benefit of the patient, the physician, and the hospital" (53). A patient's medical record is preserved to document events in a contemporaneous manner for later use. Later use includes further medical care and treatment, documentation for financial payment by third-party payers, and defense of medical

malpractice claims.

The medical record librarian becomes the custodian of the medical records. The American Association of Medical Record Librarians has a code that is similar to the Hippocratic Oath taken by physicians. Hospital policies and procedures, consistent with state and federal statutes and regulations, prevent a medical record from being released without either a patient release or court order. Under certain defined circumstances, medical records can be admitted as evidence in a court of law. They can be authenticated as business records. They also can be used to refresh a doctor's memory and document his or her actions.

The American Hospital Association, JCAHO, and other health care professional organizations have asserted that a patient's medical records are to be protected from unauthorized and unnecessary access. Their positions are generally consistent with current HIPAA regulations and state

P.97

regulations. Hematology, blood chemistry, urinalyses, and radiographic, sonographic, and electrodiagnostic findings are all considered a part of a patient's authorization or court order. Third-party payers, as a condition of their insuring the patient, almost invariably are given access to patient medical records, as are state and federal auditors.

The privilege of medical confidentiality does not extend to third parties present who are not part of the health care being delivered. That is, police officers present during an evaluation or treatment cannot be prevented from sharing with other law enforcement personnel or the courts any information that they obtained under such circumstances. When an individual engages in litigation in which his or her physical or mental status is an issue, that individual cannot assert the privilege to prevent unfavorable information from reaching the ear of the court. Thus, in a lawsuit for malpractice, the patient/ plaintiff has waived his or her right to medical confidentiality of any oral, written, or electronic communication concerning his or her medical history, diagnosis, treatment, or prognosis. Medical confidentiality statutes were and are designed to protect a patient's privacy and to encourage treatment for conditions that may bear social or other stigmas. The laws were not made to give the moving party, the patient/plaintiff in a medical malpractice case, an unfair advantage by allowing the individual to select only those records considered testimony favorable to his or her case. A medical record cannot be used as both a sword and a shield.

In 1991 the Institute of Medicine (IOM) advocated the adoption of the computer-based patient record as standard medical practice in the United States (64). A computer-based record is perceived as a continuous chronological history of a patient's medical care. The medical care record can be linked to various aids, including reminders and alerts to clinicians and clinical decision-making instruments. However, a computer-based record increases access to a patient's record and increases the array of data maintained in a single record (65). The more information compressed into an easily accessible single location, the greater the precautions needed to prevent misuse. As Annas (66) notes, in a setting of private practice, medical information that identifies a patient is supposed to be transferred from physician to physician only with the patient's written informed consent. In contrast, he explains, within a medical institution, information is generally passed around on a perceived, usually self-designated, "need to know basis" without first obtaining a patient's informed consent. Individuals who receive their medical care through managed care facilities and integrated health care delivery systems that have multiple treatment sites and use computer-based patient records can anticipate that the traditional standards of medical confidentiality will be diminished. Even a minor error, such as dialing an incorrect fax number and sending an electronic report to an unintended recipient, can result in damage to the patient and ultimately cost to the individual who authorized the report to be transmitted in error.

A release of medical information request can be general or rather specific, depending on the clinical and social circumstances, needs of the treating health care providers, and instructions of the patient or guardian. In general, medical information is released upon written instruction; however, oral instructions frequently are sufficient or necessary. This may be the case in a medical emergency. Documentation of oral permission for release of medical information is recommended.

Health Insurance Portability and Accountability Act of 1996

The HIPAA, Public Law 104–191 (4), is concerned in general about the written word and not oral communications, especially those provided in an ongoing manner in the course of clinical treatment.

HIPAA set national standards for the protection of health information, as applied to the three types of covered entities: (a) health plans—an individual or group plan that provides or pays the cost of medical care that includes the diagnosis, cure, mitigation, treatment, or prevention of disease; health plans include private entities and government organizations such as Medicaid, Medicare, and the Veterans Health Administration; (b) health care clearinghouses—a public or private entity, including a billing service or community health information system that processes medical, financial, or other data; and (c) health care providers who conduct certain health care business transactions electronically. Health care providers such as physicians, hospitals, and clinics are covered entities if they transmit health information in electronic form in connection with a transaction for which a HIPAA standard has been adopted by the Department of Health and Human Services (DHHS).

The compliance date has passed; for larger entities it was April 14, 2003, for smaller entities it was April 14, 2004. If HIPAA is more stringent than a state's law, it governs; if the state law is more stringent than HIPAA, the state law governs. Generally, "covered entities" are required to comply with both HIPAA and state law whenever possible. HIPAA preempts any contrary provision of state law, including state law provisions that require written records rather than electronic ones. State law, however, is not preempted in the following circumstances: regulation of insurance or health plans; prevention of fraud and abuse; reporting on health care system operations and costs; regulations concerning controlled substances; when a state law requires the reporting of disease or injury; child abuse, birth, or death; public health surveillance, investigation, or intervention; or when a provision of state law is more stringent than the requirements of HIPAA.

As with every issue of conflict between state and federal laws, there are exceptions. Exceptions mean health care lawyers need to be consulted when a clinician is unsure as to his or her course of action with regard to HIPAA and state confidentiality laws. There are other federal laws that may be relevant to parental conduct, such as the federal

P.98

Drug and Alcohol Confidentiality Regulations (58) which govern the release of medical records that contain information about drug and alcohol use, and the terrorism provisions of HIPAA which allow access to medical records if matters of national security may be involved.

HIPAA was designed to protect patients' medical records and their confidentiality. Other laws have existed to do this. The U.S. Congress believed, in consultation with many patient advocates, health care providers, and other commentators, that more than 1,000 additional pages of laws and regulations were required. If HIPAA serves to demonstrate two basic principles that health care professionals have long recognized, it is that first, medicine is no longer a one-on-one

relationship and second, medicine has evolved with all its disciplines, providers, and equipment to be a major economic force and component of every industrialized nation.

HIPAA has forced health care professionals to better communicate with patients and their relatives. More ironically, 9–11 and the potential for future terrorist activities, has demanded that the health care professions better communicate with potential patients, the general public, politicians, and the media. Risk communication has been transformed from an arcane technique used by military and emergency preparedness personnel to a staple of daily communication. The basic principles of risk communication are simple and totally applicable to the practice of medicine, especially neonatology: Tell what you know—clearly, succinctly, and in a manner that every sixth grader can understand. Tell what you do not know clearly, succinctly, and in a manner that every sixth grader can understand. Do not guess—information has to be data driven. It is better to say we do not know now, and when we do, we will share it with you rather than to provide incorrect information initially because incorrect information causes credibility to suffer, believability to suffer, cooperation to suffer, and ultimately there is more confusion, anxiety, and poorer outcomes. Communication issues are discussed further in the second section of this chapter.

HIPAA delegates to local health departments the task of collecting vital statistics that include birth, death, and marriage information. These documents generally are protected to some degree. Autopsy reports usually are not released beyond the treating physician and/or coroner/ medical examiner, unless there is authorization to do so. Civil or criminal courts can order the contents of an autopsy revealed if it would assist a party in asserting his or her civil claim, criminal prosecution, or defense from prosecution.

Legal Issues Specific to Managed Care

Although the incidence of malpractice litigation against health professionals has increased exponentially in the U.S. since the 1970s (67), it is not a recent phenomenon. Documented medical professional liability cases date to 1374, when a surgeon in England was sued for negligent treatment of a wound (68). However, a hybrid of lawsuits against health care providers, focusing on managed care issues, is new (69,70). Profit is the bottom line in today's health care system (71). Managed care developed in response to a perception on the part of both government and society in general that there were unnecessary medical procedures being performed with an associated overutilization of medical resources and services, and an unrestrained lack of uniformity of cost in health care. Managed care filled a vacuum; it was developed and marketed because of a perceived need to control by those who paid costs (the employers) and those who managed health care dollars (health care insurance companies). Health care providers did little to inform their constituencies of the potential problems associated with managed care.

Managed care may be defined as “any entity capable of negotiating to deliver health care to a group of recipients at a predetermined rate on a per capita basis” (71). The American Association of Health Plans claims that 150 million Americans were enrolled in health maintenance organizations (HMOs) or other managed care entities in 1995 (72). Almost 75% of those who receive health insurance through their employers are covered by some type of managed care plan (73).

Managed care has become “big business,” with the administrative costs and profit deriving in major part from cost savings and efficiencies (74). The focus of the decision maker to authorize or perform a service or procedure or order a medication now has an aspect of a real or perceived profit motive: There has been considerable media coverage of managed care programs that firmly control costs to the detriment of those paying premiums and expecting the best services available. In many cases, unqualified personnel are placed in a position of second-guessing and

overruling physician decision-making responsibilities and obligations. Delays in receiving permission for expensive procedures or outright denials for critical but costly procedures occur. In some instances, so-called "gag" orders had been inserted in physicians' contracts, which effectively prohibited physicians from disclosing expensive, and potentially more effective, alternative treatments to their patients (71). However, in February 1997 President Clinton requested that the DHHS send a letter to all state Medicaid directors informing them that "gag rules" are prohibited for Medicaid HMOs. He also supported national legislation to ban "gag rules" for all managed care organizations within the United States. Approximately half the states in the United States have enacted or introduced their own laws regulating "gag rule" provisions in medical care policies. In *Moore v Regents of the University of California*, the California Supreme Court held that the concept of informed consent is broad enough to include the physicians' duty to inform their patients that they have an economic interest which might affect that physician's professional judgment (75).

Although managed care attempts to reduce costs by creating economies of scale and coordinating care among health care providers and resources, they also attempt to reduce costs by eliminating unnecessary care, as they define it. In some instances, a managed care program's criteria

P.99

for emergency or extensive and expensive care may conflict with those held by the physician. The physician's contract may have a provision in which a percentage of fees are paid only if utilization goals are met. The physician's contract also may have a capitation provision, which means that the physician is provided a fixed amount regardless of the level of service provided to each patient. In the latter circumstances, the physicians essentially become coinsurers and may have a perceived conflict of interest in the manner and degree to which they provide services to their patients.

The most unique feature of an HMO is that an enrolled patient pays a prepaid, fixed fee for medical services. This is in contrast to "fee for services" in which the patient pays a separate fee for each service rendered by the independent physician. Preferred provider organizations (PPOs) differ from HMOs in that a PPO is an organized group of health care providers offering their services at a discount. Services are provided on a predetermined fee-for-service basis. Members may choose physicians regardless of whether they are in the members' plan but receive "discounts" only from physicians within the plan. PPO physicians have relatively minimal financial incentive to limit services, and physicians practicing under such an arrangement would appear to have greater control of their practice and potential liability.

The HMO may contract directly with physicians and pay them a salary (staff model), or they may contract with a group of physicians. The physician group may or may not devote a majority of its time to serving the needs of a specific HMO. It may offer a mixture of financial arrangements to its patients, including fee for service. The HMO may contract with an individual practice association (IPA), usually a partnership or corporation of physicians, to provide health care services to the HMO membership. The IPA then contracts with its physicians to provide services to the HMO. The fundamental difference between the IPA and the staff and group physician arrangements is that IPA physicians usually work in their own facilities, use their own equipment, and keep their own records. The HMO pays the IPA a capitation fee (a specific amount per enrollee or subscriber); the IPA pays the treating physicians on a fee-for-services basis (76).

Physicians and their managed care carriers are being sued jointly. Allegations of malpractice now are joined with allegations of bad faith, and contract theories of liability are being added to the more traditional negligence/medical malpractice theories of liability (69,70,77). Under the doctrine of *respondeat superior*, HMOs have been found responsible for the alleged negligence of their employee—physicians (78). The doctrine of *respondeat superior* states that an employer is vicariously liable for negligence of an employee acting within the scope of his or her employment

(79). The doctrine does not apply if the negligent party is a true independent contractor (80). The distinction between an employee and an independent contractor is control or independence; that is, an employee is subject to the immediate direction and control of the employer, and independent contractors use their own judgment and are not subject to direct control. In some instances, an HMO can be held vicariously liable for the negligence of a consultant requested by the HMO's physician (81). This issue may be decided on the wording in the promotional material provided to subscribers. A managed care contract can increase a physician's obligations to a patient; the contract cannot decrease or even limit the physician's obligations and legal liability to the patient. When a physician employed by an HMO makes a treatment decision, that treatment decision has financial consequences to the HMO (69). In a malpractice suit, there are now assertions that the HMO-paid physician's treatment decisions were economically motivated rather than being made in the best interests of the patient (69). Before a physician accepts a contractual obligation, whether it is the product of an employment contract with a hospital, group practice, HMO, or other form of managed or prepaid care program, it is strongly suggested that the physician seek legal advice regarding the terms of the contract and the consequences of those terms.

Regardless of the employment status of the health care provider, the hospital has an obligation to oversee the quality of patient care and services (82). Ultimately, however, the courts have held that it is the physician's responsibility to uphold good medical practice in the face of improper or incorrect cost-containment procedures put forth by HMOs or other managed care organizations. The California Court of Appeals has held that, "while we recognize, realistically, that cost consciousness has become a permanent feature of the health care system, it is essential that cost limitation programs are not permitted to corrupt medical judgment" (83). That court found for the plaintiff because the physician did not protest the health insurer's determination that a prolonged hospitalization for his patient was not necessary, with severe negative consequences for the patient (83).

The Employee Retirement Income Security Act of 1974 (ERISA) (84) "supersedes any and all state laws insofar as they may now or hereafter relate to any employee benefit" (85). In *Shea v Esensten*, a federal court found that ERISA requires HMOs to disclose to their enrollees the compensation agreement between the HMO and its physicians (86). That is, there is an affirmative duty by the HMOs to inform their subscribers of any financial incentives that the health care providers may receive as they manage their patients' care. These financial "incentives must be disclosed and the failure to do so is a breach of ERISA's fiduciary duties" (86). Physicians who have challenged managed care decisions about patient care have been removed from the HMO panels. Suits for reinstatement on the grounds that they were removed from the panel without good cause and in violation of public policy and the implied covenant of good faith and fair dealing traditionally read into contracts have had mixed results (87,88). Just as medicine has evolved significantly during the past several decades, so too has the law. Both will continue to change, and their progress, conflicts, and

P.100

resolutions will be documented in the media, professional journals, legislature, and courts.

Physician Liability Arising from Nonphysician Providers

Liability exposure arising from the use of nonphysician providers (NPPs) (e.g., neonatal nurse practitioner, clinical nurse specialist, physician assistant) is relatively new. It can be assumed, however, that as NPPs increase their roles, there will be a concomitant increase in malpractice allegations against NPPs and the physicians working with them, based upon the fact that the NPP is acting as an agent for the physician.

To the extent that NPPs exercise control over their professional activities, they will be held responsible for their negligent acts. Under the old “captain of the ship” (*respondeat superior*) doctrine, the physician was presumed to be responsible for the activities of all the NPPs working with the physician. Contemporary courts have moved away from this theory and have placed responsibility on those professionals exercising control. However, this does not eliminate the liability risk for the supervising physician.

Potential areas of risk for neonatologists working with NPPs and methods for reducing risk are listed in Table 8-1.

TABLE 8-1 LIABILITY RISK AND RISK REDUCTION FOR NEONATOLOGISTS WORKING WITH NONPHYSICIAN PROVIDERS	
Areas of Risk	Risk Reduction
<ul style="list-style-type: none"> • Inadequate supervision by physician • NPPs working beyond their scope • Parent unhappy about access to their newborn's physician • Physician viewed as “deep pocket” by plaintiff's bar • Apparent physician delay in seeing critical patient 	<ul style="list-style-type: none"> • Check NPP credentials before hiring and maintain documentation • Establish, and review at least annually, written policies, protocols, and procedures for: <ul style="list-style-type: none"> ○ patient examination ○ treatment ○ delegation ○ supervision ○ patient's/parent's right of access to physician • Instruct NPP to adhere as closely as possible to patient care protocols, using physician input when significant deviation may be required; the rationale for deviations should be documented • Document completion of skills inventory check • Document current competency and establish a quality monitoring system • Educate other staff about the role and limits of the NPP • Understand and keep current regarding statutory requirements for NPPs • Use name tags to identify the professional status of the NPP • Introduce NPP to parents and explain role • Review NPP's charts on a regular basis and cosign orders in a timely fashion • Establish protocol for physician to see patient and parents at set intervals • Obtain adequate liability insurance for NPP; physician's liability insurer should be informed that they are supervising NPPs • Ensure that NPP complies with hospital credentialing requirements and has sufficient time allotted for continuing professional education; require that copies of licensure renewal and certification of continuing education are kept on file • Inform physicians covering call of NPP's role

The National Practitioner Data Bank

Some malpractice insurance carriers retain the right to settle lawsuits independent of the wishes or sentiments of the health care provider. The federally mandated and operated National Practitioner Data Bank contains information, available to hospitals and individuals, and lists settled medical malpractice claims (89). General medical malpractice carriers may not always be knowledgeable regarding the specific nuances of specialty practice.

Health professionals should do more than comparison shop the price of a malpractice policy. They need to determine the financial soundness of the malpractice carrier and their own rights to control settlement and to determine the sophistication and knowledge of the legal representation provided by their insurance carrier.

P.101

QUALITY ASSURANCE, PERFORMANCE IMPROVEMENT, AND RISK MANAGEMENT

The process of quality monitoring and improvement (QMI) is also discussed in Chapter 7. This part of the chapter emphasizes how QMI and risk management are closely interwoven and how both monitoring systems are used to improve patient care.

The Growth of Risk Management

In the United States, risk management programs grew out of changes in the medical malpractice insurance market (insurance became more difficult and more expensive to obtain) as malpractice claims accelerated in the 1970s (67). As the cost of liability insurance increased, the establishment of risk management programs made health care facilities more attractive to insurance underwriters. When institutions formed their own self-insurance trust funds, risk management programs provided some assurances to hospital board members that the financial liability of the institution would be limited to the greatest extent possible by their own risk managers. Depending upon the size and complexity of the health care institution involved, there may be one set of professionals who provide risk management guidance relative to standards of care and a second set of professionals under the leadership of a compliance officer who assure compliance with the requirements of regulatory bodies. Ensuring compliance requires a thorough knowledge of applicable standards and a commitment of time specifically directed towards understanding compliance and related issues. In smaller institutions the compliance officer and risk manager may be the same individual.

Basic Elements of a Compliance Program

A compliance program is a set of procedures within a medical practice or other health care facility which are designed to ensure adherence to laws and regulations associated with either federal or privately insured health care programs and thereby to prevent or reduce improper conduct. Although the size (e.g., number of employees) and type of practice or organization determines in large part the extent and formality of its compliance program, even small, private, neonatology practices are expected to implement one. Compliance programs establish and communicate standards of conduct; provide channels of communication to inform employees of rights, benefits, and obligations, and to answer questions; enforce standards through the consistent application of disciplinary measures; and require ongoing auditing and monitoring to ensure that identified errors are corrected and future similar occurrences are prevented.

The rapid rise in health care costs in the United States during the past three decades has prompted a significant increase in governmental scrutiny. The results of government audits have created a dramatic change in public opinion regarding the level of waste, fraud, and abuse in the health care system. This has led to the passage of legislation that creates a trust fund for investigations and expands governmental prosecutorial powers and also has markedly increased penalties for noncompliance. For instance, a claim for payment for medical services to Medicaid or Medicare which is deemed to be "fraudulent" under the False Claims Act (90) requires payment of three times the amount of the overpayment plus a mandatory \$5,000 to \$10,000 fine per claim. And since each individual service billed for is a claim under the definitions used in the statute, penalties can become enormous. On the other hand, "erroneous" claims (i.e., those resulting from innocent errors) require only the return of the amount of the overpayment. Fraudulent claims result from three circumstances: (a) actual knowledge that the claim is false, (b) reckless disregard of the truth or falsity of the claim, or (c) deliberate ignorance of the truth or falsity of the information. To mitigate the potential and corresponding penalties for noncompliance, voluntary compliance programs have become commonplace and necessary in the health care world. The voluntary compliance programs recommended for health care providers are designed to detect and/or prevent illegal activity through self policing.

Providers meeting the requirements of an effective compliance program, listed below, demonstrate their commitment to creating an environment in which payment claims are accurate; fraudulent behavior does not occur; improper practices are prevented, detected, or rectified; wrongdoing is reduced; administrative liability is mitigated; and the mental state of reckless disregard is negated. Although all compliance programs do not need to be alike and the degree to which each element needs to be addressed varies among practice types, compliance programs should address the following seven basic elements (91):

- establish written standards of conduct, policies, and procedures
- designate a compliance officer or contact
- provide mandatory training and education
- create and publish accessible lines of communication
- audit and monitor compliance with guidelines
- enforce through clear disciplinary guidelines
- respond to violations and take corrective action

Although neonatal practitioners are not expected to be experts in law or regulation, they need to have a good working knowledge of relevant legal and regulatory requirements that relate directly to their duties and responsibilities. Regulations often are complex, ambiguous, and sometimes silent on key issues. Whenever in doubt about a legal or administrative issue, it is important for the practice or practitioner to consult with an expert before proceeding. The list of areas of law/regulation which the practitioner should understand includes, but is not limited to, the following (91):

- billing and coding
- patients' rights
- health care antifraud and antiabuse laws

Medicare/Medicaid antikickback statutes

conflicts of interest

harassment in the workplace

environmental protection laws (e.g., disposal of hazardous material and medical waste)

health and safety programs and Occupational, Safety, and Health Administration regulations

HIPAA regulations

receipt and giving of gifts, gratuities, and other business courtesies

credentialing requirements, including sanction screening

insider information and securities laws

patent, copyright, and intellectual property laws

record retention requirements

professional standards of care

Stark legislation (e.g., physician antireferral statutes)

the Privacy Act

Establishing a Risk Management Program

Health care errors rarely are due solely to a mistake made by an individual; they are usually an indication of failure of a health care system. System issues are referred by risk managers to staff trained in quality improvement and to the hospital administration, and vice versa. An effective QMI program works in close cooperation with the risk management team, with the ultimate aim being the improved care and safety of patients and lowered liability exposure. The importance of monitoring all aspects of a health care system in the prevention of medical errors was emphasized by the IOM in their 1999 report (92) on the nature and extent of medical errors in the practice of medicine.

Risk Reduction as It Relates to Quality Monitoring and Improvement and Risk Management

Risk is the possibility of harm, the uncertainty of danger, and the probability of loss. The essence of a QMI program and of risk management lies in maximizing the areas in which there is some control over the outcome while minimizing the areas in which there is absolutely no control over the outcome. The existence of risk does not imply that there are always alternatives. The terms QMI and risk management are used to describe a process of examining any potential alternatives and thereby influencing, in a positive manner, the level of risk to which patients, health care providers, and institutions are exposed. An outcome of managing risk is the identification of a level of harm or danger that is the irreducible minimum. However, QMI and risk management differ in the order of priority of their primary goals. In the health care setting, harm or danger expressed in human terms pertains to the safety of patients, visitors, and employees, and to health care delivery practices; however, harm or loss can also be expressed in financial terms, such as losses in settlements, jury verdicts, legal expenses, and payment of increased insurance

premiums. QMI is the term used for the process in which the primary expected reduction is expressed in human terms; risk management is the term used when the primary expected reduction in risk is expressed in financial terms. Risk reduction is achieved using a process that involves investigating, evaluating, planning, organizing, and implementing procedures. The resulting benefit of risk reduction is improved quality and understanding of patient care and also preservation of the financial resources necessary to provide optimal patient care when there are fewer claims made and fewer lawsuits brought against the health care providers (93,94). Financial and psychological benefits also are realized when malpractice cases are dismissed or settled for reduced amounts, based on the strength of the defense.

The level of risk exposure in the health care environment is inversely proportional to the control maintained by the health care service providers. Total control is not possible in the face of complex disease processes and complex care and treatment managed in complex patient care delivery systems. In the critical care environment, a risk reduction program must be established that anticipates, identifies, and responds to risk. When it is possible in the process of delivering care to patients, fail-safe systems are established to prevent errors from affecting the patient.

The elements of a risk reduction program also reflect the health care organization's attempt to define, describe, and impute liability within the organizational structure. Functional definitions of health care executives and their roles and responsibilities for supervising and administering health care activities enable the health care providers to identify chains of management decision making and accountability. Health care providers need to understand who supervises each administrative component of a health care facility so that complaints, comments, and recommendations reach those who are in a position to respond affirmatively. The chain of responsibility for developing, implementing, supporting, monitoring, and evaluating a risk reduction program reflects multidisciplinary health and management skills and activities. It must be recognized that a risk reduction program is both a proactive (preventing potential incidents from occurring) and reactive (responding to an incident or seminal event and preventing future similar incidents) system of intervention to protect the patient, institution, and clinician. Although assignment of responsibility does occur in either a proactive or reactive risk assessment, responsibility is not to be perceived as the same as negligence. For example, there is no negligence in a situation in which a physician orders a specific dose of medication, the nurse responsible administers the proper dosage, and there is a resultant catastrophic effect on the patient. In many instances, either the risk was known and shared with the parents or the adverse consequences could not reasonably have been foreseeable.

Risk reduction programs strive to reduce risk to the greatest extent possible and to manage the remaining risk. Quality improvement committees, safety committees, and specialized subcommittees provide the administrative and

P.103

management structures to review the various aspects of clinical care and support and to provide constructive guidance and assistance. The outcome of this effort is improved quality of care within the context of the goals of the health care team and the patient's family.

From the perspective of risk management, risk financing involves the financial arrangement (insurance) made for the payment of losses that inevitably do occur. The liability insurance program may be coordinated by the risk management department. The risk manager notifies the insurance carrier of reportable events, claims, and lawsuits. Members of the health care team have a shared responsibility to report adverse events, contribute to the data that will track these events, and alert the malpractice insurance carrier to potential financial loss. The risk manager may select defense counsel and assist counsel in the defense of the institution and/or health care providers. In addition to contributing to the quality of patient care, the risk manager, under the direction of counsel, contributes to the quality of the defense of the health care provider in a claim

or suit (94,95). Conflicts of interest between the institution and health care provider need to be identified and addressed as soon as possible. Separate counsel for the medical institution or group practice and medical practitioners may be required when there are divergent institutional and personal interests. For instance, one party may wish to settle their portion of the case while the other named party or parties may wish to litigate the allegations against them.

From the QMI perspective, adequate risk financing, malpractice insurance, requires the acknowledgment that reducing the risk to patients and staff in the health care system never means totally eliminating it. There will always remain some minimal risk for an untoward event. Hence, malpractice insurance is needed to cover the cost of defending the claims and the cost of paying any judgment, should the defense efforts prove unsuccessful.

To achieve the goals of risk management, the following activities must take place:

Systematic and continuous investigation of risk exposures. Risk managers must be made aware of potential and actual exposures (adverse events) as they occur and of system changes that may affect patient and staff potential exposure to risk. To achieve this level of awareness, it is necessary for risk managers to establish a communication network that provides real-time feedback. The risk manager utilizes the knowledge, impressions, and experience of the health care team to investigate events that have occurred and to identify events that might occur in the future. Methods of communication to risk managers include incident reports, risk management presence on committees, and ready accessibility by electronic means.

Evaluation of risk loss exposure. An examination of the nature, frequency, severity of risk, and potential impact on the patient/organization detects patterns in recurrent events, which can be used to predict their recurrence. For example, if medication errors are observed to occur just before a change of shift, examination of the human dynamics that contribute to these errors and breaking the pattern can lead to correction of an error-producing systems flaw. Administration and clinical staff are called upon to identify potential risk areas for evaluation.

Planning and organization of appropriate risk avoidance and prevention techniques to efficiently minimize loss to the organization. Currently in the United States, order, stability, and consistency are not the hallmarks of a successful health care organization. Risk management demands the establishment of an information-gathering network, which identifies emerging organizational changes. Areas of risk can be identified as projects are developed. The monitoring of system changes after implementation is used to detect any negative impact on patient care. Recommendations can then be made to adjust system changes. Anticipation is one of the most important considerations. Identifying pertinent questions regarding the level of risk for potential adverse events and those who should be involved in evaluating a system helps the direct clinical service providers avoid some significant errors (96).

Implementation of risk reduction. Good clinical staff are flexible, innovative, and creative; thus, there is constantly the potential for an adverse event to emerge from new technology or treatment modalities. Simplifying the organization or health care practices to gain control is not a realistic goal in today's complex health systems. By using reporting and communication connections within and outside the organization and analyzing data from the investigation of adverse events, areas of greatest risk can be identified. The information about potential risk is communicated to committees or individuals who then put in place mechanisms to reduce the risk to the patient and institution. That the risk cannot be controlled completely should also be communicated, particularly to the patient's family.

The Risk Management Plan

Risk management activities are outlined in a program description. Such a document provides clear

and concise information about the risk management program, which is available to all those within the institution.

Staff Education

Personnel involved in QMI or risk management must recognize that they are educators. Every committee meeting, exchange with a staff member, or participation in orientation is an opportunity to dispel misinformation and increase understanding of the risk management process.

The fundamentals of risk management are not highlighted in medical and nursing schools but are necessary to prepare future health care providers for dealing with risk issues that arise in the clinical setting. The development of a risk management curriculum gives structure to educational

P.104

efforts and provides a framework to cover essential topics, ranging from the orientation of new employees, staff physicians, and residents to seminars for advanced practitioners, department chairpersons, and administrators.

As an outcome of a core curriculum in risk management, all individuals in health care should be able to:

- define risk
- know the basics of how to set up a risk reduction study, including definitions of area of risk to be studied and sentinel events
- describe what a risk manager does and why
- understand what events need to be communicated to risk managers
- recognize that if a facility, treatment, or system is replaced, the replacement must be monitored until proven to decrease risk
- describe how to access risk managers for reporting and receiving information
- describe what relationship risk managers have with professional liability insurers

Grupp-Phelan and associates (97) reported that pediatric residents were named in 26% of malpractice suits. All health care providers, including nurses, nurse practitioners, residents, house staff, and ancillary staff such as respiratory therapists and clinical nutritionists, should know what kind of process a risk management investigation will follow (Fig. 8-2).

The Risk Management Investigation Process

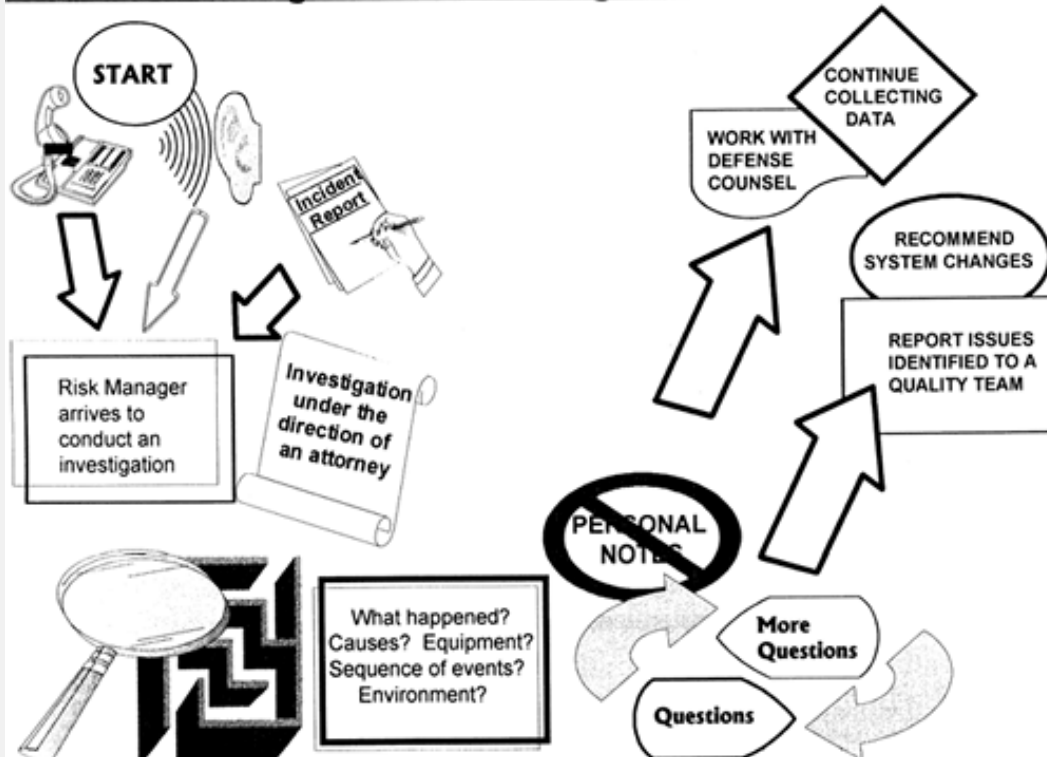

Figure 8-2 The risk management investigation process begins with the receipt of notice that an adverse event has occurred. An attorney directs some investigations in jurisdictions where the risk management activities are not protected from discovery in litigation. The personal notes of health care providers are not protected from discovery. After many rounds of questions, opportunities for improvement are reported to quality improvement councils. In a separate activity, the results of investigation directed by the defense attorney are sent to him or her.

Health care professionals should avoid making editorial comments in patient records and should not keep personal notes about clinical events. Objective clinical impressions belong in a patient's medical record. Physicians, nurses, and other health care professionals should understand that investigations take time and that the findings may be very different from the initial views of the staff. Speculation about the causes of adverse events or discussions of the events outside the peer-review/quality improvement areas should be discouraged.

With an understanding of the fundamentals of risk reduction/management, the health care provider can move on to identify systems and processes in his or her care that can be examined for safety and effectiveness. The risk manager analyzes the frequency or severity of adverse events or unexpected outcomes and the findings during the course of discovery in lawsuits, and then identifies topics that can be presented in an advanced risk reduction curriculum. These include: retroactive peer review (e.g., clinicopathologic review, regular review of perinatal or neonatal patient care statistics), documentation, communication, supervision, monitoring and assessment, coordination of care, medication administration, system failure(s)

P.105

and human error, and changes in local, state, or national regulations or laws.

Adverse Events

Adverse sentinel events were defined by the JCAHO in 1996 as unexpected occurrences involving death or serious physical or psychologic injury or risk thereof. The term "sentinel" is used because the event should sound a warning that requires immediate attention. A root cause analysis is recommended by the JCAHO as the format for an intensive assessment to reduce the variation

and prevent the event in the future. This type of analysis addresses these questions: what happened, why did it happen, and what processes were involved when it happened? The analysis can be used to piece together the reasons why a mistake or complication occurred. If the system worked previously, what elements have changed to produce the potential for error (98)

In some instances, it is not possible to sort out the exact sequence of events. Interruptions in the system of care delivery that are identified should be repaired or redesigned to prevent further breakdowns. Because serious occurrences do not occur very often, it is necessary to optimize the lessons learned from each event, including an application of those potential events that did not occur. Adverse, unexpected, or poor patient outcomes do not necessarily indicate that a mistake has been made. It is important not to make this assumption within the health care team, nor to accuse or place blame. When there is an unexpected outcome, the risk manager is called upon to perform the process of identifying the possible contributing factors.

Receiving an incident report and investigating problems that have occurred or potentially might occur is viewed by the risk manager as an opportunity for improvement in the system of care delivery. This positive outlook may not be shared by the staff. The stigma of punishment or retaliation in relation to incident reports exists and is a deterrent to obtaining the information on which to base a recommendation for change and improvement in health care delivery.

Accountability versus Blame

System and practice patterns are the focus of a risk management investigation. Investigations may reveal systems and patterns that do not provide sufficient or effective safety checks to prevent human error or miscommunication. In addition to identifying the flaw in systems or processes that potentiate mistakes, adverse event investigations studied in the aggregate identify the types of patients most likely to be affected. Andrews and associates (99) found that more patients with a serious illness had an initial adverse event, and that the likelihood of an adverse event increased 6% for each additional hospital day. The analysis of event databases provides the health care team with information that they can use to modify practice or alert other practitioners, thereby improving care and reducing the likelihood of lawsuits.

Reported predictors of the outcome of pediatric litigation include severity of resulting disability (100), defensibility of the case (101), and parental anger (102) (often exacerbated by a perception that communication with health care providers was less than satisfactory). The importance of patient or parental anger was demonstrated by Andrews and associates (99), who found that of 1,047 patents with serious injury, 17.7% experienced serious adverse events that led to longer hospital stays, but only in 1% to 2% of these adverse events was a legal claim made for compensation.

Pichert and associates (102) studied 43 closed claims, covering 8 years, involving children. A significant portion of the claims were associated with high-risk medical conditions (37%) and problems associated with intravenous therapies, central lines, and catheters (21%). In 9% of the claims physicians relied on faulty information, and in 19% the parent(s) became particularly enraged by an injury.

Conventional wisdom holds the view that human beings are intrinsically unreliable. From this it follows that when something goes wrong, someone must have erred. It is assumed that mistakes such as these are the result of inattention, carelessness, and negligence. The remedies invoked to prevent further lapses include finding the culprit, assigning blame, and acting to correct future misdeeds. The truth is that the errors people make often are traceable to extrinsic factors that predispose an individual to fail. Whenever human error is suspected, it is a sound policy to trace the error to its root cause(s). To assign blame to an individual who makes an error is no assurance that the same error will not be made again by that individual or another (103).

The health care provider should not assume that he or she or another member of the team is responsible or liable for an unexpected outcome. Frequently the first impression regarding the cause of poor patient outcomes is significantly different from the cause(s) recorded at the conclusion of an investigation. There is also a possibility that a cause may never be found. There should be no speculation by those directly or peripherally involved as to the cause or etiology of the event. A defensive position in response to the family's accusations should be avoided, as should the assignment of blame to other disciplines, departments, and/or systems.

The analysis of a single event and analysis of event trends provide the health care team with information that they can use to modify practice or alert other practitioners, thereby improving care and reducing the likelihood of repeated errors.

Communication

Risk communication includes those techniques for disseminating information that may be complex and include elements of uncertainty as to diagnosis, treatment, and prognosis. Chess and associates (104) note that some common myths often interfere with the development and implementation of effective risk communication. The manner in

P.106

which the information is provided (the style and process of information delivery) is just as important as the content of the message. Treatment options need to be provided, including the option of no treatment. Confrontation should be avoided. Questioning should be encouraged and not perceived to be a challenge to a clinician's knowledge, treatment interventions, or plans. Neonatal intensive care units are highly emotionally charged environments, both for the parents and concerned family members and health care providers.

Communication with Parents and Guardians

Many factors that lead to medical malpractice lawsuits are perceptual and qualitative in nature. In many cases, lawsuits are not the result of malpractice, but are instituted because the patient or patient's family feels that information was withheld from them or that they were not told the truth. Effective communication skills used in data collection, developing relationships, and dealing with parents' emotions help to prevent anger and possible malpractice litigation (105).

The perception by the family of the competency of the physicians, nurses, and other health care team members is drawn from their interactions with them. Ideally, contact with the family inspires trust, confidence, and openness. Positive contact with the family of a neonate is based upon the fundamentals of communication: body language that conveys attention to the family and infant, taking time to answer questions, asking for input from the family regarding their impressions of the baby's progress, and speaking in terms that can be understood by the family. These basic clinical and social skills represent the foundation of defensive medicine techniques. It is important to convey the message that team members taking care of the infant are communicating with each other, are fully aware of the treatment plan, and are coordinated in their approach to the care of the infant. Judgments and preconceived opinions about the family should be avoided, regardless of their lifestyle or behavior toward the health care team. A study by Cuttini and associates (106) concluded that parents generally are satisfied with the information received, although some complain about the style of communication and especially the need to ask repeatedly in order to be informed. The latter complaint may be more common in teaching hospitals because of the greater complexity of the health care hierarchy produced by the presence of medical students, interns, residents, and attending physicians, who may change every month. No matter how large the team caring for a neonate, the attending physician should be known to

the parents and guardians and readily accessible to all salient parties.

Those who provide health care need to understand the manner in which they communicate to parents and other concerned parties. Health care providers must communicate in a manner which is linguistically, contextually, and culturally appropriate. The reluctance of many health care providers to convey the limitations as well as the achievements of the health care can significantly increase the family's distress when negative changes in their infant's condition occur. When the neonate or infant is not doing well, that is the critical time for more communication and more interaction with parents and significant others, not less. A decrease in communication at a critical juncture can and will damage the health care team's credibility. Training in risk communication, in conveying negative information, is essential.

Covello and Allen (107) identify seven cardinal rules of risk communication. Though these rules are designed for individuals who have to deal with the general public, they generally can be adapted to a hospital setting (91):

- Accept and involve the family or guardian as a partner. Information is to be shared; concerns may not always be eliminated.
- Present the plan or course of action that may even include alternative plans.
- Listen to the concerns being stated. A concerned individual cares more about trust, credibility, competence, and empathy than cold statistics and complex details.
- Be honest, frank, and open. Recognize that once trust and credibility are lost, they are almost impossible to regain.
- Different health care providers may have different opinions; different family members may express different concerns. This is to be expected. Open and frequent communication minimize doubt and distrust. A single spokesperson, or a limited number of spokespersons, should be designated to minimize the diversity of opinions being provided.
- Concerned parties are more interested in risks, simplicity of explanations, and the danger to the patient. The focus of the discussion needs to be on the patient, not on the health care provider.
- Clear communication in a language and vocabulary understood by all parties needs to occur. Communication should be accompanied by compassion.

For the family of a critically ill neonate, the distinction is unclear between a bad outcome due to disease progression and unfortunate circumstances/errors/negligence. Anxiety over the uncertainty inherent in the care of the seriously ill may evoke feelings of helplessness. Outcomes that are expected by the physician but not clearly conveyed to the family may be a shock for the family. The nonoccurrence of expected outcomes leaves the parents feeling that a mistake has been made. Families who experience disappointments in clinical outcomes may take out their grief and despair on the health care provider. The provider may be unprepared for the parents' anger and distrust. Appearing uncertain, handling questions improperly, apologizing for oneself or the

team, not knowing the available information, not involving the family in the decision-making process, not establishing rapport, appearing disorganized, and providing the wrong information (such as discussing the wrong patient) can all lead to a breakdown in communication.

P.107

Acknowledgment of hostility is acceptable; this indicates that the health care provider recognizes the reality of the situation. Anxiety undercuts confidence, concentration, and momentum. Listen to what others have to say, even if you disagree with them; recognize expressions of frustration. State conclusions and then provide supporting data. Above all, do not lie.

If an adverse event occurs, the honest, sincere, and compassionate response of the health care team to the family will reduce the family's view that there is a need to bring a lawsuit. Without burdening the family with personal feelings of inadequacy, regret, or vague misgivings, it is helpful to show concern and to express empathy regarding the patient outcome. Silverman (108) offers insight into how parents of infants blinded by retrolental fibroplasia (RLF) (retinopathy of prematurity) view the health professional who fails to convey appropriate concern:

As compared with conversations with RLF-blind young adults, discussions with parents, singly and in groups, were much more difficult for me (and for them). Most of the parents were still bitterly angry at the medical profession, but not for the reason I imagined. They understood and accepted the fact of limited knowledge at the time their children were born. Most were convinced that physicians had rendered excellent care and had used supplemental oxygen liberally in well-meant efforts to improve the chances of the small babies for intact survival. But, almost without exception, parents recalled (with rancor) that once the diagnosis of RLF was made, a chill in relationships developed. At the very time when they needed support and advice, their physicians became distant and defensive, the parents recalled. Most blamed their doctors for failing to maintain interest and concern, not for the failure of clairvoyance! The parents said it was anger at personal, not professional, behavior of physicians which prompted many of the RLF legal suits charging malpractice which burgeoned in this country.

A member of the health care team should be designated as the primary communicator to share with the family the treatment plans that have been formulated in response to the adverse event. At the request of the family, extended family and other support may be included in family conferences and discussions of the causes or possible causes of the event. Maintenance of a coordinated and ongoing communication with the family may be difficult in the face of the family's anger and despair. However, the goal of the health care team must remain the support and treatment of the patient and family.

Communication with and within the Health Care Team

From the significant number of dangerous errors that occur in the intensive care unit, Donchin and associates (109) found many were attributed to problems of communication between physicians and nurses. They suggest that studying the weak points of communication in a unit may reduce errors, and that errors should not be considered an incurable disease but rather a preventable phenomenon. Clear oral communication is vital in a NICU; the medical record alone cannot be relied upon to adequately convey urgent information between members of a health care team.

The medical record should be designed to achieve clear communication with and among the members of the health care team. Clinical information is focused on the patient and family, and it derives from repeated assessments, analyses, judgments, and actions aimed at achieving specific goals. Documentation in the patient record allows ongoing evaluation of patient progress and review of the clinical management plan. The individual contributions of the members of the health care team are recorded and used by other team members as a basis for planning each new step in patient care. This documentation of the exchange of information among the team and the recording of the outcome of each team member's analysis of the information also helps to support the team's choices and judgments. Documenting patient care, contemporaneous with the events, provides the clinical picture that will be used in the defense of the care provided should an adverse event occur. If the clinical record has the appearance of being a battleground for warring or defensive factions of the team, the record will reflect a lack of team cohesion and direction that is difficult to defend. The record should contain the facts of the event, assessments of the patient, the decision-making processes, and the interventions undertaken.

Any documentation of an abnormality in the medical record should be accompanied by the reassuring factors that support the overall interpretation of the clinical findings. All factors that explain decisions made in the face of abnormal finding(s) should be recorded. In fact, documentation of reassuring factors should accompany the recording of abnormal factors (110).

It is very important not to draw conclusions or relate events to outcomes that are speculative in nature. Avoid placing an inappropriate medical diagnosis as a label to clinical findings. The members of the team will erroneously draw upon speculative causal relationships and refer to them further in the record as an absolute. Applying an outcome, diagnosis, or finding from incomplete data does not lessen the impact of such a premature diagnosis during the course of either treatment or litigation. Concluding, for example, based on insufficient data that the encephalopathy found on a computerized tomographic scan is hypoxic encephalopathy and that the hypoxic encephalopathy is related to a specific hypotensive episode serves no meaningful clinical purpose and may lay the foundation for an accusation of medical negligence on those purported to be responsible for causing or failing to detect that specific hypotensive episode when the abnormal finding may not be secondary to hypoxic encephalopathy in the first place.

Imposition of unsubstantiated diagnoses is a frequent occurrence during follow-up care of high-risk infants and children. Recognizing that the medical records of infants discharged from an NICU may be voluminous, if a diagnosis cannot be confirmed by review of records, it should not be made in a follow-up summary.

P.108

Clinical findings, if possible, are best graded using numeric values. Modifiers, such as the words "extreme," "severe," or "massive" do not provide objective information and will feed into the drama of a courtroom presentation. Contributors to the evaluation and care of the patient must avoid inflammatory language, markings, or punctuation that attempt to draw attention to the writer and imply that the team may be inattentive to the remarks otherwise.

TABLE 8-2 STEPS IN THE CONSULTATION PROCESS

TABLE 8-2 STEPS IN THE CONSULTATION PROCESS

- Identify when it is appropriate to obtain consultation
- Choose the type of consultant (sequencing of a variety of consultants)
- Share the purpose of the consultation with the family
- Decide what information is necessary to provide to the consultant, including the purpose of the consultation and provide as a written consultation request
- Arrange a formal consultation or designate this responsibility to a specific individual
- Give a time frame within which the consultation is to be done
- Agree with the consultant on how the consultation will be reported and who will discuss the findings with the family/parent(s)
- Share the outcome of the consultation with the family
- Tell the family what will be done with the resulting information
- Document in the medical record the reasons for requesting a consultation, discussions with the family, and plan of treatment, including the reasons why the recommendations of the consultant will or will not be followed

It is possible that an infant's condition is changing so rapidly that thorough, contemporaneous notes in the medical record cannot be made. Although "not documented, not done" (111) is a well-known legal motto, there is much that occurs that cannot be documented in the patient record at the time of a critical event. It is often hindsight that focuses the care provider on events not recorded in contemporaneous records. A decision must be made as to whether an addendum to the medical record would contribute to patient care, or whether the additional information relates to system issues and should be conveyed to the risk manager by completing an incident report. An incident report is a confidential document that provides a means to communicate system issues. References to the completion of the incident report or discussions with the risk manager are not appropriate for, and should not appear in, the medical record (110). An incident report relates to an adverse event; the patient's record reflects care and treatment delivered, the patient's response, and the further plan of care.

When additional information, identified after an adverse event, is necessary to the care of the patient, communication of this information is achieved in an addendum to the medical record. Such entries must include the date and time that they were written. Under no circumstances should an attempt be made to make this entry appear contemporaneous with the adverse event. The addendum must be placed sequentially in the medical record in the next available space, not on a separate page, and never inserted into the text of previous entries. The purpose of an addendum is not to provide a defense or to make excuses.

Communication with Consultants

The "curbside" consultation between colleagues is a thing of the past. This type of consultation tends to be documented poorly, if at all, and can lead to damaging finger pointing in a court of law. Guidelines for the consultation process are shown in Table 8-2.

When a consultant is contacted for a specific patient with a formal request for evaluation and/or management, both the primary physician and consultant should interact in such a way as to limit unnecessary risk for both (111).

CONCLUSIONS

Almost coincident with publication of the fifth edition of this textbook (at the end of 1999), the IOM published their landmark report on the quality of health care in America (92). The reported finding that between 44,000 and 98,000 patient deaths per year are due to medical errors placed this as the eighth leading cause of death in the United States. In their report, the IOM estimated

that at least 50% of these errors were preventable and challenged the health care system to reduce medical errors by 50% in the next 5 years. A further report entitled *Crossing the Quality Chasm: A New Health System for the Twenty-First Century* was published 2 years later in 2001 by the IOM (112) in which they listed six redesigned imperatives for the health care system in the United States:

- redesign of the care process
- use of information technologies
- knowledge and skills management
- development of effective teams
- coordination of care
- use of performance and outcome measurements

As the sixth edition of this textbook goes to press, there is abundant evidence that the IOM challenge has been noted and that the mouth of the quality chasm has been explored. There is little evidence however, at the 5-year anniversary of the IOM challenge that construction of a sound bridge across the quality chasm has progressed beyond the sinking of pylons.

Chapter 9

The Vulnerable Neonate and the Neonatal Intensive Care Environment

Penny Glass

Environmental factors in the neonatal intensive care unit (NICU) have major implications for the care of the sick newborn infant. Advances in medical technology during the last 3 decades are credited with dramatic reductions in mortality, with a 50% survival rate for newborns weighing 1,500 g in 1970 to a 50% survival rate for those weighing less than 700 g by 2000. Morbidity among survivors, however, is a problem of increasing proportions. Whereas the rate of major morbidity has remained fairly stable, around 10%, this focus on major morbidity has overlooked the much larger number of children born prematurely who have learning disabilities at school age. Broad evidence implicates the environment in the NICU as a factor in neonatal morbidity. Abnormal sensory input can be a source of potentially overwhelming stress and, at a sensitive period during development, can modify the developing brain. The NICU environment, therefore, assumes a crucial role in the care of the sick newborn infant.

Preterm birth is the most common single risk factor for developmental problems in childhood, and learning disability is the most pervasive developmental problem. This is a catch-all term, but includes children of low, average, or otherwise normal intelligence who have deficits in language, visual perception, or visuomotor integration; deficiencies in attention span, hyperactivity; or social immaturity. Such children require either special services to function in a regular classroom or placement in a special class. Reports of school-age children who were of very-low-birth-weight indicate that as many as half have learning disabilities (1,2,3,4,5,6,7,8). Such deficits may originate from overt damage to the brain or from a more general disturbance in brain organization.

Throughout infancy, both behavioral and neurologic differences exist between full-term and preterm infants, even when matched for conceptional age. The latter often exhibits manifestations of altered brain organization, including disrupted sleep, difficult temperament, both hyperresponsivity and hyporesponsivity to sensory input, prolonged attention to redundant information, inattention to novel stimuli, and poor quality of motor function (9,10,11,12,13,14,15). These precursors of learning problems in school are not fully explained by either the severity of illness among the preterm infants or by later conditions in the home environment (10).

The sensory environment in the NICU is different in virtually every respect, both from the environment of a fetus *in utero* and from that of a full-term newborn at home. The NICU experience also contains frequent aversive procedures, excess handling, disturbance of rest, noxious oral medications, noise, and bright light. These conditions are sources of stress and anomalous sensory stimulation, both of which may affect morbidity.

The immediate effects of stress are autonomic instability, apnea/bradycardia, vasoconstriction, and decreased gastric motility. Cortisol, adrenaline, and catecholamines are secreted during stress as part of an intricate hypothalamic-pituitary-adrenocortical system (16,17). High levels of these hormones interfere with tissue healing. Noxious stimuli disrupt sleep and can have biological consequences for the neonate. Even medical complications commonly associated with prematurity per se, such as bronchopulmonary dysplasia and necrotizing enterocolitis, may be, in part, stress-related diseases (18).

Sensory input is essential during maturation. Most of the cortex is part of one of the sensory systems. Abnormal experiences, both depriving and overstimulating, can modify the developing brain. The most vulnerable period occurs during rapid brain growth and neuronal differentiation

P.112

(19,20). The timing of these events for the human fetus corresponds to 28 to 40 weeks of gestation (21). It is assumed that, for the fetus, the optimal sensory environment is experienced within the womb. One of the most striking aspects of this environment is the bidirectional contingency between mother and fetus.

The potential impact of the anomalous NICU environment on the vulnerable newborn infant has raised unabated concerns for more than 2 decades (22,23,24,25,26,27,28). A more optimal NICU environment might reduce iatrogenic morbidity and improve the outcome of sick neonates; however, the parameters are not yet well defined. This chapter summarizes the maturation of each sensory system during late fetal development, with

particular reference to evidence for the prenatal onset of function, compares the intrauterine and NICU sensory experience, and critiques techniques of developmental intervention.

NEONATAL SENSORY SYSTEMS: DEVELOPMENT, DISORDERS, ENVIRONMENT, AND INTERVENTION

Maturation of all the sensory systems begins during the latter part of embryogenesis; however, the process is neither unitary nor fixed. Within each system some reciprocity between structure and function probably exists. To some extent, sensory input drives maturation (29). In addition, the rate of maturation of each sensory system varies, with the onset of function generally in the following order: tactile, vestibular, gustatory-olfactory, auditory, and visual (30). These sensory systems also are interrelated in a hierarchical manner—stimulation of early maturing senses (e.g., tactile, vestibular) has a positive influence on development of later-maturing ones (e.g., visual) (31). Recent research also indicates that untimely stimulation within this sequence (e.g., visual) may disrupt the normal maturational process of another sensory system (e.g., auditory) (Philbin MK. *personal communication*, 1998.).

This hierarchical organization and integration of sensory function is well supported and bolsters two guiding principles for developmental intervention in the NICU:

- Stimulation of the senses should begin with the most mature.
- The optimal form of stimulation for initial postnatal development resembles the sources naturally available to the fetus and infant—those that come from the mother.

Tactile System

The cutaneous system includes sensation of pressure, pain, and temperature. Only pressure is discussed here; pain is discussed in Chapter 57. Receptors in the skin respond to pressure and then transmit impulses to the spinal cord through the dorsal root, ascending in the posterior tract and terminating in the gray matter of the cord. At this point, connecting fibers decussate and continue in the ventral spinothalamic tract to the medulla and the thalamus, terminating in the postcentral gyrus of the cortex. Representation here is somatotopic and contralateral to the stimulated side. Increased stimulation to an area of the body or loss of a limb can alter the pattern of representation in the somatosensory cortex.

Development

Like the vestibular system, the tactile sense develops early in fetal life and is thought to play a particularly pervasive role in the early development of the organism. Receptor cells are present in the perioral region in the fetus by 8 weeks of gestation and spread to all skin and mucosal surfaces by 20 weeks. The cortical pathway is intact by 20 to 24 weeks of gestation, and some myelin is already present. Response to tactile stimulation has been observed by ultrasound as early as 8 weeks of conceptional age (32). Response to stroking in the lip region occurs first, followed by a response to stimulation of the palms. Most of the body is sensitive to touch by 15 weeks (33).

Tactile threshold is very low in the preterm infant. It is more related to postconceptional age (PCA) than to natal age but increases by term. Infants younger than 30 weeks PCA respond by an unequivocal leg withdrawal to pressure of a 0.50-g von Frey hair applied to the plantar surface of the foot compared to 1.7-g pressure by 38 weeks PCA (34). A qualitative shift occurs around 32 weeks PCA. Infants less than 32 weeks PCA respond to repeated stimulation with sensitization and a diffuse behavioral response. In contrast, infants after this age show habituation to the same stimuli.

Classic studies by Harlow and Harlow (35) demonstrated the profound importance of contact comfort for normal development. In a parallel fashion, even preterm infants will seek and maintain contact with a physical object within their incubator and even more so if the tactile source contains rhythmic stimulation (36). These findings provide strong support for intervention in the tactile modality.

Disturbances

Tactile hypersensitivity, or tactile defensive behavior, is contained in clinical reports of children with developmental delay, many of whom were born preterm. It also is seen in infants and children who otherwise appear normal. The behavior frequently is said to be a manifestation of sensory integration deficit and thought to have its origins in the prenatal or perinatal period. It appears as an infant's overreaction to touch, generally the hands or oral-facial regions. With oral hypersensitivity, the infant may withdraw, gag, or retch when touched, even around the outside of the mouth. Some infants are intolerant of food with texture and resist transition from liquids or very smooth puree. Infants also may be hypersensitive to touch on their extremities, with prolonged palmar-mental reflex, exaggerated

P.113

hand and toe grasp, or leg withdrawal. An extreme case was a 2-month-old (corrected age) infant who, when supine, arched his buttocks off the table surface in response to his legs being grasped. Additional manifestations of tactile sensitivity may appear as an intolerance for grasping toys or handling play materials of certain textures. In another extreme example, a 1-year-old infant would gag when his hand was placed in dry macaroni. Some children are intolerant of normal clothing and even may avoid body contact. Such aversion adversely affects parent-infant bonding. The link between early tactile disturbances and learning disabilities at school age is unlikely to be a causal one, but may be related to a similar mechanism of brain dysfunction.

Intrauterine Experience

The fetus is housed in a thermoneutral, fluid-filled space that is a source of cutaneous input throughout the body surface. Fetal movement provides tactile self-stimulation. Perhaps even more important, fetal movement often evokes a contingent maternal response. As term approaches and the intrauterine space becomes more constraining, the normal posture of flexion evokes hand-to-mouth, skin-to-skin, and body-on-body tactile feedback. The effect is progressive throughout gestation.

After a normal term birth, a ventral-to-ventral position is preferred by both mother and infant, with touch followed by slow stroking (37). Traditionally, the infant is then swaddled and held. As before birth, human proximity produces contingent touch.

Touch And Handling in the Neonatal Intensive Care Unit

After premature birth, tactile input is radically altered. The extrauterine fetus is frequently nursed naked, with the exception of maybe a diaper and a hat. The surface of the mattress generally is unyielding. She or he is exposed to air currents, cold stress, tape, instruments, handling by caregivers, and painful stimuli. Pressure is not uniform.

The type and frequency of tactile stimulation imposed on a preterm newborn in the NICU would be overwhelming even for a healthy adult. During a 2-week period, a sick neonate may be handled by more than 10 different nurses, in addition to physicians, occupational or physical therapists, laboratory and x-ray technicians, and, finally, the parents (38).

Handling occurs more often among the sickest infants, typically is related to procedures, generally is disturbing, and often is painful. In spite of wide attention in the literature to the consequences of excess handling in the NICU, the amount had not decreased from 1976 to 1990, even among the more severely ill infants (39). On the average, sick preterm newborns are handled more than 150 times per day, with less than 10 minutes of consecutive uninterrupted rest (26). Disturbance of sleep has biologic and immunologic consequences (40,41). Secretion of cortisol and adrenaline normally is inhibited during sleep. Growth hormone, which is released during quiet sleep, increases protein synthesis and mobilization of free fatty acids for energy use. Thus, sleep facilitates healing.

Excess handling has other significant physiologic consequences for the sick neonate. Blood pressure changes, alterations in cerebral blood flow, and episodes of oxygen desaturation are associated with noxious procedures, handling, or crying (42,43,44,45,46). Fluctuations in blood pressure may contribute to intracranial hemorrhage in the unstable preterm infant (47). Importantly, when caretakers monitor the infant's level of oxygenation during procedures, the severity of hypoxemic episodes can be reduced significantly (42).

In addition to the hemodynamic impact of obviously noxious procedures described earlier, more benign manipulations, such as those that occur during neurodevelopmental assessment, also may adversely affect the

preterm infant (25,46). Decreased plasma growth hormone has been reported after administration of the Brazelton Neonatal Behavioral Assessment Scale to preterm infants at 36 weeks PCA (48). Even at the time of discharge, the evaluation was associated with elevated cortisol levels (17,49). It is not clear whether these effects were from the neurodevelopmental assessment or from the stress associated with crying, which normally occurs during administration of the Neonatal Behavioral Assessment Scale. Thus, handling could be stressful even for stable preterm infants.

Tactile Intervention in the Neonatal Intensive Care Unit

The two general approaches to tactile intervention in the NICU provide either reduction of general handling or provision of planned touch experiences. Touch may be pressure alone or may include stroking. The neonates may be acutely ill or medically stable. These distinctions are important.

As part of an individualized approach to developmental care for acutely ill preterm infants, Als and colleagues (50) provided "minimal handling" and clustering of routine procedures, as well as positive tactile input and containment from bunting, rolls, positioning, and the like. Short- and long-term outcomes were improved for her intervention group compared to a nonintervention group. This technique has had a major impact on developmental intervention as a whole. Although it is not possible to isolate which aspect of this multimodal approach was effective, a significant change was made in the role of the nurse/caregiver.

More specific to the tactile modality, Jay (51) evaluated the effects of planned, gentle, touch for 12-minute periods four times a day for acutely ill preterm infants. This intervention, which consisted of hands-on contact but not stroking or manipulating, was associated with a lower fraction of inspired oxygen (FIO₂) after 5 days compared to a similar nonintervention group.

P.114

In apparent contrast, Field and colleagues (52) and Scafidi and colleagues (53) initiated a touch intervention that differed from that of Jay (51) and Als and colleagues (50) in several important respects. The infants were recruited when "stable and growing" rather than during an acute period.

The treatment provided three 15-minute periods a day of massage (i.e., stroking and passive limb movement) for a 10-day treatment period. The massaged infants showed a greater weight gain, even though the groups did not differ in formula intake. These early effects on growth are thought to be mediated by induction of catecholamine release (48). The massaged infants also spent more time awake, showed better performance on the Brazelton neonatal assessment, were discharged to home 6 days sooner, and had better performance on developmental assessment at 8 months past term.

Although overall effects of the tactile intervention have been positive, the response of individual infants is variable and deserves attention. For example, an increase in periods of oxygen desaturation during parent touch, compared to baseline, has been reported (54). A number of infants have responded with apnea and bradycardia to the type of intervention described by Field and colleagues (52) and Scafidi and colleagues (53). This physiologic response may occur after the intervention. It is not clear whether the intervention itself was excessive or whether the abrupt shift after the cessation of tactile input led to an unexpected physiologic response. Individual differences exist among caregivers that also affect the infants' responses to the stimulation. Finally, the distinction between touch, stroking, and massage is probably important.

All of these issues advise against standardized protocols of stroking or massage for all preterm infants. When any form of tactile and kinesthetic intervention is applied, the caregiver should continue to monitor the infant's physiologic and behavioral responses before onset, during, and after the cessation of the intervention. Consistency of contact across caregivers would help.

Soft swaddling or clothing may provide tactile input in a more sustained fashion than periodic hands-on contact. Arguments that this obscures the view of the infant and interferes with temperature regulation by servocontrol simply argue against servocontrol rather than against covers. Clothing or swaddling actually could dampen the fluctuations in temperature that occur during incubator care and inhibit exaggerated movement or agitation, which in itself may be stabilizing. Creative swaddling with crisscrossed strips and Velcro could allow for more visualization of the infant. The use of swaddling in the NICU is necessary if the parent is to retain that option at home as a means of calming and supporting sleep. Swaddling is difficult to initiate after a period of not being swaddled.

Thus, the amount and type of stimulation are important and change with acuity, maturation, and the response

of the infant. Parents need specific guidance and modeling from the beginning. The general order of tactile intervention might be:

- *If acutely ill*—minimal handling, containment (e.g., swaddling, rolls), and gentle touch (e.g., warm hand) without stroking
- *When medically stable*—holding, rocking gently, stroking, continuing to swaddle

Minimal handling protocols have a definite place in the NICU, but not as the end point. It also is important during the hospital stay to help the infant develop increased tolerance for social contact and gentle handling, especially as discharge approaches. Systematic desensitization may even be necessary in cases of chronically ill infants.

Nonnutritive Sucking

Nonnutritive sucking is an important oral-tactile intervention that supports both feeding and early behavioral regulation. It represents an early endogenous rhythm and a manifestation of sensorimotor integration (55). As such, it is reported in the fetus (56) and observed in the preterm newborn before 28 weeks of gestation. The number of sucks per burst increases with maturation, whereas the duration of burst is fairly stable across ages.

Nonnutritive sucking experience may facilitate important physiologic and behavioral mechanisms and potentially reduce cost of care. Infants provided with nonnutritive sucking during gavage feeding showed significantly improved gastrointestinal transit time, greater suck pressure, more sucks per burst, and fewer sporadic sucks. They initiated bottle-feeding earlier, showed better weight gain, and thereby had shorter hospital stays (57,58). Having a pacifier continuously available, however, may not be beneficial and may, in fact, encourage inappropriate sucking patterns, particularly in the chronically ill neonate.

Nonnutritive sucking also acts as a behavioral organizer or facilitator. It has been shown to decrease motor activity and increase quiet states in stable preterm infants (59). It dampens an infant's behavioral response after a painful procedure such as circumcision or heelstick (60,61), although it does not appear to dampen the cortisol response (17). It is noteworthy that sucking on a pacifier before the onset of repeated painful procedures, such as heelsticks, may be inappropriate, because aversive conditioning to the pacifier could occur.

Nipples used for nonnutritive sucking abound, varying in size, configuration, consistency, and utility. A feeding nipple is not designed for nonnutritive sucking and is inappropriate. It readily collapses; the infant experiences little resistance to his or her suck and may loll the device. Gauze inserted in the nipple may absorb oral secretions and breed bacteria. In larger infants, the nipple is unsafe because of possible aspiration. A variety of commercially available pacifiers should be available in any NICU to suit the individual needs of each infant. Some neonates who are hypersensitive to touch in the perioral region often respond positively to contact (and perhaps smell) from their own hands.

Vestibular System

The vestibular system, situated in the nonauditory labyrinth of the inner ear, responds to movement as well as directional changes in gravity. The three fluid-filled semicircular canals, one for each major plane of the body, lie at right angles to each other. The ampulla, located at the end of each canal, contains hair fibers in a sac, or cupula. Motion of the body or head causes pressure changes that move the cupula, which stimulates the hair cells and transmits an impulse along the vestibular portion of the eighth cranial nerve to the vestibular nuclei of the medulla. The vestibular organs consist of the utricle and saccule, which respond to changes of head position involving linear motion. The macula, a thickening in the wall of the utricle and saccule, contains hair cells sensitive to the position of the head. Impulses from the macula transmit along the vestibular nerve to the medulla and cerebellum. From there, information is transmitted to motor fibers going to the neck, eye, trunk, and limb muscles. There are no connections to the cortex (63). Vestibular stimulation affects level of alertness. Slow, rhythmic, continuous movement induces sleep. Periodic or higher amplitude swing increases arousal.

Development

Initial vestibular development is concurrent with auditory development, emanating from the same otocyst early in gestation. The three semicircular canals begin to form before 8 weeks of gestation, reaching morphologic maturity by 14 weeks, and full size by week 20 (29). The vestibular sacs probably develop at the same time. Response to vestibular stimulation has been observed by 25 weeks of gestation (33). The traditional vertex presentation of the fetus at term gestation is thought to occur from fetal activity in response to vestibular input.

Disturbances

Considerable research with animals has demonstrated the importance of both tactile and vestibular input (35,63). Lack of normal vestibular stimulation in the developing organism is thought to affect general neurobehavioral organization (31). Children who were born preterm are reported to have deficits in balance at preschool age (8), but this is not necessarily a vestibular problem.

Intrauterine Experience

The fetus experiences both contingent and noncontingent vestibular stimulation that varies during gestation. From the beginning of embryonic life, the fluid environment of the womb provides periodic oscillations and movements that emanate from normal movements of the mother as well as activity of the fetus itself. Reports by mothers of fetal movement occur around 16 weeks. After 28 weeks of gestation, there is a decrease in the relative amount of amniotic fluid, and, thus, the movement of the fetus becomes partially constrained by the more limited physical space. Vestibular experience is then less contingent on self-activation and more related to normal maternal activity and position change, which often occurs in response to fetal activity. In general, maternal activity level slows as parturition approaches.

After birth, the infant is held normally. Movement is slow from maternal breathing and shifting. Change of position is gradual, even by experienced parents. Vestibular stimulation is used to affect state—moving to upright or laying down increases arousal; monotonous side-to-side rocking and walking in the form of parental pacing reduce the level of arousal.

Vestibular Experience in the Neonatal Intensive Care Unit

Vestibular stimulation after preterm birth is limited to efficient manipulation or turning of the neonate by the caregiver. It clearly lacks any of the temporal qualities or contingencies that the maternal environment may have provided. Spontaneous limb movement generally is diffuse, often unrestricted, and typically disorganizing in its effect.

Intervention in the Neonatal Intensive Care Unit

Like the tactile sense, the early development of the vestibular system provides a theoretical basis for primary intervention with preterm neonates. More than 3 decades ago, Neal (64) demonstrated that daily rocking facilitated the development of preterm infants. Subsequent research simulated the intrauterine environment and provided compensatory vestibular stimulation. An oscillating waterbed was devised, which moved with the rhythm of maternal respirations but with an amplitude of less than 2.5 mm at the surface of the unoccupied waterbed. The safety of this paradigm, as well as efficacy in reduction in apnea of prematurity, has been well demonstrated (65). In addition, the infants on waterbeds demonstrated more organized sleep state and motor behavior, decreased irritability, enhanced visual alertness, and improved somatic growth (65,66,67,68).

Difficulty in nursing sick infants on an oscillating surface may have precluded more widespread adoption of the waterbed. An infant's own movement also can induce more than optimal movement of the surface, as, for example, an infant with gastroesophageal reflux; however, some babies still are likely to benefit. At the least, it would seem prudent to provide a trial on a waterbed for a nonventilated infant with apnea of prematurity, before introduction of pharmacologic intervention.

Other sources of vestibular stimulation, such as rocking chairs, swings, and hammocks, have not been investigated formally. Rocking chairs probably belong in any nursery. Swings are questionable, given the excessive upright position of the baby and the standard rate of oscillation (i.e., too fast). A crib has been devised that provides controlled

motion similar to a woman walking; the duration of motion may be individually controlled and proportionally reduced over time (69), but the rate of oscillation appears too rapid for a preterm infant. The device appears to be effective in modulating fussiness in full-term infants and is used with preterm infants. The infants are well swaddled and further contained on each side by rolls.

Positioning

The physical position of an infant is part of the NICU tactile-vestibular experience. Nursing sick preterm infants routinely has been with the infant in the supine position and exposed, which may simplify management but may not be advantageous for the infant. Prone positioning in the NICU has been strongly supported physiologically. The current NICU dilemma is that the prone sleep position is contrary to the recommendation by the American Academy of Pediatrics (AAP), which now supports supine positioning because epidemiologic data associate supine positioning with a lower rate of sudden infant death syndrome. The optimal position of the infant needs to address anatomic and physiologic consequences. Positioning for optimal care in the NICU needs to take account of the AAP recommendation before the infant is ready for discharge to home.

Yu (70) demonstrated that gastric emptying was facilitated in either the prone or right lateral position compared to the supine or left lateral position. This was particularly significant for the sick preterm who already showed a delay in gastric emptying. The prone position, compared to supine, is associated with more quiet sleep and less active sleep or crying. Quiet sleep, in turn, is associated with improved lung volume, more stable respiration, less apnea, and improved PAO₂ (71,72). Finally, the prone position compared to supine is associated with a higher PAO₂ among healthy preterm infants and, even more significantly, in those with respiratory distress syndrome (72,73). The evidence suggests that, when possible, the sick infant should be nursed in a prone or right lateral position.

Parents of preterm infants often complain that their baby's feet turn out. In fact, the legs more often are externally rotated at the hip. Grenier (74) described hip deformities seen on x-ray of preterm infants after prolonged nursing in a frog-leg position. The bulk of the diaper in extremely preterm infants exacerbates the problem. Winging of the scapula also is frequent in the preterm infant. Proper support of the trunk and limbs in the prone or supine position lessens this extreme rotation and may diminish orthopedic or neuromuscular complications.

In the prone position, placing the infant on a small folded strip from shoulder to hip, could allow more physiologic flexion and adduction. In side lying, it may be easier to position the infant in soft flexion. Gentle containment of the limbs usually can be managed with strips of soft cloth across the upper arm and thigh. Some movement should be allowed within a controlled range. A posture of physiologic flexion and adduction in the supine position requires swaddling. Maintenance of postures can be facilitated by nesting the infant in soft rolls, but the rolls must not reach above the level of the shoulder. Rolls placed at the buttocks don't allow for adequate leg/hip extension. Each posture should facilitate the infant bringing hands to mouth.

For older, more medically stable preterm infants, infant seats are used as an alternative to continuous lying in bed. The infant should be swaddled and nested, the angle probably no greater than 30 degrees, and the length of time should be limited. Oxygen desaturation has been reported in stable preterm infants placed in car seats.

Kangaroo Care

Kangaroo care is a technique that evolved primarily in South America (75). Traditionally, the infant is clad only in a diaper and placed under the mother's clothing between her breasts, remaining there according to the mother's comfort, and feeding on demand. The technique provides fairly sustained multimodal stimulation: tactile, vestibular, proprioceptive, olfactory, and auditory. It appears to be safe for larger preterm infants or those who are medically stable. Temperature regulation in the infant does not appear to be a problem, but needs to be carefully monitored on an individual basis. It seems to have the greatest benefit in terms of facilitating and maintaining lactation and enhancing maternal sense of competency for these infants. The studies, however, are of insufficient sample size to evaluate whether morbidity, such as intracranial hemorrhage, is increased. More data are needed among medically stable infants before kangaroo care should be attempted prior to 32 weeks conceptional age or with infants requiring mechanical ventilation. The increased tactile stimulation and additional handling easily could be overly stressful for the immature or sick infant.

Chemical Senses

The chemoreceptors include taste and olfaction. Taste receptors are in the taste buds, which are located primarily in the papillae of the tongue but also are found on the soft palate and epiglottis (29,76). Taste stimuli (i.e., sweet, sour, bitter, salt) transmit to the brainstem with a primary branch to the hypothalamus. Cortical regions are involved in learned taste preferences. The olfactory receptors are located in the lining of the olfactory epithelium in the posterior portion of the nasal passage. The afferent pathway has no cortical projection area, but is direct to the limbic system. Olfaction plays an important part in gustatory experiences. Olfaction also is an integral part of infant attachment to the caregiver and may even be mutual (77).

Development of Taste

The chemoreceptors are well developed within the first trimester (29,76). Taste buds appear around 8 to 9 weeks of gestation. The receptors are present at least by week 16

P.117

of gestation, and increase by term to adult levels. During the second half of gestation, morphologic changes occur that continue after term. Taste receptors are functional before birth. Injection of distinct tastes into the amniotic fluid of pregnant women between 34 and 39 weeks of gestation alter fetal swallowing behavior, which increases with the sweeter taste and decreases with bitter taste (29).

Taste discrimination has been measured by differential consumption, autonomic responses, and the presence of characteristic facial expressions. Plain water evokes an aversive response, which may be a biologically based protective mechanism. Taste is sufficiently sensitive at term to detect a 0.1 mol/L-concentration of NaCl in water (78). Full-term neonates, even anencephalic infants, demonstrate differential behavioral responses to sweet, bitter, sour, and salt (79). In a behavior described as "savoring," normal newborns discriminate between different concentrations of sucrose and even among various sugars (78). Preterm infants (30 to 36 weeks of gestation) show stronger sucking in response to glucose, compared to plain water, and characteristic behavioral expressions in response to sour or bitter solutions (80). Behavioral response to formula, or breast milk, administered to the tip of the tongue has been documented in preterm infants prior to 28 weeks of gestation (Zorc L. unpublished doctoral dissertation, 2000).

Stimulation of taste receptors has important implications for early feeding and behavioral regulation. Smotherman and Robinson (81) hypothesized that tastes of milk activate a centrally mediated endogenous opioid system in newborn term infants, consistent with that shown in the animal model. This would suggest that, in normal development, the mechanism to support early feeding extends beyond maintenance of chemical or caloric balance and becomes "feeding to thrive."

Development Of Olfaction

The human olfactory system is composed of four anatomically distinct but integrated subsystems:

- The main olfactory
- The vomeronasal
- The terminal
- The trigeminal

Each of these differentiates very early in gestation and is nearly mature prior to term birth (29,82). Epithelia of the main olfactory system are evident around 5 weeks in the apical part of the nasal cavities. Nerve fibers and cells form the olfactory nerve, which links the epithelium to the main olfactory bulbs and then to the ventral wall of the forebrain. The vomeronasal system consists of bipolar sensory cells in the lower nasal septum, with axons terminating in the accessory olfactory bulb. The terminal system is comprised of free nerve endings in the anterior part of the nasal septum. The nerve endings of the trigeminal system, which originates from cranial

nerve V, are diffusely distributed in the nasal cavity. The trigeminal system, although activated by touch, may be the earliest functioning chemoreceptor.

No information exists about the functional onset of human olfaction, but it is presumed to be present prenatally, having been demonstrated in a rat model. Rat fetuses exposed to citral in the amniotic fluid will selectively attach postnatally to a nipple of the same scent (83).

Human prenatal olfactory function is inferred from the sophistication present by term, including behavioral discrimination, preference, and conditioning to olfactory stimuli. For example, 1-week-old infants will reliably turn their heads away from a noxious smell (84). In response to a series of pleasant or aversive odors, infants less than 12 hours old will exhibit different facial expressions that are discriminable by adults (79). Infants younger than 1 week of age reliably prefer the odor of their mother's breast pad to the breast pad of another mother (85). Neonates who were given a period of familiarization to a novel odor subsequently demonstrated a preference for that odor, whereas infants exposed to it for the first time did not (77). Finally, classical conditioning to a novel olfactory stimulus has been demonstrated empirically within the first 48 hours after term birth (86). Given ten 30-second pairings of citrus odor with stroking, neonates the following day showed increased activity and head turning in the presence of the citrus but not to a novel odor. By 28 to 32 weeks gestation, the majority of preterm infants show reliable behavioral response to olfactory input (82).

Disorders

Feeding disorders are reported commonly among preterm infants, particularly those with chronic lung disease. The infant may even respond aversively to the introduction of food in the mouth. The cause generally is attributed to frequent stressful procedures around the mouth as well as poor coordination of suck and swallow. However, marked alteration of the orogustatory environment occurs by nature in a preterm birth. Feeding disorders also are common among neonates who have sustained brain damage. No studies have attempted to identify whether deficits in taste or smell are present in infants with feeding disorders. Certainly in adults, loss of the sense of smell radically affects eating habits.

Intrauterine Experience

The amniotic fluid is a complex solution of suspended particulate and dissolved odorants that changes in chemical composition during maturation of the fetal chemosensory system (29,82,87). Even as early as 18 weeks gestation, more than 120 compounds have been identified in single amniotic fluid samples. The mother contributes to the chemical variation through hormones and even the types of food consumed. The fetus contributes to the chemical status through urination, oral mucosa, and lung secretions. More directly, fetal respiratory movements, sucking, and swallowing cause pulsatile displacement of the amniotic fluid in contact with the chemoreceptors to probably affect

P.118

adaptation by the receptor cells (82). A link has been proposed between the intrauterine orogustatory experience and the selective behavioral preference of the newborn to breast milk.

Experience In The Neonatal Intensive Care Unit

The environment in the NICU has not been described previously in terms of gustatory or olfactory content, but it clearly is not well adapted here. The necessary restriction of oral feeding in sick or extremely premature neonates is a marked alteration of the fetal orogustatory environment. The chemical composition of initial feedings (breast milk or formula) is different from amniotic fluid or colostrum. Common changes in formula composition (brand), concentration (dilute or hypercaloric), and temperature (too cool) introduce unwanted variability. The addition of noxious oral medications and electrolyte supplements to breast milk or formula typically activate a gag response in the newborn. Negative experiences temporally associated with feeding can lead to aversive conditioning. Finally, in contrast to the healthy full-term neonate, preterm infants in the NICU lack a stable olfactory source that would be provided by sustained body contact of a consistent caretaker.

Intervention in the Neonatal Intensive Care Unit

Stimulation of both smell and taste has significant implications for enhancing care in the NICU. A period of familiarization with the odor of breast milk or formula, before the oral introduction of food, can facilitate

acquisition of oral feeding skills (77). For a medically fragile infant, the mother's breast pad can be placed nearby. From another standpoint, familiarization to the odor of medications before ingestion could make the medication less aversive by the process of habituation. Obviously, like breast milk from the source, bottle-feeding ideally should be at body temperature rather than the typical room temperature.

Small tastes of formula or breast milk before the introduction of the nipple may foster behavioral organization and facilitate the onset of feeding (87). Most babies who are restricted from oral feeds can safely tolerate a small drop of breast milk or formula on the lips or tongue tip. The limited research available suggests that gut priming in the extremely preterm or sick full-term infant probably should not bypass the mouth entirely. Based on the animal model, surfactant and colostrum may have unsuspected roles in initiation of human feeding (81).

Another important implication of orogustatory stimulation is the effect of oral feeding on activation of the endogenous opioid system, which raises the threshold to noxious tactile stimuli in the fetal rat model and human newborn infants (88), although it is no longer elicited in the human infant after 6 weeks of age (89). Sucrose solution has been applied to the tip of the tongue to decrease the pain response to a heelstick procedure or even to circumcision in healthy term infants (88,90). However, repeated use of this pathway to modulate pain in the neonatal period is currently unwarranted since it may have negative repercussions given the link to feeding behavior.

Auditory System

The auditory system is composed of both peripheral and central components (91,92,93). Sound waves are conducted through the auditory canal and physically displace the tympanic membrane. Movement of the membrane is amplified by the ossicles in the middle ear and transmitted to the oval window. This action displaces fluid in the cochlea. A mechanical disturbance differentially displaces hair cells at a specific place on the basilar membrane of the cochlea, as a function of both frequency and intensity of the sound. The hair cells are organized tonotopically, so that those that respond to high-frequency sounds are near the oval window and those that respond to low-frequency sounds are at the apex of the cochlea. The complex neural impulse thus generated proceeds to the auditory cortex via the cochlear nucleus, superior olivary nucleus, inferior colliculus, and medial geniculate body. The primary cortical reception area is the Heschl gyrus in the temporal region. Approximately 60% of the nerve fibers from each ear transmit to the contralateral hemisphere. The tonotopic organization is repeated in the cortical structures. The initial development of the central component of the auditory system is independent of peripheral maturation; however, once the auditory pathway is complete, the absence of auditory stimulation would cause cortical neuronal degeneration (93).

Development

Development of the auditory system begins around 3 to 6 weeks of gestation (93,94). By 25 weeks gestation all the major structures of the ear are essentially in place, although the adult dimensions of the external auditory canal, tympanic membrane, and middle ear cavity will not be attained until 1 year after birth. The ossicles have evolved from a thickening of mesenchymal tissue and are already of adult proportions, although residual mesenchyme may diminish auditory thresholds. The cochlear nucleus has reached adult proportions and differentiated sufficiently to be functional by this time, although microscopically the cochlea still is not mature even at term. The hair cells are fully present and in a process of differentiation. The frequency-specific place on the basilar membrane is shifting systematically during this period of development (93). The afferent pathway from the cochlea to the auditory cortex is complete, and even myelination of the auditory pathway is present.

With regard to function, both cortical auditory-evoked responses and brainstem auditory-evoked responses can be elicited by 25 to 28 weeks (95,96). Wave morphology is

P.119

different from the full-term infant's, and the latency is prolonged. A blink response to vibroacoustic stimulation has been obtained in human fetuses of 24 to 25 weeks of gestational age. A more complex behavioral response to sound occurs at least by 28 weeks, but readily fatigues. The maximum rate of electrophysiologic change occurs in the cortical auditory-evoked response and brainstem auditory-evoked response between 28 and 34 weeks of gestation. Orienting behavior to soft sound can be elicited by this time.

Maturation of the fetal auditory system is marked by an increase in spectral sensitivity, in both lower and higher frequencies, and a decrease in auditory threshold (91,92,93). The range of auditory sensitivity initially is fairly restricted: from 500 to 1,000 Hz in the third trimester compared to around 500 to 4,000 Hz at term and an adult range of 30 to 20,000 Hz. Changes in auditory threshold are related to maturation of both peripheral and

central components. Auditory thresholds in a preterm infant at 25 weeks of gestation have been obtained with a 65-dB stimulus compared to 25 dB at term.

Evidence for a functional auditory system in the fetus is strong. Specific anatomic sites are present in the cortex that are responsible for processing complex sounds, such as language. A biological predisposition to respond to the specific acoustic patterns of speech is present in full-term neonates. For example, they have lower thresholds for sound within the most important range for speech perception (i.e., 500 to 3,000 Hz) (97). Within this frequency range, they respond differently to speech and nonspeech stimuli. There are even hemispheric differences in auditory-evoked potentials that support this language sensitivity (98). Finally, healthy full-term neonates demonstrate a preference for sound they were exposed to *in utero*. Research shows that 2- to 4-day-old neonates prefer their mother's voice compared to another female voice and prefer a recording of a story read by their mother prenatally to a recording of a story read by their mother that was not read to them prenatally (99,100,101,102,103).

Deficits

Preterm infants are at increased risk for sensorineural hearing loss and developmental language disorders (20). Language disorders may be receptive or expressive dysfunctions. Receptive language disorders often are referred to as auditory processing deficits. These deficits primarily include phonemic-based disorders that involve discrimination between speech sounds, such as *ba* versus *pa*, short-term memory deficits, and difficulty in interpreting the meaning of words implied by grammatical structure. Expressive language problems may include disorders of speech (as in articulation or fluency), word-finding difficulty, and deficient or disordered sentence structure (grammar). Language disorders result from direct damage to central structures or can be incidental to more general brain dysfunction. They occur in children with normal hearing thresholds and otherwise normal intelligence. They occur more commonly among children who were born preterm (104).

Intrauterine Experience

Development of the auditory system during fetal life occurs within a uterine environment that contains rhythmic, structured, and patterned sound emanating predominantly from the mother. Internal sounds include maternal respirations, borborygmi, placental and heart rhythms, and the like. Maternal speech transmits both externally and internally. Prosody (i.e., intonation, rhythm, stress) is probably the most salient aspect of speech available to the fetus. The intensity of internally recorded sound within the amniotic fluid is approximately 70 to 85 dB, with a predominance of low frequency (Fig. 9-1) (105). External sound also is transmitted to the fetus, but is attenuated by the time it reaches the intrauterine cavity, more so at higher frequencies (i.e., 70 dB at 4000 Hz) than lower frequencies (i.e., 20 dB at 50 Hz) (106). Given these considerations, the fetus probably is minimally exposed to frequencies above 1,000 dB (107). The available frequencies *in utero* also parallel cochlear development (100).

The auditory environment in the womb likely provides the most appropriate substrate for normal development of the sensory system, but defining the acoustic properties of

P.120

the sound actually transmitted to the inner ear of the fetus is problematic. The fluid-filled womb would alter the conductive property of the middle ear; however, data on this are unavailable. The best guess generally is that fetal hearing is limited to bone conduction. Hearing thresholds are elevated in the prematurely born infant, but no unequivocal data are available on the actual hearing thresholds of the fetus *in utero*.

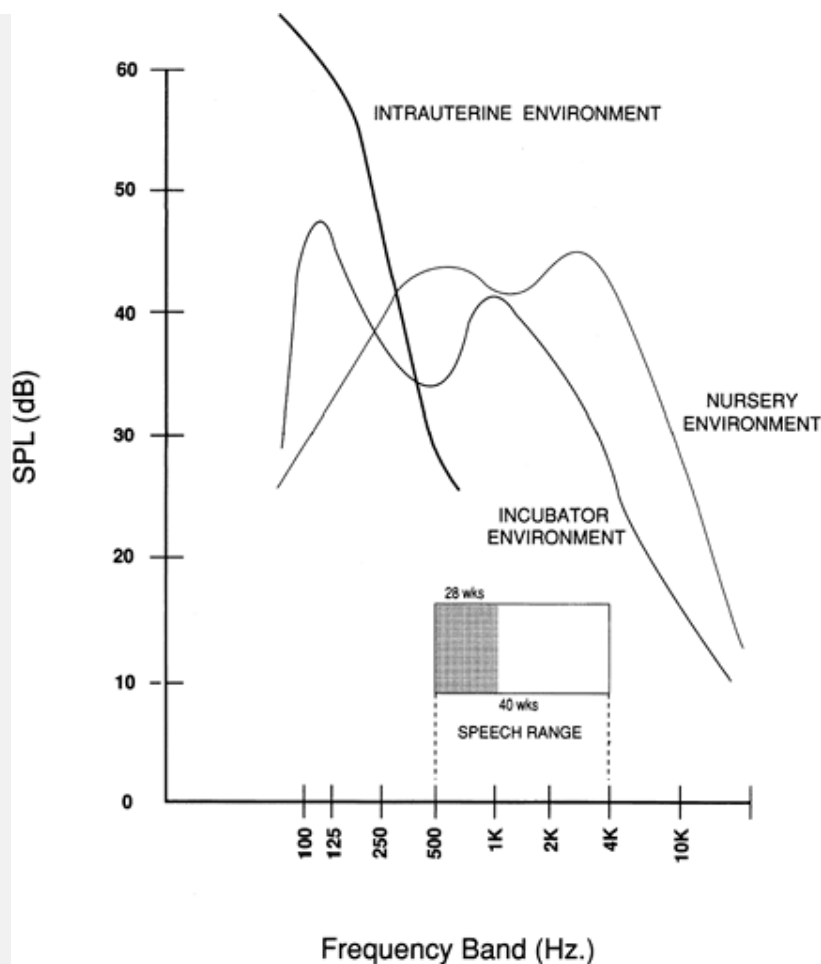

Figure 9-1 Comparison of the frequency-specific auditory environment of the fetus *in utero* and the preterm infant in the neonatal intensive care unit. SPL, sound pressure level. (From Walker D, Grimwade J, Wood C. Intrauterine noise: a component of the fetal environment. *Am J Obstet Gynecol* 1970;109:91, with permission; and Otho Boone, *personal communication*, December 1992, with permission.)

After a normal, full-term birth, the auditory environment is quiet by contrast. This may serve to increase the salience of the human voice. Early speech directed to the neonate is subdued and generally contingent on the infant's response.

Neonatal Intensive Care Unit Environment

The acoustic environment in the NICU differs from the intrauterine environment in peak intensity, spectral characteristics, and pattern (Fig. 9-1). Ambient noise is generated by motors, fans, ventilator equipment, personnel, telephones, alarms, hand-washing areas, trash lids, pagers, intercoms, and carts, to name a few. The intensity of background noise is around 50 to 60 dB and, therefore, not louder than *in utero*, although episodic bursts of higher intensity (i.e. less than 100 dB) occur. It would appear (Fig. 9-1) that speech input for the neonate is selectively masked by the NICU auditory environment.

The auditory environment is different for babies nursed in open beds versus those nursed in incubators. To some degree, the incubator may partially attenuate high-frequency room noise (Fig. 9-1), but produces its own background noise level for the baby within (i.e., 50 to 70 dB). In addition, the infant in an incubator may be subjected to the closing of porthole doors, an object being placed on the top surface, or rapping on the incubator to stimulate an infant who is apneic or bradycardic, which may peak at more than 100 dB.

Effect of the Neonatal Intensive Care Unit Environment

Exposure to aberrant noise levels in the NICU may cause sensorineural damage, induce stress, and contribute to language or auditory processing disorders in the preterm neonate. Schulte and colleagues (20) reported nearly 12% hearing loss in a followup of preterm infants. Damage to the outer hair cells of the cochlea of neonatal guinea pigs has been reported after exposure to noise of similar intensities and frequencies found in the NICU (108). These researchers found no correlation between hearing loss and duration of exposure to incubator noise, but did report an association between hearing loss and a measure of severity of illness. Although not stated,

more severely ill neonates may be exposed to increased NICU noise compared to healthy preterm infants. In other research, the combination of noise and ototoxic drugs commonly given to sick preterm infants (e.g., aminoglycosides, diuretics) was found to have a potentiating effect on hearing loss (109,110,111). The data further suggest that the immature cochlea may be more susceptible to damage than the mature one. Increased susceptibility is coincident with the final stages of anatomic development and differentiation of the cochlea (111). Given these data, incubator manufacturers have lessened the noise level emitted by the incubator motor, but limits on the environmental source of noise in the NICU itself are few.

In addition to possible sensory nerve damage, loud noise could have physiologic consequences in the newborn preterm infant in the form of stress, leading to alterations in corticosteroid levels and autonomic changes. Decreases in oxygen saturation, increases in intracranial pressure, and peripheral vasoconstriction are reported in preterm infants after exposure to sudden noise (112). Finally, sleep is disrupted by intermittent noise in the NICU.

Abnormal auditory environmental conditions could contribute to language problems in preterm children. Normal auditory habituation patterns were impaired in chicks reared in an NICU-sound environment (113). Delayed cortical auditory-evoked responses among healthy preterm infants have been reported, in addition to deficits in brainstem response to linguistic stimuli (104,114). The NICU environment, like the fetal environment, has an important role in the normal development of the auditory system.

Intervention in the Neonatal Intensive Care Unit

Auditory intervention in the NICU includes efforts both to reduce ambient noise and to induce patterned auditory input. Personnel in the NICU generally have made focused efforts to lower the level of noise in the environment. Quiet times during each shift are prevailing, and radios are less constant. Evidence would suggest the value of caring for the smallest and sickest preterm infants inside an incubator, as a shield against environmental noise. The steady incubator noise may induce sleep in the preterm infant (115). At some point, however, the continuous white noise in the incubator masks more socially relevant auditory stimuli. Prolonged housing in this environment becomes disadvantageous at some point, but the timing is unknown.

Another approach to decreasing the level of ambient noise reaching the infant is by occluding the infant's ears. Zahr and de Traversay (116), using a within-subjects design, found increased quiet sleep and fewer state changes during the two observation periods. Caution here is warranted. Auditory input could be particularly critical for hearing-impaired infants. Preterm infants' auditory thresholds generally are not tested until near the time of discharge. Thus, if attenuation is practiced, the safer device would model that provided by the womb, where higher frequencies are selectively attenuated. Without a more selective approach, speech sounds also would be dampened. The strategy is, therefore, potentially harmful. On the other hand, short-term occlusion might be appropriate

P.121

during a brief, acute phase of illness. Research is needed, with both short- and long-term consequences carefully evaluated, including speech stimuli and hearing thresholds as outcome measures.

Auditory stimulation, as a single modality, has been studied in the preterm infant. Schmidt and colleagues (115) reported that auditory stimulation, in the form of a heartbeat, lengthened the duration of the first quiet sleep period. Quiet sleep is a more stabilized state that reflects central nervous system maturity. Some NICUs have urged using sound as a protective window for the infant—when music is played, the infant will not be disturbed. This approach responds to the potential for conditioning in the preterm infant. Soothing sound is soft, simple, repetitive, and harmonic, with a limited dynamic range. Nonetheless, speech and nonspeech stimuli differentially stimulate the cerebral hemispheres (98). Availability of speech sounds may be more critical. In one of the earliest studies, Katz (117) reported using auditory stimulation in the form of recorded maternal speech, played to healthy preterm infants of 28 to 32 weeks of gestation, until each reached 36 weeks PCA. Compared to controls, the intervention group showed better neuromotor development and improved auditory and visual responses. This study highlights once more that the effects of an intervention may not be limited to the stimulated sense. Even so, exposure to recorded speech lacks the essential reciprocal nature of normal communication.

Visual System

The visual system is the most extensively studied sensory system; therefore, the mechanisms are better understood. The eye is like a window to the brain, as it contains two thirds of the afferent nerve fibers in the

central nervous system. Light energy is transmitted through the cornea, pupil, lens, and optic media to the retina. There it bypasses the retinal blood vessels, a layer of ganglion cells, and a layer of bipolar cells before it finally reaches the outer segments of the photoreceptors (i.e., rods and cones). Light is absorbed by the photoreceptors in a photochemical response that converts the radiant energy to an electrical impulse. The amount of light energy necessary to stimulate a single photoreceptor cell is extremely small—one quantum (118). In the absence of a light stimulus, retinal firing still occurs in the form of a tonic discharge. Some processing occurs even at the level of the retina (118). From the photoreceptors, the impulse travels to the ganglion cells, the optic nerve, and through the lateral geniculate nucleus to the occipital cortex. Fibers from the medial portion of each retina decussate, whereas those from the lateral half do not. Thus, information from either the left or right visual field will fall on the contralateral portion of each retina and be transmitted to the same hemisphere of the brain. Representation in the cortex is topographic, but upside down and reversed.

Development

The eye is an outgrowth of the brain from the early embryonic stage. By 24 weeks of gestation, gross anatomic structures are in place and the visual pathway is complete. As shown in Table 9-1, the visual system is undergoing extensive maturation and differentiation between 24 and 40 weeks of gestation. Corresponding functional visual responses have been elicited in the preterm infant (10,119,120,121,122,123,124,125).

As early as 24 to 28 weeks of gestation, a visual-evoked response to bright light can be obtained, but it consists of a

P.122

long-latency negative wave that readily fatigues. A behavioral response to bright light consists of lid tightening, but the response also fatigues quickly. The refractive error is approximately -5 diopters (D). The optic media is cloudy.

TABLE 9-1 MATURATION OF THE FETAL EYE IN THE THIRD TRIMESTER

Fetal Eye Components	30–32 Weeks of Gestation		
	26–28 Weeks of Gestation	30–32 Weeks of Gestation	34–36 Weeks of Gestation
Eyelid	Fused early in development, now reopens.	Less translucent.	
Pupil	Tunica vasculosa lentis begins to atrophy. No reflex present.	Fully atrophied by end of period. Sluggish reflex.	Few remnants. Complete reflex.
Lens	Second of four-layer nucleus forming.	Second layer complete, third begins.	
Media	Cloudy. Hyaloid system begins to regress.	Clears. Hyaloid almost disappeared.	Some remnants may still be present.
Retina	Rod differentiation begins.	Complete except for fovea, cone differentiation begins.	Cone number in fovea increases.
Visual cortex	Vascularization just beginning. Rapid dendritic growth and differentiation.	Nasal portion nearly complete. Marked development of dendritic spines and synapses.	Temporal region nearly fully vascularized. Morphologically now similar to full term.

Important functional changes occur around 32 weeks of gestation. The morphology of the visual-evoked response becomes more complex with the addition of a positive wave, and the latency decreases. The pupillary reflex is more efficient. A bright light will cause immediate lid closure, and the response sustains. The optic media has often cleared. The eyes may open spontaneously, and the infant may even briefly fixate. This has been described as the beginning of "attention" (119). Attention as such may be best elicited with a large, high-contrast form held closer to the eyes than would be necessary at term, but under similar conditions of low illumination (i.e., 5 foot-candles [ft-c]).

By 36 weeks, the visual-evoked response resembles that of a full-term infant, but the latency is still longer for the preterm infant and remains so. Spontaneous eye opening, even *in utero*, has been observed on ultrasound. Although alertness still is less sustained than at term, the preterm infant now shows a spontaneous orientation toward a soft light and can track an object horizontally and vertically. Additionally, the infant prefers a patterned to a nonpatterned surface, in a manner similar to a full-term infant. The refractive error is near zero.

Relative to the other sensory systems, the visual system is the least mature by term birth, with considerable development continuing over the next 6 months (126). Having less dense optic media and less macular pigmentation than an adult, the eye of the newborn infant transmits more short-wavelength light by a factor of four (78). Newborns are photophobic; thus, visual attention is facilitated under low illumination (i.e., approximately 5 ft-c). Acuity estimates are in the range of 20/200 Snellen equivalents. The refractive error is normally slightly hyperopic (i.e., +1 D).

The newborn can attend to form, object, and face. Specifically, he or she can fixate a high-contrast form (i.e., a 1/16-inch wide line at a distance of 1 foot) and can show preference for patterns along dimensions of brightness and complexity. She or he will track a bright object horizontally across midline and vertically. Attention to the human face by a neonate can be explained as a predisposition to respond to contrast (e.g., eyes, open mouth) or to edge (e.g., hairline), to slow movement (e.g., nodding), and to contingent stimulation (e.g., adult's voice). In any event, this behavior is powerfully adaptive.

Deficits

It generally is agreed that the visual system of the preterm infant is particularly susceptible to insult. The most well-known visual problem is retinopathy of prematurity (ROP), which is a proliferative vascular disease of multifactorial origin. ROP has been linked to oxygen toxicity, but it occurs in preterm infants with cyanotic heart disease who have never been hyperoxic. ROP is most strongly associated with degree of immaturity of the retina (127,128,129,130). Visual disorders—thicker lenses, poorer visual acuity, higher incidence of astigmatism, high myopia, strabismus, anisometropia, and color deficits (blue-yellow)—other than ROP are more common among children born prematurely (131,132,133). For example, among a sample of 5-year-old, low-birth-weight children, 35% lacked stereopsis and 25% had less than 20/20 corrected acuity in both eyes (132). Risk for visual disorders is inversely related to gestational age.

In addition to these visual problems, the preterm infant also has difficulty processing visual information at a more cognitive level. Performance on tests of visual attention, visual pattern discrimination, visual recognition memory, and visuomotor integration repeatedly indicates particular vulnerability for the preterm infant (9,12,13,134,135).

Intrauterine Environment

The womb generally is dark, but under certain conditions light can transmit to the fetus. A behavioral response by a fetus to light has been described (136). Transmission through all the tissue is limited to small amounts of red, or long-wavelength, light. Probably only 2% of incident light reaches the uterus (D. Sliney, *personal communication*, June 1992). In later pregnancy, the head of the human fetus is in the vertex position, the neck is flexed, and the face is posterior, thereby diminishing exposure. It is unlikely that light exposure is a necessary condition for the fetus, or that periodic exposure to low levels of long-wavelength light is harmful. Aspects of the light-dark cycle that reach the fetus probably are mediated more by maternal sources such as rest-activity cycles and hormones than by light directly.

After birth, ambient light increases markedly, although typically the room is kept dim and cycled with dark to some extent. A prolonged wake period linked to catecholamine release occurs during this transition to extrauterine life. In dim light, the newborn is more likely to open his or her eyes.

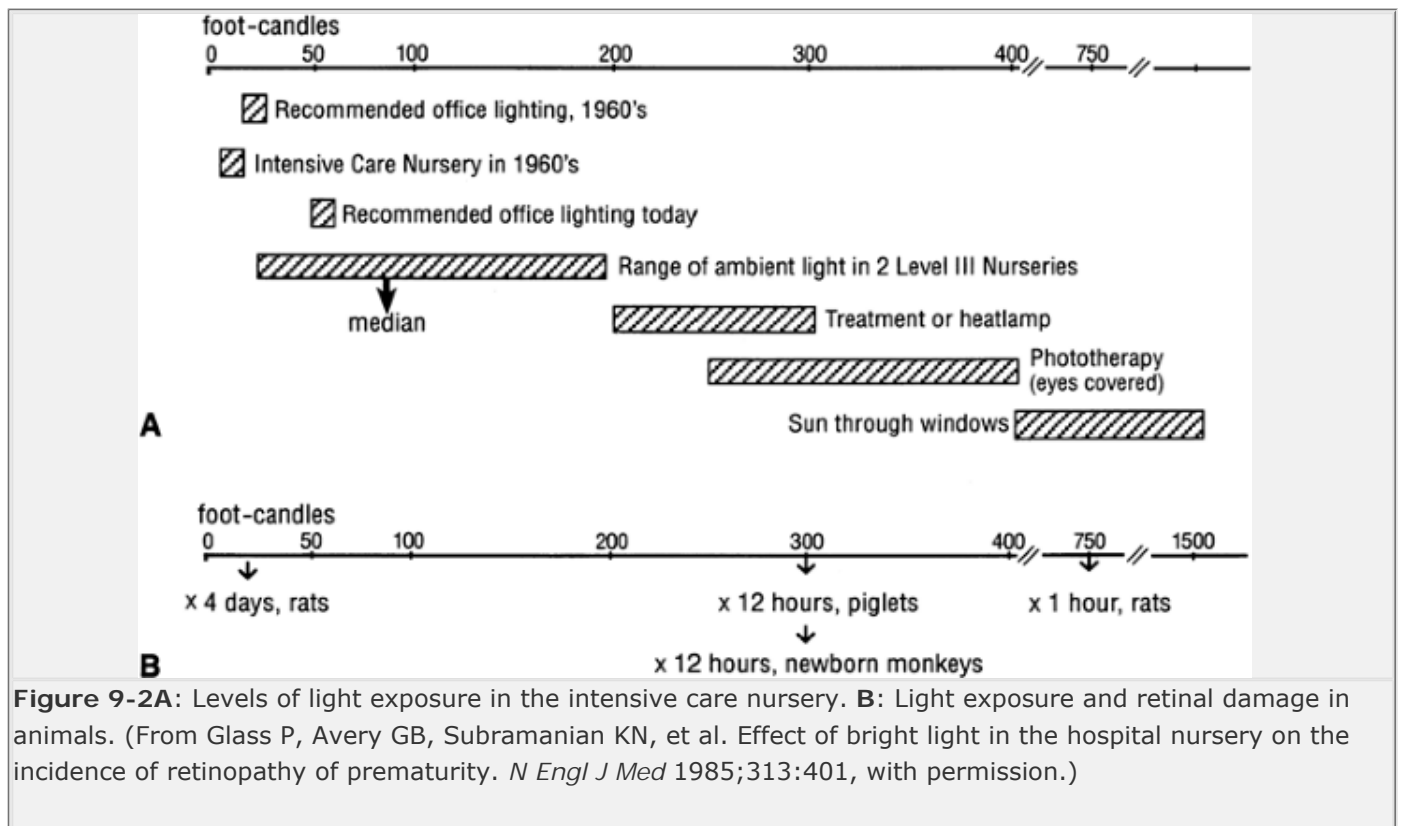

Neonatal Intensive Care Unit Environment

Modern intensive care nurseries are brightly lit environments with ambient light in excess of standard office lighting for adults (Fig. 9-2). The general range reported has been 30 to 150 ft-c, with peaks of more than 1,500 ft-c from sunlight (137,138). The intensity of ambient illumination for any individual infant is determined by the location of the crib in a room; the number of overhead light units; the size, location, and compass direction of windows; the season of the year; and even the prevailing weather conditions (i.e., sunny versus hazy). The duration of exposure generally is 24 hours a day over the length of hospital stay, which is a function of degree

of immaturity and medical complications. Thus, light exposure is greater for those most vulnerable to visual problems.

In addition to ambient light, preterm infants routinely are exposed to supplementary sources, such as a bili light, heat lamp, and indirect ophthalmoscope. The standard double-bank phototherapy unit produces 300 to 400 ft-c

of illumination. The mini bili light has an intense beam, estimated at more than 10,000 ft-c. Infants' eyes are routinely patched under phototherapy; however, in some cases the eye pads are inadequate or may slip off. A commonly used heat lamp produces an intensity of more than 300 ft-c at an infant's face. Exposure time varies, but typically is longer for younger and sicker infants. The eyes of infants typically are not covered during procedures.

Finally, an indirect ophthalmoscope is used for the routine eye examinations to rule out ROP. Exposure for 2 minutes, which is the approximate time of retinal examination, at maximum power has been estimated as equivalent to exposure at 2,000 ft-c for 3 hours (139). Extra precautions for protecting the infant's dilated eyes from ambient or supplementary sources of light before and after the eye examination are not routine. For the smallest infants, the addition of a heat lamp during the examination often is necessary to maintain the baby's temperature.

Phototoxicity in Animals

Animals exposed to similar levels of light have sustained damage to their photoreceptors, pigment epithelium, and choroid (139,140). Phototoxicity is a consequence of a photochemical effect, but may be exacerbated by heat. The effectiveness of light in producing retinal damage is proportional to its efficiency in bleaching rhodopsin. A level of 100 ft-c bleaches rhodopsin to 80% in approximately 10 minutes. Continuous illumination is more potent than cyclic, but intermittent exposure may be cumulative.

Factors that enhance photochemical damage to the animal retina strikingly parallel the perinatal course of the preterm infant (137). Retinal damage in animals is facilitated by maintenance of the animal in constant dark before light exposure, an increase in body temperature, conditions of hyperoxia, hypoxia, or ischemia, and retinal disease. Finally, light and oxygen may have a synergistic adverse effect on ROP (141). In spite of all these considerations, safety standards have not yet been determined.

Photobiological Effects of Light in the Neonatal Intensive Care Unit

Mounting data indicate that light has potent biological effects that are not considered routinely in standard NICU care. An association between light and ROP was first suggested by Terry (142) in 1946. Potential mechanisms to account for phototoxicity as one of the contributing factors in ROP have been proposed and are consistent with the oxygen toxicity hypotheses: damage to endothelial cells, alteration of normal retinal metabolism, disruption of the normal regenerative process of the retina, and generation of free radicals (137,141,143,144,145,146).

There is no evidence that light is a necessary condition for ROP or that maintaining a preterm infant in the dark will completely prevent it. Seiberth and colleagues (147) found no difference in incidence of ROP for preterm infants (birth weight less than 1,250 g) who had opaque eye patches day and night from birth to 35 weeks of gestation compared to an unpatched control group. The daytime ambient light levels were already low (30 to 40 lux, or approximately 3 to 5 ft-c), and the control group had cycled lighting at night.

Three converging lines of evidence lend empirical support to an association between light and ROP. In a prospective but nonrandomized study, preterm infants for whom the light levels were reduced for the duration of their hospital stay had a lower incidence of ROP compared to a similar

P.124

group of preterm infants exposed to standard bright levels of nursery light (148). The same effect was found in both NICUs studied. Similar findings were reported by Hommura and colleagues (149). Reynolds and colleagues (150) reported no difference in incidence of ROP for preterm infants who wore light-reducing goggles compared to infants who did not; however, the goggles were discontinued at 31 weeks of gestation. In a separate study, increased ROP was identified in the region of the retina that is more exposed to light—specifically, more in the regions around 3 o'clock and 9 o'clock compared to the superior and inferior regions (151). In addition, preterm infants with a higher degree of retinal pigment are less likely to develop ROP than infants with less retinal pigment (152,153). Retinal pigment is protective against phototoxicity.

Photobiological effects are not limited to the retina. Elevated room light or phototherapy may cause degradation of riboflavin and vitamin A, which are common components of total parenteral nutrition (154). Solutions containing these vitamins may be covered at the source, but tubing often is not shielded. Light in the visible spectrum penetrates the skin and thereby may alter more than the bilirubin concentration in the blood. Riboflavin levels were reduced *in vivo* in infants undergoing phototherapy (155). Thrombocytopenia (i.e., platelets less than 150,000/mm³) was more than tripled among preterm infants exposed to phototherapy light (156). *In vitro* experiments demonstrated inhibition in the normal constriction of immature lamb ductal rings exposed to ambient laboratory light (157). Subsequently, Rosenfeld and colleagues (158) found a significant reduction in the occurrence of patent ductus arteriosus among preterm infants whose chests were shielded from exposure to phototherapy light.

Light and Behavior

Bright light in an infant's face is a source of stress (159). Even routine ambient light level affects sleep and wake states in preterm infants. Lower ambient light is associated with significantly less active rapid eye movement sleep and significantly more quiet sleep among preterm infants at 35 to 36 weeks PCA (160). Rapid eye movement is a more destabilized state, with greater fluctuations of oxygen saturation and more frequent occurrence of apnea and bradycardia. Lower ambient light also is associated with increased eye opening and awake periods. Light level influences an infant's response to sound. Under bright light, an infant shows an aversive response to a tone, whereas under a dim light the same tone elicits an orienting response (161). Dimming the light has a quieting effect on caregivers, who are apt to behave as though someone were sleeping.

Intervention in the Neonatal Intensive Care Unit

The optimal level of NICU lighting has not been determined; however, no study supports the safety of current bright light levels. Therefore, it would be prudent to limit ambient nursery light to necessary levels and shield the infant's eyes and chest from ambient as well as supplementary sources. Shading does not mean occluding. Evidence does not suggest that infants' eyes should be patched beyond what is necessary for phototherapy. Prolonged patching may be detrimental, both in terms of stimulus deprivation and possible effects on corneal growth.

Opportunities for spontaneous eye opening under dim (i.e., 5 ft-c) or dark conditions should be provided. Visual attention is more likely to occur under low light levels. Animal studies suggest that dim-dark cycling may be beneficial for regeneration after retinal damage.

A day-night cycling regimen in the intermediate care nursery before hospital discharge affects behavior (162). Infants in the cycled nursery showed improved sleep patterns both in the hospital and after discharge, spent less time feeding, and gained more weight; however, light, noise, and handling all were reduced at night in the experimental unit. That does not negate the effect, but the necessity of entrainment of preterm infants to light-dark cycles is not supported. Rest-activity cycles may be more potent. Biological rhythms are much more complex (163,164).

The question then becomes whether to provide patterned visual stimulation. An infant's ability to respond to a level of stimulation does not necessarily mean that he or she should be stimulated at that level. For example, infants are more likely to respond to a louder sound, yet no one would recommend higher-intensity noise just because the baby hears it better. Likewise, babies attend more to high-contrast black-and-white stimuli than to pastel, but that does not necessarily mean that the baby should be stimulated with the stronger visual pattern either. Prolonged or obligatory visual attention is not a preferred behavior. Given that the visual system is the least mature, the most parsimonious approach would be to provide stimulation of the other senses first. Then the most appropriate visual stimulus to begin with is probably the human face, which bears no resemblance to strong black-and-white patterns.

GENERAL PRINCIPLES

A central issue in developmental intervention is whether to conceptualize the preterm infant as an extrauterine fetus and, therefore, attempt to reproduce the intrauterine environment, or whether by dint of being born, the system now requires other forms of stimulation to foster the unique development of the preterm infant. To some extent this is a nonissue; abrupt change to extrauterine life in altricial species most always has been modulated by the mother. The aversive conditions found in the NICU would not be conducive to development for even the healthiest full-term infant. Further research is not necessary to determine whether excess handling, noise, and bright light ought to be reduced. The NICU environment is a potential source of stress and overt damage to the preterm brain. Research is needed to establish safety limits, rather than to study whether or not aversive conditions do harm.

P.125

Sensory deprivation also can affect development. Research still is necessary to determine the optimal type, timing, duration, and level of stimuli; however, basic guiding principles for developmental intervention do exist:

- Preterm infants are not a homogeneous group. Thus, determining the appropriate level of stimulation is based on an understanding of developmental neurophysiology and evaluation of an individual infant's medical status, neurologic maturation, physiologic stability, and social and physical needs.
- Sensory development is not a simple unitary process. The hierarchical organization and integration of function among the sensory systems provides the conceptual framework for developmental intervention. Thus, intervention should begin with the most mature system, should support the normal maturational process, and should not attempt to accelerate development.
- The model of optimal stimulation for early development lies in the sources naturally available to the fetus and infant (i.e., the mother). The optimal NICU model thus would begin with the intrauterine conditions, then parallel and extend the transition period that occurs immediately after a normal term birth.

A general algorithm therefore seems possible:

- Provide, for any infant, protective care, minimal handling, undisturbed rest, dim, and quiet. Provide for stabilization of autonomic, state, and motor processes through positioning and containment. Model supportive touch.
- Consider the role of olfaction and early bonding. Include positive taste experiences.

If the infant is sufficiently mature (32 weeks gestation) and medically stable, introduce graded tactile-vestibular and auditory input. Introduce familiar forms of stimulation at lower intensity first and only if no major medical changes are occurring simultaneously. Other than a parent's face, wait for visual stimulation. Avoid any attempt to "accelerate" development.

- Monitor and modify the approach as the infant matures.

Decreasing aversive conditions, such as bright light, noise, and handling in the NICU, and enhancing comfort through touch, holding, positioning, and containment, benefit the infant and communicate directly to parents.

ACKNOWLEDGMENTS

I thank Cara Coffman and Susan Lydick for substantial contributions to a previous version of this chapter, and R. D. Walk, my mentor.

Chapter 10

Prenatal Diagnosis in the Molecular Age— Indications, Procedures, and Laboratory Techniques

Arie Drugan

Nelson B. Isada

Mark I. Evans

The modern era of molecular and biochemical genetics commenced with the observations of Sir Archibald Garrod at the beginning of the twentieth century. He proposed that four diseases—namely, alkaptonuria, albinism, cystinuria, and pentosuria—resulted from inherited disorders of chemical metabolism. He also suggested that these disorders, which he called “inborn errors of metabolism,” represented only a small fraction of every human's “chemical individuality” that had gone awry (1).

Advances in biochemistry have confirmed Garrod's concepts by characterizing the structural protein abnormality or enzymatic defect of many disorders. Other advances in molecular genetics have allowed precise identification of the defect in the deoxyribonucleic acid (DNA) message, sometimes before the protein defect itself is known (2). This knowledge has direct and immediate applications in the field of prenatal diagnosis (3). This chapter discusses gene organization; mutations and polymorphism analysis; molecular diagnostic techniques; DNA cloning; an approach to disorders diagnosable by molecular genetics; biochemical disorders not amenable to DNA technology or better studied by protein chemistry techniques; and carrier screening.

GENE ORGANIZATION

The Watson-Crick double-helix model of DNA organization is well known (4). DNA conveys information encoded by a series of four nucleotides—adenine (A), thymine (T), cytosine (C), and guanine (G)—that are connected sequentially on two strands. The two strands complement each other, with nucleotide base pairs (bp) being formed by hydrogen bonding between adenine-thymine and guanine-cytosine. Eukaryotic DNA is located in the nucleus and organized into structures called chromosomes. During interphase, chromosomes are not visible by light microscopy. They can be observed only when the genetic content has doubled and the chromosomes condense before mitosis. Chromosomal material is organized into euchromatin and heterochromatin. Euchromatin is vigorously transcribed into ribonucleic acid (RNA). Heterochromatin is relatively inactive. An example of heterochromatin is the inactivated X chromosome.

An unexpected discovery made in the 1970s was that some regions of the eukaryotic chromosome do not code for any known protein (5). Specifically, these noncoding

regions (*introns*), were noted to be interspersed within coding regions (*exons*) (6,7). Exons carry information to direct the assembly of amino acids into a protein, whereas introns do not. Messenger RNA (mRNA) acts as an intermediate molecule to convey information encoded in the DNA by a process called *translation*. Posttranslational modification of mRNA takes place such that introns are removed and exons are joined together before amino acid sequences are formed. After additional biochemical modifications, the mRNA passes out of the nucleus into the cytoplasm, where protein-synthesizing organelles are located.

Approximately 60% of the human genome is comprised of regions of unique nucleotide sequences that presumably

P.131

code for proteins (8). It is estimated that there are 50,000 to 100,000 expressed genes and proteins active in humans; however, expressed genes comprise less than 10% of total genomic DNA. A significant portion of the human genome, perhaps approximately 40%, contains repetitive DNA sequences (9). Various terms are used for the different classes of repetitive DNA sequences found in humans. Highly repetitive sequences are found in the chromosome region adjacent to the centromere. These are simple sequences that are repeated thousands of times, are present in more than 10^4 copies, and comprise approximately 20% of the genome.

Other repetitive, simple sequences are several hundred base pairs long, and are separated easily by centrifuging slightly fragmented DNA through a cesium chloride density gradient. DNA separated by this process is called *satellite DNA*, because the centrifuged DNA forms a main band and several satellite bands above and below the main band. In humans, four satellite bands comprise approximately 6% of the total DNA, each band representing tandem repeat sequences. Blocks of satellite DNA are readily localized by in situ hybridization to regions around the centromeres of metaphase chromosomes. Satellite DNA should not be confused with satellites, a cytogenetic term referring to the segment of an acrocentric chromosome distal to short arm and separated by a constriction.

Other classes of repetitive DNA include *moderately repetitive DNA*, which is gene size in length, repeated from 10 to 1,000 times, and comprises approximately 20% of genome (i.e., one-half of the 40% that is repetitive DNA); *tandem repeat sequences*, which are stretches of DNA in which a short nucleotide sequence is repeated 20 to 100 times, the exact number varying from person to person; *alphoid DNA*, which is a chromosome-specific, repeated, monomeric 170-bp unit located in centromeric regions; and *Alu sequences*, which are highly repetitive 300-bp sequences that are not clustered around centromeres, but are more evenly distributed throughout the genome and interspersed within longer stretches of unique or moderately repetitive DNA. Most contain a single cleavage site near the middle for the restriction enzyme Alu I, derived from the bacterium *Arthrobacter luteus* (see *Restriction Fragment Length Polymorphism Analysis* below). Almost 1 million *Alu* sequences are present in the human genome, accounting for 3% to 6% of the total DNA. Each individual human has a unique amount of repetitive DNA. This genetic fingerprint is used for paternity testing and forensic analysis.

A discovery involving repeat sequences demonstrates an association between changes in length of triplet repeats and human disease. A significant increase in length of the normal sequence of three repeated nucleotides is associated with marked tendency to clinical morbidity. This was first described in the fragile X syndrome, a common form of heritable male mental retardation, where a polymorphic sequence of -CGG- repeats on the X chromosome is increased from a mean of 29 repeats to more than 200 repeats in affected males. Triplet expansion of -GCT- is associated with congenital myotonic dystrophy. Triplet expansion of -CAG- is found in spinal-bulbar muscular atrophy, spinocerebellar ataxia, and Huntington disease (10,11,12).

Regulation of gene expression occurs at many levels. Substrate concentrations both enhance and repress specific enzymes, especially in bacteria. In eukaryotes and prokaryotes, a region separate from a given gene but still involved in regulation of expression is called *promoter*; it binds RNA polymerase and initiates transcription. Similar functional areas have been found that bind a large group of transcription factors. In eukaryotes, such an area or box contains a common or consensus nucleotide sequence, CAAT, and is called a *CAAT box*. A conserved area associated with RNA polymerase positioning contains repeated sequences of the nucleotides thymine and adenine and is called a *TATA box*.

Extranuclear DNA found in mitochondria (mtDNA) is inherited independently of nuclear DNA, is 16.5 kb in length, contains no introns, and is organized as a double-stranded circle. mtDNA is subject to a relatively high rate of mutation compared to nuclear DNA and is inherited maternally, the paternal spermatid mitochondria being excluded from the oocyte at the time of fertilization. A variety of neonatal and pediatric disorders, predominantly neuromuscular, are associated with mtDNA deletions (13,14,15).

ELEMENTS OF MOLECULAR GENETICS

The deciphering of DNA structure and the genetic code has advanced understanding of the molecular basis of genetic disease. Alterations in DNA sequence may affect a gene structure or function, and may result in an altered gene product that may (or may not) be expressed as genetic disease. An alteration in the sequence of nucleotides within a gene is termed a mutation.

Many types of mutations can affect a gene. The DNA within a gene contains information for the final sequence of a protein and signals for the correct expression and processing of mRNA. If the actual coding region is altered, then the resultant protein may be changed. These alterations can be in the form of deletions that may be many kilobases in length or as small as a single base, inversions or translocations that produce no net nucleotide changes but potential or actual protein changes, or single-base substitution. Even a change at the junction of a coding and noncoding region can result in abnormal mRNA formation. Defects in the promoter region may result in too little or too much expression of mRNA, which will be reflected in abnormal protein synthesis. A deletion of all or part of the gene will almost always result in the disruption of normal gene expression.

Two examples of molecular pathology can be seen in Ashkenazi Jews (16). In the severe infantile type of Tay-Sachs disease, a mutation at an exon-intron splice site in

the α -subunit has been identified (i.e., G to C transversion); another mutation is a four-base insertion in exon 11 of the

α -subunit causing a frameshift mutation and marked reduction in mRNA (17,18). Another example is the F508 mutation, the most common (approximately 70%) mutation causing cystic fibrosis (CF) in people of northern European ancestry (19,20,21). The remaining 30% of CF cases in people of northern European ancestry are caused by a heterogeneous assortment of other mutations (i.e., W1282X). Commercial testing is available and can detect more than 90% of mutations in the northern European population (22). However, other ethnic groups carry their own particular repertoire of mutations and detection rate may be as low as 50% (23).

A variety of approaches have been used to detect mutations. Optimally, determination of DNA structure and sequence, followed by elucidation of gene structure and organization in the normal allele, are completed before beginning a search for specific defects. However, only 5% to 10% of clinically significant mutations are a result of gross alterations in gene structure that are detectable by Southern blot analysis of genomic DNA, leaving unknown the remaining 90% to 95%. The problem is compounded by normal variation in the nucleotide sequence (polymorphism). Thus, when variations from the normal sequence are found, additional analysis is required before these changes can be construed as being a disease-causing mutation.

Because DNA is present in each cell nucleus, any nucleated cell theoretically is suitable for DNA analysis, regardless of whether the gene in question is being transcribed and expressed. Thus, leukocytes, amniocytes, and chorionic villi all are candidate cells for DNA analysis, using Restriction Fragment Length Polymorphism (RFLP). Other methods also used for DNA diagnosis include Southern blot, oligonucleotide probes, and polymerase chain reaction (PCR). Northern blotting is used for RNA analysis.

RFLP analysis uses bacterial enzymes that recognize and cleave DNA at specific sites. Presumably, these enzymes evolved as a defense mechanism against hostile, invading DNA, as might occur with bacteriophages. Because these cleavage sites are quite specific, that is, are restricted to specific palindromic sequences 4 to 10 nucleotides in length, these enzymes are called *restriction endonucleases*. When these enzymes are added to eukaryotic DNA, the resultant mixture contains a variety of DNA fragments of different sizes, which can be separated by gel electrophoresis and transferred for analysis by Southern blotting. Each enzyme cuts an individual's DNA according to the positions of the cleavage sites, with every person having his or her own unique pattern of cleaved DNA fragments. Thus, people are polymorphic for the resulting lengths of DNA fragments. Many of these recognition-site polymorphisms are neutral and represent normal inherited variability. These characteristics have given rise to the term *restriction fragment length polymorphisms*, which refers to the polymorphic patterns observed in specific nucleotide sequences that are cleaved by bacterial restriction enzymes (Fig. 10-1). The resultant mixture of DNA fragments can be separated and further characterized by gel electrophoresis, Southern blotting, and oligonucleotide probes (24). DNA alterations that affect an RFLP site either by creating a new site for endonuclease cleavage or eliminating a previously existing one can be detected on

Southern blot as a result of changes in the size of the DNA fragment associated with this site (25). If, by chance, either a mutation or normal sequence corresponds to an RFLP site, this situation can be exploited for allele identification by using linkage analysis.

Figure 10-1 Restriction fragment length polymorphisms. Lane 1, A1, and A2 present; lane 2, A1-A3 present; lane 3, A1-A4 present; A1-A5, hypothetical polymorphisms.

An initial use of such mapping involved the Huntington disease locus (26). Another early application was for prenatal identification of the sickle-cell mutation in the β chain of hemoglobin (27,28). For example, the restriction enzyme Dde I, derived from the bacterium *Desulfovibrio desulfuricans aestuarii*, recognizes the nucleotide sequence -CTNAG- (where N indicates that any nucleotide may occupy that position) that occurs within the hemoglobin A (-CTGAG-) and hemoglobin C (-CTAAG-) gene, but not within hemoglobin S (-CTGTG-). In hemoglobin S, the nucleotide thymine is substituted for adenine, which is not recognized by Dde I and thus is not cleaved by Dde I. This results in a much larger RFLP fragment that can be recognized on Southern blot. Initially, this technology used unamplified DNA and Southern blot transfer. Target gene sequences can now be preamplified a million-fold by PCR (see next page) and then cut by restriction endonucleases, which greatly facilitates target sequence recognition. This approach is potentially useful in prenatal diagnosis, particularly when the quantity of clinical material is limited.

When the precise nucleotide mutations of the abnormal gene causing the disease are unknown, linkage analysis is a very powerful technique that can be used for diagnosis by association of the diseased gene to a known gene or polymorphic site (29). This implies that the closer together two genetic traits are on a chromosome, the more likely they are to segregate together during meiosis and the less likely crossing-over occurs

between them. When genes are in such close proximity that crossing-over rarely occurs, such as for

hemophilia A and color blindness, the two sites are said to be linked (30). Any polymorphism that is linked with the trait of interest is termed informative. Unfortunately, family studies are not always informative, because linked molecular or clinical polymorphisms are not always present.

The likelihood that two given traits are linked can be described mathematically by the *logarithm of the odds* (LOD) score, developed in 1955 by Morton (31). It can be derived from recombination observed between clinical or biochemical traits from pedigree analysis, or from molecular polymorphisms (32). The probability of recombination during meiosis between two loci is quantified by the *recombination fraction* (i.e., θ or q), the maximum being 0.5. The LOD score is derived from various values of q . Viewed simplistically, the higher the LOD score, the higher the likelihood of linkage. Because this number is used on a logarithmic scale, each integer increase reflects a tenfold increase in likelihood of linkage. Thus, a LOD score of 4 suggests that there is linkage between two polymorphisms, the odds of random association being 10,000:1. A LOD score of zero suggests there is no linkage and that the two traits are on different chromosomes or are far apart on the same chromosome. Tight linkage indicates little or no recombination and suggests an actual physical proximity of two polymorphisms, measured in physical map distances, with the common unit of genetic distance reported as centimorgans (cM). Linkage disequilibrium describes closely linked genes that occur more frequently than would be expected from random distribution, suggesting nonrandom mating or some survival advantage from natural selection. Examples of linkage disequilibrium include the carrier states for sickle cell disease and thalassemia, where those affected have increased resistance to certain types of malarial infections.

Other methods used for DNA analysis include Southern blot, oligonucleotide probes, and PCR. Northern blot is used for RNA analysis. Southern blot is a standard method for DNA analysis in both the clinical and basic science settings. In the Southern blot technique, named after Edwin Southern, double-stranded DNA is digested by a restriction endonuclease chosen because of its ability to detect a DNA polymorphism (33). After endonuclease digestion, the resulting DNA fragments are separated using gel electrophoresis. The DNA in the gel is denatured to generate single-stranded DNA molecules. DNA fragments are transferred from the gel to nylon filter paper (blotting), and specific filter-bound DNA fragments then can be detected by hybridization. A radiolabeled DNA or RNA probe is used that has sequence homology to the DNA fragment of interest, usually 200 to 2,000 bases long. Subsequent autoradiography produces a radiographic film with banding patterns that indicate the hybridization locations on the filter that reflect the fragment sizes of the DNA sequences homologous to that particular probe (Fig. 10-2).

Allele-specific oligonucleotide hybridization has proven to be a valuable technique that measures the specific binding of short (18 to 20), labeled oligonucleotide probes, that match exactly either the wild-type) normal (or the mutant DNA sequence, under stringent washing conditions. Only the probes that exactly complement the immobilized

DNA will remain bound and thus generate a signal seen on autoradiography. Conner (34) originally described this technique for the detection of sickle cell β -globin allele. This technique greatly facilitates the evaluation of genetic disorders in which the gene has to be screened for numerous mutations such as thalassemia, Tay-Sachs, Gaucher, or CF.

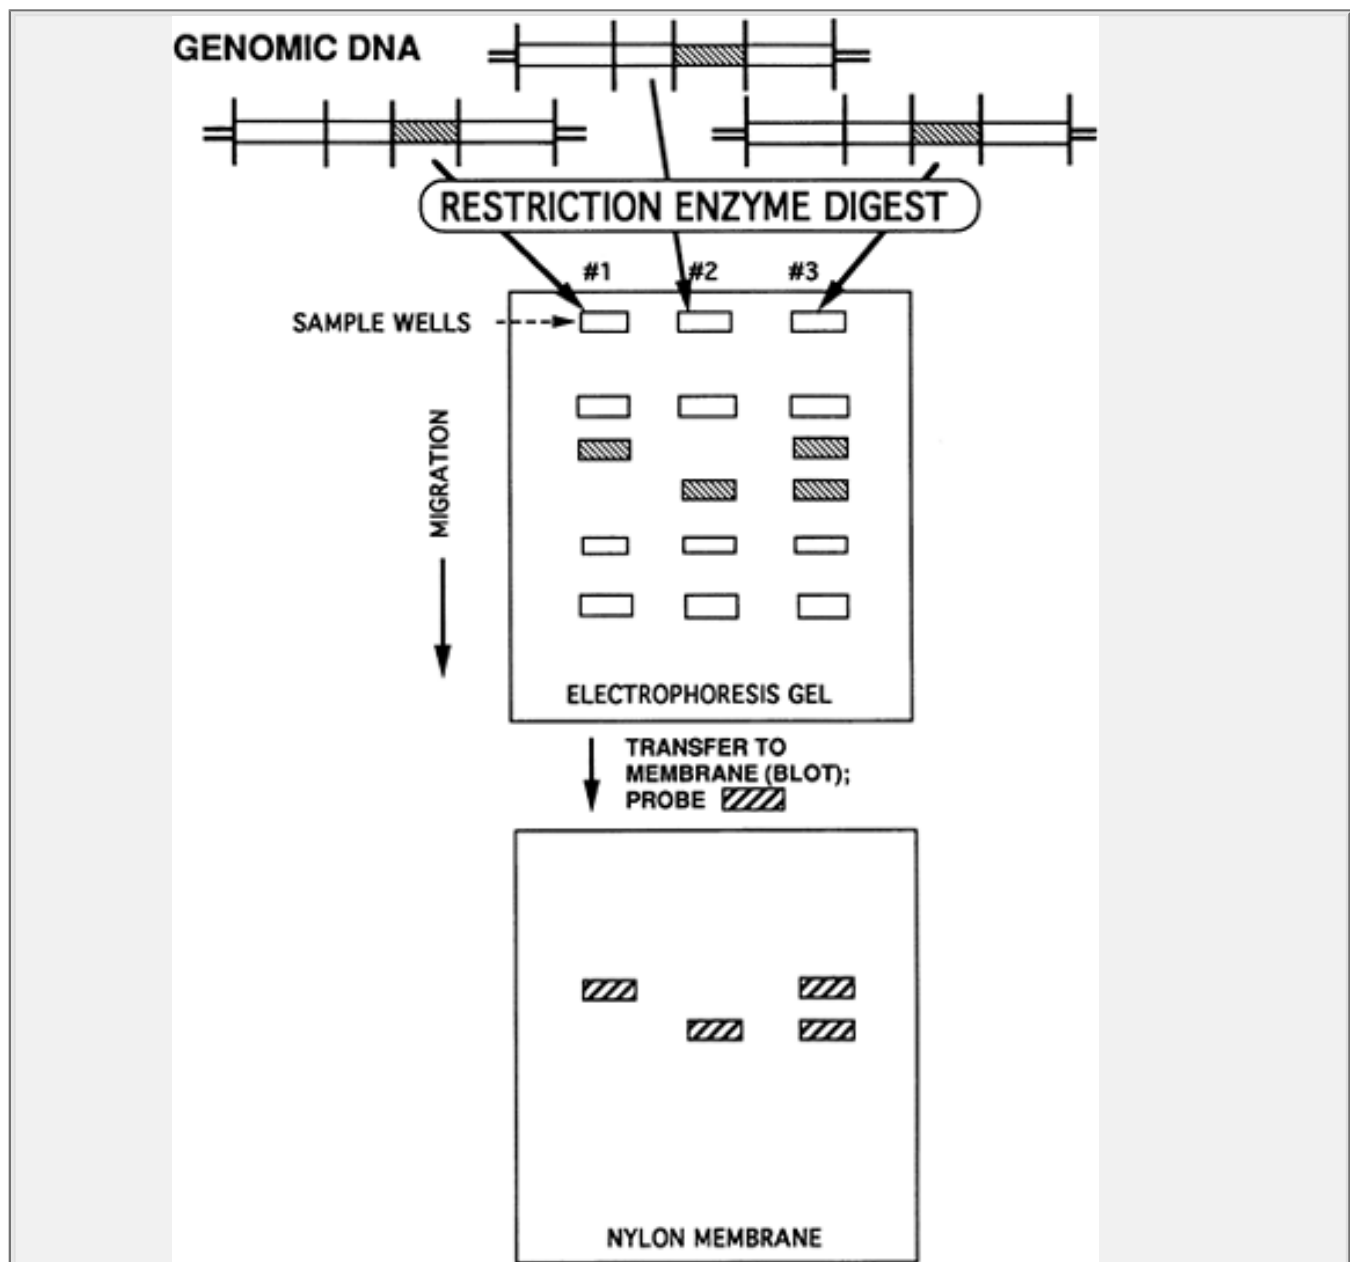

Figure 10-2 Southern blot for a hypothetical autosomal recessive disorder. Lane 1, unaffected; lane 2, affected; lane 3, carrier.

PCR has revolutionized the field of molecular genetics (35,36). It's discoverer, Kary Mullis, won the Nobel Prize in Chemistry in 1993. This procedure allows *in vitro* amplification of minute amounts of DNA to generate sufficient quantities of signal to make detection by more traditional methods possible. PCR makes use of Taq I, a relatively heat-stable bacterial enzyme derived from *Thermus aquaticus*, a thermoacidophilic bacterium. If the target nucleotide sequence is known, a specific set of oligonucleotides, called *primers*, can be synthesized to encompass the target sequence. The target DNA, oligonucleotide primers, Taq I polymerase, and free nucleotides are placed in solution. This reaction mixture is further heated to allow

already denatured DNA to anneal with the oligonucleotides, between which the polymerase synthesizes complementary strands (Fig. 10-3). Repeated cycles of heating and cooling result in cyclic primer sequence synthesis, leading to annealing and amplification of the target sequence, because

P.134

each set of DNA strands gives rise to two additional sets of sequence templates in each cycle of the reaction. This process can be automated to allow 20 to 30 cycles, which can produce more than a million-fold duplication of the target sequence within hours. Modifications of this process can be performed to allow:

- Analysis of RNA.
- Analysis of multiple DNA areas (multiplex PCR). This technique allows detection of more than 97% of deletions in Duchenne muscular dystrophy and all those of patients at risk for Becker muscular dystrophy (37).
- Selective amplification of one strand instead of both (i.e., asymmetric PCR).
- Simultaneous use of one primer set within another to increase specificity (i.e., nested PCR).
- Simultaneous use of two different primer sets, one of which selects for a normal sequence and the other for a mutant sequence (i.e., competitive oligonucleotide priming).
- Simultaneous use of a known amount of a second, easily identified target DNA to measure the amount of original DNA (i.e., semiquantitative PCR).

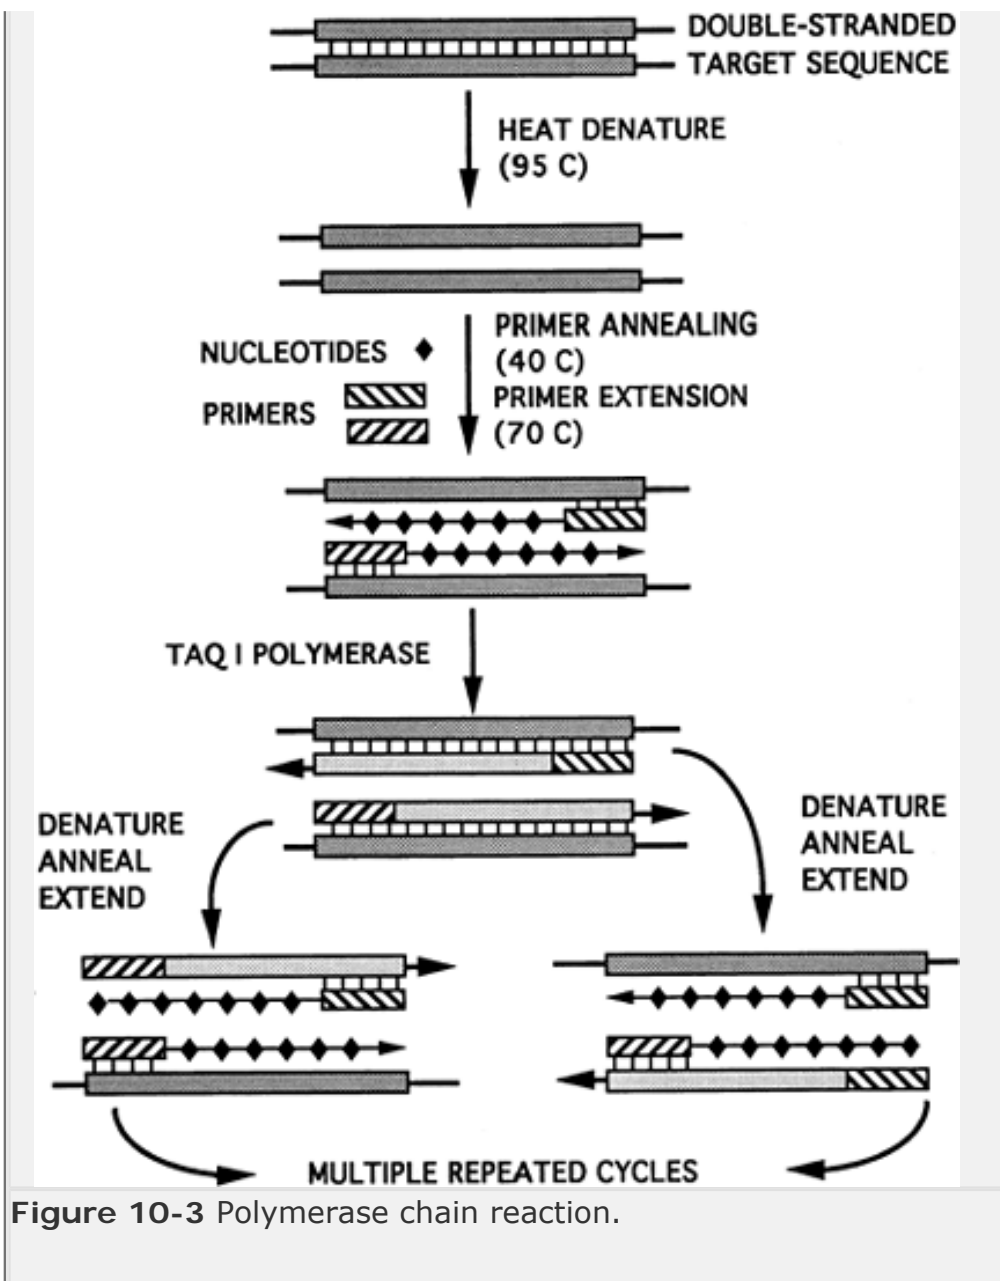

Figure 10-3 Polymerase chain reaction.

Many technical difficulties must be addressed to eliminate both false-positive and false-negative PCR results. Problems with reagent or reactant contamination can lead to false-positive results and require that appropriate control methods be performed simultaneously to verify positive PCR results. Other problems, such as primer instead of target amplification and nonspecific amplification, must be recognized and avoided.

Northern blotting is used for RNA analysis. This requires prompt specimen processing and committed laboratory reagents and instruments because of ubiquitous ribonucleases, present even on finger surfaces. The general principles of the technique are similar to those for Southern blotting. Examination of the size and amount of a mRNA transcript is a useful initial step in evaluating the expression of mutated genes in cells or tissues. Fibroblasts and lymphocytes are good sources of mRNA. Hepatic or muscle tissue is also useful, if available. Placental tissue can be used if maternal cell contamination can be avoided. Of the cell's total RNA, only 1% to 2% is mRNA, which is highly unstable at room temperature because of tissue RNA-ases. The remainder of the RNA is mainly ribosomal RNA (rRNA) and transfer RNA (tRNA). Once isolated, the mRNA is denatured, separated by agarose gel electrophoresis, transferred to a membrane filter, and analyzed by hybridization of a specific fluorescent or radiolabeled probe.

For most diseases studied at the molecular level, 5% to 10% of patients have no detectable mRNA for the gene product in question; 10% to 20% have reduced but detectable amounts of normal mRNA; and approximately 5% have some alteration in mRNA size. The approximately 50% remaining have normal amounts of normal-size mRNA. Given this information, it is possible to deduce the general type of mutation at the DNA level, such as large or total gene deletions, which are suggested by a total absence of mRNA. Mutations in promoter regions are suggested by reduced amounts of normal mRNA. Mutations at exon-intron junctions are suggested by changes in mRNA size—normal-size mRNA but abnormal function of protein hints at point mutations.

In some instances, the quantity of RNA is insufficient to be detected in the previously mentioned methods. In these cases, reverse transcriptase PCR methodology permits identification and isolation of small quantities of mRNA and thereby analyze genes in a more fastidious manner. Grompe et al. (38) were unable to detect by Northern analysis the mRNA in an ornithine transcarbamylase-deficient patient. Nonetheless, the mRNA was isolated and successfully amplified (after synthesis of a single-stranded complementary DNA [cDNA] by using the RNA-directed DNA polymerase, reverse transcriptase), and the mutation responsible for the disease was identified. This technique also allows isolation of the shorter cDNA fragments corresponding to the coding region of the gene of interest. As in Menkes' ("kinky hair") disease, a neurodegenerative disorder associated with a disturbance of copper metabolism, exon splicing is the characteristic result of the splice-junction mutations seen in this rather large gene (39). By using reverse transcriptase PCR, one can discern which exons are lacking by the size of fragment seen on agarose gel or by sequence analysis.

The basic steps in the study of a gene start with the isolation of a DNA molecule complementary to its mRNA, called cDNA, that contains only exonic sequences. The first

P.135

step in cDNA cloning is the isolation of mRNA from a particular cell or tissue that contains a significant amount of the desired mRNA. A retroviral enzyme, reverse transcriptase, is used to synthesize cDNA from the mRNA. Because the cell or tissue mRNA contains transcripts of many genes, the resultant pool of cDNA will be heterogeneous and must be sorted out. The cDNA strands are inserted into a vector to form a cDNA library. A second type of chromosome library is composed of fragments of native genomic DNA and contains introns and other noncoding regions. Vectors include viruses that can replicate within bacteria, such as bacteriophage lambda, or autonomous, self-replicating, circular DNA molecules found in bacteria, called *plasmids*. Another vector that combines properties of plasmids and bacteriophage lambda are called *cosmids*. Cosmids are plasmid vectors into which larger fragments of DNA can be cloned. The term *cosmid* is derived from the presence of internal cohesive end sites (*cos*) that have been inserted into a plasmid. *Cos* are nucleotide sequences from bacteriophage lambda between which DNA sequences are normally expressed as capsule proteins. In cosmids, these sequences can be replaced with other nucleotide sequences, which then can be expressed and concentrated *in vitro*.

An alternative approach to cDNA cloning uses mRNA itself instead of cDNA. Using mRNA

is advantageous because the mRNA pool, although heterogeneous, is not nearly so complex as a corresponding pool of genomic DNA fragments that contains a mixture of introns, nonexpressed genes, and DNA from noncoding regions. Methods of cDNA cloning to detect the presence of a specific cDNA segment include screening a cDNA library with synthetic oligonucleotide probes and screening a bacteriophage lambda library with antibodies directed against the protein of interest. Using the first approach, a set of radiolabeled oligonucleotide probes is synthesized with sequences complementary to those predicted for the mRNA from the amino acid sequence found in the protein. These oligonucleotides are used to probe a cDNA library that contains bacterial colonies infected with bacteriophage lambda. With the second approach, antibodies against the protein of interest are used to detect a corresponding protein expressed by cDNA inserted into bacteriophage lambda.

cDNA for many genes have been cloned using these approaches. Nucleotide sequencing is the first step in the analysis of a cDNA. With this information, the investigator can identify potential sites of restriction endonuclease cleavage, can compare the deduced amino acid sequence with that of the protein of interest, and can identify regions of homology with other proteins, which may suggest evolutionary relationships and previously unrecognized functions. In addition to providing nucleotide and amino acid sequence information, these cDNA can be used as hybridization probes to characterize and quantitate corresponding mRNA in cells and tissues from patients with a variety of diseases.

The process by which DNA analysis leads to an identifiable protein abnormality was previously called "*reverse genetics*"; it is now called "*positional cloning*" (40,41). Several hundred genes associated with human disease have been identified. In some diseases, such as Cystic Fibrosis, the triple-nucleotide/single-amino-acid deletion in the CFTR protein has been recognized. For other diseases, the gene and protein are better characterized, such as for neurofibromatosis type 1 (42). For most human diseases, however, the genes and the defect in protein synthesis have yet to be defined.

PRENATAL DIAGNOSIS

Whether by cytogenetic, biochemical, or molecular methods, prenatal diagnosis of an affected fetus requires obtaining either fetal tissue (i.e., blood) or other tissue for analysis that is representative of the fetus (e.g., amniocytes or placenta). Invasive procedures for prenatal diagnosis of fetal disease are available throughout gestation, from the first trimester onward. Even earlier, assisted reproduction technologies (ART) enable diagnosis (or exclusion) of several disorders on the 4- to 8-cell embryo before implantation.

Invasive procedures for diagnosis in pregnancy of fetal genetic disorders have been available for almost four decades, since the introduction of techniques for culturing and karyotyping of amniotic fluid fibroblasts in the mid-1960s (43). The first diagnosis of a fetal chromosome anomaly by amniocentesis (44) was followed shortly by the diagnosis of an enzyme deficiency in amniotic fluid cells (45). Thereafter, collaborative studies established the safety and accuracy of midtrimester amniocentesis, so that this technique became a routine part of prenatal care in high-risk patients and the gold

standard against which other procedures for prenatal diagnosis are compared (46,47).

Despite its proven efficacy, a major disadvantage of amniocentesis is the availability of results late in the second trimester, generally 18 to 20 weeks of gestation. The emotional and physical implications of termination of pregnancy this late in gestation are obvious. Improvement in ultrasonography machinery and increasing expertise in ultrasound-guided procedures enabled physicians in the late 1980s to attempt prenatal diagnosis in the first trimester, introducing chorionic villus sampling (CVS) and early amniocentesis. These technical developments are backed and reinforced by increasing preference on the part of patients for first trimester prenatal diagnosis (48). Chorionic villus sampling is usually performed between 11 and 13 weeks of gestation so that results are available by the end of the first trimester. The accuracy and safety of CVS are quite comparable to those of mid trimester amniocentesis (49,50) and the early results allow patients privacy in reproductive decisions and an earlier and safer termination of pregnancy if so opted. An alternative to CVS was offered by early amniocentesis performed between 10 and 14 weeks of gestation, but this technique has been largely abandoned (51).

Over the years, a change in the pattern of indications for prenatal diagnosis has been observed. The most common

P.136

indication for genetic counseling and prenatal diagnosis is the need to evaluate the karyotype of the fetus, this being indicated in more than 70% of cases of advanced maternal age (defined as 35 years or older at birth). Other "classical" indications to evaluate fetal karyotype include a previous, affected offspring and a balanced structural rearrangement of parental chromosomes, the latter being clinically evident as recurrent pregnancy loss (Table 10-1). In recent years, increased use of biochemical serum screening and of ultrasonographic screening for fetal chromosome anomalies have caused more young patients, previously considered to be at low risk for fetal aneuploidy, to opt for invasive prenatal testing. The combination of "double," "triple," or "quadruple" serum screening (α -fetoprotein [AFP], human chorionic gonadotropin [hCG], and unconjugated estriol [uE3], with or without inhibin A) and maternal age will select for prenatal testing a sub-group of patients among whom 65% to 75% of chromosomally abnormal conceptions will be contained. Using a risk cutoff for fetal aneuploidy equal to that of age 35 years, some 5% of young pregnant patients will have a positive screening test, and 1 in 50 amniocenteses performed for this indication will diagnose a chromosomally abnormal conception (52). In the second trimester, sonographic markers for fetal chromosome anomalies are observed in 3% to 5% of pregnancies (53) (Table 10-2) and are another indication for fetal karyotyping. The most worrisome of these findings are abnormalities of fetal neck, indicating the need for evaluation of fetal chromosomes even in association with normal biochemical serum screening in young patients (54).

TABLE 10-1 INDICATIONS FOR PRENATAL DIAGNOSIS

Increased risk of chromosome anomalies

Advanced maternal age

Previous offspring with chromosome anomalies

Parental balanced translocation or inversion

Ultrasonogram diagnosis of fetal malformations or anomalies

Abnormal biochemical screening in maternal serum

Previous offspring with neural tube defect

Parents carriers of a mendelian genetic trait

Molecular DNA diagnosis (e.g., cystic fibrosis, sickle cell anemia and fragile X syndrome)

Enzymatic activity in villi or amniocytes (e.g., Tay-Sachs and Refsum disease)

Precursor levels in cell free amniotic fluid (e.g., 17-hydroxycorticosteroids progesterone in congenital adrenal hyperplasia; 7-dehydrocholesterol in Smith-Lemli-Opitz syndrome)

TABLE 10-2 RELATIVE RISK FOR ANEUPLOIDY ASSOCIATED WITH ISOLATED SONOGRAPHIC MARKERS

Sonographic Marker	Prevalence	Relative Risk*
Choroid plexus cysts	1.25%	×9 [†]
Nuchal Thickening or hygroma	4%–5%	
>4 mm		×18
>5 mm		×28
>6 mm		×36
Left ventricular echogenic focus	5%	×4
Hyperechoic bowel	0.6%–0.8%	×14–16
Pyelectasis	2%	×3.3–3.9
Fetal biometry		
Short CRL	7%	×3
Short Femur Length	4%–5%	×2.7
Short Humerus	4%–5%	×4.1
Short Femur and Humerus	2.4%	×11.5

* Risk for trisomy 21 as calculated in relation to maternal age alone or in combination with biochemical screening.

† Risk specific for trisomy 18 and possibly trisomy 21.

The most effective screening test for Down syndrome is probably the integrated test, based on estimation of the nuchal translucency on ultrasonography, hCG, and pregnancy-associated plasma protein A (PAPP-A) in the first trimester, combined with AFP, HCG, estriol, and inhibin A in the second trimester of pregnancy. The integrated risk assessment is reported to have a 94% detection rate and a 5% false-positive rate (55). The results of biochemical or ultrasonography screening also can be used to

modify the risk of aneuploidy in the population previously considered at risk, reducing the number of invasive diagnostic procedures in patients of advanced maternal age by more than half (56,57). Furthermore, "at-risk" patients who previously declined amniocentesis may be influenced to accept invasive prenatal diagnosis following a positive screen result (57). However, a major problem of this "integrated" approach is that results obtained in the first trimester are withheld from the patient, and the advantages of first trimester diagnosis are lost.

The need for rapid karyotyping may arise when fetal anomalies are suspected near the statutory limit for termination

P.137

of affected pregnancies, that is, after an abnormal result on biochemical or ultrasonography evaluation. In those cases, the diagnostic options are "late" CVS (58) or cordocentesis and karyotyping of fetal blood lymphocytes. Other tests that may be performed on blood obtained by cordocentesis include hematologic parameters, acid-base balance, and immunologic status of the fetus (59).

Birth of a child with an inherited genetic disorder caused by malfunction in a single gene implies a 25% to 50% risk of recurrence in subsequent gestations, depending on the specific mode of inheritance of that disease. This risk and the associated genetic burden of the disease may be considered so high that many couples will opt to avoid further reproduction unless prenatal diagnosis is available. Fetal karyotype is uninformative in these cases. Prenatal diagnosis of mendelian disease is performed using biochemical or molecular techniques on fetal or placental tissue. Biochemical assays include assessment of gene products such as enzymes, receptors, and transport proteins, and metabolites such as amino acids, organic acids, vitamins, and hormones. When the underlying biochemical defect is known and is expressed in accessible fetal tissue or cells, prenatal diagnosis can be achieved by enzyme analysis of material obtained by CVS, amniocentesis, or cordocentesis. Because variability caused by different mutations and different genomic backgrounds exists among families, additional testing of leukocytes or cultured skin fibroblasts from presumably unaffected parents and siblings can provide valuable information. In addition to the benefit in interpretation of prenatal results, such studies may provide a reliable means for identification of other carriers among members of the extended family.

Prenatal diagnosis is now available for many inherited metabolic disorders. For an autosomal recessive disease, biochemical assays can be used should discriminate among homozygous affected, heterozygous unaffected, and homozygous normal fetuses. Assays for detection of autosomal dominant diseases, such as some of the porphyrias, usually are capable of identifying affected homozygotes, but sometimes fail to differentiate conclusively affected heterozygotes from unaffected fetuses. Heterozygote detection in X-linked disorders is difficult because of the random X inactivation occurring in every pregnancy with a female fetus. Depending on the ratio of an active mutant X to the normal X in tissues involved in the pathogenesis of the disease, a female heterozygous for an X-linked disorder may be clinically normal, or may have mild or even severe disease manifestations (60). To complicate matters further, measured enzymatic activities also vary depending on the ratio of mutant to

normal X chromosomes that are active in the analyzed specimen—chorionic villi, for example. Occasionally, the activity levels in chorionic villi will not correlate with clinical expression. Males, conversely, have only one X chromosome and are either hemizygous affected with deficient enzyme activity or hemizygous normal with activity in the normal range. Thus, prenatal biochemical assessment of X-linked disorders is less complicated if the fetus is male.

The use of direct and cultured fetal specimens for prenatal evaluation of metabolic disorders ideally requires the availability of normal control preparations. Except for trophoblasts and amniotic fluid cells that can be maintained in culture, availability of fresh controls is often a problem, and in most instances long-term frozen controls with partial loss of activity must be used. There are other potential pitfalls that seem specific for each of these tissue, cell, and fluid types. All samples should be analyzed as soon as possible, except those requiring initial tissue culture. Chorionic villi, fetal tissue biopsies, cell pellets, amniotic fluid supernatant, and fetal serum or plasma that are not used for tissue culture can be kept frozen and shipped on dry ice. Cell and tissue cultures, however, should be shipped at room temperature. Whenever possible, appropriate controls matched by gestational age should accompany the samples to be analyzed. Extraction and analysis of labile enzymes is especially difficult, because test results are very sensitive with respect to the duration of homogenization or sonication. Using fresh chorionic villi or amniocytes or freshly harvested trophoblasts helps preserve the activity of such labile enzymes (61).

Fetal liver and muscle biopsy should be considered only in the absence of other alternatives, because the risk for pregnancy loss associated with these invasive procedures is significantly higher. Fetal muscle biopsy has been used in rare cases of Duchenne muscular dystrophy (DMD), when molecular analysis of trophoblasts, amniocytes, or fetal leukocytes is nondiagnostic and family studies are uninformative. An *in utero* fetal muscle biopsy can be performed in the middle of the second trimester to assess dystrophin levels in myoblasts by *in situ* hybridization (62). Absence of dystrophin suggests an affected fetus.

Fetal liver biopsy also can be performed for certain rare enzyme deficiencies. For example, in one type of glycogenosis, glucose-6-phosphatase is decreased; this enzyme is expressed only in fetal liver and kidney. In the absence of direct DNA techniques, the only option available for prenatal diagnosis is fetal liver biopsy in which glucose-6-phosphatase activity can be measured. Fetal liver biopsy also is applicable in rare cases of ornithine transcarbamylase deficiency where family studies are uninformative and known deletions cannot be detected (63). In the future, it is probable that most of these procedures will be considered obsolete, and prenatal diagnosis of most genetic disorders will be performed by molecular analysis, including some mitochondrial disorders that may be amenable to prenatal diagnosis (64).

Prenatal Diagnosis in the First Trimester

Chorionic Villus Sampling

The first attempts at first trimester prenatal diagnosis were made in the early 1970s for

fetal gender determination. Prenatal diagnosis did not gain popularity in the Western world until 1983, when laboratory techniques to obtain adequate karyotypes from chorionic villi were developed

P.138

by Simoni and Brambati in Milan (65). They also reported the first diagnosis of trisomy 21 by the direct method (66). Over the years, the quality of chromosome preparation from CVS material has improved considerably, approaching the banding quality obtained from amniocytes or blood karyotypes (67). The clinical procedure also has been refined, with the use of real-time ultrasonographic guidance and malleable catheters for villi aspiration.

Two types of cells are observed in chorionic villi. The outer layer consists of cytotrophoblast, which divide spontaneously, and is used for direct evaluation of metaphases. The inner mesenchymal core is used to initiate long-term cultures and is usually considered as more representative of fetal karyotype. Fetal karyotype is obtained from direct analysis, from long-term culture, or from both in 99.6% of successful sampling of villi (67). Results of direct analysis are equivocal in 0.5% to 2% of cases, but questions raised usually are resolved by long-term CVS or amniotic cell cultures (68). Most commonly, an abnormal direct result that proves to be normal on long-term culture will not be confirmed in karyotypes obtained from amniocytes or fetal lymphocytes. The unusual situation is a normal direct result followed by an abnormal result in long-term culture, with the abnormality being confirmed in fetal tissue in one-half of cases (67). Maternal cell contamination has been observed in 1.9% of long-term cultures, but usually is not observed in direct preparations and does not contribute to diagnostic error in any case (68).

Chromosomal mosaicism in CVS material affects 1.2% to 2.5% of cases (average 1.3%), and is more common in direct preparations than in long-term culture (69). Mosaicism was restricted to extraembryonic tissue in 70% to 80% of cases. Despite mosaicism being confined to the placenta, followup of these cases documented a significantly elevated fetal loss rate (7.5% to 16.7%), mostly in the second and third trimesters, suggesting that such placental mosaicism is not entirely benign (70,71). Intrauterine growth restriction (IUGR) also appears to be more common in this situation (72). Mosaic trisomy 3 is one of the most common types of mosaicism observed in placental cells (69). An adverse impact on pregnancy outcome seems to be most common in association with confined placental mosaicism of chromosomes 13, 16, and 22 (73).

The diagnosis of mosaicism in CVS presents difficulties in genetic counseling because it implies uncertainty with respect to fetal phenotype and genotype. Using both direct preparation and long-term culture might increase the accuracy of diagnosis by CVS. When further evaluation is needed, level II ultrasonography and amniocentesis is generally adequate for followup. The use of early amniocentesis in these cases may allow earlier clarification of fetal karyotype without a significant increase in procedure related fetal loss rate (71). In our experience, however, the frequency of mosaicism in amniotic fluid cultures is not significantly different from that observed in CVS (0.35% vs. 0.56%, respectively)(74). Cordocentesis may also be used in such cases to verify

mosaicism in fetal blood (75). Even if fetal blood karyotype is normal, however, there still remains a small chance that mosaicism is confined to specific fetal tissues, as observed in trisomy 20 mosaicism.

CVS can be offered to almost every patient who needs prenatal diagnosis in the first trimester. The most common indication for CVS is evaluation of fetal karyotype, which is indicated for patients with advanced maternal age (70% to 80% of cases), a previous child with chromosome anomalies, or a parent carrier of a balanced translocation or inversion. "Mendelian" genetic disease can be diagnosed in at-risk cases by enzyme level analysis in fresh or cultured villi (i.e., disorders such as Tay-Sachs disease or the mucopolysaccharidoses)(76). However, it is crucial to obtain for analysis chorionic villi that are only of fetal origin, with maternal cells either completely absent or extremely rare. For most biochemical prenatal tests in the first trimester, the recommended practice is to use fresh chorionic villi for preliminary evaluation followed by subsequent analysis of cultured trophoblast for confirmation of the diagnosis. One exception is with nonketotic hyperglycinemia (NKH). Although the glycine-to-serine ratio in amniotic fluid is elevated in this disease, there is a significant overlap with normal values. The potential for prenatal diagnosis of this disorder would rely exclusively on the results obtained in fresh chorionic villi, because the glycine cleavage system is not expressed in amniotic fluid cells or trophoblasts, but is detectable in fresh tissue (77). When the enzyme in question is very labile (e.g., sialidase), or when its normal activity in chorionic villi is extremely low, as for α -iduronidase, the use of frozen controls may cause false-negative diagnoses. Specific problems also may be encountered because of different distribution of enzymes and isozymes (78). The characteristic presence of high levels of arylsulfatase C activity in chorionic villi hampers the differential detection of arylsulfatase A in metachromatic leukodystrophy and arylsulfatase B in mucopolysaccharidosis VI.

Chorionic villus sampling is particularly suitable for prenatal molecular diagnosis of "mendelian" genetic disease. The amount of DNA obtained from even a few villi is much larger than that contained from 40 mL of amniotic fluid. The molecular techniques described throughout this chapter and in a large number of other sources have particular application to CVS material.

Technical Aspects of Chorionic Villus Sampling

CVS procedures are commonly performed between 11 and 13 weeks of gestation by the transcervical, transabdominal, or transvaginal route (Fig. 10-4). After 13 weeks, the procedure is best performed using a transabdominal approach (69,79). Fetal viability and gestational age must always be confirmed before the procedure. Placental location will usually dictate which approach to employ. Transcervical CVS is used when the placenta is low lying, whereas fundal placentas are most commonly an indication for transabdominal needle aspiration of the villi. Transcervical or transvaginal CVS should be

avoided in patients who have an active vaginal or cervical infection (e.g., herpes); the transabdominal approach also should be avoided in patients who have an interposed

bowel or marked uterine retroversion (68). In those cases, the procedure can be performed transvaginally with a needle guided by transabdominal or transvaginal ultrasonography (80).

Figure 10-4 In transcervical chorionic villus sampling (CVS), the CVS catheter (*arrows*) is guided through the cervical canal and into the placenta.

Despite the preference of some American and European centers to use the transabdominal approach for CVS (81,82), our experience is that transabdominal sample size usually is lower than that obtained transcervically (83). Proficiency in both types of procedures is necessary, however. Tailoring the type of procedure to placental location is expected to reduce complication rates after CVS (83,84). It appears also that transabdominal CVS is more suitable for testing multifetal pregnancies and can be applied before fetal reduction (85). After the procedure, fetal heart activity should be verified by ultrasonography. Maternal vaginal bleeding should also be assessed.

The safety of CVS must be judged in view of the natural pregnancy loss rate in the first trimester. It is estimated that 3% to 5% of pregnancies are miscarried after documentation of fetal heart beats on ultrasound at 8 to 11 weeks of gestation; the likelihood of spontaneous abortion also increases with age (86). Both the Canadian and the American collaborative studies documented an excess loss of pregnancy rate in the CVS group of 0.6% to 0.8%, which was not significantly different than the loss rate in the amniocentesis group (48,49). Fundal placental location, three catheter insertions, and obtaining small amounts of villi are significantly associated with pregnancy loss after CVS. These factors may reflect technical difficulty during the procedure (68).

Concerns over an increased risk of limb reduction defects (LRDs) following CVS were raised in the early 1990s (87,88). Evaluation of more than 135,000 cases from experienced centers worldwide reveals that the incidence of LRD or of any other defect is identical to that of the background risk in this population (89). Furthermore, closer assessment of cases of LRD reported after CVS has shown that several patients had unaccounted for familial factors (90).

Because some of these cases were reported with CVS procedures done earlier than the recommended gestational age, it is advisable to postpone CVS until 10 weeks of gestation are completed. However, there are special circumstances under which earlier CVS may be appropriate. In populations at high risk for genetic disorders there is commonly a tendency for diagnosis as early in gestation as possible. For example, in Orthodox Judaism, abortions are permitted, but only until 40 days past conception (i.e., 54 days after the last menstrual period or 8 weeks). CVS in these patients has been performed at 7 weeks to get answers "in time" (91). The ethics of using a procedure with known higher risks to meet the theological needs of patients is a fascinating subject that is beyond scope of this chapter.

Another concern regarding CVS is the potential for fetomaternal transfusion. Transiently rising maternal serum AFP levels after CVS, suggest some transfer of fetal blood into maternal circulation, this being in correlation with sample size (92). The calculated mean volume of transfused fetal blood was 5.4 mL. Others have reported the volume of fetomaternal transfusion after CVS to reach 21% of fetoplacental blood volume (69). Thus, Rhesus (Rh) immunoprophylaxis (anti-D 300 µg) should be administered to Rh-negative patients. Prior Rh isoimmunization should be considered a relative contraindication to CVS.

Early Amniocentesis

Early amniocentesis refers to aspiration of amniotic fluid less than 15 weeks from the last menstrual period. The procedure is technically similar to later amniocentesis procedures; using continuous ultrasonography guidance and aseptic technique, a 22-gauge needle is inserted into a pocket of fluid, and about 1 mL of fluid per week of gestation is aspirated into a 20-mL syringe.

With improving ultrasonography technology and increasing experience with ultrasonography-guided needle manipulations, early amniocentesis late in the first trimester appeared, in the early to mid 1990s, to be an attractive alternative to CVS. However, women who had early genetic amniocentesis were more likely to have more postprocedure amniotic fluid leakage (2.9% vs. 0.2%), vaginal bleeding (1.9% vs. 0.2%), or fetal loss (2.2% vs. 0.2%) than were women undergoing amniocentesis at 16 to 19 weeks (93). Moreover, in approximately 5% of early procedures, aspiration of fluid can be hampered by tenting of membranes; rotating the needle or the use of a stylet longer than the needle allows the procedure to succeed in these situation (51,94).

The total unintentional loss rate after early amniocentesis is estimated as 1.4% to 4.2% (93,95). It appears that the principal determinant of total fetal loss after any procedure is gestational age. There seems to be a trend in all series toward increased loss rates after amniocentesis performed at 11 or 12 weeks of gestation (96,97,98).

Early amniocentesis has a lower rate of pseudomosaicism and maternal cell contamination than that observed in CVS analysis. Culture failure rates of early amniocytes have been reported as 0.32% to 1.6% (95,96,99,100). In our experience, culture failure rate is 1 in 700 after midtrimester amniocentesis, but approximately 1% after early procedures

(nearly 5% when amniocentesis was performed before 12 weeks of gestation). It also should be noted that failure of culture at amniocentesis has been reported more commonly in association with fetal chromosome anomalies (97). The mean culture time may also be somewhat longer after early amniocentesis than after midtrimester procedures (98).

AFP peaks in amniotic fluid at 12 to 13 weeks of gestation and then gradually decline, similar to fetal serum (99). Analysis of AFP and acetylcholinesterase (AChE) in early amniotic fluid specimens may permit the diagnosis of fetal structural anomalies. High amniotic fluid AFP levels have been observed with fetal neural tube defects (NTDs) or omphalocele even in these early samples (100), and low amniotic fluid AFP values accompanied some conceptions diagnosed as aneuploid, as seen in samples of amniotic fluid obtained at midtrimester. The interpretation of AChE results in early amniotic fluid specimens is more complex. Acetyl cholinesterase usually is analyzed on gel electrophoresis as a bimodal result, either positive or negative. In early amniotic fluid samples, a faint, inconclusive band is frequently observed, this being associated with fetal anomalies only in a minority of cases (101). A normal sonogram in this situation is also reassuring in regard to fetal neural or abdominal wall defects, but a higher rate of adverse outcomes has been reported in these pregnancies (102).

First-Trimester Prenatal Diagnosis: Chorionic Villus Sampling or Early Amniocentesis?

A prospective, randomized evaluation of CVS and first trimester amniocentesis suggests that the two techniques are comparable in terms of accuracy and successful results (103). It is apparent also that the two procedures are equally efficient in providing a sample for evaluation (CVS 99.3%, early amniocentesis [EA] 100%) and in giving a nonmosaic cytogenetic result (CVS 97.5%, EA 97.9%)(104). Spontaneous pregnancy loss after early amniocentesis is, however, significantly higher than after CVS (4.9% vs. 2.1%, respectively). Similar results were concluded from analysis of the Cochrane database: more spontaneous miscarriages (relative risk [RR] 1.92, confidence interval [CI] 1.14 to 3.23) and more cases of neonatal talipes were observed in the EA group (105). Concerns have also been raised that removal of amniotic fluid so early in gestation may affect fetal lung development and function (106). Moreover, results of EA are available about 4 weeks later than after CVS. Thus, in cases that are diagnosed as abnormal, one advantage of first trimester CVS (that patients can have a less traumatic and less risky termination of pregnancy) is lost when early amniocentesis is employed.

Our opinion is that CVS *is* the diagnostic procedure of choice before 14 weeks of gestation for karyotyping, enzymatic, and DNA molecular analysis. Conversely, EA (after 12 gestational weeks) may be preferable in certain biochemical disorders and in situations in which CVS may not truly represent fetal tissue (i.e., contamination with maternal cells or with tissue from a twin pregnancy with fused placenta).

Prenatal Diagnosis in the Second and Third

Trimesters

Midtrimester Amniocentesis

Midtrimester amniocentesis is the oldest, most commonly performed procedure for prenatal diagnosis. It also is considered the gold standard to which other procedures for prenatal diagnosis are compared. Indications for genetic amniocentesis include increased risk for metabolic disorders, for chromosome anomalies or for structural anomalies that may be associated with elevated AFP (see Table 10-1).

Some metabolic genetic disorders may be diagnosed by measurement of precursor levels in cell-free fluid or by enzyme activity in cultured amniocytes. Elevated concentrations of amino acids and organic acids in amniotic fluid serve as preliminary indications for several inherited disorders, such as amino and organic acidopathies or urea cycle defects.

Amniotic fluid supernatants should be divided into multiple vials to avoid the loss of activity that occurs with repeated freezing and thawing. Determinations of amniotic fluid concentrations of specific metabolites, as well as enzymes and other proteins, usually serve as supporting evidence in prenatal diagnoses. The variability in enzyme activities or in the levels of other proteins and metabolites frequently observed in cultured amniotic fluid cells and trophoblasts can be minimized by a careful choice of control cells. Preferably, the final diagnosis should rely on molecular analysis of specific mutations or on demonstration of the underlying biochemical defect in fetal cells or tissue (measuring the actual gene products responsible for the metabolic block).

In the cytogenetics laboratory, amniocytes are removed from amniotic fluid by centrifugation and cultured in flasks or on cover glasses to grow in monolayers. Dividing cells are arrested in metaphase, when chromosomes are maximally condensed, using agents such as Colchimide that prevent spindle formation. The cells are then harvested and placed in hypotonic saline, which causes intracellular swelling and better spreading of the chromosomes during slide preparation. After fixation, the chromosomes are stained with Giemsa or quinacrine for microscopic analysis. The use of triple gas incubators, specific growth media (e.g., Chang) that enhance cellular proliferation, and *in situ* culture on cover glass have shortened considerably the sampling-harvesting interval; in most laboratories, the results are available within 1 to 2 weeks. Additional improvement is obtained by computerized cytoanalyzers that expedite recognition of metaphase spreads and obviate the need for darkroom and photography.

Cytogenetic analysis of amniotic fluid cells reflects fetal status accurately in more than 99% of cases, but mosaicism sometimes may confuse the interpretation of results. In our experience, the frequency of results needing further investigation is similar in cultures from amniocentesis and from CVS (74). Differentiation between cytogenetic

abnormalities that truly reflect fetal chromosome aberrations from those that are the result of laboratory artifacts may be difficult. One or more hypermodal cells that are limited to one colony or one culture flask are identified in 2% to 3% of all amniocytes cultures and are usually associated with a normal phenotype (107). True fetal

mosaicism should be considered when hypermodal cells are identified in different culture flasks or in separate colonies in the same culture flask. The frequency of hypermodal cells in one or more colonies from the same flask is 0.7%. Hypermodal cells with the same abnormality originating from multiple culture flasks are observed in 0.2% of amniotic cultures (108). Even in the latter situation, however, the abnormality in culture may not represent true fetal mosaicism, as observed by Gosden and colleagues (75). Fetal blood sampling for karyotype should help to avoid termination of pregnancy of some normal fetuses in these cases.

The use of fluorescence *in situ* hybridization (FISH) is a valuable adjunct to standard cytogenetics (109). With this technique, fluorescent probes identify chromosome-specific repetitive DNA, unique sequence regions, or site-specific cosmids in uncultured cells. Fetal cells obtained at the time of amniocentesis or chorionic villus sampling can be analyzed with commercially available probes for chromosomes 21, 18, 13, X, and Y, the result being available in 24 hours. In addition, FISH analysis can be used to identify microdeletions that cannot be observed with standard cytogenetics, that is, microdeletions that may be found in Prader-Willi, Angelman, Williams, DiGeorge/velocardiofacial or Smith-Magenis syndromes (110). It must be emphasized that FISH is still an adjunct to standard cytogenetics and does not detect or identify some cases of mosaicism, translocations, marker chromosomes, or other rare aneuploidies; standard cytogenetics must still be performed. FISH is properly used on patients for whom rapid diagnosis is essential, for example, those with abnormalities seen on ultrasonography, or who are suspicious either at term or at the cusp of their legal options for termination, or who have had multifetal pregnancies prior to reduction. We have found it to be very reliable and efficient in allowing rapid diagnosis (111).

Technical Aspects of Amniocentesis

Genetic counseling is a prerequisite to amniocentesis as well as to any other procedure for invasive prenatal diagnosis (112). Pedigree information obtained during the counseling session will allow a more accurate ascertainment of genetic risks in patients referred for other indication (e.g., advanced maternal age or abnormal serum screening). Only experienced physicians trained in the procedure should perform amniocentesis. In general, a detailed ultrasonographic examination is performed to evaluate gestational age, placental location, and amount of amniotic fluid, and to exclude fetal anomalies. After sterile preparation of the skin, a draped sterile ultrasonography transducer is used to locate a suitable pocket of fluid. Then, under continuous ultrasonographic guidance, a 20- to 22-gauge, 3.5-inch-long spinal needle is inserted in a single, smooth motion into the pocket of fluid. When the needle, which is visualized on ultrasonography as a bright spot (Fig. 10-5), is placed satisfactorily into the pocket of amniotic fluid, the stylet is removed. Twelve to 20 mL (depending on the laboratory) of amniotic fluid are then gently aspirated, transferred into sterile tubes, and transported at room temperature to the laboratory for processing.

Figure 10-5 In amniocentesis, the needle (*arrows*) is inserted through the uterine wall and into the amniotic cavity.

The risk of Rh isosensitization in Rh-negative women with Rh-positive fetuses has been estimated to increase by 1% after amniocentesis (113). Thus, the patient's blood type and antibody status should be known before amniocentesis, and unsensitized Rh-negative women should receive Rh immunoprophylaxis after the procedure.

Amniocentesis is a safe procedure in experienced hands. The procedure-related pregnancy loss rate is 0.2% to 0.5% over and above the spontaneous loss rate at 16 weeks of gestation (the latter is estimated at 2% to 3%) (114). Pregnancy loss rates seem to be associated with the number of failed needle insertions at the same session and with vaginal bleeding after amniocentesis. Within reason, gestational age at the time of amniocentesis, volume of fluid removed, and amniocentesis repeated at a different session after a failed attempt do not seem to correlate with increased risk of pregnancy loss. Transplacental amniocentesis does not appear to increase the rate of fetal loss (115) provided the umbilical cord is avoided. However, the risk of Rh isosensitization is apparently increased by transplacental passage of the needle. With ultrasonography-guided amniocentesis, fetal injury by the needle should be very rare.

Leakage of amniotic fluid is a relatively frequent complication, affecting approximately 1% to 2% of patients after amniocentesis, but it usually is of minor long-term consequence; in most cases, it resolves with bed rest for 48 to 72 hours (116). Even patients with complete absence of fluid after amniocentesis may reaccumulate amniotic fluid and go on to have normal outcomes. Thus, as long as there is no evidence of infection, expectant management (for at least several days) seems prudent. Prolonged amniotic fluid leakage, however, may lead to

severe oligohydramnios, which can result in fetal pressure deformities (e.g., arthrogryposis) and in pulmonary hypoplasia (117).

The risk of severe amnionitis endangering maternal health appears to be very low, around 0.1% (114). However, injury to maternal bowel or blood vessels and rare cases of mortality have also been reported (118).

“Late” Chorionic Villus Sampling

The technique of transabdominal CVS also has been applied successfully in the second and third trimesters. Nicolaides and associates first reported six successful human placental biopsies at 14 to 37 weeks of gestation, and suggested that CVS should not be confined to the first trimester (119). Chieri and Aldini performed transabdominal placental biopsy and amniocentesis in 220 patients at midtrimester; 210 of the procedures were indicated for advanced maternal age (120). A sample adequate for analysis (>2 mg of cleaned villi) was obtained in 90.9% of cases. The success rate was 94% with an anterior or fundal placenta, and 83.8% with a posterior placental location. In the latter situation, the approach to the placenta was transamniotic. Cytogenetic results were obtained in 95% of samples. No discrepancy could be found between cytogenetic results obtained in villi or in amniotic fluid, and when fetal anomalies were observed on CVS, they were acted on without waiting for corroboration from the amniotic fluid culture (120). Several studies since (121,122) have documented a sampling and diagnostic success rate of 98% to 99%, with a very low rate (0.3% to 1.8%) of procedure-related pregnancy loss, even with oligohydramnion.

The collaborative results of 2,058 late CVS procedures performed at 24 centers were reported by Holzgreve and colleagues (58). A fetal karyotype was obtained in 96% of procedures. The frequency of abnormal chromosome results was 21% when fetal anomalies were observed on ultrasound, and 6.2% with normal ultrasonographic findings. The pregnancy loss rate, excluding terminations, was 10.3% in the group with abnormal ultrasonography findings, and 2.3% in the normal ultrasonography group. Holzgreve and associates further presented their own data on 301 CVS procedures in the second and third trimester, 225 (74.7%) of which were performed for abnormal ultrasonography scans (123). Fetal karyotype was obtained in 99% of cases. The rate of chromosome anomalies was 20% in the group with abnormal ultrasonographic scans, and increased to 38% when the ultrasonography findings included abnormalities of amniotic fluid volume.

It was apparent from these studies that despite the decrease in mitotic index with placental aging, direct results could be obtained even with small amounts of placental tissue. The quality of karyotypes obtained from analysis of second and third trimester samples was similar to that obtained in the first trimester (124). Moreover, the risk of maternal cell contamination in late CVS samples actually may be lower than that observed in the first trimester because of less direct contact between villi and decidua at later gestational age (125). Consequently, placental biopsies in the second and third trimesters are technically feasible procedures for prenatal diagnosis, with results apparently as accurate as those of amniocentesis and probably associated with a smaller risk of pregnancy loss than percutaneous umbilical blood sampling. The major advantage of late CVS is the possibility of obtaining rapid results in situations where such information is needed for decisions about pregnancy termination or fetal therapy.

Such situations include the ultrasonography diagnosis of fetal anomalies late in the second trimester, close to the legal limit in gestational age after which termination of pregnancy is no longer possible. Late CVS also offers a distinct advantage over cordocentesis in cases complicated by oligohydramnion. Prenatal availability of fetal karyotype in pregnancies complicated by severe IUGR or fetal anomalies may influence the mode of delivery, the management of intrapartum fetal distress, which is a common phenomenon in fetuses with chromosome anomalies, or the decision for surgical intervention within the first few hours after birth.

Cordocentesis

Freda and Adamson originally attempted to access the vascular system of the fetus for treatment of Rh isoimmunization by hysterotomy and fetal exposure (126). This method soon was abandoned because of the unacceptably high risk for the mother and fetus. Subsequently, the development of fiberoptics allowed the introduction of fetoscopy to visualize and sample vessels on the chorionic plate or the umbilical cord (127). Although the risk of maternal compromise with this method was relatively small, the residual high rate of pregnancy loss associated with fetoscopy (up to 11.3%) was considered a major disadvantage (128).

Daffos introduced ultrasonography-guided percutaneous umbilical blood sampling (PUBS) in 1983 for the diagnosis of fetal infections (129). The procedure gained rapid and wide acceptance. In experienced hands, the risk of fetal loss is relatively small, between 1% to 2.3%, although numbers as high as 5.4% have been reported (130,131). Other complications, usually associated with excessive needle manipulations, include hematoma of the umbilical cord and placental abruption, chorioamnionitis (0.6%), and preterm delivery (9%)(131). Fetal exsanguination from the puncture site is a relatively rare complication but has been reported (132). Maternal complications are negligible, although one case of life-threatening amnionitis has been reported (133). It appears that the risks are higher when the mother is obese, the placenta is posterior, and the sampling is performed relatively early in gestation (i.e., before 19 weeks)(130).

Table 10-3 lists the indications for cordocentesis. With the development of better molecular tests, the use of cordocentesis has dramatically decreased over the last 10 years. Parental counseling before cordocentesis should include the risk of that pregnancy being affected by the conditions considered and the yield of information obtained through fetal blood sampling in such a situation. The risk and

P.143

potential complications of the procedure itself also should be discussed. Before cordocentesis, a detailed ultrasonography examination should evaluate gestational age, placental location, and fetal anomalies. Fetal blood can be obtained by puncture of the fetal heart, the intrahepatic part of the umbilical vein, or by puncture of an umbilical vessel close to its placental insertion, the latter being by far the most common site for cordocentesis. When the placenta is located on the anterior or lateral wall of the uterus, the needle is introduced through the placenta into the umbilical cord (Fig. 10-6). In cases with a posterior placenta, the needle is introduced through the amniotic fluid and

the cord is punctured close to its placental insertion. Different guidance techniques (i.e., fixed-needle guides vs. freehand), needles of lengths varying from 8 to 15 cm, gauges varying from 20 g to 27 g, and differing patient preparation protocols are used by various centers. Nicolaides and colleagues advocate an outpatient setting in the ultrasonography department, without need for maternal fasting, sedation, tocolytics, antibiotics, or fetal paralysis for the procedure (134).

TABLE 10-3 INDICATONS FOR CORDOCENTESIS

INDICATIONS FOR CORDOCENTESIS

Prenatal diagnosis of inherited blood disorders

Hemoglobinopathies (e.g., homozygous thalassemia, sickle-cell disease)

Coagulopathies (e.g., hemophillia A and B, von Willebrand disease)

Prenatal diagnosis of metabolic disorders

Fetal Infections

Toxoplasmosis: specific IgM or DNA hybridization

Rubella: specific IgM

Cytomegalovirus: specific IgM and blood cultures

Varicella zoster virus: specific IgM

Human parvovirus (B19): viral DNA

Human immunodeficiency virus: specific IgM

Rapid fetal karyotyping

Late booking or failed amniocentesis

Suspected fetal mosaicism on amniocentesis

Abnormal maternal serum screening

Ultrasound diagnosis of fetal malformations

Evaluation of the small-for-gestational-age fetus

Acid–base status

Oxygenation

Assessment and treatment of fetal anemia

Diagnosis and treatment of fetal thrombocytopenia

Adapted from ref. 104.

Molecular diagnoses are now available for many of the mutations resulting in thalassemia, sickle cell disease, and hemophilia A and B, enabling diagnosis in the first trimester by CVS, with blood sampling performed only in noninformative cases or in cases with ambiguous results. Cordocentesis is, however, necessary for the diagnosis and management of congenital alloimmune thrombocytopenia (135). In alloimmune thrombocytopenia, cordocentesis allows the determination of fetal platelet phenotype and count. A low fetal platelet count in this situation can be treated by weekly infusion of platelets until delivery (136).

In Rh isoimmunization, fetal blood sampling is performed for immediate confirmation of fetal antigenic status, obviating the need for further intervention in the Rh-negative fetus. If the fetus is Rh-positive, cordocentesis enables a more accurate assessment of fetal anemia and an immediate rise in fetal erythrocyte count on correction by

intravascular transfusion. From case-control studies, it appears that at all gestational ages and at all levels of disease severity, intravascular correction of fetal anemia is more efficient and less risky to the mother and fetus than the intraperitoneal approach (137). Moreover, in cases with cardiac decompensation in which the fetus may be compromised by the volume overload needed to correct the severe anemia, better results were obtained by intravascular exchange transfusion (138). It should be noted, however, that cordocentesis might enhance maternal sensitization more than does amniocentesis, especially if blood sampling is performed by a transplacental approach (139). Rh immunoprophylaxis should be offered to all Rh-negative, nonsensitized patients with an Rh-positive fetus undergoing cordocentesis.

The diagnosis of fetal infection is based commonly on the demonstration of the agent-specific immunoglobulin (Ig) M in fetal blood, because the large molecule IgM does not cross the placenta. Fetal blood sampling should be scheduled to allow enough time from initial exposure for IgM to appear after immunocompetence develops in the fetus. For first trimester exposures, the best time for cordocentesis is probably after 20 weeks' gestation. In a few specific cases, *in utero* treatment also is available. Thus, after toxoplasmosis infection in the mother, and demonstration of IgM specific for toxoplasmosis in fetal blood, antibiotic treatment with spiramycin reduced significantly the risk of congenital toxoplasmosis, as well as the risk of late sequelae (140). Cordocentesis has also

P.144

been used for repeated blood transfusions *in utero* to hydropic fetuses with hemolytic anemia caused by parvovirus B19 infection (141).

Figure 10-6 is, the umbilical cord insertion in the placenta (*small arrows*) must be located. The needle tip (*bright spot*) is placed in the umbilical vein (*large arrow*).

Severe, early onset IUGR commonly is associated with fetal chromosome anomalies. Cordocentesis allows for rapid fetal karyotyping, which can be available within 48 to 72 hours. Other abnormalities observed in blood samples from IUGR fetuses with normal

chromosomes include hypoxemia, hypercapnia, lactic acidemia, leukopenia, thrombocytopenia, and disturbed carbohydrate, lipid, and protein metabolism (142). A statistically significant correlation was reported between increased umbilical systolic-to-diastolic ratio (>3.5) and fetal hypoxia and acidemia in cord blood (143), these relationships being even more pronounced with absent or reversed diastolic flow. Thus, when a fetus is severely growth restricted, fetal pressure of oxygen (PO_2) and pH may provide additional and crucial information to the biophysical score and umbilical blood flow studies, allowing us to decide between the risk of premature delivery and the risk of leaving the fetus to grow in a hostile intrauterine environment.

Preimplantation Genetic Diagnosis

Preimplantation genetic diagnosis (PGD) was developed for patients at high risk of transmitting an inherited disease to their offspring who, for whatever reason, do not want to have even a first trimester abortion. Patients have to go through *in vitro* fertilization (IVF) procedures to produce preimplantation embryos *in vitro*. One or two cells are biopsied from the cleavage-stage embryos, at the 6- to 8-cell stage (day 3 of development), and single-cell diagnosis with PCR or FISH is performed to determine which embryos are free of the genetic disease. This technique has been applied for a wide variety of disorders, including Tay-Sachs disease (144), β -thalassemia (145), cystic fibrosis (146), aneuploidy (147), and Marfan syndrome (148). Overall obstetric outcome appears normal (149).

Because only normal embryos are transferred to the uterus, PGD virtually eliminates the need for termination of an affected pregnancy. However, most centers still recommend that prenatal diagnosis be done, as errors have been made.

PGD appears to be the perfect solution for those couples who are at high risk of transmitting genetic diseases. However, for a multitude of reasons, relatively few centers worldwide offer the procedure, and fewer than 3,000 cycles have been performed in more than 10 years (150).

Single-Cell Diagnosis

Because it is difficult to karyotype single blastomeres, FISH has been used to analyze chromosomes in embryos. Several studies have shown that human embryos exhibit a high level of chromosome abnormalities, mainly mosaicism and chaotic chromosome makeup (151,152). Mosaic embryos can lead to problems in terms of certain PGD diagnoses because the blastomere biopsied may not be representative of the rest of the embryo; in some circumstances, this can be minimized by analyzing two independent blastomeres for PGD (152,153).

The most widespread application of FISH in prenatal diagnosis is for the rapid detection (1 to 2 working days) of the common numerical chromosome abnormalities using chromosome-specific probes applied to single blastomeres or to interphase cells from amniocentesis and chorionic villi samples (154,155). Most commonly, probes specific for chromosomes 13, 18, 21, X, and Y are used because, depending on the indications for invasive tests, numerical abnormalities involving these chromosomes account for

70% to 95% of the chromosome aberrations identified prenatally (154,155,156). The usefulness of interphase FISH in prenatal diagnosis and the test performance characteristics were recently assessed (156). The detection rate was nearly 100%, with a false-positive rate of only 0.003% and a false-negative rate of 0.024%. FISH results are now commonly acted on if, for example, a common trisomy is found, without waiting for the examination of a complete karyotype.

The diagnostic capability of interphase FISH is obviously limited by the choice of probe used; structural chromosome aberrations and numerical chromosome abnormalities other than those tested for will be missed. In addition, the incomplete hybridization of FISH probes or a reduction in signal size because of heteromorphism (154,157) may lead to false-negative prenatal FISH results. In cases of ambiguous FISH results, however, full karyotype should remain the gold standard.

FISH has also been used for the PGD of structural chromosome abnormalities (158,159). This has only been possible in recent years, as probes for the acrocentric chromosomes and specific locus probes were only recently developed. PGD of robertsonian translocations is a good example; minimum dual-color FISH with one probe for each chromosome is possible, but three-color FISH, with two probes for different areas of the most important chromosome, is better (160). PGD for reciprocal translocations is more difficult because specific probes for the region in question are required.

Another limiting factor in PGD for chromosome abnormalities is the high incidence of abnormalities, including mosaicism, seen in preimplantation embryos (160). For some translocations, 70% to 100% of embryos may be abnormal, consistent with the high reproduction failure of such couples. PGD offers these couples a potential major advantage in only transferring a chromosomally balanced embryo.

The techniques developed for PGD have also been applied to aneuploidy screening for patients going through IVF procedures (PGD-AS)(161,162). PGD-AS was initially performed for women of older reproductive age (older than age 35 years), with recurrent IVF failure (more than three attempts with no pregnancy) and after recurrent miscarriages when the couple have normal karyotypes (150). Several reports of an increased pregnancy rate have been published (161,162,163), but a randomized controlled clinical trial has not been performed.

P.145

Comparative genomic hybridization (164,165) has also now been successfully applied in PGD-AS, with one normal live birth (165). Because the time required for comparative genomic hybridization is 72 hours, embryos have to be frozen as they cannot be kept in culture for that length of time.

Whether by cytogenetics, biochemical, or molecular methods, prenatal diagnosis of an affected fetus requires obtaining for analysis either fetal tissue (i.e., blastomeres or blood) or other tissue that is representative of the fetus (e.g., amniocytes or placenta). Invasive procedures for prenatal diagnosis of fetal disease are available throughout gestation, from the first trimester onward. Assisted reproductive technologies have allowed preimplantation diagnosis (or exclusion) of several disorders. Despite its

limitations, as the technology for genetics and assisted reproductive technologies improve, we believe there will be dramatic increases in the use of this modality.

Chapter 11

Feto-Maternal Interactions: Placental Physiology, the In Utero Environment, and Fetal Determinants of Adult Disease

Gabriella Pridjian

The human placenta has become a highly evolved, sophisticated interface between mother and fetus. As the gatekeeper for maternofetal interactions, its functions are diverse and essential. The *in utero* environment not only influences fetal and newborn growth and development, but possibly the development of adult disease.

HUMAN PLACENTATION

Based on the modified classification of Grosser, which separates placentas by the number of layers interfacing the maternal and fetal circulations, the human placenta is hemomonochorial, with only the syncytiotrophoblast, fetal connective tissue, and fetal capillary endothelium forming the barrier between the two circulations (Fig. 11-1)(1). The human placenta, with this most intimate interface, is similar to that of the guinea pig and the monkey. Placentation in other animals is different, and there is great variation in mammalian placentation. For example, the ovine placenta is epitheliochorial and almost impermeable to diffusional transfer of the ketone body β -hydroxybutyrate, but human placenta is permeable to this ketone body, which has been implicated with the fetal distress accompanying diabetic ketoacidosis (2). The human placenta is discoid and made up of 8 to 10 cotyledons. Fetal blood is supplied to the placenta by two umbilical arteries and drained by one umbilical vein. On the fetal surface of the placenta, the umbilical arteries, crossing over fetal veins, decrease in caliber and increase in divisions as they travel toward the placental edges and dive deeply into the placental disc to supply individual cotyledons. Within the substance of the placenta, the caliber of the arteries decreases until only fetal capillaries exist at the level of the terminal villi. The fetal capillaries are dilated, providing a broad surface area for maternofetal transfer. The maternal blood supply to the placenta originates from the uterine artery, which divides into spiral arteries and percolates through the intervillous space, bathing the terminal villi.

PLACENTAL TRANSFER

The fetus depends almost exclusively on the placenta for nutritional, respiratory, and excretory functions. The placenta, growing steadily as gestation progresses, parallels fetal growth. Studies of placental growth and physiology in disease states suggest that placental growth and size are determined by the fetus and modulated by maternal factors. Normal placental-to-fetal weight ratios are approximately 1:6. As the placenta grows, villous processes increase in number as fetal vasculature expands, and by the third trimester, a large surface area is available to the maternal and fetal circulations.

Most placental transport is transcellular. Although the placenta often is thought of as a "separating membrane," it is actually a series of membranes. The most efficient areas for maternofetal exchange are the epithelial plates, which consist of thinly stretched, attenuated villous tissue separating maternal blood in the intervillous space from fetal

P.150

blood in the fetal sinusoids. To cross epithelial plates from the maternal to the fetal side, a substance must traverse:

- The brush border membrane of the syncytiotrophoblast
- The cellular plasma of this cell
- The basement membrane of the syncytiotrophoblast

The maternal side of the fetal capillary endothelial cell

- The fetal side of the same endothelial cell

Figure 11-1 Electron micrograph of the placental barrier of the human hemomonochorial full-term placenta. Notice the numerous endocytotic vesicles in various stages of formation located on the maternal-side brush border membrane of the syncytiotrophoblast. b, basement membrane; FC, fetal capillary; MBS, maternal blood space or intervillous space; Tr, syncytiotrophoblast with microvillous brush border membrane. Bar = 0.5 mm. (From Thornberg KL, Faber JJ. *Placental physiology*. New York: Raven Press, 1983:19, with permission.)

The microvillous brush border membrane of the syncytiotrophoblast appears to be the membrane most involved in regulation of transport, especially of active or carrier mediated transport. Certain diffusible substances traverse the trophoblast and endothelial cell intact for release on the fetal side, some substances may be partially or completely metabolized by the placenta, and others may be involved in intricate transport systems (Fig. 11-2).

Simple Diffusion

Many nutrients, metabolites, and excretory products cross the placenta by diffusion. Diffusion of substances in the placenta depends on multiple factors, as summarized in Table 11-1.

The amount of a nutrient delivered to the placenta is directly proportional to its concentration in the maternal bloodstream, which depends on nutritional intake and gastrointestinal absorption. Famine, maternal gastrointestinal diseases that interfere with absorption, or maternal pulmonary diseases that interfere with alveolar exchange may significantly affect blood concentrations and the transfer and accrual of fetal fuels. A lack of fetal fuels produces fetal and placental growth restriction. Abnormalities in maternal homeostatic mechanisms may produce either an insufficiency or an abundance of nutrients. For example, in poorly controlled diabetes, maternal hyperglycemia, hyperaminoacidemia, and hypertriglyceridemia allow un restrained nutrient delivery to the fetus with excessive growth of fetal organs, body fat, and the placenta (3).

Figure 11-2 Patterns of maternofetal transport. A: Minimal or no placental uptake and no fetal transfer (e.g., succinylcholine, highly charged quaternary ammonium compounds). B: Placental uptake, degradation, and no fetal transfer (e.g., insulin). C: Placental uptake and transfer predominantly unmodified to the fetus (e.g., β -hydroxybutyrate, bilirubin). D: Placental uptake, partial use, and transfer to the fetus (e.g., oxygen, glucose, amino acids, free fatty acids). E: Uptake, partial metabolism, and transfer to the fetus (e.g., cyclosporine). F: Uptake, modification, and transfer to the fetus (e.g., 25-hydroxyvitamin D₃, of which most undergoes 1 α -hydroxylation in the placenta to form 1,25-dihydroxyvitamin D₃). G: Carrier-coupled uptake with release of the ligand to the fetal side and regeneration of the carrier on the maternal side (e.g., transferrin-iron complex).

Delivery of a nutrient to the placenta is directly proportional to blood flow in the intervillous space. Maternal blood volume gradually increases to 30% to 40% higher than prepregnancy volume, with 40% directed to the uterus and placenta. Maternal cardiac disease with lower cardiac output may result in fetal and placental growth restriction. Even in healthy women, maternal position influences blood flow to the uterus. Normal pregnant women have an 18% lower cardiac output in the standing position compared with lying on their sides, perhaps explaining why women who stand at work throughout their pregnancy have newborns of lower birth-weight.

Fetal factors influencing diffusion are those that affect nutrient delivery to the fetal side of the placenta. The concentration of a substance in the umbilical artery depends on the amount of prior placental transfer, absorption from swallowed amniotic fluid, and fetal metabolism. Fetal blood flow to the uterus depends on fetal cardiac output

P.151

and placental vascular tone. Normally, fetal vessels on the chorionic plate are maximally dilated, providing the least resistance to flow.

TABLE 11-1 FACTORS AFFECTING THE PLACENTAL TRANSFER OF A DIFFUSIBLE SUBSTANCE

Maternal Factors	Placental Factors	Fetal Factor
Amount Delivered to the Intervillous Space	Transfer Physiology	Amount Delivered to the Fetal Capillaries
Blood concentration	Area of diffusing membrane(s)	Blood concentration
Exogenous and endogenous supplies	Diffusion resistance	Fetal metabolic production or gastrointestinal absorption
Homeostatic mechanisms	Characteristics of transferred material (size, charge, polarity, shape)	Prior placental transfer
Arteriovenous mixing in the intervillous space	Characteristics of membrane (physiochemical composition, fluidity)	Flow rate in the fetal capillaries
Flow rate in intervillous space	Diffusion pressure across each placental cell membrane	Hemodynamic factors in fetus
Hemodynamic factors in mother	Maternofetal concentration gradients	Local circulatory factors
Local circulatory factors	Placental cellular production or use	Shunting
Shunting	Maternofetal blood flow characteristics; intervillous flow	

Numerous placental factors influence diffusion. Overall, transfer is governed by the quantity of epithelial plates, which are specialized regions of enhanced diffusion where the interhemal barrier is less than a few micrometers. The human placenta has an intervillous pool flow system in which fetal capillaries in terminal villi are bathed in a maternal blood reservoir continuously filled by arteries and drained by veins (Fig. 11-3). Concurrent and countercurrent flows exist in areas of uneven distribution of flow (i.e., shunting), where a portion of the villus is well supplied by maternal blood but poorly supplied by fetal blood; in other areas, the opposite occurs.

Figure 11-3 Areas of concurrent and countercurrent flow exist in the intervillous pool flow system of the human placenta.

Stereochemical characteristics of a substance are major factors in transferability. Small, compact, nonpolar, lipophilic substances are transferred most efficiently. The placenta is relatively impermeable to large, polar molecules that do not have specific transport systems or carrier proteins or are unable to take advantage of an analogous transport system to aid in their transfer. For example, α -fetoprotein (AFP), a 70-kd fetal protein, does not transfer to the maternal side in appreciable amounts despite large quantities in fetal blood. Maternal AFP is derived from transplacental transfer from fetal blood and transmembrane (i.e., chorioamnion) transfer from amniotic fluid. The fetal blood AFP level at 17 weeks of gestation is approximately 3 mg/mL when the maternal blood level is approximately 0.1 mg/mL, resulting in a fetomaternal gradient of approximately 30,000:1. The low level of fetomaternal transplacental transfer allows detection of elevated maternal serum levels from

transmembrane (i.e., amniochorion) transfer of abnormally high amniotic fluid AFP, which provides the basis of maternal serum AFP screening for neural tube defects. False-positive elevations of maternal serum AFP (i.e., high maternal serum value with a structurally normal fetus) suggest placental microabruptions, or loss of integrity of the maternofetal barrier, and forecast a higher rate of fetal morbidity.

Membrane characteristics regulate transport. The fluidity of the membrane, determined by the degree and character of membrane-incorporated phospholipids, influences transfer of certain substances. Diseases, such as diabetes, may influence membrane fluidity (4).

The major driving force in favor of transfer by diffusion is the concentration gradient across the placenta; the resistance to diffusion is dictated by the nature of the molecule. The principles of diffusion of molecules that are generally applicable to biological membranes hold true in the placenta, although specifics remain to be defined. Availability of a substance for diffusional transfer across the placenta is not always related to blood levels of that substance,

P.152

because many metabolites, nutrients, and drugs that are poorly water-soluble are protein bound.

Although proteins aid in delivery of these substances to the placenta, they may actually hinder transfer of the substances. It is the free, unbound—or soluble—fraction of a substance that is available for transfer. Conversely, high-affinity carrier proteins on the receiving side of the placenta drive diffusional transfer to their side by decreasing a ligand's free fraction and increasing its maternofetal gradient. Oxygen, for example, is 98% bound to hemoglobin. It is the transplacental difference in the partial pressure of dissolved oxygen (PO_2) that determines the diffusion pressure. The more oxygen-avid fetal hemoglobin counterbalances the resistance to transfer from the maternal circulation. The O_2 content (i.e., dissolved and hemoglobin-bound O_2) of the blood on each side of the placental membrane is determined principally by different affinities of maternal and fetal hemoglobin for oxygen. In humans, the fetal oxyhemoglobin dissociation curve is displaced leftward of the maternal curve, facilitating a much greater uptake of oxygen by fetal blood at the placental capillary level than would be possible otherwise (see Appendix B). At any given PO_2 , a much higher O_2 content is achieved in fetal blood than in maternal blood. The O_2 content in the umbilical vein (14.5 mL/dL) is as high as that of the uterine artery (15.8 mL/dL), despite an umbilical venous PO_2 of only 27 mm Hg (Table 11-2). Relatively high fetal blood O_2 content confers on the fetus the ability to deliver sufficient oxygen to peripheral tissue despite low PO_2 . Low PO_2 may be essential to fetal physiologic adaptation to maintain high pulmonary vascular resistance and to keep the ductus arteriosus open.

The excretion of bilirubin provides an example of fetomaternal interaction using specific permeability properties of the placenta to accomplish a given objective (5). Before birth, elimination of bilirubin from the fetus is by diffusional transfer through the placenta to the mother. The placenta is extremely permeable to unconjugated bilirubin but relatively impermeable to bilirubin glucuronide (i.e., conjugated bilirubin). In the fetus, because of minimal bilirubin glucuronyltransferase, hepatic conjugation of bilirubin is suppressed. Because fetal bilirubin is predominantly unconjugated and highly lipid soluble, it diffuses freely from the fetal to the maternal side. After transfer to the mother, it is efficiently conjugated and excreted (Fig. 11-4).

TABLE 11-2 NORMAL OXYGEN VALUES IN MATERNAL AND FETAL BLOOD

Oxygen Measurements	Uterine Artery	Uterine Vein	Umbilical Vein	Umbilical Artery
PO_2 (torr)	95	40	27	15
Hemoglobin O_2 saturation (%)	98	76	68	30
O_2 content (mL/dL)	15.8	12.2	14.5	6.4
Hemoglobin (g/dL)	12.0	12.0	16.0	16.0

From Longo L. Disorders of placental transfer. In: Assali NS, ed. *Pathophysiology of gestation*. New York: Academic Press, 1972;2:11, with permission.

Facilitated Diffusion

Most substances cross the placenta by simple diffusion. Maternal glucose, the principal substrate for oxidative metabolism in the fetus, is a water-soluble, polar molecule that crosses the placenta by facilitated diffusion, which is a gradient-dependent, receptor-mediated, saturable process. In the human placenta, preferential transfer of D-glucose (over L-glucose) exists. Transfer stereospecificity implies a carrier-mediated process that provides the fetus with the appropriate isomer for metabolism. The presence of glucose transporter genes in the placenta, which code for glucose transporter proteins, confirms indirect experimental evidence for the existence of a membrane-bound D-glucose carrier protein (6,7). Under physiologic and pathologic human conditions, the carrier protein for glucose is not saturated, and the amount transferred to the fetus is directly related to the amount supplied to the placenta (8).

Active Transport

To provide appropriate fuels for fetal growth, specific energy-requiring transport mechanisms in the microvillous surface aid in transfer of substances that are not readily lipid soluble and are required in large amounts by the fetus.

Most amino acids cross the placenta by an active transport mechanism (9,10,11). Active amino acid uptake has two major purposes: transfer to the fetus and placental production of peptide hormones.

Transfer from maternal to fetal circulation is especially important for the essential amino acids required for fetal growth, including the essential adult amino acids histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine; and the proposed fetal essential amino acids cysteine, tyrosine, histidine, and taurine. Early in development, before maturation of fetal metabolic systems, all amino acids are essential to the fetus. Fetal amino acid levels are 1.5- to 5-fold higher than maternal levels, confirming a transport process against a concentration gradient.

Placental transfer of amino acids is stereospecific, with the natural L-form preferred. Transport of amino acids by animal cells is mediated by specific carrier systems that have overlapping substrate reactivities. In human villous

P.153

tissue fragments, three carrier systems exist for neutral amino acids (12). System A is sodium dependent, reversible at low pH, and most reactive with amino acids that have short, polar, or linear side chains (e.g., alanine, glycine). System L is sodium independent and most reactive with large, apolar, branched-chain, and aromatic amino acids (e.g., leucine, isoleucine, tyrosine, tryptophan, valine, phenylalanine, methionine, glutamine). The ASC system is sodium dependent and is involved in transport of alanine, serine, and cysteine (ASC). Evidence suggests that a B system exists in placenta for taurine transport (13). Taurine, although produced by the maternal liver from cysteine and methionine, is essential for fetal neurologic development but is not produced by the fetus.

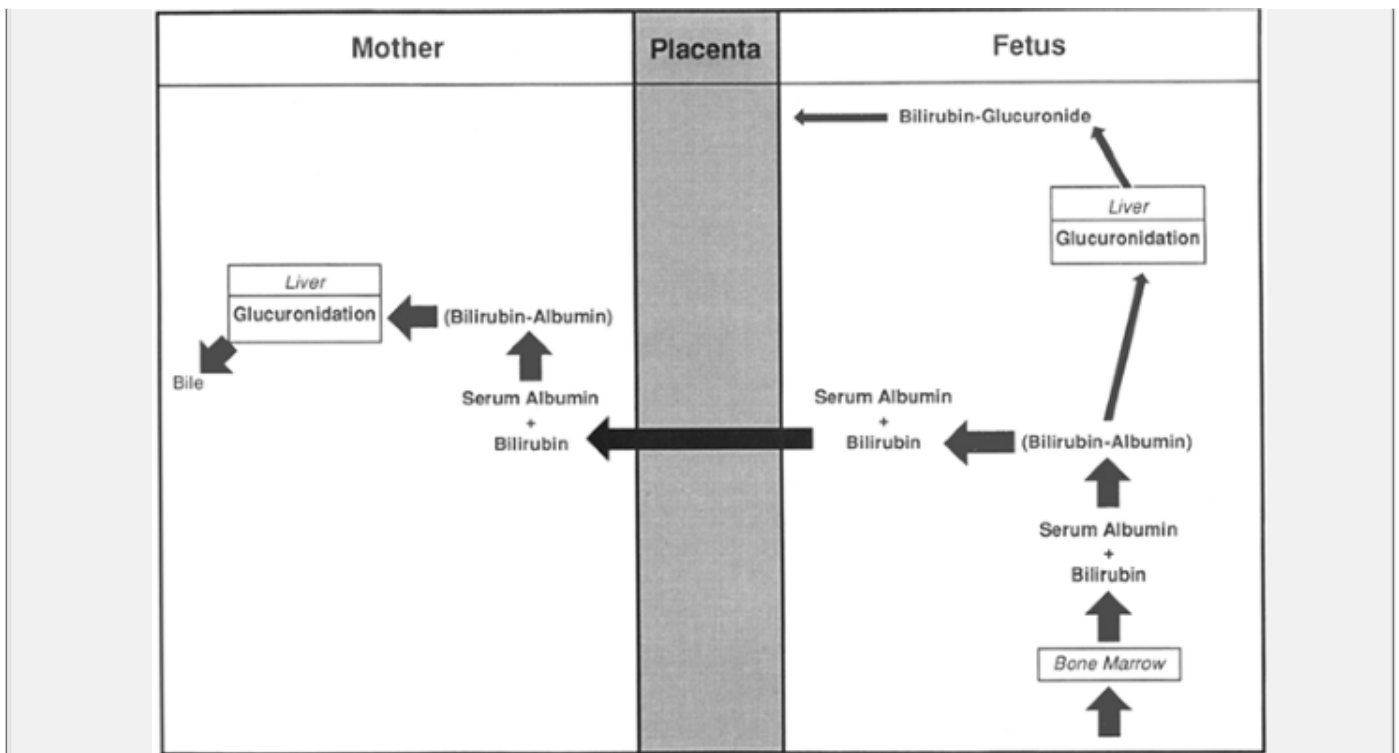

Figure 11-4 Antepartum excretion of bilirubin. Fetal bilirubin is transferred from fetal serum albumin through the placenta to maternal serum. It then is conjugated with glucuronic acid by the maternal liver and excreted into the bile. Fetal glucuronidation is suppressed. The placenta is relatively impermeable to the glucuronide.

Certain drugs cross the placenta by active transport. Zidovudine, used for treating HIV, has been found in the perfused human placental model to cross from the maternal to the fetal side by energy-dependent transport (14). Because zidovudine is a thymidine analog, it may take advantage of placental thymidine transport systems. Zidovudine levels are higher in cord blood than in maternal blood, suggesting transport against a concentration gradient and an active transport mechanism. Maternal administration of zidovudine and other antiretroviral agents has become accepted therapy in HIV-positive mothers for prevention of vertical transmission to the fetus. In a collaborative, prospective study of pregnant, HIV-seropositive women, zidovudine administered orally in the prenatal period and intravenously during labor was shown to decrease the vertical transmission to the fetus from 25.5% to 8.3% (15).

Receptor-Mediated Endocytosis

Although many large protein molecules cross the placenta by pinocytosis in extremely small quantities, specific receptor-mediated processes expedite transfer of certain larger substances that are required by the fetus. The receptor-rich microvillous brush border of the syncytiotrophoblast and the numerous coated micropinocytotic vesicles found just beneath it provide anatomic evidence for receptor-mediated endocytosis (16). The receptors involved in this process, found on the surface of the syncytiotrophoblast, are thought to extend through the glycocalyx layer of the cell membrane and bind to the protein clathrin to form a membrane complex. After the ligands are bound to their receptors, aggregation and internalization occur to form a cytoplasmic-coated vesicle (Fig. 11-5). Destiny of the contents of the vesicles depends on the ligand.

Maternal immunoglobulin (Ig) molecules are transferred to the fetus by receptor-mediated endocytosis. IgG subclasses 1 and 3 and IgA are known to cross the placenta. Once internalized, the intact Ig molecules within the vesicles are delivered from the cytoplasm of syncytiotrophoblast through the capillary endothelial cell and into the fetal circulation (17,18). Antenatal fetal transfer of maternal IgG antibodies may interfere with antibody-based

diagnostic testing in the fetus, necessitating analysis of the fetal-specific IgM antibody. Developmentally, the transfer of maternal IgG to the fetus is probably protective and beneficial, but this transfer backfires in some situations, such as immune fetal hydrops (i.e., erythroblastosis fetalis) and alloimmune fetal thrombocytopenia. By receptor-mediated endocytosis, anti-D or another blood group antibody crosses the placenta to cause fetal hemolytic anemia, and anti-PIA1 crosses the placenta to cause fetal thrombocytopenia (19).

Figure 11-5 Receptor-mediated endocytosis. The placental syncytiotrophoblast with the microvillous maternal border (Fig. 11-1) has (A) specific receptors, located in the microvillous projections (B) clustering in intervening pits on exposure to specific ligand in the maternal blood stream. Endocytosis occurs. C: The receptor-ligand complexes and associated cell wall invert to form (D) an endocytic vesicle that is internalized. The destiny of the vesicle depends on the ligand.

Transfer of transferrin-iron complex into the placental syncytiotrophoblast occurs through receptor-mediated endocytosis. Brush border membrane transferrin-specific receptors on the maternal side of the syncytiotrophoblast bind transferrin-iron complex, and aggregate and internalize it to form vesicles of transferrin-iron complexes. In the cytoplasm, the complexes dissociate to form apotransferrin and ferrous iron. Apotransferrin is recycled to the maternal circulation, and ferrous iron is stored transiently as ferritin and released to the fetal circulation to be made into a complex with fetal transferrin. No maternal transferrin or placental ferritin is transferred to the fetus (20). Maternofetal iron transport is independent of maternal levels.

Uptake of low-density lipoprotein (LDL) cholesterol from maternal blood for progesterone synthesis by the placental trophoblast is accomplished through receptor-mediated endocytosis. Specific receptors that have a high affinity for LDL but not for high-density lipoprotein (HDL) are located on the microvillous brush border of the syncytiotrophoblast. LDL binds to its receptor and is actively internalized. Within the cytoplasm, LDL vesicles fuse with lysosomes, where enzyme hydrolysis of cholesterol esters releases cholesterol for mitochondrial synthesis of progesterone.

Other Mechanisms of Transfer

A variety of other mechanisms of transfer probably are functional in the human placenta. Large protein molecules may cross the placental membranes by a slow, non-receptor-mediated process of pinocytosis. Ions may cross placental membranes with the aid of ion pumps. Evidence suggests that small molecules and ions may cross through intercellular channels.

PLACENTAL METABOLISM

The placenta is a highly metabolic organ. Oxygen is consumed at a rate of 10 mL/min per kg, representing the amount of maternal oxygen needed to supply the placenta and fetus for metabolic functions. Approximately 20% of placental oxygen uptake is used by the placenta; the remainder diffuses to the fetus. Glucose, the principle metabolic carbon source of the placenta, is converted to lactate or is oxidized to CO₂. Placental tissue requires energy for maintenance of active transfer systems, hormone production, and substrate metabolism.

PLACENTA AS AN ENDOCRINE ORGAN

It is the placenta that maintains the maternal milieu most favorable for pregnancy by elaboration of large amounts of steroid and peptide hormones, which are required to maintain the fetoplacental unit. Generally, placentally produced steroid hormones, but not peptide hormones, cross to the fetal side.

Human Chorionic Gonadotropin

Sensitive techniques demonstrate that the secretion of human chorionic gonadotropin (hCG) begins during implantation, when the cytotrophoblast differentiates into the syncytiotrophoblast. Although the messenger RNA for hCG can be found in the cytotrophoblast, this cell is thought not to be the origin of this peptide hormone, but only gains the ability to secrete hCG after it differentiates into a syncytiotrophoblast. The maternal plasma hCG level rises after implantation, peaks by 10 menstrual weeks of pregnancy, and declines to a nadir in the second trimester, after which levels remain low (Fig. 11-6).

The only well-established role of hCG is continued stimulation of the ovarian corpus luteum to produce 17-hydroxyprogesterone for maintenance of pregnancy. Although placental production of progesterone occurs early in gestation, the transition to placental autonomy from the ovary occurs

P.155

between 10 and 12 menstrual weeks. Before this transition, loss of the corpus luteum results in loss of the pregnancy, unless exogenous progesterone is administered. Primary control of trophoblastic hCG production has not been determined, but hormonal modulation is apparent (21). Proposed roles for hCG include the immunologic protection of the trophoblast and regulation of placental progesterone production. Falling levels of hCG before 10 menstrual weeks heralds pregnancy loss and is associated with miscarriage or ectopic gestation. Higher-than-normal hCG levels are seen with multiple gestations, hydatidiform mole, choriocarcinoma, fetal triploidy when associated with molar changes of the placenta, and Down syndrome (22).

Figure 11-6 Maternal blood levels of the major hormones produced by the placenta throughout pregnancy. (From Ashitaka Y, Nishimura R, Takemori M, et al. Production and secretion of hCG and hCG subunits by trophoblastic tissue. In: Segal S, ed. Chorionic gonadotropins. New York: Plenum Press, 1980:151; Selenkow HA, Varma K, Younger D, et al. Patterns of serum immunoreactive human placental lactogen and chorionic gonadotropin in diabetic pregnancy. *Diabetes* 1971;20:696; and Speroff L, Glass RH, Kase NG. *Clinical gynecologic endocrinology and infertility*, 4th ed. Baltimore: Williams & Wilkins, 1989, with permission.)

Human Placental Lactogen

Human placental lactogen (hPL) is a single-chain polypeptide that has approximately 85% similarity to human growth hormone. The quantity of hPL synthesized by the placental syncytiotrophoblast parallels placental mass, reaching its peak at term and falling dramatically after delivery of the placenta.

Functionally, hPL can be considered a fetal growth hormone, because it maintains the maternal metabolic milieu optimal for delivery of nutrients to the fetus. Despite its name, hPL has not been demonstrated conclusively to exert a lactogenic effect in humans. The physiologic role of hPL appears to be in shifting the pattern of maternal energy metabolism during pregnancy from carbohydrate to one that depends on fat. The hormone promotes

adipolysis and increases free fatty acid availability for maternal metabolism, saving glucose and amino acids for transfer to the fetus. Free fatty acids do not cross the placenta as readily as amino acids and glucose.

Human placental lactogen has antiinsulin effects thought to be mediated by the elevated free fatty acids, which promote peripheral tissue resistance to insulin. The subsequent increased pancreatic production of insulin leads to down regulation of peripheral insulin receptors.

Maternal blood levels of hPL correlate with placental function. It was once thought that low hPL levels could predict pregnancies with deteriorating placental function and those with fetal compromise (23). Unfortunately, hPL levels are not as clinically useful as other methods. Similarly, elevated maternal hPL levels were thought to be predictive of gestational diabetes or outcome in preexisting diabetes, but large biological variations in maternal levels preclude its use in prediction or diagnosis. There are no clinical applications for hPL levels at this time.

Estrogen

Estrogen production by the syncytiotrophoblast requires an elaborate concerted effort by the mother, fetus, and placenta (Fig. 11-7). Because there is no activity of 17-hydroxylase and 17,20-desmolase in the human placenta, estrogen precursors must be obtained from the fetal adrenal gland. The placenta produces three major estrogens—estradiol (E2), estriol (E3), and estrone (E1)—which are secreted predominantly into the maternal circulation. Maternal estrogen levels increase with gestational age.

Little is known about the specific functions of estrogen during pregnancy. Estrogens effect many general changes in the mother to prepare for and maintain pregnancy. The uterine myometrium responds exquisitely with increased protein synthesis and cellular hypertrophy. Estrogens cause vascular relaxation and increased blood flow to the uterus. Uterine contractility is increased by estrogens, supporting a role in the onset of parturition. Placental sulfatase deficiency, an X-linked fetal disorder, is associated with low estrogen levels. Except for dysfunctional labor, women with these fetuses have normal pregnancies.

A specific role for estrogens in the fetus has not been determined. The fetal liver can metabolize E3 to estetrol (E4), which binds to fetal estrogen receptors but has no estrogenic activity, protecting fetal tissue from massive amounts of free estrogen.

Progesterone

The placental syncytiotrophoblast produces progesterone from maternally derived LDL cholesterol (Fig. 11-8).
Fetal

P.156

contribution to progesterone synthesis is minimal. Maternal progesterone levels increase with gestational age. The major role of progesterone is to maintain the pregnancy. Early production of progesterone is by the ovarian corpus luteum. After a transition period of shared function between 6 and 12 weeks of gestation, the placenta becomes the dominant producer of progesterone, and the pregnancy continues even if the corpus luteum is removed. Low levels of progesterone may be associated with first-trimester pregnancy loss.

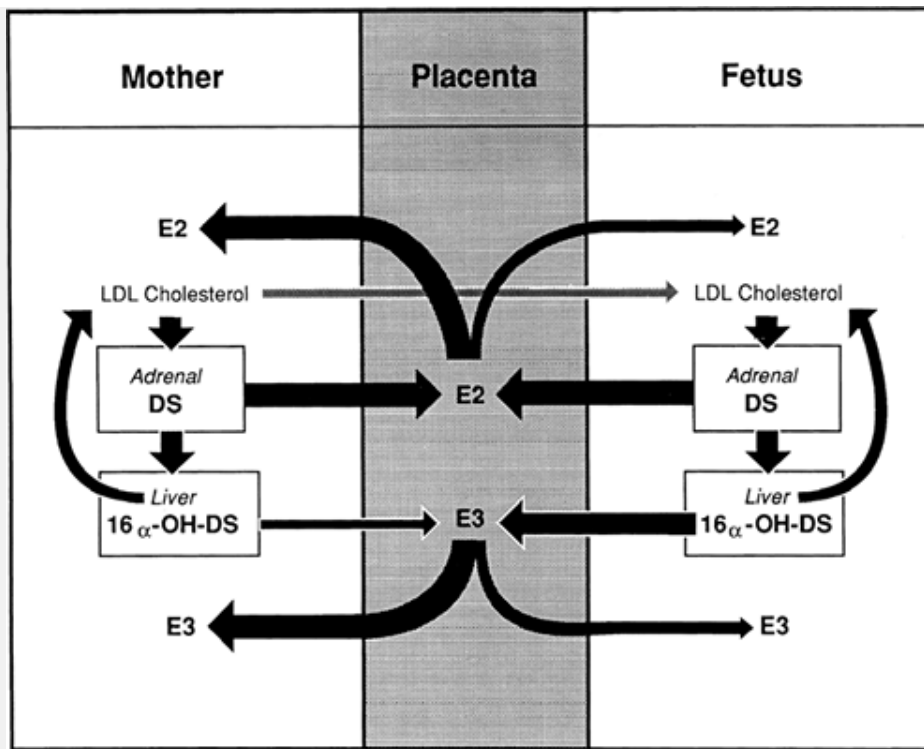

Figure 11-7 Placental estrogen synthesis from fetal and maternal precursors. After 20 weeks of gestation, the fetal compartment supplies most steroid precursors for placental estrogen production. The fetal adrenal uses low-density lipoprotein cholesterol, produced by the fetal liver or transferred from the maternal compartment, to synthesize dehydroepiandrosterone sulfate (DS). DS is converted to 16 α -OH-DS in the fetal liver. DS and 16 α -OH-DS undergo placental metabolism to estradiol (E2) and estriol (E3), respectively, which are released predominantly on the maternal side.

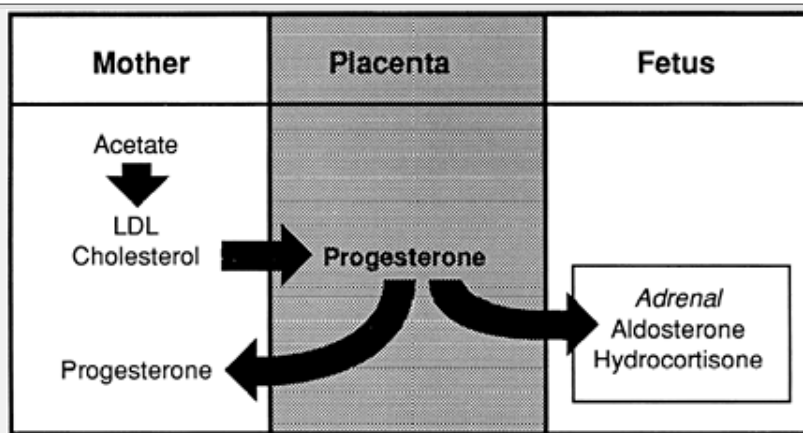

Figure 11-8 Placental progesterone synthesis depends only on maternal precursors.

The most important role of progesterone may be that of principal substrate for fetal adrenal gland production of glucocorticoids and mineralocorticoids. Progesterone may have a role in parturition and in suppressing the maternal immunologic response to fetal antigens.

AMNIOTIC FLUID

Formation and circulation of the amniotic fluid reflect intimate and dynamic maternal and fetal interactions. Amniotic fluid is ultimately derived from maternal water. Very early in pregnancy, amniotic fluid is cellular transudate with the same tonicity, but lower protein content, as maternal plasma. By at least 8 gestational weeks, when the maternal and fetal blood circulations are well established, most amniotic fluid water is thought to be derived from maternal plasma water by direct transfer from the maternal circulation to fetal capillaries in response to osmotic and hydrostatic forces. Once circulating in the fetus, water is filtered and excreted by the urinary system into the amniotic cavity. By 8 gestational weeks, the urethra is patent, and the fetal kidneys begin to form urine; by 10 to 11 weeks, a fetal bladder can be seen ultrasonographically. Concurrently, the fetus

reabsorbed into the fetal circulation to be reexcreted by the kidneys or transferred across the placenta to the mother. By the end of the first trimester, the amniotic fluid circulation has been established. Before fetal skin keratinization at 22 weeks, additional water transfer can occur directly through the highly permeable fetal skin.

The content of amniotic fluid changes over gestation. The early electrolyte content is similar to that of extracellular fluid. As the kidneys become functional, fetal urine electrolytes and excretory products become major components. As gestation progresses, the fetal kidneys mature and are better able to retain electrolytes and produce more dilute urine. At 20 weeks, the sodium content of amniotic fluid is 136 mEq/L and the osmolality is 276 mOsm/L; at 40 weeks, the sodium content is 124 mEq/L and the osmolality is 258 mOsm/L.

Amniotic fluid contains excretory products of the fetus and maternal products that can diffuse directly across the fetal membranes from the maternal compartment. In addition to electrolytes and proteins, amniotic fluid contains carbohydrates, amino acids, urea, creatinine, lactate, pyruvate, lipids, enzymes, hormones, and various other metabolites reflective of the fetal milieu. Their presence and the presence of desquamated fetal cells allow diagnosis of many fetal abnormalities by biochemical and genetic analysis of amniotic fluid. Amniotic fluid also contains fetal pulmonary fluid. The usefulness of the lecithin to sphingomyelin ratio in predicting maturity of the fetal lungs has its basis in contributions from this fluid. In fetal sheep, there is constant outpouring of pulmonary fluid into the trachea (24).

Although the range of normal amounts of amniotic fluid varies and depends on gestational age, abnormal volumes often herald fetal structural or growth abnormality. Maternal factors can affect amniotic fluid volume. Maternal plasma volume correlates with amniotic fluid volume. In hypovolemic mothers, expansion of plasma volume with albumin increases amniotic fluid volume (25). Maternal use of diuretics may influence amniotic fluid volume indirectly by decreasing maternal intravascular volume and directly by increasing fetal micturition after transplacental passage.

FETAL MEMBRANES

The fetal amnion and chorion, although simple in anatomic design, are intricately involved in fetomaternal interactions. The thin, avascular layer of epithelial cells that makes up the amnion arises from fetal ectodermal cells, and the chorion, several layers thick, arises from extraembryonic somatic mesoderm and a trophoblast layer. The trophoblast layer in the area of the chorion, which is destined to be the fetal surface of the term placenta, undergoes rapid proliferation and branching into villi. By 8 menstrual weeks, the trophoblast layer of the remaining chorion becomes compressed, attenuated, and microscopic. These microscopic cells are intimately intermingled with the outermost maternal layer, the decidua or gestational endometrium, to allow paracrine interaction of these cells.

Paracrine interactions of the fetal chorionic cells with maternal decidual cells may be involved in the control of maternal production of prolactin and amniotic fluid volume regulation. Transport studies with tritiated water suggest that the net transport of water by the chorioamnion with adherent decidua is greatest in the fetomaternal direction, suggesting a net outflow of water from the amniotic fluid compartment to maternal circulation (26). Lower osmolality in the amniotic fluid compartment favors movement of water from the amniotic cavity to the maternal compartment.

The cells of the amnion, rich in esterified arachidonic acid, are active in prostaglandin metabolism and are at least indirectly involved in cervical ripening and the onset or maintenance of labor. Initiation of human labor may involve autocrine and paracrine mechanisms within the fetal membranes and possibly maternal decidua, resulting in amnion cell production of prostaglandin E₂ (PGE₂), a potent cervical-ripening and uterotonic agent (27). Although amnion cell production of PGE₂ has been associated with initiation and maintenance of labor, control of its production is less well understood. Various inflammatory cytokines, in particular, tumor necrosis factor α , interleukin-1 α , interleukin-1 β , interleukin-6, and interleukin-8, play a role affecting the common pathway of amnion cell production of PGE₂ and subsequent labor (28,29,30,31).

UMBILICAL CORD

The umbilical cord contains one fetal vein and two fetal arteries, which are supported and protected by Wharton jelly, a gel-like connective tissue composed of a ground substance of open-chain polysaccharides in a network of collagen and microfibrils (32). Externally, the cord is covered by amniotic epithelium, but there is no chorionic

epithelium. The length of the umbilical cord ranges from 30 to 100 cm (mean 55 cm) with reported extremes from 0 to 155 cm. Fetuses with no umbilical cords have a severe, fatal abdominal wall defect because of failure of formation of the body stalk. The association of a short cord with a low IQ raises the question of whether the length of the cord is determined by fetal movement mediated by antenatal neurologic function. Fetuses with long cords are more likely to have cord entanglement. Short cords are more likely to stretch and avulse during descent of the fetus, resulting in signs of fetal distress during expulsion or hemorrhage at birth.

The normal umbilical cord increases in circumference with gestation until term, when the average circumference is 3.8 cm (33). Although excessive Wharton jelly (i.e., thick cords) has not been associated with fetal abnormalities, lack of this connective tissue has. Thin cords frequently are seen with growth-retarded fetuses and may be associated with cord strictures, umbilical vessel rupture, or thrombi (34). Thin cords are more likely to allow symptomatic

P.158

external compression, stretch, or occlusion of umbilical vessels. Resolution of umbilical venous bleeding after percutaneous umbilical blood sampling is facilitated by Wharton jelly surrounding the vessel.

PLACENTAL PHYSIOLOGY IN DISEASE STATES

Preeclampsia and Hypertensive Disorders of Pregnancy

Preeclampsia, a hypertensive disease unique to pregnancy, has its genesis in the placenta. It is more common in women with multiple gestations (i.e., multiple placentas) and molar pregnancies (i.e., excessive trophoblastic tissue), and it abates after delivery of the placenta (35). Altered placentation may be responsible for maternal vasospasm, the basic physiologic abnormality in preeclampsia (36). Vascular constriction in most maternal organs results in hypoperfusion of the uterus and placenta, making the fetus at risk for intrauterine growth restriction, placental abruption, and fetal death.

Placentas of preeclamptic women have a significantly lower total volume and volume of parenchymal and villous surface area than placentas of normal controls (37). There is a greater proportion of centrally located, infarcted areas because of poor intervillous maternal circulation. Histologically, cellular degenerative changes are found (38). An abundance of syncytial budding is common in histologic sections and teased preparations of villi. Budding, or knotting of the placental syncytiotrophoblast, consists of bunching of the cytoplasm of these cells with aggregation of nuclei, a histologic finding suggestive of perfusional compromise.

The maternal vascular response to placentation is inadequate in women who develop preeclampsia (39). Normally during implantation, cytotrophoblasts, or early placental cells, invade the lumen of the uterine spiral arterioles, anchor to the vessel wall, and cause dilatation of the arterioles to allow adequate perfusion of the placenta and, ultimately, the fetus. There is evidence of a "vascular transformation" of the cytotrophoblasts that invade the spiral arterioles manifested by at least modulation of adhesion molecules (40). In preeclampsia there is a loss of the normal modulation of adhesion molecules and an incomplete vascular invasion by the cytotrophoblasts (41). Some spiral arteries show absence of physiologic changes throughout the entire length, suggesting a complete lack of invasion by trophoblasts (Fig. 11-9).

Figure 11-9 Maternal blood supply to the placenta in normal pregnancy (left) and preeclampsia (right). Notice the lack of normal physiologic dilation of radial arteries and of some decidual segments of spiral arteries in preeclampsia. (From Khong TY, De Wolf F, Robertson, WB, et al. Inadequate maternal vascular response to placentation in pregnancies complicated by preeclampsia and by small for gestational age infants. *Br J Obstet Gynaecol* 1986;93:1049, with permission.)

Certain spiral arterioles at the implantation site undergo acute atherosclerosis. Initially, fibrinoid degeneration and mural thrombosis of decidual vessels occurs. The vessel wall then becomes replaced by fibrin, and the intima is replaced by cholesterol-laden macrophages. Eventually, fibrinoid necrosis and total obstruction of the lumen lead to loss of maternal blood flow, which is likely responsible for placental infarcts (42).

There are no microscopic or macroscopic placental changes that are pathognomonic for preeclampsia. The pathologic changes in placentas of preeclamptic women suggest the disease is indistinguishable from that of women with lupus anticoagulant syndrome, signifying a shared physiology. In the lupus anticoagulant syndrome, autoimmune antiphospholipid antibodies, detectable in the maternal bloodstream, are associated with maternal arterial and venous thrombosis, recurrent miscarriage, early onset preeclampsia, placental and fetal growth restriction, and fetal death. Placentas from these women, whether or not they show signs of overt preeclampsia, have infarctions, fibrosis, a decrease in vasculosyncytial membranes, and an increase in syncytial knots (43).

Preeclampsia is a disease resulting from abnormal maternoplacental interaction, and its cause is unknown. More recently, preeclampsia has been considered a syndrome with various etiologies leading to a final common

P.159

constellation of signs and symptoms, hypertension, proteinuria, and edema. One of the more attractive pathogenetic mechanisms of preeclampsia is that of an immune-mediated disease, supported by similarities with the lupus anticoagulant syndrome. However, in preeclampsia, neither the exact antigenic stimulus nor the antibody response has been defined, although the former probably is derived from trophoblasts.

Preeclampsia may be caused by placental production of a circulating humoral factor, perhaps immunologic, which affects prostaglandin homeostasis. Prostaglandins are involved in normal vasodilation of pregnancy. Prostacyclin (PGI_2), because of its potent effect in relaxing vascular smooth muscle and lowering systemic arterial pressure, is thought to be most involved. Prostacyclin is produced in vascular endothelial cells and is thought to exert its effect on vascular smooth muscle in a paracrine fashion. It is an inhibitor of platelet aggregation and of uterine contractility. The combined effects of this prostaglandin prevent maternal hypertension, prevent platelet aggregation, and promote uteroplacental blood flow. Thromboxane, produced predominantly by platelets, is a powerful vasoconstrictor, stimulator of platelet aggregation, and stimulator of uterine contractility, favoring maternal hypertension, decreased utero-placental blood flow, and intrauterine growth restriction.

Abnormal prostaglandin homeostasis has been found in preeclampsia (44). Excessive placental production of thromboxane and insufficient production of PGI_2 result in an abnormally high ratio of thromboxane to PGI_2 .

Prosta-cyclin production is decreased in umbilical arteries, placental veins, and uterine vessels. Thromboxane production is increased in placental tissue and in circulating platelets from preeclamptic women with infants who are small for gestational age (45).

Compared with normal placentas, placental findings in women with chronic or essential hypertension vary from lower total volume, lower parenchymal tissue, and infarcts to normal volumes and large, villous surface areas. Findings differ with various degrees of severity of disease and lack of differentiation between chronic hypertension and chronic hypertension with superimposed preeclampsia.

Diabetes

Just as the infant of a diabetic mother can be macrosomic, growth restricted, or normally grown, the diabetic placenta can have various findings. Some investigators associate these findings with severity of maternal diabetes, especially the duration and complications of the disease, and others associate them with the degree of glycemic control.

Placentas of diabetic mothers without significant vascular disease (i.e., White's classes A-D) differ from normal by having more parenchymal and villous tissue, a higher cellular content, and a larger surface area of exchange between mother and fetus in terms of peripheral villous and capillary surface areas and intervillous space

volume (46,47,48). These larger placentas are able to adequately support growth of large fetuses. Placentas of diabetic mothers with appropriate-for-gestational-age newborns are morphologically closer to control, nondiabetic placentas. It is the placentas of macrosomic infants that are heavier, predominantly because of a significant accumulation of nonparenchymal and parenchymal tissue. These placentas have retarded maturation of surface areas of terminal villi. Grossly, they appear large, thick, and plethoric. Microscopically, focal immaturity (i.e., dysmaturity) and villous edema are found.

The excessive growth and dysmaturity of these placentas suggest an accelerated growth process or a loss of the normal growth process that occurs in placentas of healthy women. Because the placenta is essentially a fetal organ, which is different from other fetal organs only in that it is subject to more direct maternal modulation, it is not surprising that macrosomic fetuses have large placentas. The major mechanism for organ enlargement, or macrosomia, in the fetus of a diabetic mother involves anabolic metabolism of excess glucose and its deposition as glycogen and fat. The placenta of a macrosomic infant of a diabetic mother has neither excessive fat nor glycogen, suggesting a different mechanism by which the fetus (or mother) increases placental size and surface areas of terminal villi to maintain fetal nutrition (the size of the placenta and quality and topography of the transfer surface regulate nutrient availability to the fetus).

Placental cells respond to maternally or fetally produced hormones directly by alterations in growth and indirectly by elaboration of certain substances that control their own growth. Insulin and its associated family of growth-promoting peptide hormones, such as insulin-like growth factor I (IGF-I) and insulin-like growth factor II (IGF-II), have been implicated in excessive placental growth of the diabetic placenta.

Insulin receptors have been localized to the apical brush border of the syncytiotrophoblast (bathed in maternal blood) (49). Maternal insulin binds to these receptors, is internalized, and eventually degraded by this cell. Investigators using the *in vitro* perfused human placental cotyledon model have shown that placental-facilitated uptake and metabolism of glucose do not appear to be regulated by insulin (50). The lack of insulin regulation of glucose transport in the intact placenta correlates with glucose transporter genes in placenta, *GLUT1* and *GLUT3*, both thought to code for insulin-unresponsive glucose transporter proteins. Why then is there active insulin uptake by the placental syncytiotrophoblast? Insulin, more likely fetal but possibly maternal, may have growth-promoting activity in the placenta and thereby affect placental size.

The placental trophoblast microvillous brush border membrane contains specific heterotetrameric IGF-I receptors that have been found in trophoblasts as early as 6 weeks of gestation (51). This somatomedin has been measured in placental explant cultures and placental fibroblast culture fluid and is thought to be involved in control of placental growth (52). Maternal serum IGF-I levels and the ratio of cord serum IGF-I to its binding protein correlate with birth-weight (53). Cord serum IGF-II levels are 50%

P.160

higher in infants of diabetic mothers than in those of nondiabetic mothers. Because fetal macrosomia in diabetic pregnancies cannot always be prevented, despite excellent maternal blood glucose control, attention has been turned to excessive placental transfer of fetal fuels other than glucose. Some investigators suggest a greater diffusional transfer of free fatty acids in diabetic pregnancies, probably related to greater maternal availability (e.g., maternal hyperlipidemia in diabetic pregnancies) and greater placental transfer surface (54). Excessive placental transfer of insulin-secretagogue amino acids (e.g., arginine) also may be responsible for fetal hyperinsulinemia and macrosomia.

Placentas of diabetic women with vascular complications (e.g., nephropathy, retinopathy, heart disease, White's class F, R, or H) frequently have infarcts and are associated with growth-retarded fetuses. The weights of the placentas of these diabetic women are lower than normal gestational age-matched placentas. There have been no specific placental findings to explain the higher stillborn rate in macrosomic fetuses of diabetic mothers.

Erythroblastosis

Erythroblastosis fetalis, or hemolytic disease of the newborn, is a condition in which specific IgG antibodies formed by the mother against erythrocyte antigens of the fetus cross the placenta by receptor-mediated endocytosis and coat fetal erythrocytes, causing splenic sequestration, intravascular hemolysis, anemia, and unconjugated hyperbilirubinemia. Unconjugated bilirubin is transported easily to the maternal side, conjugated, and excreted by the mother. Anemia stimulates fetal hematopoiesis, especially in the liver and spleen, resulting in release of immature erythrocyte precursors into fetal blood. Severe fetal anemia causes fetal and placental hydrops, and often hypoproteinemia and thrombocytopenia. The placenta of newborns with erythroblastosis fetalis is pale and enlarged, displaying villous immaturity, edema, and an increase in Hofbauer cells (i.e.,

macrophages). Erythrocyte precursors are found in the vascular spaces. The severity of placental changes parallels the severity of fetal disease. There is ultrasonographic evidence of reversal of placental thickening and edema as fetal hydrops improves with treatment.

Placental changes are secondary to the disease process and do not contribute to its formation. Hydropic placentas from fetuses with erythroblastosis fetalis are indistinguishable from those with other causes. In placentas of newborns with erythroblastosis fetalis, compensatory placental hematopoiesis, specifically in the villous stroma, is suggested because numerous erythrocyte precursors are found packed in fetal villous sinusoids mimicking *de novo* erythrocyte synthesis in the placenta. No specific erythrocyte synthesis occurs in the placenta.

Hydropic placentas produce elevated titers of hCG. Serum levels of this hormone are significantly higher than normal in women with hydropic fetuses and placentas (55). It is unclear whether this is because of overproduction of the hormone or normal production by larger placental cell mass. Other placental hormones, including hPL, are found in elevated quantities in serum of women with hydropic placentas.

Preeclampsia occurs frequently in mothers with fetal and placental hydrops. Reversal of preeclamptic signs and symptoms has been observed after fetal and placental hydrops resolved spontaneously or was reversed by fetal transfusion (56). Because hydropic placentas release greater amounts of placental hormones into the maternal circulation, this finding gives credence to a humoral placental product theory as the cause of preeclampsia.

Twin-to-Twin Transfusion Syndrome

Abnormal placental physiology because of congenital placental vascular malformations in monozygotic twins is the basis of twin-to-twin transfusion syndrome.

Although dizygotic twinning always involves separate placentas and membranes (i.e., diamnionic dichorionic), monozygotic twinning results in separation ranging from complete separation of the placentas and membranes (i.e., diamnionic dichorionic) to shared placentas and chorion (i.e., diamnionic monochorionic), to shared placentas, chorion, and amniotic cavity (i.e., monoamnionic monochorionic), to shared fetal tissues (i.e., monoamnionic conjoined).

Twin-to-twin transfusion syndrome is a disease of monochorionic twins. Extraembryonic somatic mesoderm lining the extraembryonic cavity of the developing embryo gives rise to the chorion and to the mesenchymal core of the placental villus and associated fetal vessels. Monozygotic twins who share chorions (i.e., monochorionic) also share fetal circulations by vascular connections. Fetal vascular anastomoses almost never are found on placentas of dichorionic twins, but they are usually found on those of monochorionic twins (57).

In monochorionic twin placentas, the normal 1:1 ratio between the artery supplying and the vein draining a cotyledon is lost. Haphazard vascular patterns exist (Fig. 11-10).

P.161

Certain cotyledons are supplied from a single or anastomotic artery from both twins and are drained by one or two veins. Others are supplied by an artery of one fetus and drained by a vein of the other. Drainage by the vein of the opposite fetus may not be obvious when capillaries join the venous system in a neighboring cotyledon before surfacing as a contralateral fetal vessel. An intertwin arteriovenous shunt should be suspected when an artery diving into a cotyledon is not accompanied by an adjacent emerging vein.

Figure 11-10 Diamniotic, monochorionic twin placenta, with the intervening amnion rolled in the center. Notice the haphazard vascularization (large arrow). The velamentous cord insertion (small arrow) of the smaller twin of this discordant pair is not an unusual finding in monochorionic twins.

The most common fetal vascular anastomosis on the surface of the placenta is artery to artery, occurring in two thirds of monochorionic placentas (58). Vein-to-vein anastomoses are the least common, occurring in only 1 of 20 monochorionic placentas. Arteriovenous anastomosis, or arterial supply with contralateral fetal venous drainage of a cotyledon, which occurs in approximately two thirds of monochorionic placentas, is thought to be the most common placental lesion leading to inequality of blood flow and twin transfusion syndrome. Placental injection studies using contrast have been performed to ascertain vascular anastomosis, but injection studies only demonstrate the presence of anastomosis and do not establish overall inequality of flow.

In twin-to-twin transfusion syndrome, blood from the donor twin flows to the recipient twin through intertwin placental vascular connections. Remaining anastomoses are insufficient to allow return of the lost blood volume, and an imbalance of blood flow exists. The donor twin becomes hypovolemic, anemic, malnourished, and growth restricted; and responds with oliguria (i.e., oligohydramnios) and, in severe cases, anuria (i.e., anhydramnios). The recipient twin becomes hypervolemic and plethoric, develops cardiomegaly and polyuria (i.e., polyhydramnios), and, if severe, develops cardiac failure and hydrops fetalis. Grossly, the placental portion of the donor twin is anemic, pale, and usually smaller than that of the receiving twin. If hydrops has not yet occurred, the recipient twin's placental portion is red, thick, and congested. After hydrops ensues, the placenta becomes pale from villous edema. Microscopically, anemia and villous immaturity are found in the donor's placental portion and polycythemia and congestion in that of the recipient.

Despite the high frequency of cross-placental vascular anastomoses in monochorionic placentas, the incidence of clinically evident twin-to-twin transfusion syndrome in monochorionic twin pairs is only 5% to 10%. In some twin pairs, intertwin vascular connections may produce a chronic twin transfusion syndrome in which the larger twin responds with cardiac hyperplasia and hypertrophy (59). Cardiac hyperplasia may be compensatory, and certain sets of monochorionic twins may withstand the vascular inequalities throughout gestation (i.e., subclinical twin-to-twin transfusion syndrome). In others, the pumping capabilities of the enlarged heart are exceeded, and cardiac failure occurs. It is tempting to speculate that as the heart enlarges and fails, delicate pressure-flow characteristics in the placental vasculature are disrupted, exacerbating shunting to the recipient twin.

Twin-to-twin transfusion syndrome is a condition that begins early in embryonic vascular development. Benirschke (60) described the youngest example, a pair of aborted twin embryos measuring 7 and 8 cm (10 weeks of gestation) in which the heart of the donor twin was half the size of that of the recipient. Intertwin vascular distribution established early in the embryonic period may control intertwin placental mass distribution. Inequality in placental mass distribution may have an early, direct effect on fetal growth, causing significant growth restriction in one fetus. Antenatal ultrasonographic evaluation of placentation in the first trimester, or of the number of layers in intervening membranes in the latter trimesters, has allowed diagnosis of chorionicity with high sensitivity and positive predictive value (61). The obstetrician can confirm chorionicity and assess placental vascular patterns immediately after delivery of the twin placenta and should impart this information to the pediatrician.

Some antenatal treatment approaches for twin transfusion syndrome attempt to reverse the abnormal placental physiology. Selective termination of one fetus, usually the donor, prevents further transfusion to the recipient. This treatment introduces risks to the living twin from passage of emboli from the dead twin through anastomotic channels (i.e., twin embolization syndrome). Serial amniocentesis to decompress the polyhydramniotic sac of the recipient twin has reversed twin-to-twin transfusion syndrome in a few cases (62). Loss of amniotic fluid pressure on a large placental vascular anastomosis allows changes in fetal blood flow. After amniotic fluid decompression of severe polyhydramnios, ultrasonographically observed placentas appear thickened and less stretched. Fetoscopic laser occlusion of placental vessels, reported by De Lia and colleagues (63), may prove to be the most logical therapy, because treatment is directed at the cause of the problem. At the time of delivery, the placenta is two discs, separated by an area of infarcted cotyledons previously supplied by the coagulated vessels.

Acute transplacental fetus-to-fetus bleeding can occur in monochorionic twins and is distinct from twin transfusion syndrome. Acute fetus-to-fetus bleeding occurs in placentas with medium- or large-caliber vascular anastomosis when loss of established pressure-flow relations occurs. For example, the death of one twin of a monochorionic pair may allow large shifts of blood from the living twin to the deceased twin. Shifts may be

sufficient to cause anemia and hydrops fetalis in the surviving twin. If the deceased twin was the growth-retarded donor of a twin-to-twin transfusion pair, paradoxical plethora of the donor twin may occur.

Acute transplacental fetal bleeding may occur at the time of labor. For example, during the uterine contractions, umbilical cord compression may occur to a sufficient degree that it diminishes umbilical venous return but not arterial perfusion. The resulting higher resistance in the placental venous system of the cord-compressed twin favors return of blood to the co-twin. Acute intraplacental fetal bleeding may occur after delivery of the first fetus. Loss of established placental pressure-flow relations after

P.162

clamping of the umbilical cord favors intraplacental pooling of the second twin's blood through anastomoses, resulting in hypovolemia. Acute transplacental fetal bleeding can create disparate newborn hematocrits that do not reflect hematocrit levels during fetal life.

THE IN UTERO ENVIRONMENT AND FETAL DETERMINANTS OF ADULT DISEASE

The *in utero* environment has an overwhelming impact upon birth-weight and newborn disorders. Constriction of the uterine cavity because of leiomyomata (fibroid tumors), uterine anomalies, or lack of amniotic fluid may lead to deformation abnormalities such as club feet (64). Persistent, severe oligohydramnios, particularly in the second and third trimesters may lead to Potter sequence (65). Certain metabolic abnormalities of the mother causing an abnormal metabolic uterine milieu, such as uncontrolled diabetes (66) or uncontrolled phenylketonuria (67), may lead to congenital malformations, mental retardation, and growth abnormalities. Additionally, each fetus has a certain genetic predisposition to various disorders the development of which can be influenced by the *in utero* environment. For example, *in utero* positioning or abnormalities of labor may be associated with cranial synostosis in predisposed individuals (68).

Recently, the concept of the *in utero* environment influencing development of adult disease has become popular. This "fetal origins of adult disease" hypothesis says that human development is controlled not only by a combination of predetermined genes, but the effect on the fetus of the many variables of pregnancy.

The epidemiologic associations to support *in utero* programming and the fetal origins hypothesis were initially published in 1989 (69). The majority of the abnormal fetal origin hypotheses relate to poor fetal growth. Generally, investigators in these initial studies noted that outliers of normal birth-weight, either very large or more often very small newborns, had an increased risk for coronary artery disease, hypertension, and type 2 diabetes. This concept in humans has credibility from animal studies (70,71). The fetal origins hypothesis suggests, specifically, that lack of availability or use of fetal fuels *in utero* can program an individual's risk for chronic disease later in life.

Intrauterine fetal growth restriction is not only heterogeneous in etiology, but often multifactorial. The extensive placental and maternal physiologies discussed earlier in this chapter apply. Overall, the availability, delivery, and utilization of nutrients influence the growth of the fetus. Some of these influences can be modified such as promotion of adequate nutrition, cessation of smoking, and optimization of cardiac output to the uterus and placenta. Many other etiologies of growth restriction in newborns are evasive and lack both therapeutic and preventative prenatal measures.

BIRTH-WEIGHT AND CORONARY HEART DISEASE

Epidemiologic investigators have found an association of either low- or high-birth-weight with a higher risk of coronary heart disease later in life (72,73). The majority of the supporting data come from British epidemiologists evaluating birth records in three regions of Britain, specifically Hertfordshire, Sheffield, and Preston.

In a study of men born in Sheffield from 1907 to 1924 (74), death because of cardiovascular disease evaluated by standardized mortality ratios, fell in the birth-weight categories greater than 2,495 g. The standardized mortality ratio for cardiovascular disease fell from 119 in men who weighed 2,495 g (5.5 pounds) or less at birth to 74 in men who weighed more than 3,856 g (8.5 pounds). A significant fall was seen also in premature cardiovascular deaths and was associated as well with smaller head circumference and lower ponderal index. Notably in the study, men of low-birth-weight with large placentas (highest placenta-to-birth-weight ratio) had the highest rate of mortality from cardiovascular disease. Additionally, the risk appeared to be associated more with those who were low-birth-weight newborns who experienced catch-up growth later in life (75).

The association of low-birth-weight and higher incidence of cardiovascular disease has also been seen in other areas of the world. In an Uppsala study of nearly 15,000 Swedish men born between 1915 and 1929, a 1,000-g increase in birth-weight correlated with a 0.77 reduction in the rate of coronary artery disease (76).

The association of low-birth-weight and mortality from coronary artery disease appears to be stronger for men than women, but still significant in the latter. In Nurse's Health Study, performed in the United States, 70,297 women who completed questionnaires from 1976 to 1992 were assessed. An inverse relationship between birth-weight and cardiovascular disease and stroke was noted in these women (73).

Risk factors for coronary artery disease, specifically abnormalities of cholesterol metabolism and the coagulation system, were also linked to low-birth-weight, especially head-sparing growth restriction. In an English cohort study from Sheffield, a reduction in abdominal circumference and body length at birth predicted higher serum low-density lipoprotein cholesterol and plasma fibrinogen levels in adult life. It was postulated that the small abdominal circumference reflected impaired liver growth and "reprogramming" of liver metabolism (77). In a somewhat similar British study of newborn size and corresponding adult lipid profile, men and women who had smaller abdominal circumferences at birth were found to have higher serum levels of total and low density lipoprotein cholesterol and apolipoprotein B. The association was independent of social class, adult body weight, cigarette use, or alcohol use (78).

Higher birth-weights have also been associated with a higher risk of adult onset disease, but the association has

P.163

not been as strong. Men born with large abdominal circumferences (presumed large liver as well) were also noted to have an increased risk for coronary heart disease (79).

BIRTH-WEIGHT AND HYPERTENSION

Birth-weight was associated with adult hypertension at least as early as 1985 by Wadsworth and investigators (80), who studied more than 5,000 36-year-old men and noted that, in addition to adult weight, newborn weight was also statistically related to blood pressure elevation. Law and colleagues (81) studied a national sample of British children and men and women in various age categories. At all age categories beyond the newborn period, men and women who had lower birth-weights developed a higher blood pressure in adulthood. Investigators in the Nurses' Health Study evaluated women at 30 to 55 years of age and found that their birth-weight (by recollection) was inversely proportional to blood pressure in adult life (82).

Barker and associates (83) studied adult blood pressure of 327 men and women 46 to 54 years of age in relation to the placental weight and the newborn parameters of length, ponderal index, and head circumference. Even in this small cohort, there was a strong trend of higher blood pressure in adult life with lower birth-weight. Those newborns with high placental weights were also at higher risk for development of hypertension later in life.

The association of low-birth-weight with a higher risk of hypertension in adulthood has not been found in all studies. Birth-weight has been found in at least one study (84) to have a nearly negligible influence upon adult hypertension when compared to the effect of adult body mass index. In that study, birth-weight accounted for only 5% of the risk of adult hypertension when compared to adult body mass index, which accounted for 12% of the risk.

BIRTH-WEIGHT AND DIABETES

Hales and coworkers (85) evaluated fasting plasma glucose, insulin, proinsulin, and 32/33 split proinsulin concentrations, as well as glucose levels after a 75 g glucose challenge, in 468 men in a British cohort born and raised in Hertfordshire. Men of lower birth-weight had the highest rate of glucose intolerance and diabetes. The association was independent of adult body mass at the time of the study. A higher level of 32/33 split proinsulin was also related to low-birth-weight and interpreted as representation of pancreatic β -cell dysfunction. In this cohort, hypertension in adulthood was also associated with impaired glucose tolerance in adulthood. Low-birth-weight has also been associated with a higher risk of syndrome X (type 2 diabetes, hypertension, and hyperlipidemia) in adult life (86).

In a British study of forty 21-year-old men, glucose intolerance after a 75 g glucose challenge was associated with lower birth-weight independent of gestational age at birth and adult body mass, height, and social class (87). In a different study, ponderal index at birth was indirectly correlated with insulin resistance in late adulthood as measured by the rate of drop of glucose concentration after injection of insulin (88). Thinner

newborns had greater glucose intolerance in adulthood. The authors remarked that thinness at birth and thinness in adult life had opposing effects. Insulin resistance and glucose intolerance increased with a low-birth-weight, but decreased with high adult weight.

Huxley and colleagues (89), as well as others (90), question the fetal origins of adult disease hypothesis. They conducted a meta-analysis of 55 studies and concluded that the association of at least low fetal weight and an increased risk of high blood pressure in adulthood is at best weak. They believe that the strength of this association was primarily because of random error, selective emphasis of particular results, and inappropriate adjustments for adult weight and confounding factors.

Current epidemiologic data regarding fetal origins, fetal programming, and intrauterine effects on development of adult disease need further evaluation to confirm both association and causation. Both genetic and environmental factors affect fetal growth. For example, women with hypertension (and at risk for coronary artery disease later in life) are more likely to have growth-restricted newborns because of their hypertension during the pregnancy. These growth-restricted newborns are genetically at higher risk of developing hypertension and thus coronary heart disease irrespective of intrauterine conditions. Confounding variables need further evaluation. It remains to be seen if a newborn's small size alone is a risk factor for adult-onset disease. Nonetheless, it is exciting to think that efforts to promote a healthy pregnancy and optimize normal fetal growth may decrease development of certain common and widespread adult disorders.

Chapter 12

Fetal Imaging: Ultrasound and Magnetic Resonance Imaging

Dorothy I. Bulas

Advances in high-resolution sonographic imaging and rapid sequencing magnetic resonance imaging (MRI) have provided exquisite detail regarding the fetus and intrauterine environment. The ability to assess the health of the fetus and identify anomalies has changed the practice of both obstetrics and neonatology. By identifying the fetus with anomalies or at risk for intrauterine compromise, management can be guided by appropriate specialists with resultant improved outcome.

ASSESSMENT OF FETAL AGE, GROWTH, AND MATURITY

Accurate assessment of fetal age is crucial for perinatal management. Overestimating the age of a fetus can result in the delivery of a premature infant, whereas underestimating the age of a growth-retarded fetus can result in a fetal death.

Fetal age can be determined based on obstetric history and clinical data, but estimations can be inaccurate in up to 40% of patients (1). The use of ultrasound provides a method of significantly improving the accuracy of gestational age determination. Measurements used to assess age have been chosen on the basis of their relationship with gestational age and ease in obtaining these measurements and reproducibility. The fetal biparietal diameter (BPD) measurement was the first measurement used because the cranium was the most easily visualized body part (2). There are many tables and nomograms that describe the normal growth of various fetal organs. Most predictions of gestational age are based on the 50th percentile measurement with a wide range of normal values. At the various gestational ages, each fetal dimension differs in how easily and reliably it can be measured. Thus, a combination of measurements is superior to a single measurement, with computer software that permits instantaneous calculation of fetal age and weight estimates and plotting growth curves. Functional studies of the fetus, such as breathing patterns, can also aid in the determination of gestational age.

DETERMINING FETAL AGE

First-Trimester Assessment

In the first trimester, fetal imaging using a transabdominal approach is often difficult because the uterus is low within the maternal pelvis and may be obscured by overlying gas. Transvaginal ultrasound transducers greatly improve fetal visualization in early pregnancy. The probe is placed into the maternal vagina in close proximity to the uterus and fetus. High-resolution fetal images can thus be obtained for accurate assessment of fetal morphology. By use of transvaginal scanning, a gestational sac can be seen by 5 weeks menstrual age, and fetal heart activity by 6 weeks menstrual age. With abdominal scanning, these findings are first identified reliably a week later, at 6 and 7 weeks, respectively.

Crown-rump length is the most accurate dimension for assessing gestational age in the first trimester, with a 95% confidence interval of 6.2 to 3.5 days (3). Measurement of the gestational sac diameter can also be used to estimate age, although it is not as accurate as a result of variability in the shape of the sac. Fetal biparietal diameter and abdominal circumference are also relatively good predictors of menstrual age in the first trimester (4).

TABLE 12-1 RELATIONSHIPS AMONG SELECTED FETAL INDICES AS MEASURED BY ULTRASOUND AND GESTATIONAL AGE AS DETERMINED BY MENSTRUAL WEEKS

Menstrual Age (wk)	Biparietal Diameter (cm)	Head Circumference (cm)	Abdominal Circumference (cm)	Femur Length (cm)
12	2	7.1	5.6	0.8
13	2.3	8.4	6.9	1.1
14	2.7	9.8	8.1	1.5
15	3	11.1	9.3	1.8
16	3.3	12.4	10.5	2.1

P.167

Second- and Third-Trimester Assessment

After 12 weeks of gestation, the crown-rump length is difficult to obtain accurately. In the second and third trimesters, the main parameters of fetal age are the BPD, head circumference, abdominal circumference, and femoral length (Table 12-1).

The fetal BPD is quick, reliable, and easy to obtain. It measures the transverse diameter of the upper midbrain at the level of the thalamic nuclei and cavum septum pellucidum from the external surface of one proximal parietal bone to the inner surface of the contralateral parietal bone (Fig. 12-1) (5). The earlier the gestational age the greater the predictive accuracy of this measurement.

Inaccuracies in measurements of the BPD may result from improper selection of the measurement plane (6). In late pregnancy, the fetal head may be too low in the pelvis to measure. Cranial molding, either from fetal position or oligohydramnios, may result in BPD measurements that do not accurately reflect true gestational age (Fig. 12-2).

P.168

The cephalic index, which measures the relationship between the short and long axes of the fetal head, should be measured if the head shape appears abnormal. If this index is below 70 or above 86, the biparietal diameter should not be used in the age and weight estimates (7). The accuracy of BPD measurements decreases with advancing gestational age. In the second trimester, a BPD measurement carries a predictive accuracy of ± 7

days, whereas in the late third trimester it carries a predictive accuracy of ± 3 weeks (7). Serial measurements of BPD can improve the predictive accuracy (8). The fetal head circumference is obtained from the same axial image used for the BPD. This measurement is more accurate than the BPD in the third trimester, as it is less affected by shape (7).

Figure 12-1 Fetal biparietal diameter (BPD). Axial scan of the head at the standardized level for BPD measurement shows the thalami.

Figure 12-2 Transverse image of the brain of a 23-week fetus with severe oligohydramnios demonstrates a narrow and elongated skull. Cephalic index was abnormally low.

The measurement of the fetal abdominal circumference is made from an axial image of the abdomen at the level of the portal vein. The circumference of the head is typically larger than the abdominal circumference up to 34 weeks of gestation, and the abdomen becomes larger thereafter. In the presence of intrauterine growth retardation (IUGR), head size tends to be preserved compared to abdominal size altering the head circumference to abdominal circumference ratio.

Femur length is defined as the distance between the greater trochanter and the distal end of the femur (Fig. 12-3) (9). Gestational age prediction from femur length is subject to error either from measurement difficulties caused by difficulty in visualizing the ends of the bone or from biological variation. The predictive accuracy of femur length ranges from ± 1 week at 12 weeks of gestation to ± 3 weeks at 36 weeks of gestation (10).

Estimation of fetal age is best accomplished using a composite assessment of multiple fetal measurements. A combination of head size (BPD or head circumference), femur length, and abdominal circumference is most commonly used. Estimates have an error of ± 1.46 weeks between 24 and 30 weeks of gestation and increase to 2.3 weeks at 36 weeks of gestation (11). Individual measurements should not be used for assessing gestational age when they are affected by a pathological process; for example, head measurements in a hydrocephalic fetus or long bone measurements in the fetus with a bone dysplasia. After 22 weeks, age-independent fetal body ratios are useful in identifying asymmetric measurements. If the cephalic index is normal, the ratio of femur

length to BPD can be measured, with normal results ranging between 71 and 87. The ratio of femur length to abdominal circumference should range between 20 and 24 (12).

Figure 12-3 Longitudinal scan of the fetal thigh demonstrates a femur length of 3.5 cm consistent with a 21-week gestation. Measurement is from the greater trochanter to the distal end of the femur.

FETAL WEIGHT ESTIMATES

It would be helpful in the assessment of fetal age, growth, and maturity if an accurate, reproducible method of determining fetal weight were available. Ultrasonographic estimates of fetal weight have been derived from single measurements such as BPD or abdominal circumference (13) and by a combination of measurements such as abdominal circumference and BPD (14). All ultrasonographic methods for fetal weight estimations, however, contain inherent error. Measurement of abdominal circumference yields an average error of 18% (13). The BPD and abdominal circumference yield a similar error (20%) (15). The absolute estimated error decreases as birth weight decreases.

The use of multiple parameters, especially head, abdomen, and femur measurements, provides the most accurate measurement of fetal weight. However, it is still not accurate in extremely low or high birth weight fetuses. Because fetal weight estimates remain imprecise, estimation of fetal age based solely on estimates of fetal weight should not be used. Incremental fetal weight change can be determined with serial ultrasounds and is one way of detecting abnormal fetal growth (10). In the future, three-dimensional fetal MRI reconstruction and volume estimates may improve the accuracy of fetal weight determination (16).

P.169

ASSESSMENT OF FETAL GROWTH

Fetal growth abnormalities are often associated with increased risk of perinatal morbidity and mortality. The rate of growth in the normal fetus varies with gestational age, with an increasing exponential curve in the first trimester, a linear curve in the second and most of the third trimester, and a decreasing exponential curve after 36 weeks of gestation (17). Serial ultrasonographic measurements can be plotted to evaluate fetal growth and may include weight estimates derived from a combination of these variables.

Intrauterine Growth Retardation

The infant whose birth weight is below the tenth percentile for gestational age is considered small for gestational age (SGA). The population of SGA infants whose weight falls below the tenth percentile is heterogeneous. Normal but small fetuses represent up to 60% of the SGA group, fetuses with congenital anomalies account for up to 15%, and fetuses with true IUGR account for 25% (18). Management varies among these groups. The normal but small fetus is not at increased risk and does not require intervention. The small fetus with true growth restriction may be at high morbidity or mortality risk and may require immediate intervention. The small infant with congenital abnormalities may or may not require intervention. It can be difficult determining which

group an SGA fetus falls into, particularly when the true gestational age is unknown.

Ultrasound's ability to identify the truly IUGR fetus is variable and is most successful when the disease state is severe. A slowing of the rate of head and femur growth is apparent with severe IUGR (19,20) but is more difficult to identify when the retardation is mild or early. Growth-adjusted sonographic age determination based on BPD or abdominal circumference (6,20) uses serial ultrasonographic measurements. This method assumes that fetal growth should remain within a narrow percentile band and that deviation from this may be an early sign of growth disorders (21). Because of the inherent errors, serial estimation of fetal weight identifies only the most severe growth disturbances. Asymmetric growth suggests IUGR. Abnormal ratios of head circumference to abdominal circumference, as a result of loss of liver mass with normal head growth, can be seen in severe IUGR but may not be present in milder cases (22).

Secondary signs aid in assessing the presence and severity of IUGR. Oligohydramnios often develops during episodes of uteroplacental insufficiency, most likely because of decreased fetal urine production and pulmonary fluid during episodes of fetal hypoxemia (23). Amniotic fluid volume may be assessed subjectively or by the semiquantitative method of measuring the vertical diameter of the largest visible pocket of amniotic fluid. The amniotic fluid index (AFI) is calculated by adding the vertical depths of the largest pocket in each of four equal uterine quadrants (24). Oligohydramnios has been defined by the absence of identifiable amniotic fluid pockets or when the maximum vertical pocket measures less than 2 cm in two perpendicular planes or when the amniotic fluid index measures less than 5 cm. Oligohydramnios as defined by any one of the methods is predictive of increased peripartum morbidity and mortality (24,25,26). Milder cases of IUGR, however, may not be associated with oligohydramnios (27).

Assessing fetal condition using the biophysical profile score (BPS) or Doppler velocity ratios of the umbilical artery and/or fetal middle cerebral artery are additional useful adjuncts in the diagnosis of IUGR (see Doppler Assessment of Blood Velocities in Umbilical and Fetal Vessels) (28). If a fetus who is being followed for IUGR has no signs of asphyxial compromise, continued observation rather than intervention may be reasonable.

Macrosomia

The infant whose birth weight is above the 90th percentile for gestational age is labeled large for dates (LGA) or macrosomic. This group of large infants is heterogeneous, composed of normal but large infants and infants with abnormally increased growth. Macrosomia is usually associated with maternal glucose abnormalities.

Macrosomia may lead to obstetric complications such as shoulder dystocia, although maternal diabetes may cause neonatal complications such as hypoglycemia, polycythemia, and cardiac abnormalities (29). Detection of macrosomia sonographically includes serial assessment of growth and the relationship of the variables. The ratio of abdominal circumference to head circumference is particularly useful in identifying an enlarging abdomen indicative of excessive weight gain. Other measurements have been proposed to aid in the diagnosis of macrosomia, including soft tissue thickness of the humerus or femur and cheek-to-cheek diameter (30).

Fetal Maturity

The sonographic assessment of fetal maturity is useful in the optimal timing of perinatal management. The perinatologist must maintain a balance between the risk of fetal death and the risk of neonatal death based on an estimate of whether a fetus has reached an age and weight at which lung maturity is possible. Fetal age and weight determinations, evaluation of placental architecture, and the biophysical profile have been used to assess fetal maturity. Studies on elective deliveries based on BPD, or weight estimates based on BPD and abdominal circumference, have shown good results (31,32 and 33). The grading of placental maturity sonographically, however, has not been shown to be as accurate in assessing lung maturity as examination of the amniotic fluid (34).

FETAL ANATOMY

Congenital anomalies are present in 2% to 5% of newborns and account for 20% to 30% of perinatal deaths (35). High-resolution ultrasonography has produced significant

changes in the diagnosis and management of these anomalies, including the potential for therapeutic intervention. Factors to be considered in the counseling of these cases include gestational age, effect on maternal outcome, and neonatal prognosis with or without therapy. Amniocentesis should be considered in cases

at risk for a chromosomal anomaly.

Figure 12-4 Transvaginal scan of the fetal brain in the coronal plane clearly demonstrates mild dilatation of both occipital horns.

Ultrasound is the initial imaging modality of choice for the assessment of the fetus as it is safe, inexpensive, and easily performed. A comprehensive sonographic review includes a survey of the fetus, followed by evaluation of amniotic fluid volume, cord structure, and the placenta. A functional review of the fetus including hand clenching and swallowing is informative. Because some anomalies may not become evident until later in gestation (such as progressive hydrocephalus, congenital diaphragmatic hernia), follow-up evaluation of the fetus at risk is important. Transvaginal sonography and three-dimensional sonographic imaging have provided a means of improved visualization of fetal anomalies, particularly of the face and brain (Fig. 12-4).

Fetal Magnetic Resonance Imaging

Factors such as fetal lie, maternal obesity, and oligohydramnios may interfere with the sonographic evaluation of fetus. MRI is an alternative modality to evaluate the fetus as it uses no ionizing radiation, has excellent tissue contrast, large field of view and multiplanar capabilities (Fig. 12-5) (36,37). The development of faster scanning techniques now allow studies to be performed without sedation in the second trimester with superior contrast, and without significant motion artifact.

Although there currently is no evidence that the use of clinical MRI produces deleterious effects on human embryos, the safety of MRI during pregnancy has not been definitively demonstrated (37,38). While there has been concern that prolonged exposure to electromagnetic radiation may be linked to deleterious effects on embryogenesis, animal studies on embryos have so far demonstrated no growth abnormalities (40,41). Limited follow-up studies on children exposed to fetal MRI also have not demonstrated developmental abnormalities (40,42,43). Due to the possibility of unknown effects, MRI currently is used as a complementary study only when ultrasound results are inadequate for diagnosis or when MR imaging is expected to provide important additional information.

Figure 12-5 Large field of view T2 weighted sagittal image demonstrates the brain, chest, abdomen, and leg of a 20 week fetus.

With advances in the diagnosis and treatment of fetal abnormalities there is an increasing need for precise depiction of abnormalities. Fetal MRI not only confirms the presence of lesions noted by ultrasound, but also can demonstrate additional subtle anomalies. This information helps appropriate specialists, including the neonatologist, counsel families when difficult decisions must be made regarding early and potentially invasive intervention and allows for optimal delivery planning.

Fetal Central Nervous System Abnormalities

Fetal central nervous system (CNS) abnormalities may be detected in the first trimester in severe cases such as anencephaly. The most favorable time to evaluate the fetal neural axis, however, is 18 to 24 weeks of gestation, when resolution is sufficient to identify most structures including the spine. Abnormal measurements of BPD and head circumference may be the first suggestion of a CNS abnormality. Structural evaluation includes the shape and size of the head, ventricles, and posterior fossa and an evaluation of the spine. If a CNS anomaly is identified, careful evaluation for other anomalies, especially of the face, heart, and kidneys, follows.

The ventricular diameter normally measures less than 10 mm throughout the second and third trimesters

P.171

(44,45). Other criteria of ventriculomegaly include separation of choroid plexus from the medial ventricular wall. If the diagnosis of ventriculomegaly is established, a search for its etiology should be made. A differential diagnosis ranges from cerebral atrophy (hydranencephaly, porencephaly) (Fig. 12-6), dysgenesis (holoprosencephaly, agenesis of the corpus callosum), to true hydrocephalus.

Figure 12-6 A: Axial sonogram of the brain at 29 weeks of gestation demonstrates unilateral dilatation of the left lateral ventricle (cursors). **B:** Follow-up CT scan at birth confirms the finding of left hemispheric porencephaly (arrow).

There are significant limitations in the sonographic evaluation of the fetal brain as a result of refraction artifact from the skull and low sensitivity to cortical malformations. MRI better defines anomalies of the posterior fossa, corpus callosum, and developing gray and white matter. Three planes of the brain can be obtained with excellent delineation of the extraaxial spaces (Fig. 12-7). Sulcal and gyral development can be assessed allowing for estimation of brain maturity (Fig. 12-8) (46,47 and 48).

Figure 12-7 Coronal T2 weighted image through the brain of a 25 week fetus with aqueductal stenosis demonstrates moderate lateral and third ventricular dilatation.

Hydrocephalus

Hydrocephalus can be caused by an increased rate of cerebrospinal fluid (CSF) formation as in choroid plexus papilloma, decreased resorption of CSF after hemorrhage, or obstruction of CSF flow as a result of tumor or aqueductal stenosis (49). In many cases, the etiology of hydrocephalus remains unknown. Up to 85% of cases are associated with other neurological, cardiac, renal, gastrointestinal (GI), or skeletal anomalies. Up to 10% are associated with chromosomal abnormalities (50). Fetuses with other anatomic or chromosomal abnormalities have a grim prognosis for long-term development. When ventriculomegaly is mild, and no associated abnormalities are identified, outcome is less severe. Up to 20% of these cases, however, may demonstrate neurological abnormalities later in life (51,52 and 53).

Figure 12-8 Oblique T2 weighted image through the brain of a 32 week fetus with trisomy 21 demonstrates moderate ventriculomegaly with a more mature sulcation pattern.

Figure 12-9 Coronal T2 weighted image through the brain of 19 week gestation demonstrates agenesis of the corpus callosum and high riding third ventricle.

P.172

MRI is useful in confirming the presence of ventriculomegaly, and can assess symmetry of ventricular size and contour. Irregularity of the ventricular wall and adjacent parenchymal abnormalities may indicate post-inflammatory and destructive changes. Atrophy, hemorrhages, or masses may be identified (48). Identifying the etiology for ventriculomegaly, however, may still be difficult as subtle gyral abnormalities and parenchymal changes may be impossible to detect by MRI in the second trimester.

Multiplanar views are particularly useful in the evaluation of the corpus callosum, which develops between 8 to 17 weeks gestation (Fig. 12-9). When severe, holoprosencephaly can be identified by ultrasound; less severe semilobar and lobar types are more difficult to diagnose even by MRI.

The posterior fossa and brain stem are well delineated by MRI and can help differentiate Dandy Walker malformation for posterior fossa arachnoid cysts or mega cisterna magna (Fig 12-10).

Figure 12-10 Sagittal T2 weighted image of a 22 week gestation demonstrates a Dandy Walker cyst with absent inferior vermis.

Vascular CNS anomalies including vein of Galen aneurysms are well demonstrated by MRI. Hemorrhage and or encephalomalacia suggests a poorer prognosis and is better demonstrated by MRI.

Neural Tube Defects

The most common condition leading to ventriculomegaly is spina bifida. Evaluation of the fetal spine and cerebellum allows prenatal identification of over 95% of fetuses with meningomyeloceles. Screening programs using maternal serum α -fetoprotein identify pregnancies at risk for neural tube or ventral wall defects. Sonographic findings of meningomyelocele include splaying of pedicles, presence of a cystic collection posterior to the fetal spine with absent skin covering, and scoliosis. Because of the difficulty in identifying small spinal defects prenatally, the association of cranial abnormalities is useful in evaluating cases at risk. The Arnold-Chiari

malformation, which often accompanies spina bifida, results in the herniation of the cerebellum through the foramen magnum into the upper cervical spinal canal. Cranial sonographic findings of this malformation include frontal bone scalloping (lemon sign), abnormal curvature of the cerebellum (banana sign), and obliteration of the cisterna magna (54,55). MRI is useful in the confirmation of Chiari malformations, with amount of tonsillar herniation measured (46).

Cranial defects involving brain (encephalocele) or meninges (meningocele) may present with ventriculomegaly (Fig 12-11). Typically on ultrasonography there is a posterior paracrannial mass that is cystic or solid. It is important to identify a true skull defect because the diagnosis can be confused with scalp edema, cystic hygroma, or scalp hemangiomas, which carry a better prognosis (56). MRI is particularly useful in identifying intracranial anomalies associated with encephaloceles. Because encephalocele is a feature of other syndromes including Meckel-Gruber, additional anomalies should be excluded (57).

Figure 12-11 Sagittal T2 weighted image of a 24 week fetus demonstrates an occipital meningocele with microcephaly and sulcation anomalies.

Figure 12-12 Transverse image through the chest of a 25-week fetus demonstrates bilateral large pleural effusions (white arrowheads). The heart (black arrow) is slightly deviated to the right.

Fetal Chest Abnormalities

Many major intrathoracic structures can be identified sonographically by the second trimester. A small chest circumference suggests pulmonary hypoplasia in the presence of oligohydramnios or skeletal dysplasia (58). Pleural effusions appear as fluid collections surrounding collapsed echogenic lung (Fig. 12-12). Effusions may be primary in chylothorax or secondary in nonimmune hydrops. In the presence of effusions, prognosis is variable, with 15% mortality if an effusion is isolated but up to 95% mortality if it is associated with severe hydrops (59,60).

The normal fetal mediastinum lies in the center of the chest, anterior to the spine, with the cardiac

interventricular septum forming a 45-degree angle with the midline. Deviation of this axis or shift of the heart suggests a mass effect or cardiac pathology.

Figure 12-13 Cystic adenomatoid malformation. Sagittal image of the left fetal chest at 26 weeks of gestation demonstrates multiple cysts (arrows) within the left hemithorax dispersed between unusually echogenic lung parenchyma.

Fetal lung parenchyma should be homogeneously echogenic. If it is heterogenous and/or there is shift of midline structures, a chest mass is likely. Sonographic findings will vary depending on the type of chest mass. Cystic adenomatoid malformations (CCAM) type 1 are the most common and appear as a single or multiple macrocysts. Type 2 CCAM contain small cysts less than 1 cm in size and are often associated with other anomalies. Type 3 CCAM contain multiple microcysts that appear sonographically as a homogeneously echogenic mass (Fig. 12-13) (61,62). Sequestrations are intralobar or extralobar masses of pulmonary tissue that lack a tracheobronchial communication and have a vascular supply from the aorta. They present as a solid or mixed solid and cystic mass in the inferior portion of the chest (63). Up to 25% have a CCAM component that may be cystic. With color Doppler, a vessel can often be seen coursing from the aorta to feed the mass, confirming the diagnosis. Bronchogenic cysts typically present as a simple mediastinal or lower lobe cyst without a feeding vessel (64).

MRI is particularly valuable in the evaluation of fetal thorax. Fetal lungs are homogeneously intermediate in signal and clearly delineated from mediastinal structures, liver, and bowel (64,65). Cystic lung masses are typically higher in signal as a result of the high fluid content and can be separated from normal surrounding lung parenchyma (Fig. 12-14a and b) (67,68).

Prognosis depends on the size of the intrathoracic mass because marked lung compression during fetal development leads to hypoplastic lungs. Polyhydramnios, ascites, and hydrops are likely secondary to compression of the esophagus and vena cava and correlate with poor outcome (61). Type 3 CCAM tend to have the worst prognosis. The prenatal placement of shunts in cysts or pleura has resulted in some success in lung reexpansion (68). Spontaneous resolution of pleural effusions and pulmonary masses in utero has been reported (Fig. 12-13) (60,61,62). Prenatal therapy is reserved for those cases at highest risk for poor outcome (e.g., hydrops) (61,69,70,71). A fetus with a lung mass has an excellent prognosis if there is no hydrops and only minimal pulmonary hypoplasia (71).

Fetal neck masses such as cystic teratomas and lymphangiomas can occlude the airway resulting in hypoxic brain injury or death on delivery. The prenatal detection of a neck mass allows for the planning of a more controlled delivery such as Exutero Intrapartum Treatment (EXIT) procedure to establish an airway (72,73). Fetal MRI is particularly useful in providing additional detailed anatomic information in three planes of the larynx and trachea which are not visualized sonographically (72,73).

Congenital Diaphragmatic Hernia

When a fetal thoracic mass is identified, the differential diagnosis includes congenital diaphragmatic hernia. This defect results from incomplete fusion of the pleuroperitoneal membranes during the seventh week of gestation. Passage of bowel and liver may occur into the thorax at any

time during pregnancy. Sonographic findings include contralateral mediastinal shift and fluid-filled loops of bowel within the chest that mimic pulmonary "cystic" masses (Fig. 12-15). Findings specific to congenital diaphragmatic hernia (CDH) include absence of an intraabdominal stomach bubble or loops of bowel within the chest. Doppler flow studies demonstrating mesenteric vessels extending into the hemithorax confirm the diagnosis. Bowing of the umbilical portion of the portal vein suggests liver herniation. Associated anomalies often present include cardiac, genitourinary, CNS, and GI. Other conditions associated with congenital diaphragmatic hernia are Fryns' syndrome with nuchal thickening and limb anomalies and Pallister Killian syndrome (74).

Figure 12-14A. Coronal T2 weighted image of a fetal chest at 22 weeks gestation demonstrates multiple high signal cysts occupying the left hemithorax. **B.** Axial CT of the chest following delivery demonstrates multiple air filled cysts in the left upper lobe compatible with a cystic adenomatoid malformation.

Figure 12-15 Congenital diaphragmatic hernia. Transverse sonographic image through the chest of a 23-week fetus demonstrates the heart (white arrow) to be shifted to the right by a herniated fluid-filled stomach (black arrow).

Further evaluation includes fetal chromosomal analysis and fetal echocardiograms. Fetal MRI is particularly useful in differentiating a CCAM from a CDH. MRI can assess how much residual lung parenchyma remains expanded, and determine the amount of liver and bowel that has herniated into the thorax (Fig. 12-16) (36). Serial sonograms every 2 to 4 weeks are important as up to 75% of cases develop polyhydramnios, and all are at risk for IUGR (75). The mortality rate for infants with diaphragmatic hernia is variable. Cases with multiple anomalies are likely to be lethal. Less clear is whether sonographic findings such as marked mediastinal shift, IUGR, hydrops, and polyhydramnios predict uniformly poor outcome (75,76). Ratios of right lung area to head circumference and the presence of liver in the chest appear most useful in identifying which cases carry the poorest prognosis (77,78).

Congenital Heart Disease

Congenital heart disease is one of the most commonly recognized birth defects with a reported frequency of 0.8%. Any woman with a risk factor for a cardiac anomaly should undergo a detailed ultrasound examination of the fetal heart. Risk factors include nonimmune hydrops, suspected abnormality by screening sonogram, teratogen exposure, parental or sibling heart defect, aneuploidy, extracardiac anomalies, maternal diabetes, and fetal arrhythmia (80).

Detailed cardiac evaluation is difficult before 18 weeks of gestation. Examination includes visualization of the

P.175

four chambers and outflow tracts. A dedicated fetal echocardiogram requires additional cross-sectional views to demonstrate fetal heart integrity. M-mode echocardiography measures chamber size, wall thickness, and wall motion and facilitates cardiac rhythm assessment. Pulsed Doppler and color flow Doppler are useful to define blood flow. Sensitivity in detecting anomalies is dependent on fetal position, maternal size, and amniotic fluid volume and equipment and expertise. Ventricular septal defects, anomalous pulmonary venous return, and aortic or pulmonic stenosis are especially difficult to diagnose. Ott, in 1995, reported a 14% sensitivity for detection of congenital heart disease in a low-risk population compared with a 63% sensitivity in the high-risk group (81). Heart disease diagnosed prenatally is often severe and associated with a poor long-term prognosis with chromosomal or extracardiac structural defects often present (82).

Figure 12-16 Congenital diaphragmatic hernia. Coronal T2 weighted image of a chest at 32 weeks gestation demonstrates herniation of stomach, bowel, and spleen into the left hemithorax. There is minimal deviation of mediastinal structures with the right lung and left upper lobes expanded.

Fetal Gastrointestinal Tract

The ultrasound appearance of fetal bowel varies, with significant overlap between normal and abnormal patterns (83). The stomach is first visualized at 13 to 16 weeks of gestation. If it is not identified by 16 weeks, especially in the presence of polyhydramnios, an abnormality such as esophageal atresia or congenital diaphragmatic hernia should be suspected (84). The esophagus is typically collapsed and not visualized by ultrasound scans (US), but the absence of a fluid-filled stomach and presence of polyhydramnios and a dilated proximal pouch are findings suggestive of esophageal atresia. In cases of tracheoesophageal fistula, 70% have a fluid-filled stomach, with polyhydramnios developing in only 60% of cases. Thus, sonographic detection of tracheoesophageal fistula (TEF) is unlikely (85). TEF may be detected by MRI if a proximal dilated esophageal pouch is noted and the distal esophagus is not visualized (86).

When an enlarged fluid-filled duodenum and stomach are identified, duodenal obstruction is present. Duodenal atresia is the most common cause, but the differential diagnosis includes annular pancreas, or duodenal stenosis. Up to 30% of fetuses with isolated duodenal atresia have trisomy 21, so chromosome analysis and fetal echocardiography are indicated. Serial sonograms will indicate development of polyhydramnios or IUGR.

In a normal fetus, small bowel is only occasionally visualized, and loops measuring over 7 mm in diameter are considered abnormal and suggestive of obstruction (87) (Fig. 12-17). Differential diagnosis includes a duplication cyst, mesenteric cyst, ovarian cyst, and hydroureter. Polyhydramnios is not always present and depends on the site of obstruction. Because a fetus with a large bowel obstruction or anal atresia typically does not develop polyhydramnios or dilated bowel, these entities are less readily diagnosed in utero. At times, bowel obstruction is associated with perforation and meconium spilling into the peritoneum, otherwise known as meconium peritonitis. Sonographic findings include fetal ascites, peritoneal calcifications, and meconium pseudocysts (88). The most common cause of small bowel obstruction is atresia felt to be secondary to an in utero vascular infarct. Fifteen percent of infants with cystic fibrosis present with meconium ileus and sonographic findings similar to those of bowel atresia. Echogenic bowel, meconium peritonitis, and pseudocyst formation occur in both meconium ileus and isolated bowel atresia. Echogenic bowel has also been associated with cytomegalovirus (CMV) and with chromosomal abnormalities such as trisomy 21 (89). Amniocentesis allows for karyotyping, CMV cultures, and analysis of amniocytes for the common cystic fibrosis (CF) mutations. In cases of suspected bowel abnormalities, serial sonograms will detect new onset of polyhydramnios and meconium peritonitis.

Fetal bowel is well visualized by MRI. Meconium is low signal on T2w and high signal on T1w. Proximal bowel loops are high signal on T2w and low on T1w. MR can provide additional information regarding level of obstruction. Anal atresia, typically missed by US may be identified by MRI (90).

Ventral Abdominal Wall Defects

The most common abdominal wall defects identified sonographically include omphalocele and gastroschisis (91). Through maternal serum alpha-fetoprotein screening, these defects can be diagnosed early in pregnancy. Omphaloceles result from failure of intestines to return to the abdomen during the tenth week of gestation with herniation of bowel or liver into the umbilical cord. A

surrounding peritoneal membrane is present, and the cord insertion is central (Figs. 12-18, 12-19). Gastroschisis, on the other hand, is a paraumbilical defect located to the right of the umbilicus and is a full-thickness abdominal wall defect without a covering membrane. It is important to distinguish between the two entities for associated diagnosis and prognosis. Gastroschisis is classically an isolated entity felt to be caused by a vascular event and is not associated with chromosomal anomalies but is complicated by bowel fibrosis (92).

Figure 12-17 A: Transverse image of a 33-week gestation fetal abdomen demonstrates multiple dilated loops of bowel (black arrowheads). Echogenic focus (white arrow) is consistent with a peritoneal calcification. **B:** Following delivery at term, a water-soluble enema demonstrates a normal-caliber colon with dilated air-filled small bowel loops (arrow). Jejunal atresia was found at surgery.

Figure 12-18 Omphalocele. Transverse sonographic image at the level of the umbilical cord insertion demonstrates a large outpouching (arrows) with a covering membrane containing liver and bowel.

Omphaloceles, although not as likely to have bowel fibrosis, are more at risk for associated chromosomal abnormalities (30%-50%) and syndromes such as Beckwith-Wiedemann syndrome (macroglossia, organo-

megaly) and pentalogy of Cantrell (ectopia cordis) (93).

Normal fetal bowel migrates into the base of the cord by 12 menstrual weeks. Thus, the sonographic diagnosis of abdominal wall defects should be made only with caution before the second trimester. Chromosomal analysis and fetal echocardiography should be offered, and consultation with a pediatric surgeon is helpful. Serial sonograms will diagnose the development of polyhydramnios and IUGR (94,95).

Genitourinary Tract

Many asymptomatic genitourinary abnormalities are now being identified prenatally by sonography. Most renal lesions that are identified are cystic or obstructive. Increased detection and earlier diagnosis aid in minimizing

P.177

the risk of further renal damage after birth. Detection of the fetus with irreversible or lethal renal disease also assists in obstetric and perinatal management. Renal anomalies that can be diagnosed prenatally include renal agenesis, dilated obstructed or nonobstructed collecting systems, renal cystic disease, and tumors. It is estimated that 1 in 1,000 fetuses have a renal anomaly (96,97). In a series of 17,000 women screened prospectively at 16 to 18 weeks, renal anomalies were identified in 313 cases, 55 of which were significant. Upper tract dilation was the most common finding (298 cases), but it was transient in two-thirds of these cases. Obstruction was noted in 23 infants on follow-up, with 15 of these requiring surgery. Eight infants had unilateral multicystic kidney disease, and three had posterior urethral valves (98). Mortality after prenatal identification of fetal uropathy ranges from 20% to 50%.

Figure 12-19 Omphalocele. Sagittal T2 weighted imaged demonstrates liver outpouching at the level of the cord insertion.

A systematic approach to urinary tract abnormalities includes an assessment of amniotic fluid, characterization of the urinary tract abnormality, and a search for additional abnormalities. The kidneys contribute little amniotic fluid until 16 weeks of gestation, making it difficult to assess renal function before the second trimester. The presence of oligohydramnios secondary to a urinary abnormality carries a poor prognosis. Rarely, polyhydramnios may be present in a fetus with a mesoblastic nephroma, incomplete ureteropelvic junction (UPJ) obstruction, or associated cranial or GI abnormalities.

Fetal kidneys can be visualized as early as 14 weeks of gestation. Standard renal measurements include length [age in weeks = fetal kidney length (mm)], AP diameter, and renal circumference to abdominal circumference ratio (0.27–0.33). If a fetal renal pelvis is dilated and fluid-filled, one must determine if it is physiological, obstructive, secondary to reflux, or simply nonobstructive megacystis. In most cases, if the pelvic diameter measures less than 1 cm, the finding is nonpathological. When the pelvic diameter measures over 1 cm, the ratio of pelvic diameter to renal diameter measures greater than 0.5, or caliectasis or hydroureter is present, a pathological process is likely (99).

Obstructive Uropathy

The most common cause of fetal pyelectasis is UPJ obstruction (98). Differential includes extrarenal pelvis, vesicoureteral reflux, or a multicystic dysplastic kidney. When bilateral, the severity of obstruction is usually

asymmetric. Rarely, dysplasia, urinoma, or urine ascites develops. MRI is helpful in defining anatomy of complex renal anomalies such as bladder extrophy and cloacal anomalies (100). If associated nonrenal anomalies are identified, chromosome analysis is indicated. The frequency of follow-up sonograms depends on whether both kidneys are involved and the severity of obstruction. Outcome is variable, with 10% increasing in dilation, 50% remaining stable, and 40% improving (101). Prophylactic antibiotics should be provided to the infant after delivery, until work up, including renal scans can document whether the dilatation is truly obstructive.

Bladder Outlet Obstruction

If hydroureter and pyelectasis are bilateral, the differential diagnosis includes urethral obstruction, bilateral reflux, or bilateral megacystis. In the male fetus, the differential also includes posterior urethral valves and prune belly syndrome. Accurate diagnosis of posterior valves includes the finding of a dilated, thick bladder with keyhole posterior urethral expansion, dilated tortuous ureters, and caliectasis. Fetal MRI may aid in the assessment of ureteral and urethral dilatation particularly if oligohydramnios is present. Urinary ascites may be present (Fig. 12-20). Findings that suggest a poor outcome include dysplastic echogenic renal parenchyma and oligohydramnios (102). If fetal bladder aspirate demonstrates elevated fetal urine electrolytes and elevated osmolarity, a poor outcome is also suggested.

Frequent sonograms will detect progressive oligohydramnios and IUGR. If severe oligohydramnios is present, up to 95% die from pulmonary hypoplasia. Those who survive require an emergency voiding cystourethrogram to confirm the diagnosis and valvuloplasty or cystostomy to relieve the obstruction. Up to 40% of survivors may develop renal failure at a later date.

Cystic Renal Disease

Cystic changes of the fetal kidneys may be secondary to hereditary diseases (autosomal recessive infantile polycystic

P.178

kidneys), dysmorphology (multicystic dysplastic kidney disease), or severe obstruction (Potter type II). Differentiating the various diagnoses, at times, may be difficult. When renal cystic disease is identified, the most important factors to evaluate are amniotic fluid volume and whether one or both kidneys are affected. If the cysts are unilateral and amniotic fluid is normal, prognosis typically is good.

Figure 12-20 Longitudinal image of a right kidney in a 23-week gestation male fetus with posterior urethral valves demonstrates a kidney with a large upper pole cortical cyst (black arrow), caliectasis (arrowheads), and urinary ascites (white arrow).

Multicystic dysplastic kidneys are felt to be an early error in development of mesonephric blastema or early obstructive uropathy. Up to 75% of multicystic dysplastic kidneys are associated with other renal abnormalities in the contralateral kidney, especially UPJ obstruction and vesicoureteral reflux. Sonographically, multiple cysts are identified in various sizes that do not connect to a renal pelvis. No normal renal parenchymal tissue is seen. Following delivery, the diagnosis is confirmed by renal radionuclide scan, and vesicoureteral reflux is excluded by voiding cystourethrogram.

Autosomal recessive infantile polycystic kidneys typically present with bilateral large echogenic kidneys with a

large abdominal circumference. If severe oligohydramnios develops, outcome is poor because of pulmonary hypoplasia (Fig. 12-21).

Skeletal Dysplasia

Skeletal dysplasias include a heterogeneous group of over 160 disorders. The prevalence is 2.4 per 10,000 births (103). Up to one-fourth of affected infants are stillborn, with another one-third dying by 1 week of age. The most common lethal dysplasias include thanatophoric dysplasia, osteogenesis imperfecta type II, and achondrogenesis. The most common nonlethal skeletal dysplasia is achondroplasia (104).

Prenatally, a systematic approach is needed to analyze skeletal anomalies. Long bones should be evaluated for size, shape, bowing, and symmetry. Shortening of the extremities can involve the proximal segment (rhizomelic), midsegment (mesomelic), distal segment (acromelic), or the entire limb (micromelic). Fractures appear as bones that are irregular, angled, or bowed sonographically (Fig. 12-22). The skull should be evaluated for frontal bossing or cloverleaf deformity. Decreased skull echogenicity may be noted with osteogenesis imperfecta and hypophosphatasia. Hyper-telorism, micrognathia, and abnormally shaped ears may be identified. Hands and feet should be evaluated for polydactyly, missing digits, or equinovarus deformities. The presence of hemivertebrae, scoliosis, and platyspondyly should be explored. Although short ribs may be difficult to recognize sonographically, the thoracic circumference can be measured and compared to normal values for gestational age. If gestational age is unknown, the ratio of thoracic to abdominal circumference can be used. A small thorax suggests a poor prognosis because chest restriction results in pulmonary hypoplasia and, at times, hydrops. Additional findings such as cleft lip, cardiac, and renal anomalies help narrow the differential diagnosis.

Figure 12-21 Infantile polycystic kidney disease. Coronal image of a 24-week fetus demonstrates bilateral enlarged echogenic kidneys (arrows). Severe oligohydramnios is present.

When there is a positive family history of a skeletal dysplasia, accurate prenatal diagnosis is possible. When a skeletal abnormality is noted incidentally, a precise diagnosis is more difficult. Fetal radiographs help confirm a diagnosis if fractures or joint calcifications are identified. Additional biochemical testing or karyotyping is useful. Because dysplasias may progress with time (e.g., achondroplasia and osteogenesis imperfecta), serial sonograms are useful for assessment of skeletal growth in cases at risk

P.179

(105). The potential development of polyhydramnios and/or hydrops should also be noted. Differentiating intrauterine growth retardation or constitutional short stature from a true dysplasia is more difficult in the third trimester. Assessment of fetal well-being including the biophysical profile and umbilical arterial flow patterns aids in establishing the correct diagnosis.

Figure 12-22 Osteogenesis imperfecta type III. **A:** Longitudinal image of a fetal thigh at 38 weeks of gestation demonstrates a short, bowed femur (cursors). **B:** Radiograph after delivery confirms the presence of short bowed femurs, tibia, and fibula bilaterally.

DETECTION OF FETAL ASPHYXIA

Fetal asphyxia is a common cause of fetal injury or death. Fetal asphyxia is a spectrum of conditions ranging from transient episodes of hypoxemia to sustained hypoxemia with resultant metabolic acidosis. There are diverse signs of asphyxia with multiple organs potentially affected and a wide range in severity, duration, and chronicity. When asphyxia develops, the fetus redistributes cardiac output from nonvital organs (lung, kidney, skeleton) to vital organs (brain, adrenals, and myocardium). This protective redistribution is reflexive, resulting from hypoxemic or acidemic stimulation of aortic body chemoreceptors (23). When sustained, redistribution can be profound. Diminished amniotic fluid production develops as a result of decreased urine production. Oligohydramnios further endangers the fetus because the umbilical cord is more at risk for compression, especially during uterine contractions. Cerebral asphyxia results in alterations in biophysical activities and responses. It is unclear whether increasing degrees of hypoxemia cause progressive loss of a biophysical function or if all functions are lost simultaneously. Fetal breathing has been noted to disappear early, whereas fetal movements disappear only with more severe disease (106,107).

Identification of an asphyxiated fetus is important because emergency delivery may improve outcome. Acute fetal asphyxia is rare except in cases of cord prolapse or placental abruption. These obstetric complications can be recognized sonographically and suggest appropriate intervention (108). Unfortunately, most asphyxiated fetuses exhibit both subacute and chronic signs of asphyxia. The fetus suffering from uteroplacental insufficiency typically has intermittent hypoxemic episodes induced during episodes of uterine contraction. Between these periods, the fetus can be normally oxygenated or demonstrate minimal compensated hypoxemia. Signs of hypoxemia thus depend on the duration, progression, and frequency of hypoxemic episodes.

The biophysical signs of asphyxia may be acute, such as loss of breathing movements and heart rate reactivity, or they may be chronic, such as oligohydramnios. Biophysical responses will change during hypoxemic episodes. Experiments in fetal lambs have demonstrated a decrease in fetal breathing and gross movements during hypoxemia (109,110). Fetal muscle tone and heart rate response to movement (i.e., accelerations) also decrease during hypoxemia (111). Maternal depressant medication and fetal cerebral anomalies can alter fetal biophysical activities, so these causes should be excluded. Ultrasound findings of chronic effects of intermittent hypoxemia include intrauterine growth retardation. Oligohydramnios should be considered a sign of fetal asphyxia unless renal abnormalities or premature rupture of membranes is identified (22).

Fetal Biophysical Profile

Monitoring fetal activity and its responses has altered the practice of perinatology (112,113). Any fetus at risk for uteroplacental insufficiency is a candidate for fetal evaluation in the third trimester. The first electronic fetal heart rate evaluation developed was the contraction stress test (CST), which relies on the fetal heart rate response to uterine contractions. The test records the fetal heart response as contractions are induced with oxytocin. If no fetal decelerations are recorded, uteroplacental function is considered normal. Disadvantages include the need to administer oxytocin intravenously and the length of the examination (average time of 90 minutes) (114).

The nonstress test (NST) evaluates fetal heart rate acceleration in response to fetal movement. As with a negative CST, a reactive NST is predictive of intrauterine survival for approximately 7 days subsequent to the test. This test has become popular because it requires relatively little time, cost, and technical skill (115). Reproducibility of NST interpretation, however, is problematic (116). Past acute asphyxial events are not excluded solely with a NST, and nonreactive patterns may exist for benign reasons.

The differentiation of the normal from the compromised fetus may be most accurate when several fetal and environmental parameters are evaluated together. Manning proposed the combined use of five ultrasound-monitored fetal variables to assess risk of asphyxia to reduce both false-positive and false-negative results. These include fetal breathing movements, gross body movements, tone, amniotic fluid volume, and heart rate reactivity (117). Each variable is evaluated according to tested criteria, and they are assigned scores of 2 when normal and 0 when abnormal (Table 12-2). Observation of each variable is continued until normal criteria are met or 30 minutes of continuous observation has been completed. The total score, termed the biophysical profile score (BPS), is an accurate method of differentiating if a fetus is normal or compromised (Table 12-3). Manning et al. reported that in a series of over 19,000 pregnancies, there was a false-normal test rate of approximately one per 1,000, with more than 97% of pregnancies tested having normal test results (118). Clinical studies from other centers have reported similar results with this method (119). In a follow up study, Manning and associates reported on 493 fetuses in which BPS were performed just before umbilical venous blood pH values were obtained via cordocentesis. A BPS of zero was associated with significant fetal acidemia, whereas scores of 8 or greater were associated with a normal pH (120). A score of 6 was a poor predictor of abnormal outcome, but a decrease from a score of 2 to 4 to a score of zero was an accurate predictor of abnormal outcome. In a similar study, for each of the four acute variables of the BPS, a substantial difference in mean umbilical venous pH was noted for the normal and abnormal results (121). Manning and associates prospectively studied the incidence of cerebral palsy in 22,336 high-risk pregnancies managed with serial BPS compared with 30,224 low-risk pregnancies that did not receive antepartum testing. Cerebral palsy (CP) diagnosed by 3 years of age was significantly associated with a low BPS. Incidence of CP was 0.8 per 1,000 when the BPS score was normal (10/10) and 250 per 1,000 when the BPS was very abnormal (0/10) (122).

TABLE 12-2 BIOPHYSICAL PROFILE SCORING: TECHNIQUE AND INTERPRETATION

Biophysical Variable	Normal (score 2)	Abnormal (score 0)
FBMs	At least one episode of FBM of at least 30-sec duration in a 30-min observation period	Absent FBM or no episode of ≥ 30 sec in 30 min
Gross body movement	At least three discrete body or limb movements in 30 min (episodes of active continuous movement are considered a single movement)	Two or fewer episodes of body or limb movements in 30 min
Fetal tone	At least one episode of active extension with return to flexion of fetal limb(s) or trunk; opening and closing of hand considered normal tone	Either slow extension with return to partial flexion or movement of limb in full extension or absent fetal movement
Reactive FHR	At least two episodes in 30 min of FHR acceleration of ≥ 15 bpm of at least 15-sec duration associated with fetal movement	Less than two episodes of acceleration of FHR or acceleration of < 15 bpm in 30 min
Qualitative AFV	At least one pocket of AF that measures at least 2 cm in two perpendicular planes	Either no AF pockets or a pocket < 2 cm in two perpendicular planes

AF, amniotic fluid; AFV, amniotic fluid volume; bpm, beats per minute; FBM, fetal breathing movement; FHR, fetal heart rate.

From Manning FA, Morrison I, Lange IR, et al. Fetal assessment based on fetal biophysical profile scoring: experience in 12,620 referred high risk pregnancies. I. Perinatal mortality by frequency and etiology. *Am J Obstet Gynecol* 1985;151:343, with permission.

Because the BPS is labor intensive, abbreviated screening tests have been evaluated. When normal, the four ultrasound monitored variables appear equal to that achieved by the addition of the NST component. The NST should be

(123). Provided amniotic fluid volume is normal, a BPS of 8 to 10 by whatever combination can be considered normal. All equivocal or abnormal BPS results should be based on a complete assessment including a NST (124).

TABLE 12-3 BIOPHYSICAL PROFILE SCORING: MANAGEMENT PROTOCOL

Score	Interpretation	Management
10	Normal infant, low risk for chronic asphyxia and patients over 42 weeks of gestation	-Repeat testing at weekly intervals; repeat twice weekly in diabetics
8	Normal infant, low risk for chronic asphyxia-diabetics and patients over 42 weeks of gestation;	-Repeat testing at weekly intervals; repeat testing twice weekly in oligohydramnios is an indication for delivery
6	Suspicion of chronic asphyxia	Repeat testing in 4–6 hours; deliver if oligohydramnios present
4	Suspicion of chronic asphyxia -weeks of gestation and L/S ^a <2, repeat test in 24 hrs;	-If past 36 weeks of gestation and favorable, deliver; if less than 36 repeat score £4, deliver
0-2	Strong suspicion of chronic asphyxia regardless of gestational age	-Extend testing time to 120 min; if persistent score £4, deliver

^a L/S, lecithin-sphingomyelin ratio.

Biophysical evaluation should be performed in patients with recognized high-risk factors. It allows for accurate differentiation of the normal fetus from the compromised one, information crucial in the timing of intervention. The variables used in the fetal BPS were selected because of ease and rapidity of measurement. Additional variables such as swallowing, fine hand movement, rapid-eye-movement state, peristalsis of fetal gut, urine output, and umbilical vessel flow rates may be found to add to the more precise evaluation of the fetal condition (125).

DOPPLER ASSESSMENT OF BLOOD VELOCITIES IN UMBILICAL AND FETAL VESSELS

Doppler ultrasound velocimetry can provide the clinician with important information on the hemodynamics of various vascular regions. Flow waveforms provide important information 12 through 40 weeks gestation from maternal vessels, placental circulation, and fetal systemic vessels. Gestational age-related reference values have been established for maternal uterine and arcuate artery, umbilical artery, fetal descending aorta, and fetal cerebral, renal, and femoral arteries (126). Values are obtained by directing an ultrasound beam toward a vessel and recording the frequency shift (Doppler effect) in the returning echoes. The Doppler shift principle states that echoes returning from moving structures are altered in frequency, and the amount of shift is directly proportional to the velocity of the moving structure. The frequencies of echoes returning from blood moving toward the transducer are increased, whereas the frequencies of echoes returning from blood moving away from the transducer are decreased. This method may not accurately measure velocity, but it does accurately evaluate the relative resistance to flow (127). The frequency spectrum can be analyzed by comparing the systolic to diastolic flow velocities. There are several different ratios for measurement of flow impedance. These include the difference between peak systolic and diastolic flow velocity over the mean flow velocity (pulsatility index), the difference between peak systolic and diastolic flow over the peak systolic flow (resistive index), and the ratio of the peak systolic to diastolic flow (S/D ratio). All indices are independent of the angle of insonation.

Measurement of flow velocity waveforms in the uterine artery, which depicts maternal vascular effects of the invading placenta, has been shown to be a method for early recognition of the pregnancy at risk for preeclampsia and IUGR (128,129). Uterine arterial remodeling occurs following successful placentation. Prepregnancy, uterine arteries show high resistance, elastic recoil with early diastolic notches and low diastolic flow. Successful placental invasion removes intimal muscle with increasing diastolic flow and loss of elasticity (130). Indices decrease as term approaches, with diastolic velocity increasing with advancing gestation. Fetal growth retardation has been reported when indices increase or notching in the waveform at end-systole develops at 22–24 weeks gestation (130,131). Uterine flow velocity waveforms are useful in predicting the frequency and severity of preeclampsia and intrauterine growth retardation (128,129,130,131). A major clinical obstetric application has been in the measurement of umbilical arterial flow using the S/D ratio (Fig. 12-23). In a normal pregnancy, the placental resistance declines slowly with advancing gestational age. The umbilical artery peak systolic flow velocity gradually decreases although diastolic flow velocity increases. Thus, the umbilical artery S/D ratio declines with advancing gestational age and should be less than 3 after 30

weeks of gestation (132). In growth-retarded fetuses and fetuses developing intrauterine distress, the umbilical artery blood velocity waveform changes as placental vascular resistance increases.

P.182

Abnormalities are progressive with reduction, loss, and finally reversal of diastolic flow. Absent or reversed end-diastolic flow (AREDV) is associated with a high risk of morbidity and mortality. Studies have compared the prediction of fetal acidosis by Doppler and cord blood gases. A statistically significant correlation has been found between an increased umbilical S/D ratio and fetal hypoxia particularly when diastolic blood flow is absent or reversed (133). In the preselected population of high-risk pregnancies, this method has a high predictive value regarding diagnosing fetal compromise and can be used for monitoring fetal health (128,134,135). If an abnormal umbilical velocimetry is identified in an SGA fetus, fetal heart rate variability should be tested. Fetuses that remain normal after a nonstress test have a low morbidity and can be closely followed (136,137).

Figure 12-23 Umbilical artery velocimetry. S, systolic velocity; D, diastolic velocity. Note S/D ratio of approximately 3.

Applied as a screening test in an unselected pregnant population, umbilical velocimetry has currently not been found to be cost-effective (138). A significant change in indices does not develop until more than 60% of the terminal placental arteries are obliterated (129). On the other hand, in preselected populations of high-risk pregnancies, Doppler of the umbilical artery has a high predictive value regarding diagnosing fetal compromise (135). These abnormal Doppler velocities are associated with higher mortality and morbidity in the neonatal period. Long term follow-up studies have shown an association between the abnormal intrauterine umbilical and fetal blood flow and subsequent postnatal neurodevelopmental impairment including mental retardation and severe motor impairment (139,140,141). Absent diastolic flow velocity of the umbilical artery has been noted in up to 25% of fetuses with anomalies, typically trisomy 13 or 18 (136). Because abnormal velocimetry may indicate a chronic fetal abnormality and not acute distress, delivery should not be undertaken based on umbilical artery Doppler velocimetry alone (130,137). In the fetus with IUGR and equivocal umbilical blood flow studies, Doppler studies of fetal systemic vessels can be useful.

The fetus with an abnormal umbilical artery velocimetry will redistribute blood flow detectable as vasodilation of the main arteries of the fetus including the heart and brain (23). Measurable fetal flow velocities include the middle cerebral, descending aorta, renal arteries and ductus venosus (142,143). These measures provide a means of assessing the distribution of fetal blood flow and can be useful in assessing the fetal cardiovascular adaptive responses to chronic hypoxemia. Doppler studies of the fetal circulation in intrauterine growth retardation and hypoxia have demonstrated a compensatory redistribution of arterial blood flow with increased flow to the brain and myocardium with decreased flow to the periphery (144,145). Redistribution of cardiac output reflects rising placenta resistance and results in "brain sparing" when cerebrovascular dilatation occurs (130).

Doppler waveforms of the middle cerebral artery (MCA) can be obtained at the level of the circle of Willis with a high degree of reproducibility. Normally, the MCA impedance decreases with advanced gestational age but remains higher than that of the umbilical artery (144). Fetal brain sparing during hypoxia is characterized by increase in diastolic and mean blood flow

velocity in the MCA. If vasodilation of the MCA is lost, the fetus will begin to enter the acidotic stage. At term, evidence of fetal hemodynamic redistribution may exist in the presence of normal umbilical artery indices, so ratios such as the MCA/uric acid (UA) ratio can be useful. Normal cerebral to placental resistance ratio (CPR) is typically greater than 1 (146,147,148).

In the compromised IUGR fetus, precordial veins can illustrate fetal cardiac function. Which venous waveforms provide the best data are still being investigated (130,131). The ductus venosus regulates venous control, is a conduit of right atrial retrograde pulse waves, and is responsive to changes in oxygenation. In fetuses compromised by anemia or hypoxia, changes in pulsatile venous flow are being evaluated

(130,131,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34,35,36,37,38,39,40,41,42,43,44,45,46,47,48,49,150). When umbilical artery flow becomes abnormal, further evaluation of the fetal systemic Doppler may improve analysis of fetal distress. Doppler studies of fetal intracranial arteries and ductus venosus may thus result in improved timing of intervention to minimize morbidity (145,146,147,148,149).

SUMMARY

Ultrasonography has profoundly influenced the practice of perinatal medicine. Doppler and fetal MRI have also become useful adjuncts in the evaluation of the fetus. The ability to distinguish the normal from abnormal pregnancy has many applications. Serious complications such as developmental anomalies, intrauterine asphyxia, and growth

P.183

abnormalities are now identified with greater frequency and accuracy as a result of these advances. Recognition of high-risk conditions such as placental abruption and cord prolapse and more chronic conditions such as intrauterine asphyxia allow for optimal preventive care. The improved accuracy in identifying fetal anomalies by ultrasound and MRI has increased the potential for prenatal intervention and optimizing the care and delivery of the fetus.

Chapter 13

Fetal Therapy

Mark I. Evans

Mark P. Johnson

Alan W. Flake

Yuval Yaron

Michael R. Harrison

Over the past three decades, physicians from multiple specialties have developed numerous methods for the diagnosis of structural and physiological fetal abnormalities (1,2). When they are severe or lethal, pregnancy termination is viewed by many as a reasonable consideration. For couples in countries that permit its availability and in cultures in which the fetus does not have more rights than the mother, a variable portion of patients chose this option (3,4). With more moderate fetal anomalies, obstetrical care can be modified to optimize outcomes and prevent secondary complications. In some instances, prenatal treatments of the underlying problem have become possible. In general, structural malformations are more logically approached with surgery, although metabolic disorders may benefit from pharmacological or genetic therapies (2).

Fetal therapy has evolved into four major areas: open surgical approaches, "closed" endoscopic surgical approaches, pharmacological therapy, and stem cell/gene therapy. Advances in the field have been characterized by alternating exuberance at spectacular successes, but also periods of intense frustration at technical challenges to be overcome to bring new approaches on line. "Moving goal posts" have also been a common problem, secondary to improvements in ancillary care that keep raising the bar to show intervention as having a positive benefit to risk ratio.

Even after four decades since the first transfusions by Lilley, the single most misunderstood and continuous issue about fetal therapy continues to be "why before and not after birth." There is no one single answer; rather there are multiple disorder-specific considerations. If something cannot be treated safely postnatally, then there is generally justification for prenatal intervention. However, for many conditions profound and irreparable damage occurs before birth, making fetal intervention the best or sometimes only way to ameliorate the damage. Some procedures have been quite rare. Others are more common. The expectation is that with improvements and increasing utilization of prenatal diagnosis, more women will choose to consider the opportunities to treat fetuses before birth.

SURGICAL THERAPY

In Utero "Closed" Fetal Surgery

The most successful *in utero* fetal surgery has been for the evaluation and treatment of obstructive uropathy (5,6). Lower urinary tract obstruction (LUTO) is a heterogeneous entity that affects 1:500–8,000 newborn males (5,6,7,8). Posterior urethral valves or urethral atresias are the most common causes, although stenosis of the urethral meatus, anterior urethral valves, ectopic insertion of a ureter and tumors of the bladder have also been observed. Massive distention of the bladder can be seen with compensatory hypertrophy and hyperplasia of the smooth muscle within the bladder wall. Loss of compliance and elasticity, and poor postnatal function generally require postnatal surgical reconstruction (9). Elevated intravesicular pressures prevent urine inflow from

the ureters, eventually distortion of the ureterovesical angles contributes to reflux hydro-nephrosis (5,6,7). Progressive pyelectasis and calyctasis compress the delicate renal parenchyma within the encasing serosal capsule, leading to functional abnormalities within the medullary and eventually the cortical regions (5,6,7,8,9,10). Focal compressive hypoxia likely contributes to the progressive fibrosis and perturbations in tubular function resulting in urinary hypertonicity. Obstructive processes can eventually lead to type IV cystic dysplasia and renal insufficiency (8,9).

The effects extend beyond the genitourinary tract. Progressive oligo/anhydramnios leads to compressive deformations as seen in Potter sequence, including extremity contractures, facial dysmorphism, and disruptions of abdominal wall musculature, as in prune belly. Absence of normal amniotic fluid volume profoundly impedes pulmonary growth and development. Constant compressive pressure on the fetal thorax leads to restriction of expansion of the chest through normal physiological "breathing movements." Babies born with LUTO mostly die because of pulmonary complications. They do not live long enough to die of renal failure.

Figure 13-1 Oligohydramnios and dilated bladder in a fetus at 17 weeks with good electrolytes.

P.187

Sonographic findings in LUTO include dilated and thickened walls of the bladder, hydronephrosis, and oligohydramnios (Fig. 13-1). Urethral strictures or atresia, urethral agenesis, megalourethra, ureteral reflux, and cloacal anomalies may be present and have a very similar appearance on ultrasound. The typical "keyhole sign" of proximal urethral dilation is secondary to urethral obstruction present in posterior urethral valves or atresia. However, the precise diagnosis can only be made after birth (9).

The prenatal evaluation and management of fetuses with the sonographic findings of LUTO require multiple steps (5,6,7,8). Ruling out other congenital anomalies such as cardiac and neural tube defects is necessary before intervention can be considered.

Karyotyping is essential to confirm a normal male chromosomal status. Most are isolated problems, but the incidence of aneuploidy is higher than the general population. Female fetuses, however, almost always have more complex syndromes of cloacal malformations and do not benefit from *in utero* shunt therapy. Because of the presence of oligo/anhydramnios, we commonly obtain karyotypes by transabdominal chorionic villus sampling, which gives reliable results within several days during which the remainder of the prenatal evaluation is underway. Fluorescence in situ hybridization is now commonly used to get rapid status of chromosomes 13, 18, 21, X & Y (11,12).

Essential to the prenatal workup is the evaluation of underlying renal status in the fetus. Over the past 15 years, a multicomponent approach has developed for the analysis of fetal urine that evaluates proximal tubular and possible glomerular status using sodium, chloride, osmolality, calcium, β -2 microglobulin, albumin, and total protein concentrations (6,8). It has been shown to be significantly improved by sequential samplings at 48- to 72-hour intervals to be useful approach. The degree of impaired renal function and damage with the extent of urinary hypertonicity and proteinuria can then be directly correlated. The ability to counsel patients about the renal status of their fetus and the long-term prognosis has been dramatically improved as a result.

Figure 13-2 Vesicoamniotic shunt with the proximal portion lying within the fetal bladder although the distal portion lies within the amniotic fluid space allowing diversionary draining of urine into the appropriate space.

Vesicoamniotic catheter shunts bypass the urethral obstruction diverting the urine into the amniotic space to allow appropriate drainage of the upper urinary tract and prevention of pulmonary hypoplasia and physical deformations (Fig. 13-2). In fetuses with isolated LUTO, a normal male karyotype, and progressively improving urinary profile that meet threshold parameters (Table 13-1), intervention has been very successful in salvaging fetuses using percutaneous vesicoamniotic shunt therapy.

Subsequent experience in humans has been widely variable and appears to be related to the extent of prenatal evaluation prior to shunt placement, and the etiology of obstruction. Freedman and associates found that prune

belly infants, without complete urethral obstructions have very good renal outcomes following vesicoamniotic shunt therapy (9). They also found significant improvement in survival and renal function in infants with posterior urethral valves treated by shunting. However, many such children develop mild-to-moderate renal insufficiency at birth and several of these have progressed to renal failure, requiring dialysis, and transplantation. The worst prognosis appears to be for those with urethral atresia. There have been survivors, including some with urethral atresia, following early shunt intervention. Animal studies have indicated that early onset, complete obstructions result in more severe renal damage than later onset or partial obstructions. Such data emphasizes the necessity of early diagnosis, evaluation, and intervention to achieve the best outcomes in such

cases.

TABLE 13-1 UPPER THRESHOLD VALUES FOR SELECTING FETUSES THAT MIGHT BENEFIT FROM PRENATAL INTERVENTION FOR URINARY OBSTRUCTION

Sodium	<100 mg/dl
Chloride	<90 mg/dl
Osmolality	<190 mOsm/L
Calcium	<8 mg/dl
β-2 microglobulin	<6 mg/L
Total protein	<40 mg/dl

Data from our experience over the past 15 years suggest that patients having bladder shunts had a 91% survival, but that long-term renal function was not guaranteed. Just under half had “normal renal function,” and about a quarter had mild impairments. The experience depended largely on the exact etiology of the disorder with posterior urethral valve having the best outcomes and urethral atresia the worst. Our experience suggests that close pediatric urological/renal function assessment is essential to maximize outcomes. The Paris group has found, consistent with our experience, that about 25% of children had serious, long-term renal impairments and about 15% actually developed end-stage renal disease requiring trans-plant (10).

Although vesicoamniotic shunting has certainly improved survival and renal function in cases of early obstructive uropathy, complications of this procedure remain unacceptably high. We found in the eighties and nineties that in 40% of our cases, the shunts became physically displaced into the amniotic or intraperitoneal space, or have become blocked causing loss of drainage function and necessitating replacement. On balance, intervention for LUTO has clearly saved fetuses, who would otherwise have surely died. Many have normal to moderately impaired renal function. A carefully balanced approach in counseling is required for patients to determine what is right for them.

Other Shunt Procedures

Shunting was attempted for obstructive hydrocephalus, in the late 1970s (13). The results were almost uniformly dismal. Most of the patients operated on were, in retrospect, very poor candidates for intervention. Many had multisystem syndromic disorders, including aneuploidy, and hopeless congenital anomalies such as holoprosencephaly.

Ventriculoamniotic shunts were abandoned the early eighties. However, with a better understanding of the poor natural history of the anomaly, and improved, more accurate diagnostic techniques, there may eventually be some limited applications for prenatal neurological shunting. It may eventually be useful in cases of early onset, isolated, progressive obstructive hydrocephaly.

The other use of percutaneously placed shunts has been for thoracic abnormalities (14,15). The macrocystic form of congenital cystic adenomatoid malformation (CCAM) can present with a very large intrathoracic mass with a dominant macrocyst which causes cardiac and mediastinal shifts. Potential hemodynamic changes can result along with pulmonary compression and risk of lung hypoplasia. Such dominant cysts can be approached using pleuroamniotic shunts to chronically drain these structures, reducing their volume, and diminishing their space occupying effects within

the thoracic cavity.

Isolated pleural effusions can enlarge, causing hemodynamic changes and onset of generalized hydrops and pulmonary compression. The mass interferes with normal lung development increasing the risk of hypoplasia. Small, unilateral effusions generally do not warrant intervention, but cannot be ignored as they have the potential for rapid progression (15).

As with all fetal interventions, prenatal evaluation prior to intervention is critical for appropriate case selection. Seemingly isolated effusions may be associated with cardiac malformations, aneuploidy, anemia, or an infectious process. Thoracoamniotic shunting is effective in carefully evaluated cases when the risk of pulmonary hypoplasia from large effusions early in gestation is present, or early signs of progressive hydrops (unilateral or bilateral effusion, skin or scalp edema, ascites, pericardial effusion) appear. Fetal anemia, per se, is not an indication for thoracoamniotic effusion shunting. Hydropic changes will usually resolve with timely fetal transfusion therapy. By the time the fetus develops significant ascites, the prognosis even with successful shunt intervention, diminishes considerably (15). However, several cases with suddenly progressive pleural effusions and onset of generalized hydrops have been treated with complete resolution of all hydropic complications and normal postnatal infants.

Open Surgery

Open fetal surgery has been performed for a limited number of indications for nearly two decades (3). There are appropriate concerns for maternal risks, rigorous selection criteria, and somewhat frustrating results. There has been continuing innovation and development of instruments and techniques, motivated by the clinical necessity to improve the safety of open fetal surgery for both the fetus and the mother, which have turned the field upside down in many instances.

Congenital Diaphragmatic Hernia

The surgical approach to congenital diaphragmatic hernia (CDH) has evolved considerably since the first attempted CDH repair in 1986 and the first success in 1989 (16,17,18). Definitive repair of CDH by reduction of viscera from the chest, diaphragmatic patch placement, and abdominal silo construction (to reduce intraabdominal pressure) satisfied the desire for a single step approach but had unacceptable

P.189

mortality, particularly after a clinical trial showed that open fetal repair was no better than postnatal repair when the liver was herniated into the chest (19,20). The definitive repair was then abandoned and *in utero* tracheal occlusion took its place (Fig. 13-3) (20,21,22,23,24,25,26).

Figure 13-3 Surgical isolation of the fetal trachea prior to placement of hemoclips in a tracheal occlusion procedure for congenital diaphragmatic hernia. (See color plate)

Tracheal occlusion produces increased lung size through accumulation of pulmonary secretions. The herniated viscera are reduced from the chest and therefore decrease the risk for lung hypoplasia. The technique of achieving reliable, complete and reversible tracheal occlusion has evolved. Initially, it could only be accomplished by open fetal surgery and fetal neck dissection (taking care to avoid the recurrent laryngeal nerves) and placement of occlusive hemoclips. Then, a fetoscopic technique was developed to accomplish the same neck dissection and tracheal clip (the Fetendo Clip Procedure) (24). While successful, it proved difficult, with a significant learning curve. Attempts to simplify the procedure by developing an appropriate polymer to use as a tracheal plug inserted through the fetal mouth have been generally unsuccessful. Unless there was complete occlusion, the pulmonary secretions would leak, thereby defeating the purpose of the plug. Finally, a relatively simple technique was developed in which a fetoscope passed through a single port is advanced into the fetal trachea (fetal bronchoscopy) and a detachable silicone balloon is inflated to occlude the trachea.

CDH has a prototype of rapid changes in technology, further clouding any simple attempts to understand the role for fetal surgery. With increasing sophistication of the surgical approach and concomitant improvements in neonatal care using extracorporeal membrane oxygenation, it was impossible to accurately determine the relative benefits of each approach without a prospective, randomized comparison that held all other details constant. Thus, after much debate, a randomized trial of surgery for CDH vs. optimal postnatal care was funded by National Institute of Child Health and Human Development (NICHD) (21). The principal component of the trial was that patients in the postnatal care arm (control group) would receive the same neonatal care by the same center as the surgical arm.

It was originally expected that patients having the surgery would have a survival rate of about 70%. The best data on controls showed survivals of about 35%. The surgically treated patients achieved the expected survival rate. However, by having the controls cared for at the same tertiary specialty centers as the surgical group, survival in the controls was essentially the same as the surgical group. Therefore, the trial was stopped prematurely. Such data show dramatically the principle of "the moving target" and how our use of technology must continually adapt to changing conditions (27).

Congenital Cystic Adenomatoid Malformation

CCAM is a space occupying congenital cystic lesion of the lung. Hydrops evolves by causing

mediastinal shift which compromises venous return to the heart. When fetuses with CCAM develop hydrops, the fetal mortality approaches 100% (Fig. 13-4) (28,29,30). Fetal resection of CCAM can reverse hydrops and has improved survival dramatically (17). The fetal operation is performed by exposure of the arm and chest wall on the side of the lesion through the maternal hysterotomy. A large muscle sparing thoracotomy is performed through the midthorax of the fetus and the lobe containing the CCAM is isolated. The attachments of

P.190

the lobe to adjacent lung tissue are bluntly divided and the lobar hilum is divided by use of a stapler or a bulk ligature. During the remainder of the pregnancy, the remaining normal lung shows compensatory growth to fill the space left following removal of the mass.

Figure 13-4 Microcystic congenital cystic adenomatous malformation (microcystic) with beginnings of hydrops.

Sacroccocygeal Teratoma

Fetal sacrococcygeal teratoma (SCT) arises from the presacral space, which may grow to massive proportions and in some fetuses induces high output congestive heart failure from tumor vascular steal. Fetal SCT with high output physiology and associated placentomegaly or hydrops uniformly results in fetal demise (Fig. 13-5) (31,32). The pathophysiological rationale for fetal surgery is to ligate the vascular connections to the tumor, remove the vascular shunt, and reverse the high output physiology. The fetal operation is performed by exteriorization of the fetal buttocks with attached tumor (31). The head, torso, and lower extremities of the fetus are kept *in utero* if at all possible. Since the tumor can sometimes be larger than the fetus, significant loss of uterine volume occurs, and the uterus may contract increasing the risk for placental abruption, placental dysfunction because of compression, or postoperative preterm labor. Once exteriorized, the anus is identified, and the fetal skin is incised posterior to the anorectal sphincter complex to avoid injury to the continence mechanism. A tourniquet is then applied at the base of the tumor and brought down gradually as the tumor is finger fractured down to its vascular pedicle. The vascular pedicle is then ligated or stapled depending on the width of the pedicle. The entire fetal procedure can be performed in less than 15 minutes with minimal blood loss. Because of the increase in afterload following ligation of the low resistance tumor circuit, the fetal hemodynamic status must be monitored by fetal echocardiography during and in the immediate period following the ligation.

Figure 13-5 Sacroccocygeal teratoma in a fetus. (See color plate)

Neural Tube Defects

Neural tube defects (NTDs) result from abnormal closure of the neural tube which normally occurs between the third and fourth week of gestational age. The etiology is complex, with both genetic and environmental factors involved. There are historical data in humans suggesting increased NTD frequencies in subjects with poor dietary histories or with intestinal bypasses. Analysis of recurrence patterns within families and of twin-twin concordance data provides evidence of a genetic influence in nonsyndromal cases. However, factors such as socioeconomic status, geographic area, occupational exposure, and maternal use of antiepileptic drugs are also associated with variations in the incidence of NTDs (33). In 1980, Smithells and associates suggested that vitamin supplementation containing 0.36 mg folate could reduce the frequency of NTD recurrence by sevenfold (33,34,35). For almost a decade, there has been a great deal of controversy regarding the benefit of folate supplementation for the prevention of NTDs³ (36,37,38,39). In 1991, a randomized double-blinded trial designed by the Medical Research Council Vitamin Study Research Group demonstrated that preconceptual folate reduces the risk of recurrence in high risk patients (40). Subsequently, it was shown that preparations containing folate and other vitamins also reduce the occurrence of first time NTDs (41). In response to these findings,

P.191

guidelines were issued calling for consumption of 4.0 mg/day folic acid by women with a prior child affected with an NTD, for at least 1 month prior to conception through the first 3 months of pregnancy. Additionally, 0.4 mg/day folic acid is recommended to all women planning a pregnancy to be taken preconceptually. The data on NTD recurrence prevention is now very well established, and has become routine practice for high-risk cases. As of January 1998, the United States Food and Drug Administration have mandated that breads and grains be supplemented with folic acid. The impact of food fortification with folic acid on NTDs birth prevalence during the years 1990-1999 was evaluated by assessing birth certificate reports before and after mandatory fortification

(42). It was found that the birth prevalence of NTDs reported decreased by 19%. It is important to note that the continuing decline in NTDs rates are estimated to be as a result of the introduction and increased utilization of prenatal diagnosis in addition to the recommendation for multivitamin use in women of childbearing age and the population-wide increases in blood folate levels because food fortification was mandated (43). Recently, Evans and associates have shown a 32% drop in high maternal serum alpha-fetoprotein (MSAFP) values in the United States comparing 2000 values versus 1997 before the introduction of folic acid supplementation (44).

Folate plays a central part in embryonic and fetal development because of its role in nucleic acid synthesis mandatory for the widespread cell division that takes place during embryogenesis. Folate deficiency can occur because of low dietary folate intake or because of increased metabolic requirement as seen in particular genetic alterations such as the polymorphism of the thermolabile enzyme methyltetrahydrofolate reductase (MTHFR). However, evidence regarding its role in NTD is unsupported, except in certain populations, suggesting that these variants are not large contributors to the etiology of NTDs (45,46). Additional candidate genes other than MTHFR may be responsible for an increased risk for NTDs (47). It has recently been reported that methionine synthase polymorphisms are associated with increased risk for NTDs, that is not influenced by maternal preconception folic acid intake at doses of 0.4 mg/day (48). Other candidate genes include the mitochondrial membrane transporter gene UCP2 (49). Despite previous studies suggesting zinc deficiency to play a role in the etiology of NTDs (50,51), further studies were inconclusive (52,53). Because methionine deficiency may be involved in NTDs, it may be beneficial in NTD risk reduction (54). Preconception folic acid intake as a sole vitamin or as multivitamin supplementation reduces the risk of recurrence and first time NTDs.

Babies with meningomyeloceles have impaired lower motor function, loss of bowel, and bladder control. A significant percentage develop obstructive hydrocephalus, which requires ventriculoperitoneal shunting (55,56). Experience from the 1970s and 1980s showed that babies with meningomyelocele delivered atraumatically by cesarean section had a better level of motor function for the given level of anatomic defect, than those babies delivered through the vaginal canal (55). Such data suggest that compression and trauma to the cord in the delivery process can have permanent long-term sequelae to motor function. In theory, trauma to the spinal cord *in utero*, either from banging into the uterine wall or the toxic effects of the amniotic fluid in the third trimester, could be detrimental to the function of the spinal cord. Traditional dogma held that the pathogenesis of meningomyelocele was that an abnormally developed spinal cord, which did not engender the proper development of the bony spinal column, may not be the whole story. It is possible that the primary defect is in the bony spinal column, which exposes a presumptively undamaged spinal cord. The cord is then damaged by the toxic affects of amniotic fluid and trauma from the uterine environment and repeated contact with the uterine wall. Thus, the rationale for attempts to cover and protect the spinal cord in utero, to minimize the sequelae (57).

Three groups (58,59,60) have done most of the work in this area and have attempted to repair meningomyeloceles in utero, both as an open surgical procedure, and endoscopically, with the stated attempt to reduce long-term morbidity and mortality. The principal benefit of the surgery is likely secondary, i.e., a significant reduction in the number of babies requiring ventriculoperitoneal shunting for obstructive hydrocephalus (58,61). There is still much controversy surrounding the data (54). A randomized, prospective trial comparing fetal to postnatal neurosurgical closure began in 2003 but will take several years to be completed. A major milestone of this trial has been the agreement among the participating centers not to perform any cases outside the trial, and other centers around the country have agreed not to start programs until the trial is completed.

The Ex Utero Intrapartum Therapy Procedure

The ex utero intrapartum therapy procedure (EXIT) procedure is a modified cesarean delivery and

may be applied to deliver fetuses after fetal surgical procedures such as tracheal ligation, or for fetuses with difficult airway problems such as massive cervical teratomas or cystic hygromas (62,63). The most important component of the EXIT procedure is maintenance of uteroplacental perfusion until the fetal airway is secured and ventilation is established. In direct contrast to cesarean section in which uterine contraction for hemostasis is encouraged, uterine relaxation is maintained by deep general anesthesia. The fetal manipulations are then performed with maternal support via the placenta. Clips can be removed, chest masses removed, bronchoscopy performed, and stable airway access established in otherwise very difficult circumstances with this approach. Once the fetus is ready for transport to the nursery or adjacent operating suite following these preliminary steps, the cord is clamped, cut and the cesarean delivery completed.

P.192

ENDOCRINE DISORDERS

Adrenal Disorders

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia is actually not a single disorder but a group of autosomal recessive metabolic disorders, characterized by enzymatic defects in the steroidogenic pathway (64). A compensatory increase in adrenocorticotrophic hormone secretion leads to overproduction of the steroid precursors in the adrenal cortex resulting in adrenal hyperplasia. Excess precursors often are converted to androgens that may result in virilization of female fetuses. The phenotype is determined by the severity of the cortisol deficiency and the nature of the steroid precursors which accumulate proximal to the enzymatic block. The most common abnormality, responsible for greater than 90% of patients with congenital adrenal hyperplasia (CAH) is caused by a deficiency of the 21-hydroxylase (21-OH) enzyme. Other, less common causes for CAH, include deficiencies in 11 β -hydroxylase, 17 β -hydroxylase, and 3 α -hydroxysteroid-dehydrogenase. Reduced 21-OH activity results in accumulation of 17-hydroxyprogesterone (17-OHP) as a result of its decreased conversion to 11-deoxycorticosterone. Excess 17-OHP is then converted via androstenedione to androgens, the levels of which increase by as much as several hundred-fold (Fig. 13-6). The excess androgens cause virilization of the undifferentiated female external genitalia. The degree of virilization may vary from mild clitoral hypertrophy to complete formation of a phallus and scrotum. In contrast, genital development in male fetuses is normal. The excess androgens cause postnatal virilization in both genders and may manifest in precocious puberty (64).

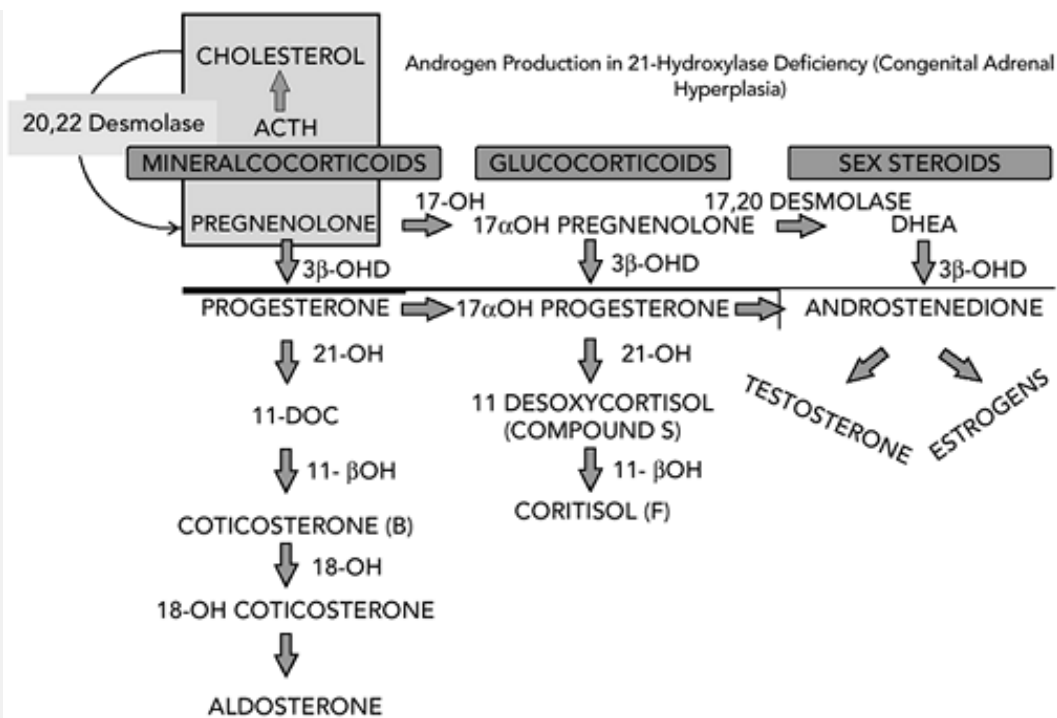

Figure 13-6 STEROIDOGENIC PATHWAY—Pathway of conversion from Cholesterol to Cortisol is vulnerable to enzymatic errors. Blockage at 21 hydroxylase leads to over production of 17 hydroxyprogesterone which ultimately leads to excess androgens that produce masculinization of the external genitalia.

The “classical” form of CAH involves a severe enzyme deficiency or even a complete block of enzymatic activity, which is associated in two-thirds to three-fourths with salt-loss that may be life-threatening. The classical form is easy to recognize in female newborns but may be overlooked in males, which may present at a later stage with severe dehydration and even demise. The “nonclassical” attenuated form of 21-OH deficiency results in partial blockade of the enzymatic activity and is usually clinically apparent as simple virilization in women only later in life. It is estimated to occur in about 3.5% in Ashkenazi Jews and about 2% in Hispanics (65). In the late seventies and early eighties, diagnosis of CAH was made on amniocentesis by the finding of elevated levels of 17-OHP in the supernatant. In the eighties, with the development of chorionic villus sampling (CVS) linkage based molecular diagnosis in the first trimester became available, because the gene for 21-OH was found to be linked to the human leukocyte antigen (HLA) complex on chromosome 6 (66). The gene for 21-OH (CYP21B) was later mapped, allowing direct mutation analysis in informative families (67).

It has been known for two decades that the fetal adrenal gland can be pharmacologically suppressed by maternal replacement doses of dexamethasone (68). Suppression can prevent masculinization of affected female fetuses in couples who are carriers of classical CAH. Evans, and associates were first to administer dexamethasone to a carrier

P.193

mother beginning at 10 weeks of gestation in an attempt to prevent masculinization (68). Serial maternal estriol and cortisol levels indicated that adrenal gland suppression had been achieved. The female fetus was born at 39 weeks gestation with normal external genitalia. A similar approach was employed successfully by Forrest and New (69,70). Differentiation of the external genitalia begins at about 7 weeks of gestation. Thus for a carrier couple, pharmacological therapy has to be initiated prior to diagnosis. Direct deoxyribonucleic acid (DNA) diagnosis or linkage studies are then performed by CVS in the first trimester and therapy is continued only if the fetus is found to be an affected female. Detailed inclusion criteria for treatment have been issued by the European Society for Pediatric Endocrinology and Wilkins Pediatric Endocrine Society (71).

Thyroid Disorders

Hyperthyroidism

Neonatal hyperthyroidism is rare with an incidence of 1:4,000 to 1:40,000/live births (72). Fetal thyrotoxic goiter is usually secondary to maternal autoimmune disease, most commonly, Graves' disease or Hashimoto's thyroiditis. As many as 12% of infants of mothers with a known history of Graves' disease are affected with neonatal thyrotoxicosis, which may occur even if the mother is euthyroid (73). The underlying mechanism is the transplacental passage of maternal IgG antibodies. In this case the antibodies, known as TSAb, are predominantly directed against the thyroid-stimulating hormone (TSH) receptor. Often in these cases, the fetal goiter is first diagnosed on ultrasound in patients with elevated thyroid stimulating antibodies. In some cases, fetal goiters are incidentally detected on routine ultrasonography. Others may be discovered in patients referred for scan because of polyhydramnios. Untreated fetal hyperthyroidism may be associated with a mortality rate of 12%-25% as a result of high-output cardiac failure (73).

Once the diagnosis of fetal hyperthyroidism is confirmed, fetal treatment should be initiated. Authors have attempted treating fetal hyperthyroidism with maternally administered antithyroid drugs. Porreco has reported maternal treatment of fetal thyrotoxicosis with propylthiouracil (PTU), which lead to a good outcome (74). The initial dose used was 100 mg p.o. three times a day, which was later decreased to 50 mg p.o. three times a day. A favorable outcome was shown using maternal methimazole to treat fetal hyperthyroidism in a patient who could not tolerate PTU (75). Hatjis also treated fetal goiterous hyperthyroidism with a maternal dose of 300 mg PTU (75). This patient however, required supplemental Synthroid to remain euthyroid. There was good fetal outcome in this case as well.

Hypothyroidism

Congenital hypothyroidism is relatively rare affecting about 1:3,000 to 1:4,000 infants (76). About 85% of the cases are the result of thyroid dysgenesis, a heterogeneous group of developmental defects characterized by inadequate amount of thyroid tissue. Congenital hypothyroidism is only rarely associated with errors of thyroid hormone synthesis, TSH insensitivity, or absence of the pituitary gland. Fetal hypothyroidism may not necessarily manifest in a goiter before birth because maternal thyroid hormones may cross the placenta. Congenital hypothyroidism presenting with a goiter can be found in only about 10%-15% of cases (77).

Fetal goiterous hypothyroidism is usually secondary to maternal exposure to thyrostatic agents such as PTU, radioactive I131, or iodide exposure used to treat maternal hyperthyroidism (78). Maternal ingestion of amiodarone or lithium may also cause hypothyroidism in the fetus. Finally, fetal hypothyroidism may follow transplacental passage of maternal blocking antibodies (known as TBIAb or TBII). Rarely it may be a result of rare defects in fetal thyroid hormone biosynthesis (72).

An enlarged fetal goiter may cause esophageal obstruction, polyhydramnios, leading to preterm delivery or premature rupture of membranes. Rarely, a goiter may even lead to high-output heart failure (78). A large fetal goiter can also cause extension of the fetal neck leading to dystocia. The effects of the fetal hypothyroidism itself may be devastating. Without treatment, postnatal growth delay and severe mental retardation may ensue. Even with immediate diagnosis and treatment at birth, long-term follow-up of children with congenital hypothyroidism has demonstrated that they have lower scores on perceptual-motor, visuospatial, and language tests (79).

In suspicious cases, an extensive maternal and family history should be obtained. In patients with a positive history, maternal thyroid hormone levels, and blocking immunoglobulin levels should be measured. Additionally, all women with a history of any thyroid disease (both hypothyroidism and

hyperthyroidism) are advised to have monthly fetal ultrasound scans to screen for fetal goiter, polyhydramnios, or fetal tachycardia (79).

Occasionally, fetal goiterous hypothyroidism may be identified by a routine ultrasound performed as a result of increased uterine size caused by polyhydramnios secondary to esophageal obstruction and impaired swallowing. Sometimes, a fetal goiter may incidentally be discovered on a routine scan. Before the advent of cordocentesis, amniotic fluid levels of TSH and free thyroxine were used as potential indicators of fetal thyroid function. However, these proved to be inconsistent (80). With cordocentesis, fetal thyroid status can be directly and accurately evaluated; fetal response to therapy can therefore be reliably measured using available appropriate nomograms for fetal serum levels of free T4, total T4, free T3, total T3, and TSH (81,82). In utero treatment was initially suggested by Van Herle and associates using i.m. injection of levothyroxine sodium (83). Subsequent studies however, have indicated that intraamniotic (IA) administration of thyroxine may be superior and can lead to resolution of the polyhydramnios as well. The dose of the

P.194

injected drug may be refined using the fetal thyroid profile in the amniotic fluid and the thyroid size (84). The doses commonly used for treatment range from 200-500 mg IA every week (23). With this regimen, fetal goiters have been shown to regress, the hyperextension of the fetal head have been shown to resolve and fetal and newborn TSH levels have normalized (84).

INBORN ERRORS OF METABOLISM

Methylmalonic Acidemia

The methylmalonic acidemias (MMA) are a group of autosomal recessive enzyme-deficiency diseases. Some cases are caused by mutations in the gene encoding methylmalonyl-coenzyme-A mutase. Others are a result of a defect that reduces the biosynthesis of adenosylcobalamin from vitamin B12. The disease has a wide clinical spectrum ranging from a benign condition to a fatal neonatal disease characterized by severe metabolic acidosis, developmental delay and biochemical abnormalities that include methylmalonic aciduria, long chain ketonuria, and intermittent hyperglycinemia. Neurological abnormalities may result from diminution of myelin content and of ganglioside *N*-acetylneuraminic acid in the cerebrum (85). Patients with defects in adenosylcobalamin biosynthesis may respond to administration of large doses of B12, which may enhance the amount of active holoenzyme (mutase apoenzyme plus adenosylcobalamin).

Ampola and associates first attempted prenatal diagnosis and treatment of a B12-responsive variant of MMA (86). Their patient previously had a child who died of severe MMA. In the subsequent pregnancy, amniocentesis at 19 weeks revealed an elevated methylmalonic acid level. Cultured amniocytes also demonstrated defective propionate oxidation and undetectable levels of adenosylcobalamin. When adenosylcobalamin was added, normal succinate oxidation and methylmalonyl-coenzyme-A mutase activity were noted, confirming that the fetus also suffered from MMA. Late in the pregnancy, cyanocobalamin (10 mg/day) was orally administered to the mother, only marginally altering maternal serum B12 level. They noted a slight reduction of maternal urinary methylmalonic acid excretion that remained several-fold above normal. At 34 weeks gestation, 5 mg of cyanocobalamin per day was administered intramuscularly. The maternal serum B12, level then rose gradually to more than sixfold above normal and was accompanied by a progressive decrease in urinary methylmalonic acid excretion. Maternal urinary methylmalonate was only slightly above the normal range when delivery occurred at 41 weeks. Amniotic fluid methylmalonic acid concentrations were three times the normal mean at 19 menstrual weeks and four times the normal mean at term, despite prenatal treatment. Postnatally, the diagnosis of methylmalonic acidemia was confirmed. The infant suffered no acute neonatal complications and

had an extremely high serum B12 level. Long-term postnatal management involved protein restriction but continuous B12 treatment was not required.

It is not clear whether *in utero* treatment actually resulted in an improved outcome but it is likely that correction of the biochemical abnormality in the fetus had some beneficial effect on fetal development. In a cohort of 8 children with MMA, Andersson and associates described congenital malformations, probably caused by prenatally abnormal cyanocobalamin metabolism (87). Growth was significantly improved in most cases after initiation of therapy postnatally and in one case microcephaly resolved. However, developmental delay of variable severity was always present regardless of treatment onset. These data suggest that prenatal therapy of MMA may be effective and perhaps ameliorate some of the prenatal effects. Evans and associates have documented the changing dose requirements necessary over the course of pregnancy to maintain adequate levels of B12. They sequentially followed maternal plasma and urine levels in a prenatal treated pregnancy (88).

Multiple Carboxylase Deficiency

Biotin-responsive multiple carboxylase deficiency is an inborn error of metabolism caused by diminished activity of the mitochondrial biotin-dependent enzymes (pyruvate carboxylase, propionyl-coenzyme-A carboxylase and 3-methylcrotonyl-coenzyme-A carboxylase). The condition may arise from mutations in the holocarboxylase synthetase gene (HCS) or the biotinidase gene (89,90,91,92,93). Affected patients present with dermatitis, severe metabolic acidosis, and a characteristic pattern of organic acid excretion. Normal metabolism can be restored toward normal levels by biotin supplementation. Prenatal diagnosis is based on the demonstration of elevated levels of typical organic acids (3-hydroxyisovalerate, methylcitrate) in the amniotic fluid or in the chorionic villi. However, the existence of a mild form of HCS deficiency can complicate prenatal diagnosis as organic acids level in amniotic fluid might be normal (94). Therefore, prenatal diagnosis must be performed by enzyme assay in cultured fetal cells in biotin-restricted medium.

Roth and colleagues treated a fetus whose two previous siblings died of multiple carboxylase deficiency (95). The mother was first seen at 34 weeks gestation and prenatal diagnosis was not performed. Oral administration was begun at a dose of 10 mg/day of biotin. There were no apparent untoward effects. Maternal urinary biotin excretion increased by 100. Nonidentical twins were delivered at term. Cord blood and urinary organic acid profiles were normal, and cord blood biotin concentrations were 4-7 times greater than normal. The neonatal course for both twins was unremarkable. Subsequent study of the cultured fibroblasts of both twins indicated that the cells of one twin had complete deficiency of carboxylase activities. This was later confirmed by genetic studies. Other cases of such treatment were also reported (94,96,97).

P.195

Smith-Lemli-Optiz Syndrome

Smith-Lemli-Optiz syndrome (SLOS) is an autosomal recessive disorder characterized by multiple anomalies, dysmorphic features, growth and mental retardation. Males with SLOS frequently have ambiguous genitalia (98). The severe form is associated with a high rate of neonatal mortality (99). SLOS is estimated to occur in 1:20,000-40,000 live births with an estimated carrier frequency of 1:70 (100,101). SLOS is caused by an inborn error of cholesterol biosynthesis as a result of a deficiency of the enzyme dehydrocholesterol- Δ^7 reductase leading to reduced cholesterol levels and elevated 7- and 8- dehydrocholesterol levels (7-DHC and 8-DHC respectively) in all body fluids and tissues including amniotic fluid and chorionic villi (100,102,103,104). The diagnosis is based on elevated levels of 7-DHC (100-1,000 times the normal value). Clinical manifestations correlate with cholesterol levels. Prenatal diagnosis of SLOS

has been available since 1994 by either amniocentesis or chorionic villus sampling (105,106,107). Since the identification of the cholesterol metabolic defect in SLOS, a treatment protocol has been attempted providing exogenous cholesterol. This form of therapy has now been provided to many patients with SLOS for the past several years in many centers in the United States and internationally (108,109,110), with the goal of raising cholesterol levels and decrease the precursors, 7-DHC and 8-DHC. It has been shown that dietary cholesterol supplementation can restore a normal growth pattern in children and adolescents with SLOS, alleviate behavioral abnormalities, and improve general health (108,109,110). Since significant development of the central nervous system and myelination occurs prior to birth it is reasonable to assume that providing cholesterol to the fetus, as early as possible would result in the most clinical benefit. However, providing cholesterol to the mother is of no use because cholesterol does not cross the placenta well in the second trimester and there is lack of evidence that it crosses the placenta in the third trimester. It is impractical to inject cholesterol into the amniotic fluid because it would precipitate. However, cholesterol can be given to the fetus by giving fresh frozen plasma in the form of low-density lipoprotein-cholesterol. A group at Tufts University has attempted treatment antenatally in several affected fetuses. In cases in which treatment was started late in pregnancy, the results were inconclusive. Although few descriptions of fetal therapy for SLOS exist, the latest report of antenatal treatment comes from that same group of investigators (111). Therapy was begun at 34 weeks of gestation and resulted in increased fetal cholesterol levels and red blood cell mean corpuscular volume with subtle improvement in fetal growth. However, no significant change in 7-DHC and 8-DHC levels was observed, further emphasizing the inconclusiveness of that treatment.

Galactosemia

Galactosemia is an autosomal recessive disorder caused by decreased activity of galactose-1-phosphate uridylyltransferase (GALT). Clinical manifestations include cataracts, growth deficiency, and ovarian failure. Clinical symptoms appear in the neonatal period and can be largely ameliorated by elimination of galactose from the diet. Cellular damage in galactosemia is thought to be mediated by accumulation of galactose-1-phosphate intracellularly and of galactitol in the lens. Several disease-causing mutations in the GALT gene have been reported in classical galactosemia (112). Galactosemia can also be diagnosed prenatally by biochemical studies of cultured amniocytes and chorionic villi.

There are suggestions that even the early postnatal treatment of galactosemic individuals with a low galactose diet may not be sufficient to ensure normal development. Some have speculated that prenatal damage to galactosemic fetuses could contribute to subsequent abnormal neurological development and to lens cataract formation. Furthermore, it has been recognized that female galactosemics, even when treated from birth with galactose deprivation, have a high frequency of primary or secondary amenorrhea because of ovarian failure. This is because oocytes have already been damaged irreversibly long before birth (113,114). There also may be some subtle abnormalities of male gonadal function as well. Thus, galactose restriction during pregnancy may be beneficial in affected fetuses. In humans, ovarian meiosis begins at 12 weeks and ovarian damage may occur prior to prenatal diagnosis. Thus, anticipatory treatment in pregnancies at risk for having a galactosemic fetus might best be initiated very early in gestation or even preconceptually. There are no studies that adequately assess the impact of prenatal administration of a low-galactose diet to galactosemic infants. Nevertheless, prenatal galactose restriction is probably desirable in galactosemia and should be harmless.

PRENATAL HEMATOPOIETIC STEM CELL TRANSPLANTATION

The engraftment and clonal proliferation of a relatively small number of normal hematopoietic stem cells (HSCs) can sustain normal hematopoiesis for a lifetime. This observation provides the compelling rationale for bone marrow transplantation (BMT) and is now supported by thousands of long-term survivors of BMT who otherwise would have succumbed to lethal hematological disease (115,116). Realization of the full potential of BMT, however, continues to be limited by a critical shortage of immunologically compatible donor cells, the inability to control the recipient or donor immune response, and the requirement for recipient myeloablation to achieve engraftment. The price of HLA mismatch remains high: the greater the mismatch, the higher the incidence of graft failure, graft-versus-host disease (GVHD), and delayed immunological reconstitution. Current methods of myeloablation have high morbidity and mortality. In combination, these problems remain prohibitive for most patients who might benefit from BMT. A theoretically attractive alternative, which potentially can address many of the limitations of

P.196

BMT, is *in utero* transplantation of HSC. This approach is potentially applicable to any congenital hematopoietic disease that can be diagnosed prenatally and can be cured or improved by engraftment of normal HSCs.

Rationale for *In Utero* Transplantation

The rationale for *in utero* transplantation is to take advantage of the window of opportunity created by normal ontogeny of hematopoietic cell lines. There is a period, prior to population of the bone marrow and prior to thymic processing of self-antigen, when the fetus theoretically should be receptive to engraftment of foreign HSC without rejection and without the need for myeloablation. In the human fetus, the ideal window would appear to be prior to 14 weeks' gestation, before release of differentiated T lymphocytes into the circulation and although the bone marrow is just beginning to develop sites for hematopoiesis (117). It certainly may extend beyond that in immunodeficiency states, particularly when T-cell development is abnormal. During this time, presentation of foreign antigen by thymic dendritic cells theoretically should result in clonal deletion of reactive T cells during the negative selection phase of thymic processing. Recent advances in prenatal diagnosis have made possible the diagnosis of a large number of congenital hematological diseases during the first trimester. Technical advances in fetal intervention make transplantation feasible by 12 to 14 weeks' gestation. The ontological window of opportunity falls well within these diagnostic and technical constraints, making application of this approach a realistic possibility.

Because of the unique fetal environment, prenatal HSC transplantation could theoretically avoid many of the current limitations of postnatal BMT. There would be no requirement for HLA matching, resulting in expansion of the donor pool. Transplanted cells would not be rejected, and space would be available in the bone marrow, eliminating the need for toxic immunosuppressive and myeloablative drugs. The mother's uterus may ultimately prove to be the ultimate sterile isolation chamber, eliminating the high risk and costly 2 to 4 months of isolation required after postnatal BMT and prior to immunological reconstitution. Finally, prenatal transplantation would preempt the clinical manifestations of the disease, avoiding the recurrent infections, multiple transfusions, growth delay, and other complications that cause immeasurable suffering for the patient and often compromise postnatal treatment.

Source of Donor Cells

Identifying the best source of donor cells may ultimately prove to be the most critical factor for the success of engraftment. The most obvious advantage of the use of fetal hematopoietic stem cells is the minimal number of mature T cells in fetal liver-derived populations prior to 14 weeks'

gestation. This alleviates any concern about GVHD and avoids the necessity of T cell depletion processes, which can negatively impact potential engraftment (115,116,117,118,119).

Although there may be important homing, proliferative, and developmental advantages to the use of fetal cells, there are practical and ethical advantages to the use of cord blood or postnatal HSC sources. Legitimate ethical concerns regarding the use of fetal tissue for transplantation must be addressed by the medical and lay community. Fetal tissue obtained by the usual methods at the time of elective abortion has a high degree of microbial contamination (120). The transplantation of transmissible viral, fungal, or bacterial disease could have disastrous consequences for the recipient fetus or mother. Although the fetal liver is a rich source of HSC, small size limits total cell yield, and current technology does not yet allow undifferentiated expansion of donor cells. In contrast, the use of adult-derived cells would allow a renewable, relatively infection-free, ethically acceptable source of donor cells. Tolerance induction by the in utero transplantation of highly purified adult bone marrow HSC from a living related donor, followed by a single or multiple postnatal "booster" injections offers an intriguing approach in situations in which postnatal BMT is necessary but an HLA-matched donor is not available (121,122,123).

Diseases Amenable to Prenatal Treatment

Generally speaking, any disease that can be diagnosed early in gestation, which is improved by BMT, and for which postnatal treatment is not entirely satisfactory, is a target disease. Some diseases, however, are far more likely to benefit from prenatal transplantation than others. The list can be divided into three general categories: hemoglobinopathies, immunodeficiency disorders, and inborn errors of metabolism. Each of the diseases has unique considerations for treatment, and in fact each disease may respond differently (Table 13-2). Issues such as availability of engraftment sites within the bone marrow at time of transplantation, and capacity of a needed enzyme to cross the blood-brain barrier at a particular gestational age need to be considered. Of particular relevance to the prenatal approach, in which experimental levels of engraftment have been relatively low, is the observation that in many of the target diseases, engrafted normal cells would be predicted to have a significant survival advantage over diseased cells. This would have the clinical effect of amplification of the level of engraftment in the peripheral circulation. Additionally, even with minimal levels of engraftment, specific tolerance for donor antigen should be induced, allowing additional cells from the same donor to be given to the tolerant recipient after birth.

Hemoglobinopathies

The sickle cell anemia and thalassemia syndromes make up the largest patient groups potentially treatable by prenatal stem cell transplantation (122,123,124,125). Both groups can be diagnosed within the first trimester. Both have been cured by postnatal BMT, but BMT is not recommended routinely because of its prohibitive morbidity and mortality,

P.197

and the relative success of modern medical management. In both diseases the success of BMT is indirectly related to the morbidity of the disease, that is, the younger the patient, the fewer transfusions received, and the less organ compromise from iron overload, the better the results. With both diseases the primary questions relevant to prenatal transplantation are: (a) what levels of normal peripheral cell expression are necessary to alleviate clinical disease, and (b) can adequate levels of donor cell engraftment be achieved by in utero HSC transplantation? At present only indirect evidence exists to answer these questions.

Hematopoietic Disorders

Disorders affecting lymphocytes

- SCID (sex linked)
- SCID (adenosine deaminase deficiency)
- Ommen syndrome
- Agammaglobinemia
- Bare Lymphocyte syndrome

Disorders affecting granulocytes

- Chronic granulomatous disease
- Infantile agranulocytosis
- Neutrophil membrane GP-180
- Lazy leukocyte syndrome

Disorders affecting erythrocytes

- Sickle cell disease
- α -Thalassemia
- β -Thalassemia
- Hereditary spherocytosis
- Fanconi anemia

Mannosidosis

- α -Mannosidosis
- β -Thalassemia

Mucopolidoses

- Gaucher disease
- Metachromatic leukodystrophy
- Krabbe disease
- Niemann-Pick disease
- β -Glucuronidase deficiency
- Fabry disease
- Adrenal leukodystrophy

Mucopolysaccharidoses

- MPS I (Hurler Disease)
- MPS II (Hunter Disease)
- MPS III B (Sanfilippo B)
- MPS IV (Morquio)
- MPS VI (Maroteaux-Lamy)

In sickle cell disease (SCD) the pathophysiology is directly related to the concentration of hemoglobin S (HbS) within red cells, which results in marked rheological abnormality, including hyperviscosity, cellular adherence, and sickling, with a result of vaso-occlusion and tissue ischemia. In examining the in vitro relationships between hematocrit (HCT) and viscosity using mixtures of sickle and normal red blood cells (RBCs), Schmalzer observed that the primary determinant of viscosity is the sickle HCT (fraction of RBCs that contain HbS) (126). Adverse effects of HCT on viscosity were seen at a sickle HCT level in the low twenties. Oxygen delivery, as gauged by the maximal point on the HCT vs. viscosity curve, was markedly improved by exchanging normal for sickle RBCs (even when the total HCT was held constant). The clinical correlate of this in vitro information presently is chronic exchange transfusion therapy with its inherent discomfort and potential complications. However, prenatal transplantation of normal hematopoietic stem cells was thought to offer a solution to this problem. Normal cells were expected to have a developmental advantage over HbS cells such that overall production of Hb-

normal RBCs may exceed that of HbS cells. This could potentially decrease the overall HbS fraction, reducing the risk of hyperviscosity and vaso-occlusive/ischemic complications. However, experimental data have not yet borne this out.

The clinical manifestations of thalassemia are secondary to hypoxia related to severe anemia and ineffective erythropoiesis. It is now standard therapy to transfuse patients with thalassemia major chronically from an early age, which suppresses endogenous erythropoiesis and maintains oxygen delivery. When instituted at an early age this effectively prevents the bone marrow expansion and secondary bony changes, and the hemodynamic and cardiac manifestations of the disease. The necessary normal hemoglobin (Hb) level required is controversial, but good results have been achieved with maintenance of an Hb of 9 g/dL.

Although these levels of normal Hb are higher than have been achieved experimentally (30% donor Hb is maximal), there would be a significant survival advantage of normal cells in both diseases. In SCD, erythrocytes have a circulating half-life of 10 to 20 days (normal half-life = 120 days) prior to destruction. In thalassemia, most cells (80%) never leave the bone marrow and also have shortened survival in the periphery. Therefore, engraftment of even a relatively small number of normal stem cells could result in significantly increased levels of peripheral donor cell expression. The problem, however, is creating spaces in the bone marrow for engraftment, which is an unsolved dilemma.

Immunodeficiency Diseases

These represent an extremely heterogeneous group of diseases, which differ in their likelihood of cure by their capacity to develop hematopoietic chimerism (115,116). Once again, the most likely to benefit from even low levels of donor cell engraftment are those diseases in which a survival advantage exists for normal cells. The best example of this situation is severe combined immunodeficiency syndrome (SCID). Several different molecular causes of SCID have been identified, with approximately two-thirds of cases being of X-linked recessive inheritance (X-SCID). The genetic basis of X-SCID has been defined recently (127) as a mutation of the gene encoding the common γ chain (γc), which is a common component of several members of the cytokine receptor superfamily, including those for interleukin-2 (IL-2), IL-4, IL-7, IL-9, IL-15, and possibly IL-13. Children affected with X-SCID have simultaneous disruption of multiple cytokine systems, resulting in

P.198

a block in thymic T-cell development and diminished T-cell response. B cells, although present in normal or even increased numbers, are dysfunctional, either secondary to the lack of helper T-cell function or an intrinsic defect in B-cell maturation. Another form of SCID is secondary to adenosine deaminase (ADA) deficiency. Clinical experience with HLA-matched sibling bone marrow, fetal liver or thymus transplantation generally has been successful without myeloablative therapy, suggesting that the lymphoid progeny of relatively few engrafted normal HSC have a selective growth advantage in vivo over genetically defective cells (128). The competitive advantage of normal cell populations in X-SCID is best supported by the discovery of skewed cross-inactivation in female carriers (129). Only T cells containing the normal X chromosome were found to be present in the circulation of recipients. Evidence that ADA production confers a survival advantage derives from the early experience with gene therapy for ADA deficiency SCID. ADA-gene-corrected autologous T cells have persisted for prolonged periods despite discontinuation of the T-cell infusions (130). Transfer of ADA-gene-corrected cells versus uncorrected cells from the same SCID patient into immunodeficient beige, nude, x-linked (BNX) mouse results in survival of the corrected cells and death of the uncorrected cells, confirming a survival advantage for ADA-producing cells even when there is normal ADA production in the surrounding environment. Unfortunately, other diseases such as chronic granulomatous disease would not be expected to provide a competitive

advantage for donor cells. Nevertheless, in all these conditions even a partial engraftment and expression of normal cell phenotype might at least partially ameliorate the clinical manifestations of the disease and should result in donor-specific tolerance for later transplantation. If higher levels of engraftment are needed, further HSC transplants from the same donor could be performed after birth without fear of rejection.

Flake and associates reported the successful treatment of a fetus with X-SCID in a family in which a previously afflicted child died at 7 months of age (131). Diagnosis by chorionic villous sampling at 12 weeks in the second pregnancy showed another affected male. For this couple, abortion was not an option. After lengthy informed consent, paternal bone marrow was harvested, T cells depleted, and enriched stem cell populations injected intraperitoneally into the fetus beginning about 16 weeks of gestation. Subsequent injections were performed at 17 and 18 weeks. The baby presently shows a split chimerism with all of his T cells being his father's and the majority of B cells being his own. He has achieved developmentally normal milestones and immune progress through 8 years of age (123). Other cases have been recently tried using less T cell-depleted populations resulting in higher T cell concentrations that have ended in fetal demise (117,132,133,134).

Inborn Errors of Metabolism

An even more heterogeneous group of diseases, inborn errors of metabolism, can be caused by a deficiency of a specific lysosomal hydrolase, which results in the accumulation of substrates such as mucopolysaccharide, glycogen, or sphingolipid. Depending on the specific enzyme abnormality and the compounds that accumulate, certain patterns of tissue damage and organ failure occur (116). These include central nervous system (CNS) deterioration, growth failure, dysostosis multiplex and joint abnormalities, hepatosplenomegaly, myocardial or cardiac disease, upper airway obstruction, pulmonary infiltration, corneal clouding, and hearing loss. The potential efficacy of prenatal HSC transplantation for the treatment of these diseases must be considered on an individual disease basis. The purpose of BMT in these diseases is to provide HSC-derived mononuclear cells that can repopulate various organs in the body, including the liver (Kupffer cells), skin (Langerhans' cells), lung (alveolar macrophages), spleen (macrophages), lymph nodes, tonsils, and the brain (microglia). Patients who have been corrected by postnatal BMT, such as Gaucher's disease or Maroteaux-Lamy syndrome (minimal CNS involvement), are reasonable candidates for prenatal treatment. In many cases postnatal BMT has corrected the peripheral manifestations of the disease and has arrested the neurological deterioration. However, postnatal BMT has not reversed neurological injury that is present in such disorders as metachromatic leukodystrophy and Hurler's disease (115,116). In these cases the neurological injury may begin well before birth. Postnatal maturation of the blood-brain barrier restricts access to the CNS of transplanted cells or the deficient enzyme. These considerations suggest that prenatal treatment may be beneficial and offer the possibility for a cure. The primary unanswered question is whether donor HSC-derived microglial elements would populate the CNS, providing the necessary metabolic correction inside the blood-brain barrier.

To date, the only definitively successful transplants have been for SCID (115,116). All others have either failed to take or were afflicted with graft versus host disease. Much more work needs to be done to determine the optimal dosing, timing, and specific protocols for different conditions.

As reviewed recently by Shields and associates (116), as of 2002 there have been 39 published cases of in utero stem cell transplants. Since the first successful case performed in 1995, only immunodeficiency cases continued to be successful. Of 14 cases of α and β -thalassemia, none have been successful. Three sickle cell, 3 Rh isoimmunization, and 7 storage disease cases have likewise been unsuccessful (116). Of 12 immunodeficiency cases, 6 have shown at least split chimerism or "alive and well." The dosages used, timing, fresh vs. frozen tissue, and methods of

evaluation before and after transplantation have been widely varied. While no definitive conclusions are possible at this time, it is clear that our lack of understanding of the mechanics or development of immunocompetency are persuasive. Until a better understanding of the processes obtained, better theories on treatment to achieve better outcomes may be limited.

P.199

CONCLUSION

There are an increasing number of congenital and genetic abnormalities for which in utero treatment is possible, and are in some cases, relatively routine now. Advances in therapies have progressed at different paces for different disorders, but there is great hope and enthusiasm that progress will continue to expand the number of disorders for which therapy can be effective (60).

Chapter 14

The Impact of Maternal Illness on the Neonate

Helain J. Landy

Progress in obstetric and neonatal care has directly contributed to improvements in neonatal outcome. The infant mortality rate (deaths in the first year of life per 1,000 live births), an established indicator of a nation's health status and well-being, has declined exponentially in the twentieth century with a drop of 46% since 1980 (1,2). The infant mortality rate, directly related to birth weight, has declined in spite of the increase in the percentage of low-birth-weight infants (2). These encouraging data largely reflect neonatal and pediatric advances in combination with regionalization of perinatal services and delivery of high-risk mothers in tertiary centers (2,3,4,5).

The mother's well-being during pregnancy has direct relevance for the newborn. Potential complications such as preterm delivery, growth disturbances (intrauterine growth restriction [IUGR] or macrosomia), congenital malformations, or chronic maternal illness may be important factors. This chapter discusses the impact of maternal illness on fetal development and well-being.

PRETERM DELIVERY

Preterm delivery is responsible for the majority of neonatal deaths and a major proportion of perinatal morbidity; in 1999, for the first time, prematurity constituted the leading cause of infant deaths in the first month of life (5,6). Approximately 11% of all deliveries in the United States occur prior to term (7) and these children are at higher risks of lifelong problems, including cerebral palsy, deafness, blindness, learning disabilities, and developmental delay (8). Encouraging data reveal increasingly effective care for pregnant women and neonates. This translates into a better prognosis for preterm infants, including increased survival rates (greater than 80%, compared with 74% in 1988) without an associated increase in morbidity (9).

Despite intense research efforts and technological advances, data demonstrate a steady rise in the preterm delivery rate in the United States over the past 20 years. In 1981, the preterm delivery rate was 9.4% and rose to 10.6% in 1990 (2). Recent data show a minor drop in the preterm birth rate from 11.8% in 1999 to 11.6% in 2000 (the latest year for which information exists); this represents the first such decline since 1992 (2). Compared with other industrialized nations, the United States ranks poorly (2,10). A number of confounding variables may

explain these facts. These include a racial disparity regarding persistently higher mortality statistics for black infants, a lack of agreement in the diagnosis of preterm labor, an overlap in the characteristics of actual and threatened preterm labor, controversies over the effectiveness of available screening techniques and therapies for preterm labor, and varying dosages and administration of tocolytic medications (2).

Preterm Labor and Premature Rupture of Membranes

A significant proportion of spontaneous preterm deliveries result from preterm labor and premature rupture of the membranes (PROM). Approximately 70% of preterm births may be associated with clinical evidence of ruptured membranes or underlying maternal, obstetric, or fetal conditions (Table 14-1) (10,11,12,13).

Predisposing factors for preterm labor remain largely unknown. Epidemiologic studies consistently report an association with nonwhite race (African American relative risk [RR] = 3.3), lower socioeconomic status (RR = 1.83-2.65), low prepregnancy weight (odds ratio [OR] = 2.72), and maternal age younger than 17 years or older than 40 years (RR = 1.47-1.95) (14). Lack of prenatal care is strongly associated with higher rates of preterm delivery, low birth weight, and maternal and infant mortality (15). Other particularly important risk factors include maternal history of preterm birth, especially during the second trimester, with or without rupture of membranes, and vaginal bleeding in at least two trimesters (14,16,17,18). Prostaglandins, thought to be

P.203

important mediators in the onset of labor at term, may have a role in preterm labor; in the absence of intrauterine infection, however, the data are not convincing (19).

Although PROM occurs in only 3% of pregnancies before term (20), it is associated with 20% to 50% of preterm deliveries (21) and represents the foremost predisposing factor for admissions to neonatal intensive care units (22). The pathophysiology underlying PROM appears to be multifactorial; evidence suggests that inflammatory weakening of the membranes or choriodecidual infection may be involved, especially at early gestational ages (20,23). Some clinical characteristics seen with PROM are also common to cases with preterm labor (e.g., lower socioeconomic status, young maternal age, sexually transmitted diseases, cigarette smoking, and vaginal bleeding) (20). Many studies suggest an association between bacterial vaginosis, a relatively common condition in which the normally predominant lactobacilli are overgrown by anaerobes and other peroxide-producing bacteria, and complications of premature birth, preterm labor,

and PROM (14,24,25,26); however, conflicting data exist (27).

In most patients, spontaneous labor begins after the membranes rupture. The latency period, defined as the time between membrane rupture and onset of contractions, is shorter in patients close to term. More than half of preterm patients will be in labor within 24 hours of ruptured membranes, and 50% to 60% will deliver within 1 week despite conservative management (7,20,28,29). PROM remote from viability is associated with significant rates of maternal and fetal morbidity and low rates of neonatal survival (7,8,19,29). Neonatal respiratory distress syndrome (RDS) is the most common complication at all gestational ages (7,8). Fetal demise resulting from intrauterine infection, umbilical cord compression, or placental abruption occurs in approximately 1% of cases of PROM at 30 to 36 weeks of gestation and up to 21.7% of cases of PROM in the mid-trimester (7,8). Prolonged oligohydramnios can also be associated with fetal pulmonary hypoplasia, limb-positioning deformities, and abnormal facies (e.g., low-set ears and epicanthal folds) (19,30).

Pharmacologic tocolysis, employed in an attempt to prevent progression of preterm labor, is implemented most often before 34 weeks of gestation. The various agents used in pharmacologic tocolysis, which are administered orally, subcutaneously, or parenterally, can have potentially serious maternal and/or fetal side effects (Table 14-2) (31). Despite the widespread use and evaluation of tocolysis over the past 20 years, data fail to demonstrate benefits of tocolysis in terms of medical costs, improvements in neonatal survival, or improvements in other long-term outcome parameters (31). The major benefit of tocolysis is its ability to provide short-term pregnancy prolongation in order that corticosteroids can be administered (31).

Corticosteroids, which are given between 24 and 34 weeks of gestation to patients who are at risk for preterm delivery, are used to induce fetal pulmonary maturity. The recommended protocol includes a single course of betamethasone (12 mg intramuscularly [i.m.] given in 2 doses 24 hours apart) or dexamethasone (6 mg i.m. given in 4 doses every 12 hours). Optimal benefit is seen within 24 hours and through 7 days after administration (32,33). A recent meta-analysis evaluating multiple randomized studies confirmed the decreased incidence and severity of neonatal RDS with antenatal administration of corticosteroids (34). Additional neonatal benefits include reductions in rates of intraventricular hemorrhage and death, even with treatment of less than 24 hours' duration and in gestations earlier than 30 to 32 weeks with ruptured membranes (33). Long-term data of infants exposed *in utero* to a single course of corticosteroids failed to demonstrate any significant adverse effects on physical development, growth, cognitive or motor skills, or early school performance (31).

The use of antibiotic therapy, particularly aimed at treating bacterial vaginosis, group B streptococcus, and other genital tract organisms, has been studied widely in recent years. Initially shown to decrease rates of preterm delivery, preterm

labor, and neonatal sepsis in some studies, the data show mixed results (31,35,36,37). Routine antibiotic administration is not recommended if used only in an attempt at prevention of preterm delivery (31). While conservatively managing preterm PROM remote from term, however, aggressive antibiotic therapy with erythromycin and ampicillin or amoxicillin prolongs pregnancy and

decreases major neonatal morbidity (e.g., RDS, early sepsis, severe intraventricular hemorrhage, severe necrotizing enterocolitis) (20,38,39).

TABLE 14-2 POTENTIAL COMPLICATIONS OF VARIOUS TOCOLYTIC AGENTS^a

Agent	Side Effects
Magnesium sulfate	<i>Maternal:</i> Decreased respiratory, cardiovascular, and renal function; contraindicated in myasthenia gravis <i>Fetal:</i> Alterations in fetal heart rate patterns
Betamimetic agents (e.g., ritodrine, terbutaline)	<i>Maternal:</i> Pulmonary edema; myocardial ischemia or infarction (rare); hypotension; hyperglycemia; hypokalemia <i>Fetal:</i> Alterations in fetal heart rate patterns
Prostaglandin synthetase inhibitors (e.g., indomethacin, sulindac)	<i>Maternal:</i> Gastrointestinal bleeding <i>Fetal:</i> Constriction of ductus arteriosus; reversible, dose-dependent oligohydramnios from decreased fetal urinary output; pulmonary hypertension seen with prolonged use (rare)
Calcium channel blockers (e.g., nifedipine)	Well tolerated

Screening for Preterm Delivery

Because a woman's past obstetric history may be important for subsequent pregnancies, several risk-scoring systems have been developed. The most widely applied system was devised by Papiernik and modified by Creasy (40). Application of these systems to various populations in the United States, however, has been

disappointing (41), and applicability to nulliparae has not been accepted. A 1996 study of almost 3,000 gravidas that attempted to develop a risk-assessment system for predicting spontaneous preterm delivery by using clinical information at 23 to 24 weeks of gestation was similarly disappointing (18). A recent study demonstrated the utility of the preterm labor index, a clinical tool to assess the likelihood of overall preterm delivery and delivery within 1 week (42). The preterm labor index, originally proposed in 1973, combines four clinical parameters (uterine contractions, PROM, vaginal bleeding, and cervical dilation) and is comparable to newer biochemical markers for predicting preterm delivery (42,43). Its utility across populations remains to be studied.

Other screening tools have been proposed to help identify the pregnancy at risk for preterm delivery, including home uterine activity monitoring, screening for fetal fibronectin in vaginal secretions, cervical examination, and screening for genital tract colonization and/or infection.

Home Uterine Activity Monitoring

The working premise behind home uterine activity monitoring (HUAM) is that uterine contractions may increase in frequency in the 24 hours before the development of preterm labor (14,44). The use of HUAM involves tocodynamometric recording of uterine contractions combined with interpretation and daily telephone contact by health care providers to try to detect early preterm labor. Oral tocolysis often is used in conjunction with HUAM. Data from many randomized studies evaluating the efficacy of HUAM are conflicting and the quality of supportive evidence is limited by study designs (14,31,45-47). Its use in clinical practice is widespread in spite of the lack of endorsement by the U.S. Preventive Services Task Force (46) and the American College of Obstetricians and Gynecologists (ACOG) (14).

Fetal Fibronectin

Fetal fibronectin (fFN), a protein produced by the fetal membranes, most likely functions to bind the placenta and membranes to the decidua. Disruption of this normal interface, as with preterm labor or PROM, allows leakage of fibronectin into cervicovaginal secretions. In normal pregnancy it is rarely present after 20 weeks of gestation, and it has been found to be of value in predicting preterm delivery (48,49,50). Positive tests for fFN can be seen in women with bacterial vaginosis or subsequent maternal and fetal infections (48,51). The most useful aspect of the fFN assay is its negative predictive value: Less than 1% of women with questionable preterm labor will deliver within the next 2 weeks with a negative test for fFN compared with approximately 20% of women with a positive test (31). At this time, however, its use as a routine screening test for the general obstetric population has not been endorsed by the ACOG Committee on Obstetric Practice

Cervical Examination

The value of routine digital cervical examination in otherwise uncomplicated pregnancies is controversial. Asymptomatic cervical dilation may be a normal anatomic

P.205

variant, and may represent the earliest sign of impending preterm delivery, implying cervical incompetence or undiagnosed preterm labor (53,54,55). Sonographic cervical examination is superior to digital assessment of cervical dilation, length, and effacement, and confirms the association of cervical shortening with preterm delivery (56,57,58,59,60). Predictive sonographic findings for increased risks of preterm delivery include cervical shortening (generally described as less than 2.5 to 3 cm), funneling or ballooning of membranes at the level of the internal os, and cervical dilation (57,60,61). Currently, routine use of sonographic cervical length in the prediction of preterm delivery is not recommended because of the lack of proven treatments affecting outcome (14). Combining transvaginal sonography with other biochemical markers, such as fFN, may prove more predictive, however (14,62).

Genital Tract Screening

Routine screening for various infections (e.g., syphilis, hepatitis B, and rubella) is recommended early in pregnancy. Additional testing for other sexually transmitted disorders, however, is left to the discretion of the practitioner based on the patient's history and physical examination (63). Infections with *Neisseria gonorrhoeae*, *Trichomonas vaginalis*, *Chlamydia trachomatis*, and group B streptococci, as well as urinary tract infections, asymptomatic bacteriuria, and bacterial vaginosis, are associated with premature delivery (64,65,66). Some investigators recommend more aggressive screening and treatment for these conditions during gestation, as well as in women contemplating pregnancy (65). Recently adopted guidelines from the Centers for Disease Control and Prevention in conjunction with ACOG and the American Academy of Pediatrics recommend the routine screening for group B streptococcus colonization in late pregnancy and antibiotic treatment for carriers in labor (67). This strategy reflects attempts to prevent early onset neonatal disease rather than impact on rates of prematurity (31,67).

MATERNAL NUTRITION

Recognition of the importance of proper nutrition during pregnancy has varied over the years. Earlier in this century, restrictions in maternal diet were

implemented to lessen fetal growth in order to decrease the rates of preeclampsia and labor complications (68). Fetal growth, which is determined by complex interactions of environmental, genetic, and physiologic factors, is influenced by both maternal prepregnancy body mass index and pregnancy weight gain. Whereas low birth weight and IUGR are seen in infants of underweight mothers and mothers with poor weight gain, macrosomia is common in infants of overweight mothers and mothers with excessive weight gain (68,69,70). Current weight-gain recommendations for singleton pregnancies are 25-35 pounds for normal weight gravidas, 28-40 pounds for underweight gravidas, and 15-25 pounds for overweight gravidas; in twin gestations, ideal weight gain is 35-45 pounds (71). Recent epidemiologic evidence suggests an independent association between maternal obesity and fetal neural tube defects and other malformations (72), as well as increased maternal risks of diabetes mellitus, preeclampsia, and cesarean delivery (73).

Although it is common for multivitamins to be prescribed to pregnant women in the United States, a balanced diet with appropriate weight gain should supply the required vitamins and make supplementation unnecessary. In certain conditions, however, specific recommendations are warranted. There are relatively few food sources high in vitamin D, for example; in the United States, its major source is vitamin D-fortified milk (74). Vitamin D synthesis in the skin depends on ultraviolet light skin exposure; however, there is generally insufficient exposure in winter, especially at higher latitudes (74). Vitamin D deficiency in pregnant women varies based on the patient's racial and ethnic background as well as dietary customs; a fairly high prevalence has been reported among Indian and Pakistani women living in Britain (74). Maternal deficiency of vitamin D may be seen with neonatal hypocalcemia and tetany. If supplementation is to be administered, 400 to 500 IU doses daily have been reported as safe and adequate; excessive supplementation can result in calcium hyperabsorption, hypercalcemia, and calcification of soft tissues (74).

Vitamin supplementation of vitamin B₁₂ and zinc are indicated for strict vegetarians; additional folic acid is suggested for women taking anticonvulsant medications, carrying multiple gestations, or with hemoglobinopathies. To prevent anemia, iron supplementation in the second and third trimesters is recommended (74). In contrast, excessive vitamin A, in daily doses of at least 25,000 to 50,000 IU, is teratogenic, producing malformations similar to those seen with maternal exposure to 13-*cis*-retinoic acid (Accutane) (75).

High-dose folic acid supplementation (4 mg/day) reduces the risk of a subsequent neural tube defect in women with a prior affected infant (76), and such doses, beginning 1 month before conception and continuing through the first 3 months of pregnancy, are advocated (77). Further studies led to the Centers for Disease Control and Prevention statement that all women of child-bearing age in the United States who are capable of becoming pregnant should consume 0.4 mg of

folic acid daily (78). Beginning January 1998, the U.S. Food and Drug Administration ordered folic acid fortification of bread, flour, and other grain foods to help prevent these birth defects (79).

MATERNAL ILLNESSES

Hypertension

Hypertension complicates 5% to 8% of pregnancies and constitutes a major cause of maternal and perinatal

P.206

morbidity and mortality (80,81,82). Potential fetal and neonatal complications associated with chronic hypertension include prematurity, increased overall perinatal morbidity, IUGR, and fetal death (80,81,82). Several studies document that the risk of perinatal mortality is increased two to four times if the mother is hypertensive compared with the general obstetric population (83). Maternal complications include superimposed preeclampsia, placental abruption, cesarean delivery, and potentially life-threatening complications such as pulmonary edema, hypertensive encephalopathy, retinopathy, cerebral hemorrhage, and acute renal failure (80,81,82,83,84,85). Low-risk patients have mild essential hypertension and no organ involvement; those with severe hypertension or superimposed preeclampsia are considered to be at high risk. The risks of significant complications are especially increased in patients with uncontrolled severe hypertension and underlying renal or cardiac disease prior to or early in gestation (82).

Classification and terminology of the different subdivisions of the hypertensive disorders in pregnancy is confusing. A recent recommendation by the National High Blood Pressure Education Program Working Group replaces the term "pregnancy-induced hypertension" with "gestational hypertension" to describe situations in which elevated blood pressure without proteinuria develops after 20 weeks of gestation and blood pressure levels return to normal postpartum (80,85). Up to 25% of women with gestational hypertension will develop proteinuria or preeclampsia; with severe chronic hypertension, this rate can approach 50% (84). Proteinuria is classified by at least 0.3 g of protein in a 24-hour urine specimen, which usually corresponds to 1+ or greater on a urine dipstick evaluation (83).

Preeclampsia is defined as hypertension with proteinuria in addition to other possible symptoms of headache, edema, visual disturbances, and epigastric pain; laboratory abnormalities may involve hemolysis, elevated liver enzymes, and low platelet count (known by the acronym HELLP). HELLP syndrome can occur in up to 20% of women with severe preeclampsia and may have a variety of clinical presentations (86). In past years, the diagnosis of preeclampsia included specific

blood pressure elevations above the patient's baseline blood pressure; these clinical parameters have not been found to be a reasonable prognostic indicator of outcome (85). Eclampsia involves the development of seizures and/or coma, which represents central nervous system involvement, in a preeclamptic patient. Severe preeclampsia can be defined by the criteria listed in Table 14-3 (80,85). Thrombocytopenia (platelet count below 100,000/mL) is the most consistent finding in patients with preeclampsia (87). Table 14-4 outlines the risk factors for the development of preeclampsia (80,85).

The precise pathophysiologic factors involved in preeclampsia have been difficult to elucidate. Trophoblastic invasion by the placenta appears to be important because the severity of hypertension appears to be related to the degree of trophoblastic invasion (80,88). Vascular changes, specifically vasospasm, seem responsible for many of the serious clinical manifestations (e.g., hypertension and diminished renal function). Earlier investigations demonstrated support for the involvement of vasospasm in the etiology of preeclampsia. Specifically, the failure of the blunted pressor response to angiotensin II present in normal pregnancy is not seen in preeclampsia (89), and a progressive sensitivity to the pressor effects of infused angiotensin can be demonstrated after 18 weeks in patients destined to become preeclamptic (90). Other factors may involve an imbalance in the production of prostacyclin, a potent vasodilator, relative to levels of thromboxane, a vasoconstrictor, and alterations in the synthesis of nitric oxide and/or endothelin 1 (85).

TABLE 14-3 CLINICAL MANIFESTATIONS OF SEVERE PREGNANCY-INDUCED HYPERTENSION^a

- Systolic blood pressure ≥ 160 mm Hg or diastolic blood pressure ≥ 110 mm Hg on two occasions at least 6 hours apart with the patient at bed rest
- Proteinuria ≥ 5 g in a 24-hour collection or $\geq 3+$ on two random urine samples collected at least 4 hours apart
- Oliguria (< 500 mL in 24 hours)
- Cerebral or visual disturbances
- Pulmonary edema
- Right upper quadrant or epigastric pain
- Hepatocellular dysfunction
- Thrombocytopenia
- Intrauterine growth restriction

P.207

Some fetal effects of preeclampsia reflect vasospasm with regard to placental perfusion. A decrease in uteroplacental perfusion may result in abruption, IUGR, oligohydramnios, or nonreassuring fetal status demonstrated on antepartum testing. Placental abruption, which occurs in fewer than 2% of patients with chronic hypertension, can be twice as high in those with superimposed preeclampsia (82,83). In 1990, Burrows and Andrews (91) found that neonatal thrombocytopenia occurred in more infants of hypertensive than in those born to normotensive mothers (9.2% compared with 2.2%).

Prematurity significantly contributes to the increased rates of perinatal morbidity and mortality associated with preeclampsia. Conservative management, recommended in a tertiary care setting or in consultation with a maternal- fetal medicine subspecialist, may be attempted for women with severe preeclampsia remote from term (80,82). Delivery remains the only definitive treatment, and ultimately may be required (92,93). In cases managed conservatively, patients are hospitalized; bed rest with frequent clinical and laboratory assessments and corticosteroids are administered to enhance fetal pulmonary maturity. Magnesium sulfate, an agent long recognized for its anticonvulsant effects, is often

administered (85). Although phenytoin sulfate may be used, magnesium sulfate is the preferred drug (94,95). Blood pressure control is achieved with the use of antihypertensive agents such as labetalol, hydralazine, or nifedipine (80,81,82). A protocol of high-dose corticosteroid administration stabilizes both clinical and laboratory parameters in patients with HELLP syndrome before term (96,97).

Several different antihypertensive agents are used during pregnancy. α -Methyldopa is frequently used because it is a safe, effective agent that has been studied extensively. Newer antihypertensive drugs that are safe in pregnancy include beta-blockers, labetalol (a combination alpha- and beta-blocker), and calcium channel blockers such as nifedipine. There is concern about using diuretics during pregnancy because of an accompanying plasma volume reduction (83). The National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy suggests that diuretics can be used safely except in situations in which there is already evidence of diminished uteroplacental function (80,81). Angiotensin-converting enzyme (ACE) inhibitors, commonly used in young, nonpregnant adults, are both teratogenic and fetotoxic if administered during gestation. Skull defects (hypoplastic calvaria and encephalocele) and *in utero* renal failure leading to oligohydramnios, pulmonary hypoplasia, long-standing neonatal anuria, and fetal or neonatal death have been reported (98,99,100). In women using an ACE inhibitor, antihypertensive medication is changed to another agent once pregnancy is confirmed.

Over the years, prevention of preeclampsia has been attempted. Initially, a beneficial effect was demonstrated in high-risk groups that were given low-dose aspirin (60 to 80 mg daily), but subsequent studies have been conflicting and a similar effect was not found in low-risk women (101,102,103,104). Similarly, other studies have obtained disappointing results in evaluating supplementation with calcium, magnesium, zinc, fish oil, or use of different antihypertensive medication (103). More recently, evaluation of the uteroplacental circulation via transvaginal Doppler sonography at 12 to 16 weeks suggests an association with abnormal waveforms and increased risks of developing preeclampsia later in gestation (103,104,105,106,107). Further study is ongoing.

Diabetes Mellitus

Diabetes mellitus complicates nearly 4% of pregnancies (108,109). The disease is classified based on the requirement for insulin therapy into type 1 (insulin-dependent) or type 2 (non-insulin-dependent) diabetes. The White classification system for diabetes in pregnancy, developed in 1949, is based on age of onset and duration of disease, as well as disease progression with respect to vascular complications (110). With continued improvements in glucose control, assessment of fetal well-being, and neonatal management, the White classification is no longer as helpful as it once was in the management of the pregnant diabetic (111). Instead, the distinction can be made between diabetes that preceded a

woman's pregnancy (pregestational diabetes) and diabetes first recognized during pregnancy (gestational diabetes).

Fetuses of diabetic mothers may have growth disturbances at both ends of the spectrum: IUGR and macrosomia. IUGR, fetal growth less than or equal to the 10th percentile for gestational age, is not an infrequent finding in pregnancies of women with vascular complications of pregestational diabetes. In diabetic pregnancies, IUGR often results from uteroplacental insufficiency, usually associated with maternal hypertension, although fetuses with congenital anomalies also may exhibit signs of IUGR.

Infants of mothers with both pregestational and gestational diabetes are at risk for macrosomia, which refers to fetal growth beyond a specific weight regardless of gestational age, usually above 4,000 g or 4,500 g (112). With the development of a new national reference for fetal growth based on data from over 3.8 million births (113), clinicians can distinguish between macrosomia and large-for-gestational-age (above the 90th percentile for a given gestational age) (112,113). Several large studies support the continued use of 4,500 g as a value above which a fetus should be considered to be macrosomic (112,114,115,116,117). The antenatal sonographic diagnosis of macrosomia remains inaccurate, especially in diabetics (118,119,120). In women with normal glucose tolerance, 2% of infants weighed more than 4,500 g compared with 6% of women with untreated borderline gestational diabetes (112,121). Even in the absence of gestational diabetes, however, higher infant weights are associated with higher maternal glucose levels (112,122,123). In patients with untreated gestational diabetes, up to 20% of infants may be macrosomic (112,124).

Macrosomia is accompanied by the additional risks of prolonged labor, fracture of the clavicle, birth trauma from

P.208

shoulder dystocia, and instrumented or cesarean deliveries (125,126,127,128,129). Shoulder dystocia occurs in only 1.4% of all vaginal deliveries (130). Among deliveries of diabetic mothers, however, shoulder dystocia occurs two to six times more frequently than in the nondiabetic population (120,129,131). The complication has been reported to occur in 20% to 50% of infants of diabetic mothers with birth weights above 4,500 g (114,115,116,117,120). Brachial plexus injury is the most serious complication resulting from shoulder dystocia. Fortunately, it is rare, occurring in approximately 0.05% to 0.19% of vaginal deliveries (112,120), but that risk is increased 18- to 21-fold among vaginally delivered infants weighing more than 4,500 g (114,120,132,133,134,135). The majority of cases of brachial plexus injury resolve within 1 year (136,137), yet permanent injury is more commonly seen among infants with birth weights greater than 4,500 g (138). Important information for the practicing clinician to remember is that most cases of shoulder dystocia and brachial plexus injuries occur among infants who are not macrosomic

(135). Clavicular fracture, which usually resolves without any permanent effect, can be seen in 0.3% to 0.7% of all deliveries (134,139,140), and its occurrence is increased up to ten times in the macrosomic infant (134).

Polyhydramnios, defined as excessive amniotic fluid, is not an unusual finding in diabetic pregnancies. A four-quadrant sonographic assessment of the amniotic fluid index (AFI) defines polyhydramnios as an AFI greater than the 95th percentile for gestational age (141). In diabetic pregnancies, the etiology is not clear, although fetal malformations or poor glucose control may be related. When polyhydramnios complicates maternal diabetes, higher rates of perinatal morbidity and mortality are reported (142).

Pregestational Diabetes Mellitus

Estimates from 1999 indicate that approximately 10,000 women in the United States with pregestational diabetes delivered live births (143). Pregnancies of women with pregestational diabetes are at significant risk for both spontaneous abortion and fetal anomalies (144,145,146,147,148,149,150), the latter representing the major cause of perinatal mortality in this group of patients (144,149,150). The frequency of congenital anomalies in infants of diabetic mothers occurs at two to three times the rate in the nondiabetic population (151). These malformations, which occur before 7 weeks of gestation, commonly include open neural tube defects, congenital heart defects, and the caudal regression syndrome (144,151,152).

Hyperglycemia is responsible for the increased risks of both fetal malformations and spontaneous abortion seen in diabetics (146,147,148,149). Poor glycemic control, combined with derangements in amino acid and lipid concentrations, is believed to underlie the development of fetal malformations (147,153).

Hypertrophic cardiomyopathy, which can cause cardiomegaly and congestive heart failure, may result from elevated maternal glucose levels throughout pregnancy (154,155). A patient's degree of hyperglycemia can be assessed by the level of glycosylated hemoglobin (hemoglobin A_{1c}), a retrospective marker of glucose control (153). Intensive glycemic control in the periods before conception and organogenesis can lower the frequency of congenital anomalies in infants of diabetic mothers (144,156,157).

In the past, a major source of perinatal mortality among diabetic pregnancies was fetal demise, often unexplained and sudden. Among well-controlled diabetics, stillbirth is an uncommon event (144). With diabetic ketoacidosis, however, perinatal mortality rates may be as high as 50% to 90% (158). Fetal blood sampling has confirmed that these previously designated unexplained stillbirths result from hyperglycemia, metabolic disturbances, polycythemia, and acidemia (159,160). Efforts to prevent fetal demise at the Joslin Clinic in the 1960s resulted in the strategy of scheduled preterm deliveries. Even though reductions in the

number of stillbirths occurred, neonatal deaths from RDS were prevalent, predominantly as a result of errors in estimates of gestational age (161). Although older data from the 1980s suggested a delay in fetal pulmonary maturation in diabetic pregnancies (162,163,164) more recent studies have disproved this assumption, especially in patients with good glucose control (165,166,167,168). Other complications seen in women with pregestational diabetes mellitus, especially those with end-organ dysfunction from long-standing vascular disease, include preterm delivery and pre-eclampsia (85).

In the immediate neonatal period, infants of diabetic mothers are at higher risks for a number of metabolic irregularities. Hypoglycemia may occur from a rapid decline in neonatal glucose levels after delivery. This results from a combination of removal of the continued placental source of glucose and fetal islet cell hyperplasia from chronic maternal hyperglycemia. Close maternal glucose control during labor with continuous insulin and glucose infusions can lessen the development of neonatal hypoglycemia (169). Other neonatal metabolic derangements include hypercalcemia, polycythemia, and hyperbilirubinemia (160,170,171).

Gestational Diabetes Mellitus

In the United States, gestational diabetes mellitus (GDM) is diagnosed by at least two abnormal values on a 3-hour 100-g oral glucose tolerance test subsequent to an elevated 1-hour 50-g glucose challenge test (108). GDM occurs in 2% to 5% of pregnancies but comprises the majority of cases of diabetes in pregnancy (108). Recent estimates suggest rising prevalence rates as a result of increased detection following the 1980s' recommendations for universal screening (172,173). In women with GDM, the risk of developing diabetes mellitus 20 years later is approximately 50% (174).

For most patients with GDM, glucose levels may be controlled with dietary therapy alone. Insulin therapy is suggested when fasting glucose levels exceed 95 mg/dL, 1-hour postprandial values exceed 130 to 140 mg/dL, or 2-hour postprandial value exceed 120 mg/dL (108). Regular exercise may help with glucose regulation in this

P.209

group of patients (108). One randomized trial found similar results among patients with GDM comparing use of insulin versus glyburide, a second-generation sulfonylurea, although additional study is needed (175). In general, infants of mothers with GDM are at risk for macrosomia, operative and cesarean deliveries, birth trauma (including fracture of the clavicle, shoulder dystocia, and brachial plexus injury), fetal death, and neonatal hyperglycemia and/or hyperbilirubinemia (108,112). Patients diagnosed with GDM early in pregnancy and in whom glucose levels require intensive therapy with diet and insulin behave much like those with

pregestational diabetes; these patients has a higher risk of fetal malformations and stillbirth than do patients with mild GDM (111). Postpartum recommendations for women diagnosed with GDM during pregnancy include evaluation of glucose status using a 75-g glucose tolerance test (108).

Fetal Assessment

Several tools are used to assess fetal well-being in diabetic and in other high-risk pregnancies. Obstetric ultrasonography can be of value in determining early fetal viability and in screening for various anomalies. Fetal echocardiography is employed generally after 20 weeks' gestation to evaluate fetal cardiac structure. In the third trimester, sonography can assess fetal growth and aid in the diagnosis of macrosomia, polyhydramnios, or septal hypertrophy. An ongoing sense of fetal well-being can be obtained through maternal perception of fetal movement counts. Serial fetal biophysical testing (e.g., nonstress tests and biophysical profiles) is usually implemented by 32 weeks in most insulin-dependent diabetics; pregnancies with well-controlled gestational diabetes, considered to be at low risk for fetal demise, may not require testing except in the presence of other obstetric factors (161).

Autoimmune Disorders

A number of disorders that involve circulating autoantibodies and/or deposition of immune complexes may have direct effects on pregnancy. These include the rheumatologic or connective tissue diseases and conditions associated with circulating antiphospholipid antibodies.

Rheumatologic Disorders

Rheumatologic disorders are chronic inflammatory diseases usually affecting the connective tissues and joints. The most common disorders occurring in young women include systemic lupus erythematosus, rheumatoid arthritis, scleroderma, and Sjögren's syndrome.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is the most common connective tissue disorder seen among reproductive-age women. Its various clinical presentations include polyarthritis, skin manifestations, Raynaud phenomenon, and nephritis; laboratory abnormalities such as anemia, leukopenia, thrombocytopenia, and the presence of autoantibodies are common. The disease is characterized by remissions and exacerbations. Patients with SLE have a high prevalence of fetal wastage: spontaneous abortion, IUGR, preterm delivery, stillbirth, and perinatal death (176,177,178,179,180,181). A majority of the pregnancy losses result from

fetal death in the second and third trimesters (182). Many lupus patients have pregnancies with high rates of preterm and term PROM (183). Fetal survival is higher when the disease is in remission (176,177,181,182,183,184). Other predictors of fetal wastage include active nephritis, hypertension, and circulating antiphospholipid antibodies (e.g., lupus anticoagulant or anticardiolipin antibodies), the latter likely the most important factor associated with pregnancy loss (176,177,179,180,181,182,184,185).

Despite older data that supported the opinion of disease exacerbation in lupus patients during pregnancy, most authorities now agree that pregnancy has no effect on disease progression (176,186,187). Treatment with corticosteroids is standard (178,179,180,185,188). Salicylates and other nonsteroidal antiinflammatory agents (e.g., paracetamol) are commonly used, although high doses are discouraged (188,189,190,191). Azathioprine, an immunosuppressive that has been used predominantly in renal transplantation patients (188,192,193,194), and antimalarial agents are used widely in SLE patients and considered to be safe during pregnancy (179,188,195,196,197,198). In some cases, plasmapheresis has been performed (199,200).

Infants of mothers with SLE are at risk for the neonatal lupus syndrome. This constellation of findings consists of abnormalities in the heart and skin or development of clinical features of SLE and occurs from transplacental passage of maternal antibodies (201). Congenital complete heart block is the most frequently seen heart abnormality (202), occurring in fewer than three percent of infants at risk (189). The pathophysiology involves deposition of immunoglobulin, specifically circulating IgG autoantibodies directed against ribosomal nucleoprotein antigens (anti-Ro or SSA and, to a lesser extent, anti-La or SSB antibodies) in fetal cardiac tissue (201,203). Anti-Ro (SSA) and anti-La (SSB) antibodies are detectable in 40% to 50% of SLE patients (181,202). Most cases of congenital complete heart block occur in fetuses whose mothers do not have overt clinical SLE (204). Many studies, however, indicate that the majority of mothers with affected children have detectable anti-Ro (SSA) antibodies (201,202). Heart block in the absence of structural defects has been documented as early as 16 weeks of gestation (205).

The presenting finding of congenital heart block is fetal dysrhythmia; sonography may reveal a pericardial effusion or hydrops resulting from either congestive failure or an immune mechanism (myocarditis) (203,206,207,208). Maternal treatment with dexamethasone and/or plasmapheresis, used to lower circulating antibody levels and to minimize inflammatory injury, has had some success in reversing fetal heart block and improving fetal cardiac contractility (207,208,209,210). Resolution of ascites has been

reported with corticosteroid use (209). The technique of *in utero* cardiac pacing, demonstrated to be technically feasible in a hydropic 24-week fetus with heart

block (211), may be a future option in severe cases. After birth, heart block is usually permanent; intermittent and incomplete cases, as well as unusual late presentations, have been described (201,212,213,214). Cardiac pacemaking is instituted for those infants that survive; however, mortality rates are high (12% to 28%) (201,215). Coexistent cardiac anomalies among infants with congenital heart block are common (214,216).

The skin is the other major organ system involved in the neonatal lupus syndrome. Cutaneous lesions are frequently widespread macular rashes, although a butterfly rash and discoid lesions are found occasionally (181,201). These histologically inflammatory lesions generally appear within the first few weeks of life and disappear spontaneously within 6 months, coexistent with the clearance of maternal autoantibodies from the neonatal circulation (181,201). Hematologic manifestations, such as anemia and thrombocytopenia, glomerulonephritis, hepatosplenomegaly, and neurologic symptoms, are unusual (201,202).

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is the most common inflammatory joint disease, affecting approximately 1% of the population in North America and complicating approximately 1 in 1,000 to 2,000 pregnancies (217). The disorder affects women three times as often as men, with a peak incidence between the fourth and sixth decades of life (217). There is a familial preponderance associated with the tissue antigen HLA-DR4 (217). RA is characterized by chronic polyarthritis and inflammatory synovitis, usually of the peripheral joints, resulting in bone and cartilage destruction and joint deformities. Other clinical manifestations include anorexia, weakness, fatigue, and vague musculoskeletal complaints. The diagnosis is made based on specific criteria outlined by the American Rheumatism Association (218). Despite much study, it is not known why the symptoms of RA are ameliorated during pregnancy; studies evaluating cortisol levels and sex hormone concentrations have not provided any solid answers (219,220). In contrast to SLE, perinatal morbidity and mortality are not increased in patients with RA (220).

The major therapies for RA are acetylsalicylic acid (aspirin) and nonsteroidal antiinflammatory agents; concerns for adverse fetal and/or neonatal effects (such as impaired hemostasis, premature closure of the fetal ductus arteriosus, prolonged gestation, and long labor) have been largely theoretical (188,219). Gold therapy, which lowers the levels of rheumatoid factor, has been used for many years; antimalarial agents are also administered (188,219). Although D-penicillamine has been used, some reports have shown connective tissue defects similar to Ehlers-Danlos syndrome in children with antenatal exposure (221).

Scleroderma

Scleroderma is an autoimmune connective-tissue disorder that occurs at least five times more frequently in women of childbearing age than in men, affecting the skin, gastrointestinal tract, especially the esophagus, lungs, and kidneys (222). The typical remissions and exacerbations of the disease make it difficult to assess the effect of pregnancy. According to a 1989 report on 94 cases of scleroderma in pregnancy and a review of the literature, pregnancy had either no effect on the disease or was associated with exacerbations (223). A retrospective case control study of 48 women revealed an association with first trimester pregnancy loss in those patients with long-standing diffuse scleroderma and a 29% prematurity rate (222). Fetal mortality may be as high as 20% and the development of neonatal scleroderma has been described.

Sjögren Syndrome

This rare autoimmune disorder, also known as keratoconjunctivitis sicca or sicca syndrome, involves lymphocytic infiltration of the salivary and lacrimal glands resulting in loss of saliva and tears. Sjögren syndrome is both clinically and immunologically related to SLE. Many circulating autoantibodies are present, as well as anti-Ro (SSA) and anti-La (SSB) antibodies. Approximately 50% of patients with Sjögren syndrome have rheumatoid arthritis (224). Pregnancy complications of fetal loss and congenital heart block have been reported (225).

Antiphospholipid Antibodies and the Antiphospholipid Syndrome

Circulating antiphospholipid antibodies and the antiphospholipid syndrome (APS) are associated with clinical complications such as adverse pregnancy outcomes, autoimmune thrombocytopenia, and thrombosis (226). These antibodies are directed against negatively charged phospholipids present on cell membranes, notably platelets and endothelial cells (227). The most common antiphospholipid antibodies are the lupus anticoagulant and anticardiolipin antibodies. The lupus anticoagulant was originally described as a circulating anticoagulant identified in two patients with SLE (228). It is paradoxically named, however, for the anticoagulant activity is seen *in vitro*, whereas it acts as a potent thrombotic agent *in vivo*.

Antiphospholipid antibodies may be found in the normal population, but they are more frequently detected in patients with SLE (229,230). Diagnosis of the APS involves both clinical and laboratory parameters: moderately high levels of the antiphospholipid antibodies (lupus anticoagulant and/or anticardiolipin antibodies) plus one clinical parameter (thrombosis, autoimmune thrombocytopenia, or pregnancy loss) (226,231,232,233). Potential pregnancy complications include those listed in Table 14-5 (226,227,234). The most striking adverse fetal outcomes associated with APS are fetal death and IUGR. Pregnancy loss may be

the only clinical marker associated with the presence of antiphospholipid antibodies, however. A 1994 study demonstrated a very high rate of development of thrombotic complications after the identification of these antibodies, even

P.211

in asymptomatic individuals (235). Other unusual reported complications include fetal or neonatal thrombosis resulting from transplacental passage of maternal antibodies (236,237) and fetal effects of therapy.

TABLE 14-5 PREGNANCY COMPLICATIONS SEEN IN ASSOCIATION WITH ANTIPHOSPHOLIPID ANTIBODIES^a

- Fetal loss, including recurrent embryonic loss or fetal death after 10 weeks
- Intrauterine growth restriction
- Placental infarction
- Preterm birth
- Early onset severe preeclampsia
- Nonreassuring fetal heart rate patterns
- Unusual postpartum syndrome (e.g., cardiopulmonary disease, fever, hemolytic uremic syndrome)

Postpartum hemolytic uremic syndrome associated with antiphospholipid antibodies. A case report and review of the literature. *Am J Nephrol* 1992;12:126–133.

Initial treatment of the APS involved use of low-dose aspirin (75 mg) and corticosteroids (238,239); successful pregnancy outcomes were reported by many investigators worldwide using similar regimens (227). Oropharyngeal candidiasis, gestational diabetes, osteoporosis, and PROM are some of the complications seen with corticosteroid use (227,240,241,242). An alternative regimen consisting of low-dose aspirin and heparin currently is the preferred therapy (226,240,243,244). Potential problems associated with heparin include thrombocytopenia and heparin-induced osteoporosis, although these complications are fewer with administration of low-molecular-weight heparin (243,245). Intravenous immunoglobulin also has been used (246,247). In spite of aggressive treatment, however, successful pregnancy outcomes are not guaranteed.

Thyroid Disorders

The second most common endocrine disorder in women of reproductive age consists of disorders of thyroid metabolism (248). Pregnancy significantly affects thyroid physiology. Normal pregnancy is characterized by hypermetabolic effects that resemble the clinical findings of hyperthyroidism. Although some thyroid function tests may be altered during pregnancy, largely by hyperestrogenemia and the resulting increase in thyroid-binding globulin, levels of free-circulating hormone (T_4 and T_3) and thyroid-stimulating hormone (TSH) are unchanged.

Moreover, several obstetric conditions, notably hyperemesis gravidarum or gestational trophoblastic disease, may cause abnormalities in thyroid function. These principles must be understood when making the diagnosis of thyroid disease during pregnancy.

Hyperthyroidism

Approximately 1 in 2,000 pregnancies will be complicated by thyrotoxicosis; the condition that results from excessive production of thyroid hormone. Most cases of hyperthyroidism are due to Graves disease, an autoimmune disorder characterized by production of thyroid-stimulating immunoglobulin (TSI) and thyroid-stimulating hormone-binding inhibitory immunoglobulin (TBII), both of which act on TSH production (248,249,250). Graves disease accounts for 95% of hyperthyroidism during pregnancy, affecting 1% of American women (249,250). Other causes of hyperthyroidism include excess TSH production, gestational trophoblast tumors, toxic multinodular goiter, subacute thyroiditis, overactive thyroid adenoma, and extrathyroid source of thyroid hormone (248). Poorly controlled or untreated hyperthyroidism during pregnancy is associated with greater risks of severe preeclampsia, congestive heart failure, and preterm delivery (248). The most serious consequence of uncontrolled thyrotoxicosis, thyroid storm, presents with exaggerated features of thyrotoxicosis including fever, altered mental status, vomiting, diarrhea, and cardiac dysfunction manifested by arrhythmia and heart failure (248). Usually, this rare condition is triggered by a precipitating event such as infection, trauma, or delivery; though the diagnosis can be difficult to make, treatment of the underlying condition is critical (248).

Medical treatment of hyperthyroidism involves blocking thyroid hormone production and controlling the peripheral clinical symptoms. Propylthiouracil (PTU) and methimazole, which block production of thyroid hormone, are safe in pregnancy (251). Both agents cross the placenta, but methimazole has been associated with a scalp disorder known as aplasia cutis (252). Peripheral manifestations such as tachycardia are controlled with beta-blockers, notably propranolol, widely used during pregnancy. In difficult cases, thyroidectomy may be performed during pregnancy after medical control of thyrotoxicosis has been

achieved. Iodides may be used for short periods in preparation for thyroidectomy or for management of thyroid storm.

Most fetal morbidity and mortality develop from uncontrolled maternal hyperthyroidism. Prolonged iodide exposure after 10 to 12 weeks of gestation may result in fetal hypothyroidism and goiter (248,250). Fetal thyrotoxicosis, which results from transplacental passage of TSI (253), has been reported in approximately 1% of infants of mothers with Graves disease and is associated with fetal death (248,254,255,256). Fetal blood sampling has been helpful in measuring fetal thyroid status (255,256).

Hypothyroidism

Overt hypothyroidism rarely complicates pregnancy, although retrospective studies show high rates of stillbirths, low-birth-weight infants, medically indicated preterm delivery, preeclampsia, and abruption in women with inadequately treated hypothyroidism (248). In many cases, hypothyroidism develops after thyroidectomy or

P.212

radioiodine therapy; other causes of hypothyroidism include Hashimoto thyroiditis, carcinoma, or insufficient thyroid replacement (248,250). Replacement therapy with thyroxine is recommended for these patients and TSH levels are used to guide therapeutic dosages. Replacement doses of thyroxine may need to be increased during pregnancy (257). Neonatal hypothyroidism needs to be excluded if maternal antenatal treatment involved radioactive iodine; however, because congenital hypothyroidism is a difficult diagnosis, screening for all infants is routine (248,258).

Perinatal Infections

Any infection occurring during pregnancy has the potential for causing infectious or teratogenic complications in the fetus, some with devastating effects. The two important routes for fetal infection are hematogenous via the placenta and ascending via the vagina and cervix, the latter usually occurring intrapartum. The effect of an infectious agent on fetal growth and development depends on, among other things, the type of organism, the infectious load, timing in gestation, and potential organ systems affected. Many different organisms have been implicated in causing fetal infection; Table 14-6 lists some of the important perinatal viral infections (259,260,261,262,263,264,265), and Table 14-7 lists some of the important perinatal nonviral infections (259,260,261,266,267,268).

Treatment of many perinatal infections either does not exist, as in cases with viruses, or may not prevent congenital infection, as with syphilis. Consequently, efforts to minimize the effect on the neonate focus primarily on prevention.

Examples include cesarean delivery in cases of active maternal genital herpes infection, thereby decreasing the risk of intrapartum ascending infection, neonatal administration of the hepatitis B vaccine, or administration of prophylactic eyedrops to newborns to prevent gonococcal ophthalmia neonatorum. Attempts at preventing early onset neonatal disease from group B streptococcus have resulted in guidelines from the Centers for Disease Control and Prevention, adopted by ACOG, for universal third-trimester screening and administration of intrapartum antibiotics to carriers (266). There is much work to be done, however, in devising strategies to prevent other perinatally transmitted illnesses such as congenital cytomegalovirus infection or human immunodeficiency virus that may have damaging effects on a significant number of children annually.

Thromboembolic Disorders

The risk of venous thromboembolism is five times greater during pregnancy than in the nonpregnant population, with an absolute risk of 0.5 to 3.0 per 1,000 women (269). The most constant predisposing factor for thromboembolic disease during pregnancy is venous stasis, although other factors include prolonged bed rest, operative vaginal or cesarean delivery, sepsis, hemorrhage, multiparity, and advanced maternal age (269,270). Although older reports demonstrated the greatest risk for development of thromboembolism during the third trimester and the immediate postpartum period, newer reports raise concerns that older studies may have been skewed by the practices of common operative deliveries, delaying postpartum ambulation, and suppression of lactation with oral estrogen (269,270,271). Newer data suggest not only equal frequencies in all trimesters but that antepartum events may occur at least as often as those postpartum (269,271).

Maternal thromboembolism may result from an underlying inherited coagulopathy (also known as thrombophilia). Most of these autosomally dominant disorders result in deficiencies of antithrombin III, protein C and protein S, or activated protein C resistance because of the factor V Leiden mutation (269,271,272,273,274,275,276). Other inherited thrombophilias include the prothrombin G20210A mutation, 4G/4G mutation in plasminogen activator inhibitor 1 (PAI-1) gene, and the thermolabile variant of methylenetetrahydrofolate reductase (C677T MTHFR), the latter resulting in hyperhomocysteinemia (269,272,273,274). Individuals with inherited coagulopathies have significantly increased risks of thromboembolism as well as pregnancy complications such as stillbirth, IUGR, and severe preeclampsia (269,271,272,273,274,275,276). The APS may also cause thromboembolic events (226,269,271).

The clinical diagnosis of deep vein thrombosis during gestation is imprecise. Noninvasive tests, such as impedance plethysmography or real-time Doppler sonography, accurate in nonpregnant patients, may be difficult to interpret during

pregnancy; the data they provide as initial tests, however, may be useful (269,270). Duplex ultrasound venography has been the standard in diagnosing deep venous thromboembolism (277). For both pregnant and nonpregnant patients suspected of having a pulmonary embolism, the ventilation-perfusion (V/Q) scan is the recommended study (278). In recent years the utility of spiral computed tomography (CT) has been demonstrated (279). With a 90% sensitivity and 90% specificity, some authors recommend replacing the V/Q scan with the spiral CT scan, although studies in pregnancy are lacking (269).

Treatment for acute deep vein thrombosis or pulmonary embolism during pregnancy involves 5 to 10 days of intravenous heparin followed by subcutaneous heparin in doses to achieve full-dose anticoagulation for a minimum of 3 months (269,270,271). Antepartum prophylactic heparin therapy is indicated in patients with a previous thrombotic event (269,271). The preferred anticoagulant during pregnancy is heparin because it does not cross the placenta (280); the newer low-molecular-weight heparins are safe in pregnancy (269,281). Warfarin is avoided because of associated fetal malformations: first-trimester exposure may produce an embryopathy involving stippled epiphyses, nasal and limb hypoplasia, and hypertelorism (269,282,283), and second- or third-trimester exposure is associated with central nervous system abnormalities (284). Warfarin may be used postpartum in women who are breast-feeding (271).

Renal Disorders

Mild renal dysfunction typically has little, if any, effect on pregnancy outcome; however, adverse pregnancy events are well described in women with moderate to severe renal insufficiency (e.g., serum creatinine >1.4 mg/dL) (285,286,287). These pregnancies are especially risky: maternal complications include anemia, vascular accidents, placental abruption, chronic hypertension, pregnancy-induced hypertension, preeclampsia, proteinuria, and worsening renal function; perinatal complications such as IUGR, stillbirth, prematurity, polyhydramnios, and midtrimester pregnancy loss are not unusual (285,287,288).

Dialysis may be used during pregnancies complicated by renal insufficiency. More literature is available for hemodialysis than for continuous ambulatory peritoneal dialysis (289,290, 291,292,293). Pregnancy success rates in dialysis patients are at most 52% (290), and outcomes generally are more promising for women in whom dialysis has been initiated during pregnancy compared to patients already on dialysis before

conception (289,291). Complications associated with peritoneal dialysis in pregnancy include preterm labor (289) and acute peritonitis (291,294). Hemodialysis involves intermittent and often significant fluid shifts, which may be accompanied by hypotension, electrolyte imbalances, and preterm labor (288). In one reported case, in spite of efforts to eliminate major fluid shifts and changes in arterial pressure in a patient at 32 weeks gestation, uterine artery Doppler studies showed a significant increase after hemodialysis; redistribution of flow away from the uteroplacental vascular bed during hemodialysis was postulated (288).

TABLE 14-6 SOME PERINATAL VIRAL INFECTIONS^a

Virus;	Type of Virus	Route of Transmission	Time of Critical Exposure	Potential Severe Fetal or Neonatal Effects(s)
Cytomegalovirus (CMV)	Double-stranded DNA herpesvirus	Transplacental more than ascending; also breast-feeding	Gestational age not critical; primary infection more severe than recurrent	<i>Fetus:</i> IUGR, nonimmune hydrops, hepatosplenomegaly, chorioretinitis, microcephaly, cerebral calcifications, microphthalmia, hydrocephaly. <i>Newborn:</i> jaundice, petechiae, LBW, hepatosplenomegaly, thrombocytopenia
Rubella	RNA virus	Transplacental	First trimester	Congenital heart disease, purpura, cataracts, retinopathy, IUGR, microcephaly
Herpes simplex virus (HSV)	Double-stranded DNA virus	Ascending intrapartum	Intrapartum	Microcephaly, seizures, mental retardation, microphthalmia, retinal dysplasia, meningitis, chorioretinitis (HSV-2 more important than HSV-1)

Varicella zoster	DNA herpesvirus	Transplacental	<i>Congenital varicella</i> If <20 weeks <i>neonatal varicella</i> if 5 days before or 2 days after delivery	<i>Congenital varicella</i> : limb hypoplasia, cutaneous scars, chorioretinitis, cortical atrophy, microcephaly; Neonatal varicella if contracted peripartum
Parvovirus B-19	Single-stranded DNA virus	Transplacental	Severe effects seen with exposure before 20 weeks	Low risk for fetal morbidity; possibly spontaneous abortion, hydrops (from aplastic anemia, myocarditis or chronic hepatitis) and/or stillbirth
Human immunodeficiency virus (HIV)	Retrovirus	Transplacental; ascending intrapartum; breastfeeding	Any	Neonatal acquired immunodeficiency syndrome (AIDS)
Hepatitis B	DNA virus	85%–95% ascending intrapartum; rest transplacental during acute hepatitis or postnatal via breastfeeding and close contact		Postnatal chronic hepatitis, cirrhosis, hepatocellular carcinoma

DNA, deoxyribonucleic acid; IUGR, intrauterine growth restriction; LBW, low birth weight; RNA, ribonucleic acid.

Pregnancy is no longer an unusual event among women of childbearing age with functioning renal transplants, occurring in approximately 1 of 20 to 50 women (193,295). More than 7,000 pregnancies have been reported in renal transplant recipients (296). Overall, these pregnancies have low success rates, although repeated successful pregnancies have been reported (297,298). Hypertension before or during early pregnancy is associated with adverse perinatal events (295). Typically, pregnancy results in increased renal function, which transiently declines in late pregnancy. As many as 15% of patients with kidney disease may experience permanent renal impairment (298). High rates of preterm delivery, IUGR, hypertension and/or preeclampsia, and stillbirth are reported (193,295,296,298). The risk of graft rejection, however, is not influenced by pregnancy (193). Cyclosporine A, a potent anti-T-cell immunosuppressive agent, has replaced older regimens of azathioprine and steroids in preventing graft rejection (299). Cyclosporine has been used successfully during pregnancy without evidence of teratogenicity (299,300,301).

Heart Disease

Maternal cardiac disease may be accompanied by significant maternal and perinatal morbidity and mortality. Although the etiology of cardiac disease has changed in the past 30 years, with congenital heart disease now more common than rheumatic heart disease, the underlying pathophysiology remains the same. Functional status before or early in pregnancy is an important prognostic indicator of maternal and fetal outcome. A helpful and commonly used system for assessing cardiac function is the New York Heart Association classification (Table 14-8) (302,303). Better prognoses are expected during pregnancy for women with functional classes I and II than for those with classes III or IV. Gravidæ with severe functional limitations account for 75% of the maternal deaths (304).

Preconception counseling is critical in this group of patients. The added cardiovascular demands of pregnancy may be associated with cardiac deterioration: more than 40% of women with heart disease will develop pulmonary edema for the first time during the third trimester (302,305). Maternal risks vary with the individual cardiac

P.215

lesion, several specific defects being associated with especially high risks of maternal mortality (Table 14-9) (302,303,306).

TABLE 14-8 THE NEW YORK HEART ASSOCIATION (NYHA) FUNCTIONAL CLASSIFICATION OF HEART DISEASE^a

Class	Symptoms
Class I	Asymptomatic
Class II	Symptoms with greater than normal activity
Class III	Symptoms with normal activity
Class IV	Symptoms at rest

^a From American College of Obstetricians and Gynecologists. *Cardiac disease in pregnancy. ACOG Technical Bulletin 168*. Washington, DC: ACOG, 1992; Criteria Committee of the New York Heart Association. *Nomenclature and criteria for diagnosis of diseases of the heart and great vessels*, 8th ed. Boston: Little Brown, 1979.

Fetal risks include premature delivery, IUGR, and stillbirth, especially with maternal cyanotic heart disease (302,307). A 2% to 5% incidence of fetal cardiac anomalies has been suggested in women with congenital heart disease, although with specific lesions, the risk may be as high as 26% (302,306,308). Most of the drugs used in the treatment of cardiac disease are well tolerated and rarely associated with significant fetal problems (e.g., beta-blockers, calcium channel blockers, digitalis, and heparin) (304,306). Newer agents have not been well studied during pregnancy.

Cardiac Lesion	Specific Information
Aortic insufficiency	Well tolerated
Aortic stenosis	Valve diameter must decrease to $\leq 1/3$ for hemodynamic significance; increased risk of angina, MI, syncope, or sudden death with severe disease because CO is fixed and may not be able to compensate; frequently associated with ischemic heart disease; most critical time is at pregnancy termination or delivery; PA catheterization may be most useful in labor
Ebstein anomaly	Right-to-left shunt \pm pulmonary HTN; association with thromboembolism, CHF, arrhythmias; 25% of patients have Wolf-Parkinson-White syndrome and increased risk for tachyarrhythmias

Eisenmenger syndrome	Pulmonary HTN with left-to-right shunt; grave prognosis; maternal mortality 30% to 50%; high association with thromboembolism; therapeutic termination is recommended
Marfan syndrome	Autosomal dominant; aortic dissection or aortic or splenic artery aneurysm or rupture associated with worse outcomes; 50% mortality seen with aortic root diameter >40 mm
Mitral insufficiency	Well tolerated; CHF rare; pulmonary edema more likely with preeclampsia because of increase in afterload; because of increased risk of atrial enlargement and fibrillation, prophylactic digitalis recommended in severe disease
Mitral stenosis	Tachycardia may result in fall in CO and BP; fluid balance crucial; most critical time is immediately postpartum; hemodynamic monitoring is recommended
Mitral valve prolapse	Common; mostly asymptomatic; chest pain or palpitations possible; responds to beta-blockers
Tetralogy of Fallot	VSD, overriding aorta, RVH, and pulmonary stenosis; patients are cyanotic; maternal mortality 4% to 15% in uncorrected patients; corrected cases fairly good outcome
Tricuspid or pulmonic valve disease	Well tolerated

BP, blood pressure; CHF, congestive heart failure; CO, cardiac output; HTN, hypertension; MI, myocardial infarction; PA, pulmonary artery; RVH, right ventricular hypertrophy; VSD, ventricular septal defect.

^a From American College of Obstetricians and Gynecologists. *Cardiac disease in pregnancy. ACOG Technical Bulletin 168*. Washington, DC: ACOG, 1992; Criteria Committee of the New York Heart Association. *Nomenclature and criteria for diagnosis of diseases of the heart and great vessels*, 8th ed. Boston: Little Brown, 1979.

Cardiac surgery should be delayed until after completion of pregnancy if possible. If it is required, however, surgery during the second trimester is preferable (306).

Maternal and perinatal mortality varies with the type of procedure. For example, in mitral valve commissurotomy, the cardiovascular procedure that has been performed the most during pregnancy, maternal mortality is under 3% and perinatal mortality is less than 10%; in contrast, with open-heart surgery, although maternal mortality is not significantly higher, fetal loss may be as high as 20% (306).

Myocardial infarction (MI) rarely occurs during pregnancy; the incidence is estimated at 1 in 10,000 pregnancies (309). Cases show a preponderance during the third trimester and in multiparous women older than age 33 years (310), with the majority of MIs located in the anterior wall (310,311). Maternal mortality ranges from 19% to 37%

P.216

(310,311,312). Fetal mortality is similarly high, most resulting from maternal death (310,311,312). Given that electrocardiography can be nondiagnostic in 50% of pregnant women with an acute MI, the use of cardiac troponin I levels has been found to be reliable in making an accurate diagnosis (309). Acute coronary artery angioplasty recently was successful during pregnancy (313,314). Treatment with thrombolytic agents for maternal myocardial infarction has been reported during the second trimester, although the fetal risk of such therapy has not been established (315). Some patients have had successful subsequent pregnancies (316,317).

Successful pregnancies have been reported in women who have undergone heart transplantation (304,318,319,320,321,322). Reported cases include four patients who initially received their allograft because of peripartum cardiomyopathy from an earlier pregnancy (322). Maternal hypertension, pre-eclampsia, and jaundice, as well as fetal IUGR, are common (322). Immunosuppression issues are the same as those discussed for patients with renal transplants.

Cancer

Cancer develops in approximately 1 of 1,000 pregnancies. The most common invasive carcinoma originates in the cervix, affecting one of 2,200 pregnancies (323,324). Almost 3% of all cervical cancers are diagnosed during pregnancy (325). The second most common site for malignancy during pregnancy is the breast, with cancer estimated to occur once in every 1,360 to 3,200 pregnancies (326). Other frequently seen neoplasias include vulvar, ovarian, and colorectal carcinoma, as well as leukemia, Hodgkin disease, and melanoma. Stage for stage, comparing diagnoses in nonpregnant women with those in pregnant women, carcinoma identified during pregnancy may be more advanced. Currently, this is thought to reflect a delay in diagnosis, possibly because of the physiologic changes of pregnancy, and not necessarily because the cancer is more aggressive during the pregnant state (327). It has never been substantiated that pregnancy

termination alters cancer progression (327). Metastasis to the fetus or placenta has been reported in fewer than 70 cases, mostly involving the breast, cervix, leukemia, lymphoma, melanoma, and thyroid (328).

Decisions regarding the management of malignancies during pregnancy are difficult and involve risk assessment for both mother and fetus. The difficulty of these decisions is compounded by the timing in gestation. In general, first-trimester treatment risks spontaneous abortion or fetal malformation, and early third-trimester therapy places the pregnancy at risk for preterm labor. Surgery can be performed at any time, although it is preferred during the second trimester. Radiation or chemotherapy exposure in the first trimester may affect organogenesis, resulting in either pregnancy loss or fetal structural defects (329,330,331).

Radiation exposure just prior to and immediately after implantation poses the greatest risk of spontaneous abortion (330). Animal studies demonstrate an "all-or-nothing" effect because at this early point in development, the few embryonic cells are not yet differentiated; therefore, the embryo either dies or develops normally (330). During the first 3 weeks of gestation, radiation exposure of at least 250 rads (2.5 cGy) poses the greatest risk for miscarriage (332). Exposure to more than 50 rads (0.5 cGy) is more commonly associated with development of severe malformations (333); however, congenital anomalies are unusual in embryos exposed to more than 5-rads (0.05 cGy) (332). Some malformations associated with radiation exposure during weeks 3 through 10 include microcephaly, low birth weight, mental retardation, cataracts, retinal degeneration, and skeletal abnormalities (332,333). Radiation exposure between 11 and 20 weeks of gestation is not commonly associated with fetal malformations (327,330). Pregnancy termination has been suggested when fetal exposure is greater than 10 rads (0.1 cGy) (334). In cases in which local irradiation is used to treat malignancies of the pelvis, spontaneous abortion or fetal demise usually occurs (325).

Use of cytotoxic chemotherapy is generally avoided in the first trimester, although data vary for different agents (325,329). Exposure beyond the first trimester has not been found to be associated with increased risks of congenital anomalies (325,331). Long-term developmental data are lacking, however. In treating patients with chemotherapeutic agents, recognition of the physiologic changes of pregnancy may alter the efficacy, toxicity, and/or dosage regimens.

SUMMARY

Many maternal conditions have relevance for a developing pregnancy. Counseling pregnant women with underlying medical disorders must encompass the effects of the illness on the pregnancy, the effects of the pregnancy on the condition, as well as potential complications of therapeutic interventions, and the risks of possible

premature delivery. Statistics indicating reductions in neonatal mortality rates are encouraging; however, there is much yet to be learned in perinatology in order to impact on the unacceptably high rates of premature deliveries and to improve the health of women before and during pregnancy.

Chapter 15

The Effects of Maternal Drugs on the Developing Fetus

David A. Beckman

Lynda B. Fawcett

Robert L. Brent

Every conception has a risk of ending in abortion or serious congenital anomaly (Tables 15-1,15-2). Furthermore it is axiomatic that every drug administered or taken by a pregnant woman presents the mother and fetus with both risks and benefits. The controversies in this field are primarily related to the nature and magnitude of the risks for these drugs.

Abortion and birth defects have some common etiologies, but in many instances the causes of these two areas of adverse reproductive outcome are divergent. Most human teratogens affect the embryo during a relatively narrow period of early embryonic development (18-40 days for major malformations excluding genital malformations and cleft palate which have longer periods of sensitivity). However, there are a few teratogens and many fetotoxic agents that have deleterious effects during the second and even the third trimester.

In this chapter, we evaluate the data concerning the potential risks of selected prescribed and self-administered drugs in human pregnancy. The evaluations were made after a review of the available clinical, epidemiological and experimental data and an analysis based on reproducibility, consistency and biological plausibility. Only key references or reviews are cited which will guide the reader to additional relevant literature.

CHARACTERIZATION OF ADVERSE REPRODUCTIVE OUTCOMES

Spontaneous Abortion

The definition of spontaneous abortion is based on the stage of embryonic development when viability was not possible outside the uterus. This stage is presently considered to be 20 weeks or less of gestation and a fetal weight of less than 500 grams, although these criteria are not universally accepted.

The frequency of spontaneous abortion varies with the stage of gestation Tables 15-2: more than 80% of abortions occur in the first trimester and there is a

steady decline in the risk of abortion as pregnancy progresses. Therefore it is essential that epidemiological studies into the cause of abortion compare control and "exposed" populations with the same mean stage and range of abortion. Two pregnant populations with a 2-week difference in mean stage of pregnancy will have a different background incidence of abortion. Abortion in human populations include the following causes Tables 15-3:

Chromosomal Abnormalities

The earlier the abortion, the higher the proportion of chromosomal abnormalities (1,2). Approximately 53% of spontaneous abortions in the first trimester are as a result of chromosomal abnormalities, 36% are as a result of chromosomal abnormalities in the second trimester and only 5% of stillbirths in the third trimester are as a result of chromosomal abnormalities. Over 95% of abortuses with chromosomal abnormalities were as a result of autosomal trisomy, double trisomy, monosomy, triploidy or tetraploidy (3,4). Most chromosomal abnormalities are not the cause of repetitive abortion, although in about 4% of couples with two or more spontaneous abortions, a normal-appearing parent could be a carrier for a balanced translocation or may be a mosaic with abnormal cells in the germ cell line. Environmental exposures during pregnancy cannot account for any of these abortions because most aneuploidies result from meiotic nondisjunction during gametogenesis before conception.

TABLE 15-1 FREQUENCY OF REPRODUCTIVE RISKS IN THE HUMAN

Reproductive Risk	Frequency
Immunologically and clinically diagnosed spontaneous abortions per 10 ⁶ conceptions	350,000
Clinically recognized spontaneous abortions per 10 ⁶ pregnancies	150,000
Genetic diseases per 10 ⁶ births	110,000
Multifactorial or polygenic (genetic-environmental interactions)	90,000
Dominantly inherited disease	10,000
Autosomal and sex-linked genetic disease	1,200
Cytogenetic (chromosomal abnormalities)	5,000
New mutations	3,000
Major congenital malformations per 10 ⁶ births	30,000
Prematurity per 10 ⁶ births	40,000
Fetal growth retardation per 10 ⁶ births	30,000
Stillbirths per 10 ⁶ pregnancies (>20 wks)	20,900

Abortions With Normal Chromosomes (Euploidy)

Hertig (1) and many other investigators reported the occurrence of malformed or blighted embryos as a cause of abortion. These embryonic losses may occur later in the first trimester and have been shown to have normal karyotypes (3). The etiology of these abortions are manifold and include the following:

TABLE 15-2 ESTIMATED OUTCOME OF 100 PREGNANCIES VERSUS TIME FROM CONCEPTION

Time from Conception	Percent Survival to Term	Last Time for Induction of Selected Malformations^a
Preimplantation		
0-6 days	25	
Postimplantation		
7-13 days	55	
14-20 days	73	
3-5 wk	79.5	22-23 days; cyclopia; sirenomelia, microtia 26 days; anencephaly 28 days; meningomyelocele 34 days; transposition of great vessels
6-9 wk	90	36 days; ccenter lip, 6 wk; diaphragmatic hernia, rectal atresia, ventricular septal defect, syndactyly 9 wk; ccenter palate
10-13 wk	92	10 wk; omphalocele
14-17 wk	96.26	12 wk; hypospadias
18-21 wk	97.56	
22-25 wk	98.39	
26-29 wk	98.69	
30-33 wk	98.98	
34-37 wk	99.26	

38 + wk

99.32

38 + wk; central nervous system (CNS) cell depletion

^a Modified from Schardein JL, ed. *Chemically induced birth defects*. New York: Marcel Dekker, 1993.

Genetic Abnormalities

Dominant mutations (lethals), polygenic genetic abnormalities, and recessive disease may rarely account for repetitive abortion but in most instances they will occur sporadically. A review of gene knockouts and mutations in mice suggests that embryonic death resulted from disrupting basic cellular functions, vascular circulation, hematopoiesis or nutritional supply from the mother rather than affecting embryonic organ systems (5).

Maternal Diabetes

Type I (insulin dependent) diabetes mellitus with poor metabolic control increases the risk of abortion and still births but there is no increased risk with good metabolic control.

Maternal Hyper- and Hypothyroidism

Abnormal thyroid function is rare in patients with recurrent abortion.

Corpus Luteum or Placental Progesterone Deficiency (Luteal Phase Deficiency)

It is controversial whether low hormone levels after implantation result from impending abortion or are the cause of the abortion.

Maternal Infection

Infections of the genital tract could be responsible for abortion but it is not easy to document causality. The data

P.226

suggesting that infection with *Chlamydia trachomatis*, *Borrelia burgdorferi*, *Mycoplasma hominis*, *Listeria monocytogenes*, and *Ureaplasma urealyticum* result in abortion are not conclusive. In contrast, maternal disease resulting in fetal infection with *Treponema pallidum*, *Plasmodium falciparum*, *Toxoplasma gondii*, herpes simplex virus, parvovirus B19, or cytomegalovirus has the potential to cause stillbirth or spontaneous abortion.

TABLE 15-3 ETIOLOGY OF SPONTANEOUS ABORTION IN THE HUMAN

Chromosomal Abnormalities

Chromosomal abnormalities from either the maternal or paternal gonadocytes account for 50%-70% of abortions

Abortions with Normal Chromosomes (Euploidy)

Genetic abnormalities: dominant mutations (lethal), polygenic genetic abnormalities, recessive disease from either the maternal, paternal, or both parents gonadocytes.

Severe maternal disease states: diabetes, hypothyroidism, hepatitis, collagen diseases, untreated hyperthyroidism, severe malnutrition

Corpus luteum or placental progesterone deficiency (luteal phase deficiency)

Maternal infection which results in fetal infection: *Treponema pallidum*, *Plasmodium falciparum*, *Toxoplasma gondii*, *herpes simplex virus*, *parvovirus B19*, or *cytomegalovirus*

Antiphospholipid antibodies: lupus anticoagulant, anticardiolipin antibodies

Maternal-fetal histocompatibility

Overmature gametes

Mechanical or physical problems: uterine abnormalities, multiple pregnancies, very rarely trauma

Cervical incompetence

Abnormal placentation: hypoplastic trophoblast, circumvallate implantation

Embryos and fetuses with severe malformations or growth retardation

Severe, Debilitating Maternal Diseases

Hepatitis, collagen diseases, untreated hyperthyroidism, Wilson's disease or severe malnutrition can lead to abortion.

Antiphospholipid Antibodies

Lupus anticoagulant and anticardiolipin antibodies predispose women to recurrent abortion in both first and second trimesters as a result of vascular disruption in the placenta.

Maternal-Fetal Histocompatibility

It is suggested that embryonic loss increases if the mother and fetus are more histocompatible at the human leukocyte antigen (HLA) locus, resulting in the failure to develop maternal blocking antibodies against paternal antigens.

Overmature Gametes

Either the ovum or sperm could age because insemination occurred a few days prior to ovulation or ovulation occurred prior to insemination. The magnitude of this risk factor as a cause of spontaneous abortion is not known and some investigators are skeptical that this phenomenon is clinically significant.

Mechanical or Physical Problems Related to Uterine Abnormalities, Multiple Pregnancies or Trauma

A hostile intrauterine environment can result from submucosal or intramural myomas, adhesions (Asherman's syndrome), multiple embryos or abnormalities of the uterus (bifid uterus, infantile uterus). Uterine trauma from a direct blow or penetrating injury may rarely be responsible for an abortion and if this type of injury occurs it would be more likely to result in a still birth at midgestation or later.

Cervical Incompetence

Cervical incompetence is more likely to result in second trimester than first trimester abortions.

Abnormal Placentation

Hypoplastic trophoblast and circumvallate implantation increase the risk of fetal loss.

Some Environmental Teratogens and Reproductive Toxins

Severe malformations or growth retardation implantation increase the risk of fetal loss.

Congenital Malformations

The etiology of congenital malformations can be divided into three categories: unknown, genetic, and environmental Tables 15-4. The etiology of 65%-75% of human malformations is unknown. A significant proportion of congenital malformations of unknown etiology is likely to have an important genetic component. Malformations with an increased recurrence risk, such as cleft lip and

palate, anencephaly, spina bifida, certain congenital heart diseases, pyloric stenosis, hypospadias, inguinal hernia, talipes equinovarus, and congenital dislocation of the hip, fit in the category of multifactorial disease and in the category of polygenic inherited disease (6). The multifactorial/threshold hypothesis postulates the modulation of a continuum of genetic characteristics by intrinsic and extrinsic (environmental) factors (6). Although the modulating factors are not known, they probably include: placental blood flow, placental transport, site of implantation, maternal disease states, maternal malnutrition, infections, drugs, chemicals, and spontaneous errors of development.

Spontaneous errors of development may account for some of the malformations that occur without apparent abnormalities of the genome or environmental influence. We postulate that there is some probability for error during embryonic development based on the fact that embryonic development is such a complicated process. It is estimated that 75% of all conceptions are lost before term; 50% within the first 3 weeks of development (1,2). The World Health Organization estimated that 15% of all clinically recognizable pregnancies end in a spontaneous abortion, 50%-60% of which are as a result of chromosomal abnormalities

P.227

(4,7,8). Finally, 3%-6% of offspring are malformed, which represents the background risk for human maldevelopment. This means that, as a conservative estimate, 1,176 clinically recognized pregnancies will result in approximately 176 miscarriages and 30 to 60 of the infants will have congenital anomalies in the remaining 1,000 live births. The true incidence of pregnancy loss is much higher because undocumented pregnancies are not included in this risk estimate.

TABLE 15-4 ETIOLOGY OF HUMAN CONGENITAL MALFORMATIONS OBSERVED DURING THE FIRST YEAR OF LIFE

Suspected Cause	Percent of Total
Unknown	65-75
Polygenic	
Multifactorial (gene-environment interactions)	
Spontaneous errors of development	
Synergistic interactions of teratogens	
Genetic	15-25
Autosomal and sex-linked inherited genetic disease	
Cytogenetic (chromosomal abnormalities)	
New mutations	
Environmental	10

Maternal conditions: alcoholism; diabetes; endocrinopathies; phenylketonuria; smoking and nicotine; starvation; nutritional deficits	4
Infectious agents: rubella, toxoplasmosis, syphilis, herpes simplex, cytomegalovirus, varicella-zoster, Venezuelan equine encephalitis, parvovirus B19	3
Mechanical problems (deformations): Amniotic band constrictions; umbilical cord constraint; disparity in uterine size and uterine contents	1-2
Chemicals, drugs, high dose ionizing radiation, hyperthermia	<1

Modified from Brent RL. Environmental factors: miscellaneous. In: Brent RL, Harris ML, eds. Prevention of embryonic fetal and perinatal disease. Bethesda: DHEW (NIH), 1976:211–218; Brent RL. Definition of a teratogen and the relationship of teratogenicity to carcinogenicity [Editorial]. Teratology 1986;34:359–360.

Based on his review of the literature, Wilson (9) provided a format of theoretical teratogenic mechanisms: mutation; chromosomal aberrations; mitotic interference; altered nucleic acid synthesis and function; lack of precursors, substrates, or coenzymes for biosynthesis; altered energy sources; enzyme inhibition; osmolar imbalance, alterations in fluid pressures, viscosities, and osmotic pressures; and altered membrane characteristics. We suggest a revised list of mechanisms for teratogenesis Tables 15-5.

Even though an agent can produce one or more of these pathological processes, exposure to such an agent does not guarantee that maldevelopment will occur. Furthermore, it is likely that a drug, chemical or other agent can have more than one effect on the pregnant woman and the developing conceptus and therefore the nature of the drug or its biochemical or pharmacological effects will not in themselves predict a teratogenic effect in the human. In fact, the discovery of human teratogens has come primarily from human epidemiological studies. Animal studies and in vitro studies can be very helpful in determining the mechanism of teratogenesis and the pharmacokinetics related to teratogenesis (10). However, even if one understands the pathological effects of an agent, one cannot predict the teratogenic risk of an exposure without taking into consideration the developmental stage, the magnitude of the exposure and the reparability of the embryo.

TABLE 15-5 MECHANISMS OF TERATOGENESIS

1. Cell death or mitotic delay beyond the recuperative capacity of the embryo or fetus.
2. Inhibition of cell migration, differentiation and cell communication.
3. Interference with histogenesis by processes such as cell depletion, necrosis, calcification, or scarring.
4. Biologic and pharmacological receptor-mediated developmental effects.
5. Metabolic inhibition or nutritional deficiencies.
6. Physical constraint, vascular disruption, inflammatory lesions, amniotic band syndrome.

Various maternal viral, bacterial, and parasitic infections are known to cause maldevelopment in humans including cytomegalovirus, fetal herpes virus infections (type 1 or 2), parvovirus B19 (erythema infectiosum), rubella virus, congenital syphilis (*Treponema pallidum*), *T. gondii* infection, varicella-zoster virus, and venezuelan equine encephalitis (11). The incidence of serum antibody to human immunodeficiency virus (HIV) in pregnant women is increasing from the 1991 estimate of 1.5 per 1,000 women delivering in the United States (12); the incidence is as high as 31% in pregnant women in some African cities (13). Several studies support the conclusion that asymptomatic HIV pregnancies are not associated with an increased risk of congenital malformations, low birth weight or abortion (14,15,16,17). It is likely that sexually transmitted diseases, opportunistic maternal infections, and symptomatic HIV pregnancies may increase the risk of low birth weight and morbidity in noninfected offspring.

The lethal or developmental effects of infectious agents are the result of mitotic inhibition, direct cytotoxicity or necrosis. Repair processes may result in metaplasia, scarring or calcification, which causes further damage by interfering with histogenesis. Infectious agents appear to be exceptions to some of the principles of teratogenesis because the relevance of dose and time of exposure cannot be demonstrated as readily for replicating teratogenic agents. Transplacental transmission of an infectious agent does not necessarily result in congenital malformations, growth retardation, or lethality.

Vascular disruption is a rare event associated with intrauterine death and a wide range of structural anomalies, including cerebral infarctions, certain types of visceral and urinary tract malformations, congenital limb

amputations of the nonsymmetrical type; and orofacial malformations such as mandibular hypoplasia, cleft palate, and Moebius syndrome, which vary too widely to constitute a recognized syndrome. Some anomalies associated with twin pregnancies can be explained by vascular disruption resulting from placental

anastomoses in shared placenta of monozygotic twins, anastomoses in a small percentage of dichorionic placentas in the case of dizygotic twins, or death of one twin resulting in emboli, intravascular coagulation and altered fetal hemodynamics in the co-twin (18,19). Vascular disruption may also result from physical trauma causing chorion bleeding, such as chorionic villous sampling, and exposure to some developmental toxicants, such as cocaine and misoprostol. Although uterine bleeding during the first trimester may result in fetal anomalies, the malformations associated with vascular disruption can also occur later in gestation. This topic is discussed in greater detail below with specific drugs.

Adverse Effects Produced Later in Pregnancy

The fetal period is characterized by histogenesis involving cell growth, differentiation, and migration. Drugs that produce permanent cell depletion, vascular disruption, necrosis, specific tissue or organ pathology, physiological decompensation, or severe growth retardation have the potential to cause deleterious effects throughout gestation. Sensitivity of the fetus for induction of mental retardation and microcephaly is greatest at the end of the first and the beginning of the second trimester. Other permanent neurological effects can be induced in the second and third trimesters.

The classic example of a drug that presents little risk to the developing embryo during organogenesis but can affect the near-term fetus if high doses are used is aspirin. It is possible that other antiinflammatory drugs present a similar risk.

FACTORS THAT AFFECT SUSCEPTIBILITY TO THE DELETERIOUS EFFECTS OF DRUGS

A basic tenet of environmentally produced embryo- and fetotoxicity is the effects of teratogenic or abortigenic milieu which have certain characteristics in common and follow certain basic principles. These principles determine the quantitative and qualitative aspects of developmental toxicity Tables 15-6.

Stage of Development

The induction of developmental toxicity by environmental agents usually results in a spectrum of morphological anomalies or intrauterine death, which varies in incidence depending on stage of exposure and dose. The developmental period at which an exposure occurs will determine which structures are most susceptible to the deleterious effects of the drug or chemical and to what extent the embryo can repair the damage. The period of sensitivity may be narrow or broad, depending on the environmental agent and the malformation in question. Limb defects, produced by thalidomide, have a very short period of susceptibility Tables 15-7 although microcephaly produced by radiation has a long period of susceptibility.

Our knowledge of the susceptible stage of the embryo to various environmental influences is continually expanding and is vital to evaluating the significance of individual exposures or epidemiological studies.

TABLE 15-6 FACTORS THAT INFLUENCE SUSCEPTIBILITY TO DEVELOPMENTAL TOXICANTS

Stage of development: The developmental period at which an exposure occurs will determine which structures are most susceptible to the adverse effects of chemicals and drugs and to what extent the embryo can repair the damage.

Magnitude of the exposure: Both the severity and incidence of toxic effects increase with dose.

Threshold phenomena: The threshold dose is the dose below which the incidence of death, malformation, growth retardation, or functional deficit is not statistically greater than that of nonexposed subjects.

Pharmacokinetics and metabolism: The physiologic changes in the pregnant woman and during fetal development and the bioconversion of compounds can significantly influence the developmental toxicity of drugs and chemicals by affecting absorption, body distribution, active metabolites, and excretion.

Maternal diseases: A maternal disease may increase the risk of fetal anomalies or abortion with or without exposure to a chemical or drug.

Placental transport: Most drugs and chemicals cross the placenta. The rate and extent to which a drug or chemical crosses the placenta are influenced by molecular weight, lipid solubility, polarity or degree of ionization, plasma protein binding, receptor mediation, placental blood flow, pH gradient between the maternal and fetal serum and tissues, and placental metabolism of the chemical or drug.

Genotype: The maternal and fetal genotypes may result in differences in cell sensitivity, placental transport, absorption, metabolism, receptor binding and distribution of an agent, and account for some variations in toxic effects among individual subjects and species.

During the first period of embryonic development, from fertilization through the early postimplantation stage, the embryo is most sensitive to the embryolethal effects of drugs and chemicals. Surviving embryos have malformation rates similar to the controls not because malformations cannot be produced at this stage but because significant cell loss or chromosome abnormalities at these stages have a high likelihood of killing the embryo. Because of the omnipotentiality of early embryonic cells, surviving embryos have a much greater ability to have normal developmental potential. Wilson and Brent (20) demonstrated that the all-or-none phenomenon, or marked resistance to

teratogens, disappears over a period of a few hours in the rat during early organogenesis utilizing ionizing X-irradiation as the experimental teratogen. The term all-or-none phenomenon has been misinterpreted by some investigators to indicate that malformations cannot be produced at this stage. On the contrary, it is likely that certain drugs, chemicals, or other insults during this stage of development can result in malformed offspring, but the nature of embryonic development

at this stage will still reflect the basic characteristic of the all-or-none phenomenon which is a propensity for embryo lethality rather than surviving malformed embryos.

TABLE 15-7 DEVELOPMENTAL STAGE SENSITIVITY TO THALIDOMIDE-INDUCED LIMB REDUCTION DEFECTS IN THE HUMAN

Days from Conception for Induction of Defects	Limb Reduction Defects
21-26	Thumb aplasia
22-23	Microtia
23-34	Hip dislocation
24-29	Amelia, upper limbs
24-33	Phocomelia, upper limbs
25-31	Preaxial aplasia, upper limbs
27-31	Amelia, lower limbs
28-33	Preaxial aplasia, lower limbs; phocomelia, lower limbs; femoral hypoplasia; girdle hypoplasia
30-36	Triphalangeal thumb

Modified from Brent RL, Holmes LB. Clinical and basic science lessons from the thalidomide tragedy: what have we learned about the causes of limb defects? *Teratology* 1988;38:241-251, with permission.

The period of organogenesis (from day 18 through about day 40 of postconception in the human), is the period of greatest sensitivity to teratogenic insults and the period when most gross anatomic malformations can be induced. Most environmentally produced major malformations occur before the 36th day of gestation in the human. The exceptions are malformations of the genito-urinary system, the palate, the brain or deformations as a result of problems of constraint, disruption or destruction. Severe growth retardation in the whole embryo or fetus may also result in permanent deleterious effects in many organs or tissues.

The fetal period is characterized by histogenesis involving cell growth, differentiation, and migration. Teratogenic agents that produce permanent cell

depletion, vascular disruption, necrosis, specific tissue or organ pathology, physiological decompensation, and/or severe growth retardation have the potential to cause deleterious effects throughout gestation. Additionally, sensitivity of the fetus for induction of mental retardation and microcephaly is greatest at the end of the first and the beginning of the second trimester. Other permanent neurological effects can be induced in the second and third trimesters. Effects such as cell depletion or functional abnormalities, not readily apparent at birth, may give rise to changes in behavior or fertility which are apparent only later in life. The approximate last gestational day on which certain malformations may be induced in the human is presented in Table 15-2.

Magnitude of the Exposure

The dose-response relationship is extremely important when comparing effects among different species because usage of mg/kg doses are, at most, rough approximations. Dose equivalence among species can only be accomplished by performing pharmacokinetic studies, metabolic studies, and dose-response investigations in the human and the species being studied. Furthermore, the response should be interpreted in a biologically sound manner. One example is that a substance given in large enough amounts to cause maternal toxicity is likely to also have deleterious effects on the embryo such as death, growth retardation, or retarded development. Another example is that because the steroid receptors that are necessary for naturally occurring and synthetic progestin action are absent from nonreproductive tissues early in development, the evidence is against the involvement of progesterone or its synthetic analogues in nongenital teratogenesis (21,22).

An especially anxiety-provoking concept is that the interaction of two or more drugs or chemicals may potentiate their developmental effects. Although this is an extremely difficult hypothesis to test in the human, it is an especially important consideration because multichemical or multitherapeutic exposures are common. Fraser (23) warns that the actual existence of a threshold phenomenon when nonteratogenic doses of two teratogens are combined could easily be misinterpreted as potentiation or synergism. Potentiation or synergism should be invoked only when exposure to two or more drugs is just below their thresholds for toxicity.

Several considerations affect the interpretation of dose-response relationships:

Active metabolites: Metabolites may be the proximate teratogen rather than the administered chemical, i.e., the metabolites phosphoramidate mustard and acrolein may produce maldevelopment resulting from exposure to cyclophosphamide (24).

Duration of exposure: A chronic exposure to a prescribed drug can contribute to an increased teratogenic risk, e.g., anticonvulsant therapy; in contrast an acute exposure to the same drug may present little or no teratogenic risk.

Fat-solubility: Fat-soluble substances such as polychlorinated biphenyls (25) can produce fetal maldevelopment for an extended period after the last ingestion or exposure in a woman because they have an unusually long half life.

Threshold Phenomena

The threshold dose is the dosage below which the incidence of death, malformation, growth retardation, or functional deficit is not statistically greater than that of controls. The threshold level of exposure is usually from less than one to three orders of magnitude below the teratogenic or embryopathic dose for drugs and chemicals that kill or malform half the embryos. A teratogenic agent therefore has a no-effect dose as compared to mutagens or carcinogens, which have a stochastic dose response curve. Threshold phenomena are compared to stochastic phenomena in Table 15-8. The severity and incidence of malformations produced by every exogenous teratogenic agent that has been appropriately tested have exhibited threshold phenomena during organogenesis (9).

TABLE 15-8 STOCHASTIC AND THRESHOLD DOSE-RESPONSE RELATIONSHIPS OF DISEASES PRODUCED BY ENVIRONMENTAL AGENTS

Relationship	Pathology	Site	Diseases	Risk	Definition
<i>Stochastic phenomena</i>	Damage to a single cell may result in disease	deoxyribonucleic acid DNA	Cancer, mutation	Some risk exists at all dosages; at low exposures the risk is below the spontaneous risk	Incidence of disease increases but severity and nature of the disease remain the same
<i>Threshold phenomena</i>	Multicellular injury	High variation in etiology, affecting many cell and organ processes	Malformation, growth retardation, death, chemical toxicity, etc.	No increased risk below the threshold dose	Both severity and incidence of the disease increase with dose

Modified from Brent RL. Definition of a teratogen and the relationship of teratogenicity to carcinogenicity [Editorial]. *Teratology* 1986;34:359–360, with permission.

Pharmacokinetics and Metabolism

The physiological alterations in pregnancy and the bioconversion of compounds can significantly influence the teratogenic effects of drugs and chemicals by affecting absorption, body distribution, active form(s), and excretion of the compound. Physiological alterations in the mother during pregnancy which affect the pharmacokinetics of drugs include the following: decreased gastrointestinal motility and increased intestinal transit time may delay absorption of drugs absorbed in the small intestine as a result of increased stomach retention but enhance absorption of slowly absorbed drugs; decreased plasma albumin concentration, which alters the kinetics of compound normally bound to albumin; increased plasma and extracellular fluid volumes that affect concentration-dependent transfer of compounds; renal elimination, which is generally increased but is influenced by body position during late pregnancy; inhibition of metabolic inactivation in the liver late in pregnancy; and variations in uterine blood flow, although little is known about how this affects transfer across the placenta (26,27,28).

The fetus also undergoes physiological alterations, which affect the pharmacokinetics of drugs (28): the amount and distribution of fat varies with development and affects the distribution of lipid-soluble drugs; the fetal circulation contains a higher concentration of unbound drug largely because the plasma fetal proteins are lower in concentration than in the adult and may lower drug affinity; the functional development of pharmacological receptors is likely to proceed at different rates in the various tissues; and i.v. drugs excreted by the fetal kidneys may be recycled by swallowing of amniotic fluid.

The role the placenta plays in drug pharmacokinetics, reviewed by Juchau and Rettie (29) and Miller (25), involves transport [discussed in detail in the section Placental Transport; the presence of receptors sites for a number of endogenous and xenobiotic compounds (β -adrenergic, glucocorticoid, epidermal growth factor, IgG-Fc, insulin, low-density lipoproteins, opiates, somatomedin, testosterone, transcobalamin II, transferrin, folate, retinoid)] (25); and the bioconversion of xenobiotics. Bioconversion of xenobiotics has been shown to be important in the teratogenic activity of several xenobiotics. There is strong evidence that reactive metabolites of cyclophosphamide, 2-acetylaminofluorene, and nitroheterocycles (niridazole) are the proximal teratogens (30). There is also experimental evidence that suggests that other chemicals undergo conversion to intermediates that have deleterious effects on embryonic development including phenytoin, procarbazine, rifampicin, diethylstilbestrol, some benzhydrylpiperazine antihistamines, adriamycin, testosterone, benzo(a)pyrene, methoxyethanol, caffeine, and

paraquat (29,30).

The major site of bioconversion of chemicals *in vivo* is likely to be the maternal liver. Placental P450-dependent monooxygenation of xenobiotics will occur at low rates unless induced by such compounds as those found in tobacco smoke (29). However, the fetus also develops functional P450 oxidative isozymes capable of converting proteratogens to active metabolites.

Maternal Disease

Maternal disease states such as diabetes mellitus, epilepsy, phenylketonuria, and endocrinopathies are associated with adverse effects on the fetus. In some cases, it may be difficult to determine whether a maternal disease or the treatment for the disease plays a role in the etiology of malformations associated with the treatment for that disease during pregnancy. For example, the genetic and environmental milieu, which cause epilepsy may also contribute to the maldevelopment associated with exposure to diphenylhydantoin (31).

The role of maternal malnutrition is an important area for investigation because it may be a contributing factor to many teratogenic milieu. A series of investigations provided evidence suggesting that folic acid supplementation could reduce the incidence of recurrence of neural tube defects in the human (32,33,34,35). It was later shown convincingly that periconceptional supplementation with folic acid, 4 mg/day, reduces the risk of recurrence of neural tube defects in subsequent siblings of children with neural tube defects (36). Furthermore, low-dose folic acid supplementation, 0.8 mg/day, was reported to decrease the

P.231

incidence of neural tube defects in a population not at increased risk for these defects (37). Although folate supplementation reduces the incidence of neural tube defects, folate supplementation will not prevent all neural tube defects and it is not known whether folic acid supplementation corrects an undefined metabolic defect or a nutritional deficiency.

Placental Transport

The exchange between the mammalian embryo and the maternal organism is controlled by the placenta which includes the chorioplacenta, the yolk sac placenta and the paraplacental chorion. The placenta varies in structure and function among species and for each stage of gestation. As an example, the rodent yolk sac placenta continues to function as an organ of transport for a much greater part of gestation than in the human. Thus differences in placental function and structure may affect our ability to apply teratogenic data developed in one species directly to other species, including the human (38). As pharmacokinetic techniques and the actual measurement of metabolic products in the embryo

become more sophisticated, the appropriateness of utilizing animal data to project human effects may improve.

Historically a placental barrier was thought to exist, which prevented harmful substances from reaching the embryo. It is now clear that there is no "placental barrier" per se. The fact is that most drugs and chemicals cross the placenta. It will be a rare substance that will cross the placental barrier in one species and be unable to reach the fetus in another (39). No such chemical exists except for selected proteins whose actions are species-specific.

Even before there were chemical techniques to demonstrate the presence of drugs or chemicals in the embryo there was clear evidence that they had reached the fetus because of clinical manifestations of the drugs: anticoagulants such as warfarin can affect the clotting of fetal blood; many drugs can affect the fetal cardiac rate; changes in the fetal electroencephalogram (EEG) can be demonstrated as a result of the many drugs that affect the central nervous system (CNS); and newborns may exhibit withdrawal symptoms from drugs taken by their mothers, either medications or substances of abuse such as alcohol or opiates.

These observations demonstrate clinically significant placental transport of drugs only in the latter portion of gestation and may not be a means of evaluating embryonic exposure during early organogenesis.

Those factors which determine the ability of a drug or chemical to cross the placenta and reach the embryo include: molecular weight, lipid affinity or solubility, polarity or degree of ionization, protein binding, and receptor mediation. Compounds with low molecular weight, lipid affinity, nonpolarity, and without protein-binding properties will cross the placenta with ease and rapidity. As an example, ethyl alcohol is a chemical which reaches the embryo rapidly and in concentrations equal to or greater than the level in the mother.

High molecular weight compounds like heparin, 20,000 daltons, do not readily cross the placenta and therefore heparin is used to replace warfarin-like compounds during pregnancy for the treatment of hypercoagulation conditions. Rose Bengal does not cross the placenta. In general, compounds with molecular weights of 1,000 or greater do not readily cross the placenta, although 600 dalton compounds usually do; most drugs are 250-400 daltons and cross the placenta (40).

In addition to the particular properties of the drug or chemical, three other conditions affect the quantitative aspect of placental transport: (a) placental blood flow, (b) the pH gradient between the maternal and fetal serum and tissues, and (c) placental metabolism of the chemical or drug. The biotransformation properties of the placenta and/or maternal organism are important because a number of chemicals or drugs are not teratogenic in their original form.

The most important concept regarding placental transport of teratogens must be reemphasized. An agent is teratogenic because it affects the embryo directly or indirectly by its ability to produce a toxic effect in the embryo or extraembryonic membranes at exposures which are attained in the human being, not because it crosses the placenta per se.

Genotype

The genetic constitution of an organism is an important factor in the susceptibility of a species to a drug or chemical. More than 30 disorders of increased sensitivity to drug toxicity or effects have been reported in the human as a result of an inherited trait (41). The effect of a drug or chemical depends on both the maternal and fetal genotypes and may result in differences in cell sensitivity, placental transport, absorption, metabolism (activation, inactivation, active metabolites), receptor binding, and distribution of an agent. This accounts for some variations in teratogenic effects among species and in individual subjects.

Estimating the Developmental Risks of Drugs During Human Pregnancy

Evaluation of Data Available for the Human

Although chemicals and drugs can be evaluated for fetotoxic potential by utilizing *in vivo* animal studies and *in vitro* systems, it should be recognized that these testing procedures are only one component in the process of evaluating the potential teratogenic risk of drugs and chemicals in the human. The evaluation of the teratogenicity of drugs and chemicals should include, when possible, (a) data obtained from human epidemiological studies, (b) secular trend data in humans, (c) animal developmental toxicity studies, (d) the dose-response relationship for developmental toxicity and the relationship to the human pharmacokinetic equivalent dose in the animal studies, and (e) considerations of biological plausibility Tables 15-9 (42,43). This method is of greatest value when utilized for

P.232

the evaluation of chemicals and drugs that have been in use for some time or for evaluating new drugs that have a similar mechanism of action, structure, pharmacology and purpose similar to other, extensively studied agents. The ability to establish a causal relationship between an environmental agent and abortigenic effect is more difficult, for the following reasons:

- Abortion is a very frequent reproductive event and therefore the incidence can vary considerably between different populations of women. Differences

in the abortion incidence between two populations in a single study may be as a result of chance alone.

- There are multiple causes of abortion and most epidemiological studies dealing with abortion make no attempt to determine the etiology of the abortions. Since most abortions are as a result of preconceptual or periconceptual events, it is extremely difficult to match patients in case control studies and it would be necessary to have large increases in a particular etiological category of environmentally induced abortion to demonstrate a statistically significant increase in the incidence of spontaneous abortion in an “exposed” population of pregnant women.
- Confounding factors appear to be more significant in abortion studies than in birth defect studies (cocaine, smoking, alcohol, syphilis, narcotics, caffeine). This further decreases the possibility that the agent being studied has a direct abortigenic effect.
- The incidence of therapeutic abortions is difficult to estimate or control for in most epidemiological studies (44,45).

TABLE 15-9 EVIDENCE FOR POTENTIAL DEVELOPMENTAL TOXICITY IN THE HUMAN

Epidemiological studies: Epidemiological studies consistently demonstrate an increased incidence of pregnancy loss or of a particular spectrum of fetal effects in exposed human populations.

Secular trend data: Secular trends demonstrate a relationship between the incidence of pregnancy loss or a particular fetal effect and the changing exposures in human populations. The percent of the population exposed must be large for this analysis.

Animal developmental toxicity studies: An animal model mimics the human developmental effect at clinically comparable exposures. Since mimicry may occur in only one animal species, if it occurs at all, it would not necessarily be observed during an initial developmental toxicology study. Developmental toxicity studies are therefore indicative of a potential hazard in general rather than the potential for a specific adverse effect on the fetus.

Dose-response relationship: Developmental toxicity in the human increases with dose and the developmental toxicity in animals occurs at a dose that is pharmacokinetically equivalent to the human dose.

Biological plausibility: The mechanisms of developmental toxicity are

understood or the results are biologically plausible.

Modified from Brent RL. Method of evaluating alleged human teratogens [Editorial]. *Teratology* 1978;17:83; Brent RL. Definition of a teratogen and the relationship of teratogenicity to carcinogenicity [Editorial]. *Teratology* 1986;34:359–360, with permission.

One of the advantages of reproductive effects is that there is frequently, but not always, concordance of effects involving more than one parameter (growth, malformations, abortion, stillbirth, prematurity, etc.). Isolated abortion studies that do not study the totality of reproductive effects are at a serious disadvantage, because spurious or nonetiological results may be misinterpreted as being causally related to a drug or environmental toxicant.

Some investigators and regulatory agencies divide drugs and chemicals into developmentally toxic and nontoxic compounds. In reality, potential developmental toxicity can be evaluated only if one considers, as a minimum, the agent, the dose, the species and the stage of gestation. Working definitions for developmental toxicity in the human are suggested in Table 15-10.

Potential human teratogens and abortifacients comprise a large group of drugs because they include all drugs and chemicals that can produce embryotoxic and fetotoxic effects at some exposure. Since these exposures are not utilized or attained in the human, they represent no or minimal risks to the human embryo.

Misconceptions in Evaluating Developmental Toxicity in the Human

Misconceptions have lead to confusion regarding the potential effects of even proven teratogens. Examples of erroneous concepts include: if an agent can produce one

P.233

type of malformation, it can produce any malformation; an agent presents a risk at any dose, once it can be proven to be teratogenic; and an agent that is teratogenic is likely to be abortigenic.

TABLE 15-10 DEFINITIONS OF POTENTIAL FOR DEVELOPMENTAL TOXICITY IN THE HUMAN

Developmental toxicant: An agent or milieu that has been demonstrated to produce permanent alterations or death in the embryo or fetus following intrauterine exposures that usually occur or are attainable in the human.

Potential for developmental toxicity: An agent or milieu that has not been demonstrated to produce permanent alterations or death in the embryo or fetus following intrauterine exposures that usually occur or are attainable in the human, but can affect the embryo or fetus if the exposure is raised substantially above the usual exposure. Most chemicals and drugs have the potential for interrupting a pregnancy or inducing developmental defects if the exposure is increased sufficiently.

Little or no potential for developmental toxicity: An agent or milieu that has been demonstrated to produce no embryo- or fetotoxicity at any attainable dose in the human. In contrast, an environmental agent may be so toxic that it has no developmental toxicity in the human because it kills the mother before or at the same dose that it begins to have adverse effects on the embryo.

Modified from Brent RL. Method of evaluating alleged human teratogens [Editorial]. *Teratology* 1978;17:83, with permission.

These concepts are incorrect. The data clearly indicate that proven teratogens do not have the ability to produce every birth defect. Many teratogens can be identified on the basis of the malformations that are produced. Thus, the concept of the syndrome is probably more appropriate in clinical teratology than any other area of clinical medicine. Some symptoms or signs appear in many teratogenic syndromes, such as growth retardation or mental retardation, and therefore are not very discriminating. On the other hand, rare or specific effects, such as deafness, retinitis, or a pattern of cerebral calcifications, may point to a specific teratogen. It is also true that there is substantial overlap in malformation syndromes which may not always be separable. Environmentally produced birth defects may be confused with genetically determined malformations. Using thalidomide as an example, a patient with bilateral radial aplasia and a ventricular septal defect may have the Holt Oram syndrome or the thalidomide syndrome. It may or may not be possible to make a diagnosis with absolute certainty, even if one has a history of thalidomide ingestion during pregnancy. It is possible, however, to refute the suggestion that thalidomide was responsible for congenital malformations in an individual by the nature of the limb malformation.

The specificity of some teratogens can sometimes point to the mechanism or site of action. For instance, the predominant central nervous system effects of methyl mercury are understood when one realizes the propensity for organic mercury to be stored in lipid.

Epidemiologists sometimes use poor judgment when grouping malformations. As an example, limb reduction defects are frequently studied regarding their

association with environmental teratogens but, in some studies, limb defects that are clearly related to problems of organogenesis are lumped with congenital amputations even though it is very unlikely that any agent will be responsible for both types of malformations. It is clear that epidemiological studies could be markedly improved if there was more input from clinical teratologists in planning and performing the studies.

Case control studies concerning spontaneous abortion may contain serious errors unless the populations being studied are similar regarding the stage of pregnancy when abortion occurred. This study design diminishes the possibility that the abortion rate will differ on the basis of the selection process and not the drug or environmental agent being studied. Unfortunately most epidemiological studies dealing with drug or environmentally induced abortion do not attempt to determine the etiology of the abortion.

Potential Embryo- and Fetotoxicity of Selected Prescribed and Self-administered Drugs

We evaluated the literature concerning selected drugs that cause or are suggested to cause deleterious effects during pregnancy in the human. The data included human epidemiological studies, secular trend data in humans where appropriate, and animal developmental toxicity studies. In our analysis we considered the dose-response relationship of teratogenicity, the relationship to the human pharmacokinetic equivalent dose in the animal studies and biological plausibility Tables 15-9 (42,43). Table 15-11 focuses on these drugs, listing their potential adverse effects in the human. Although these drugs account for a small percentage of all malformations and abortions, they are important because these exposures may be preventable.

Alcohol

Adverse effects in offspring from excessive alcohol consumption during pregnancy were recognized more than 200 years ago (46). It was Jones and associates (47) however, who defined the fetal alcohol syndrome (FAS) in children with intrauterine growth retardation, microcephaly, mental retardation, maxillary hypoplasia, flat philtrum, thin upper lip, and reduction in the width of palpebral fissures. Cardiac abnormalities were also seen. Many of the children of alcoholic mothers had FAS and all of the affected children evidenced developmental delay (47,48).

A period of greatest susceptibility is not clearly established but the risk for adverse effects increases with increased consumption and binge drinking early in pregnancy may be associated with an increased risk of alcohol-related effects (49). The risk of decreased brain growth and differentiation that results from high

alcohol consumption is greater during the second and third trimester. Chronic consumption of 6 oz of alcohol per day constitutes a high risk although the FAS is not likely when the mother consumes fewer than two drinks (equivalent to 1 oz of alcohol) per day (50). Reduction of alcohol consumption or cessation of drinking early in pregnancy will reduce the incidence and severity of alcohol-related effects (49,51,52,53) but may not entirely eliminate the risk of some degree of physical or behavioral impairment. The human syndrome is likely to involve the direct effects of alcohol and the indirect effects of genetic susceptibility and poor nutrition. Alcoholism can have maternally deleterious effects on intermediary metabolism and nutrition, especially if alcoholic cirrhosis is present, which can contribute to an adverse milieu for the developing embryo.

Although alcoholic mothers frequently smoke and consume other drugs, there is little doubt from the human and animal data that alcohol ingestion alone can have a disastrous effect on the developing embryo or fetus. The reported incidence of FAS varies widely in different studies but appears to be approximately 6% in offspring of women who drink heavily during pregnancy (51). Fetal alcohol syndrome may be the most commonly recognized cause of environmentally induced mental deficiency; there are at least several hundred children born each year with full FAS and probably many more with subtler fetal alcohol effects (50,54).

TABLE 15-11 EFFECTS AND ESTIMATED RISKS OF SELECTED PRESCRIBED AND SELF-ADMINISTERED DRUGS HUMAN PREGNANCY

Selected Drugs	Reported Effects or Associations and Estimated Risks	Comments ^a
Alcohol	Fetal alcohol syndrome: intrauterine growth retardation, maxillary hypoplasia, reduction in width of palpebral fissures, characteristic but not diagnostic facial features, microcephaly, mental retardation. An increase in spontaneous abortion has been reported but since mothers who abuse alcohol during pregnancy have multiple other risk factors, it is difficult to determine whether this is a direct effect on the embryo. Consumption of 6 oz of alcohol or more per day constitutes a high risk but it is likely that detrimental effects can occur at lower exposures.	Quality of available information: good to excellent. Direct cytotoxic effects of ethanol and indirect effects of alcoholism. While a threshold teratogenic dose is likely it will vary in individuals because of a multiplicity of factors.
Aminopterin, methotrexate	Microcephaly, hydrocephaly, cleft palate, meningomyelocele, intrauterine growth retardation, abnormal cranial ossification, reduction in derivatives of first branchial arch, mental retardation,	Quality of available information: good. Anticancer, antimetabolic agents; folic acid antagonists that inhibit dihydrofolate reductase, resulting in cell death.

postnatal growth retardation. Aminopterin can induce abortion within its therapeutic range; it is used for this purpose to eliminate ectopic embryos. Risk from therapeutic doses is unknown but appears to be moderate to high.

Androgens

Masculinization of female embryo: clitoromegaly with or without fusion of labia minora. Nongenital malformations are not a reported risk. Androgen exposures which result in masculinization have little potential for inducing abortion. Based on animal studies, behavioral masculinization of the female human will be rare.

Quality of available information: good. Effects are dose and stage dependent; stimulates growth and differentiation of sex steroid receptor-containing tissue.

Angiotensin-converting enzyme (ACE) inhibitors

The therapeutic use of ACE inhibitors has neither a teratogenic effect nor an abortigenic effect in the first trimester. Since this group of drugs does not interfere with organogenesis, they can be used in a woman of reproductive age; if the woman becomes pregnant, therapy can be changed during the first trimester without an increase in the risk of

Quality of available information: good. Antihypertensive agents; adverse fetal effects are related to severe fetal hypotension over a long period of time during the second or third trimester.

teratogenesis. Later in gestation these drugs can result in fetal and neonatal death, oligohydramnios, pulmonary hypoplasia, neonatal anuria, intrauterine growth retardation, and skull hypoplasia. Risk is dependent on dose and length of exposure.

Antibiotics

Streptomycin:

Streptomycin and a group of ototoxic drugs can affect the eighth nerve and interfere with hearing; it is a relatively low-risk phenomenon. There are not enough data to estimate the abortigenic potential of streptomycin. Because the deleterious effect of streptomycin is limited to the eighth nerve, it is unlikely to affect the incidence of abortion.

Tetracycline: Bone staining and tooth staining can occur with therapeutic doses. Persistent high doses can cause hypoplastic tooth enamel. No other congenital malformations are at increased risk. The usual therapeutic doses present no increased risk of abortion to the embryo or fetus.

Quality of available information: fair to good. Long duration maternal therapy during pregnancy is associated with hearing deficiency in offspring.

Quality of available information: good. Effects seen only if exposure is late in the first or during second or third trimester, since tetracyclines have to interact with calcified tissue.

These antibiotics are used in late pregnancy for the treatment of sexually transmitted diseases.

Penicillin G benzathine used for the treatment of syphilis produces no adverse fetal effects in the usual therapeutic regimens:

Ceftriaxone and doxycycline used for the treatment of gonorrhea produces no adverse fetal effects in the usual therapeutic regimens.

Erythromycin base or stearate used for the treatment of Chlamydia involves a possible increased risk of cholestatic hepatitis in the usual therapeutic regimens.

Antihypertensive
(excluding ACE
inhibitors)

Clonidine: a direct alpha adrenergic agonist that appears to be relatively safe during pregnancy but there are few available data.

Hydralazine: a vasodilator often used in combination with methyldopa and is considered to be safe.

Methyldopa: a centrally acting adrenergic antagonist and currently the safest antihypertensive drug available for use during pregnancy with no reported adverse effects on the fetus or on mental and physical

development.

Nifedipine: a calcium channel blocker whose potential for adverse effects with its long term use in the treatment of hypertension is unknown.

Propranolol: a β -blocker whose prolonged use may increase the risk of intrauterine growth retardation.

Antituberculosis therapy

Drugs prescribed for the treatment of tuberculosis include aminoglycosides, ethambutol, isoniazid, rifampin, and ethionamide. The ototoxic effects of streptomycin (discussed above) are the only proven adverse effects of these drugs on the fetus. Therapeutic exposures to other tuberculostatic drugs appear to represent a very small risk of teratogenesis and even less risk of abortion.

Aspirin

No increased risk for malformations or abortion low dose regimen (60–50;150 mg per day). Aspirin should be discontinued 1 week before anticipated delivery to reduce the risk for maternal or neonatal bleeding.

Used for treatment of preeclampsia, idiopathic placental insufficiency, systemic lupus erythematosus, increased platelet aggregation

Benzodiazepines

Benzodiazepines appear to have minimal or no increased risk of malformations at therapeutic ranges; higher exposures may increase the risk. The risk for abortion is unknown.

Chlordiazepoxide (Librium), appears to have a minimal risk for congenital anomalies and no increased risk for abortion at therapeutic doses. Higher exposures are likely to increase the risk of adverse effects on the fetus but the magnitude of the increase is not known.

Diazepam (Valium): third trimester exposure can reversibly affect the fetus and neonate there is minimal increased risk of congenital malformations and no demonstrated increased risk of abortions from therapeutic exposures.

Meprobamate: weakly associated with a variety of congenital malformations but the data are not sufficient to confirm or rule out a small increase risk of malformations due to exposures early in pregnancy.

The benzodiazepines are widely used as tranquilizers during pregnancy.

Caffeine	<p>Caffeine is teratogenic in rodent species with doses of 150 mg/kg. There is no convincing data that moderate or usual exposures (300 mg per day or less) present a measurable risk in the human for any malformation or group of malformations. On the other hand, excessive caffeine consumption (exceeding 300 mg per day) during pregnancy is associated with growth retardation and embryonic loss.</p>	<p>Quality of available information: fair to good. Behavioral effects have been reported and appear to be transient or temporary; more information is needed concerning the population with higher exposures.</p>
Carbamazepine	<p>Minor craniofacial defects (upslanting palpebral fissures, epicanthal folds, short nose with long philtrum), fingernail hypoplasia, and developmental delay. Teratogenic risk is not known but likely to be significant for minor defects. There are too few data to determine whether carbamazepine presents an increased risk for abortion. Since embryos with multiple malformations are more likely to abort, it would appear that carbamazepine presents little risk because an increase in these types of malformations has not</p>	<p>Quality of available information: fair to good. Anticonvulsant; little is known concerning mechanism. Epilepsy may itself contribute to an increased risk for fetal anomalies.</p>

Cocaine

been reported.

Preterm delivery; fetal loss; placental abruption; intrauterine growth retardation; microcephaly; neurobehavioral abnormalities; vascular disruptive phenomena resulting in limb amputation, cerebral infarctions and certain types of visceral and urinary tract malformations. There are few data to indicate that cocaine increases the risk of first trimester abortion. The low but increased risk of vascular disruptive phenomena due to vascular compromise of the pregnant uterus would more likely result in midgestation abortion or stillbirth. It is possible that higher doses could result in early abortion. Risk for deleterious effects on fetal outcome is significant; risk for major disruptive effects is low, but can occur in the latter portion of the first trimester as well as the second and third trimesters.

Quality of available information: fair to good. Cocaine causes a complex pattern of cardiovascular effects due to its local anesthetic and sympathomimetic activities in the mother. Fetopathology is likely to be due to decreased uterine blood flow and fetal vascular effects. Because of the mechanism of cocaine teratogenicity, a well-defined cocaine syndrome is not likely. Poor nutrition accompanies drug abuse and multiple drug abuse is common.

Coumarin derivatives	<p>Nasal hypoplasia; stippling of secondary epiphysis; intrauterine growth retardation; anomalies of eyes, hands, neck; variable central nervous system anatomical defects (absent corpus callosum, hydrocephalus, asymmetrical brain hypoplasia). Risk from exposure 10% to 25% during 8th to 14th week of gestation. There is also an increased risk of pregnancy loss. There is a risk to the mother and fetus from bleeding at the time of labor and delivery.</p>	<p>Quality of available information: good. Anticoagulant; bleeding is an unlikely explanation for effects produced in the first trimester. CNS defects may occur anytime during second and third trimester and may be related to bleeding.</p>
Cyclophosphamide	<p>Growth retardation, ectrodactyly, syndactyly, cardiovascular anomalies, and other minor anomalies. Teratogenic risk appears to be increased but the magnitude of the risk is uncertain. Almost all chemotherapeutic agents have the potential for inducing abortion. This risk is dose-related; at the lowest therapeutic doses the risk is small.</p>	<p>Quality of available information: fair. Anticancer, alkylating agent; requires cytochrome P450 mono-oxygenase activation; interacts with DNA, resulting in cell death.</p>

Diethylstilbestrol (DES)	<p>Clear cell adenocarcinoma of the vagina occurs in about 1:1,000 to 10,000 females who were exposed <i>in utero</i>. Vaginal adenosis occurs in about 75% of females exposed in utero before the 9th week of pregnancy. Anomalies of the uterus and cervix may play a role in decreased fertility and an increased incidence of prematurity although the majority of women exposed to DES <i>in utero</i> can conceive and deliver normal babies. <i>In utero</i> exposure to DES increased the incidence of genitourinary lesions and infertility in males. DES can interfere with zygote survival, but it does not interfere with embryonic survival when given in its usual dosage after implantation. Offspring who were exposed to DES <i>in utero</i> have an increased risk for delivering prematurely, but do not appear to be at increased risk for first trimester abortion.</p>	<p>Quality of available information: fair to good. Synthetic estrogen; stimulates estrogen receptor-containing tissue, may cause misplaced genital tissue which has a greater propensity to develop cancer.</p>
Digoxin	<p>No adverse fetal effects reported with usual therapeutic regimens.</p>	<p>Used for treatment of fetal dysrhythmia.</p>

Diphenylhydantoin	<p>Hydantoin syndrome: microcephaly, mental retardation, cleft lip/palate, hypoplastic nails and distal phalanges; characteristic, but not diagnostic facial features. Associations documented only with chronic exposure. Wide variation in reported risk of malformations but appears to be no greater than 10%. The few epidemiological data indicate a small risk of abortion for therapeutic exposures for the treatment of epilepsy. For short term treatment, i.e., prophylactic therapy for a head injury, there is no appreciable risk.</p>	<p>Quality of available information: fair to good. Anticonvulsant; direct effect on cell membranes, folate, and vitamin K metabolism. Metabolic intermediate (epoxide) has been suggested as the teratogenic agent.</p>
Glucocorticoids	<p><i>Dexamethasone, Betamethasone, Dexamethasone, Hydrocortisone, Methylprednisone:</i> Glucocorticoids have not been shown to be teratogenic but chronic glucocorticoid therapy may result in prematurity and intrauterine growth retardation.</p>	<p>Glucocorticoids are used late in pregnancy to reduce respiratory distress in premature infants and to treat congenital adrenal hyperplasia. They are also used in the treatment of rheumatic diseases, other acute and chronic inflammatory diseases, and organ transplantation.</p>

Indomethacin	Can prolong labor and may predispose neonate to necrotizing enterocolitis when used as a tocolytic.	Used for the prevention or reduction of intraventricular hemorrhage in premature infant and for treatment of polyhydramnios.
Lithium carbonate	Although animal studies have demonstrated a clear teratogenic risk, the effect in humans is uncertain. Early reports indicated an increased incidence of Ebstein's anomaly, other heart and great vessel defects, but as more studies are reported the strength of this association has diminished. Lithium levels within the therapeutic range (1.2 mg%) do not increase the risk of abortion.	Quality of available information: fair to good. Antidepressant; mechanism has not been defined.
Methylene blue	Hemolytic anemia and jaundice in neonatal period after exposure late in pregnancy. There may be a small risk for intestinal atresia but this is not yet clear. No indication of increased risk of abortion.	Quality of available information: poor to fair. Used to mark amniotic cavity during amniocentesis.

Misoprostol	Misoprostol is a synthetic prostaglandin analog that has been used by millions of women for illegal abortion. A low incidence of vascular disruptive phenomenon, such as limb reduction defects and Mobius syndrome, has been reported.	Quality of available information: Fair Classical animal teratology studies would not be helpful in discovering these effects, because vascular disruptive effects occur after the period of early organogenesis.
Oxazolidine-2,4-diones (trimethadione, paramethadione)	Fetal trimethadione syndrome: V-shaped eye brows, low-set ears with anteriorly folded helix, high-arched palate, irregular teeth, CNS anomalies, severe developmental delay. Wide variation in reported risk. Characteristic facial features are documented only with chronic exposure. The abortifacient potential has not been adequately studied, but appears to be minimal.	Quality of available information: good to excellent. Anticonvulsants; affects cell membrane permeability. Actual mechanism of action has not been determined.
D-Penicillamine	Cutis laxa, hyperflexibility of joints. Condition appears to be reversible and the risk is low. There are no human data on the risk of abortion.	Quality of available information: fair to good. Copper chelating agent; produces copper deficiency inhibiting collagen synthesis and maturation.
Phenobarbital	No adverse fetal effects reported for usual therapeutic regimens.	May be used for the prevention or reduction of intraventricular hemorrhage in premature infant.

Progestins

Masculinization of female embryo exposed to high doses of some testosterone-derived progestins and may interact with progesterone receptors in the liver and brain later in gestation. The dose of progestins present in modern oral contraceptives presents no masculinization or feminization risks. All progestins present no risk for nongenital malformations. Many synthetic progestins and natural progesterone have been used to treat luteal phase deficiency, embryos implanted via *in-vitro* fertilization (IVF) threatened abortion or bleeding in pregnancy with variable results. Conversely, synthetic progestins that interfere with progesterone function may cause early pregnancy loss; RU-486 is presently used specifically for this purpose.

Quality of available information: good. Stimulates or interferes with sex steroid receptor-containing tissue.

<p>Retinoids, systemic (isotretinoin, etretinate)</p>	<p>Increased risk of CNS, cardio-aortic, ear, and clefting defects. Microtia, anotia, thymic aplasia and other branchial arch, aortic arch abnormalities and certain congenital heart malformations. Exposed embryos are at greater risk for abortion. This is plausible since many of the malformations, such as neural tube defects, are associated with an increased risk of abortion.</p>	<p>Quality of available information: fair. Used in treatment of chronic dermatoses. Retinoids can cause direct cytotoxicity and alter programmed cell death; affect many cell types but neural crest cells are particularly sensitive.</p>
<p>Retinoids, topical (tretinoin)</p>	<p>Epidemiological studies, animal studies and absorption studies in humans do not suggest a teratogenic risk. Regardless of the risks associated with systemically administered retinoids, topical retinoids present little or no risk for intrauterine growth retardation, teratogenesis or abortion because they are minimally absorbed and only a small percentage of skin is exposed.</p>	<p>Quality of available information: poor. Topical administration of tretinoin in animals in therapeutic doses is not teratogenic, although massive exposures can produce maternal toxicity and reproductive effects. More importantly, topical administration in humans results in non-measurable blood levels.</p>
<p>Rh immune globulin</p>	<p>No adverse fetal effects have been associated with Rh-Ig prophylaxis against Rh immunization.</p>	

Smoking and nicotine	<p>Placental lesions; intrauterine growth retardation; increased postnatal morbidity and mortality. While there have been some studies reporting increases in anatomical malformations, most studies do not report an association. There is no syndrome associated with maternal smoking. Maternal or placental complications can result in fetal death. Exposures to nicotine and tobacco smoke are a significant risk for pregnancy loss in the first and second trimester.</p>	<p>Quality of available information: good to excellent. While tobacco smoke contains many components, nicotine can result in vascular spasm vasculitis which has resulted in a higher incidence of placental pathology.</p>
Thalidomide	<p>Limb reduction defects (preaxial preferential effects, phocomelia), facial hemangioma, esophageal or duodenal atresia, anomalies of external ears, eyes, kidneys, and heart, increased incidence of neonatal and infant mortality. The thalidomide syndrome, while characteristic and recognizable, can be mimicked by some genetic diseases. Although there are fewer data pertaining to its abortigenic potential, there appears to be an</p>	<p>Quality of available information: good to excellent. Sedative—hypnotic agent. The etiology of thalidomide teratogenesis has not been definitively determined.</p>

Thyroid: iodides, antithyroid drugs (thioamides)	<p>increased risk of abortion.</p> <p>Fetal hypothyroidism or goiter with variable neurologic and aural damage. Maternal hypothyroidism is associated with an increase in infertility and abortion. Maternal intake of 12 mg of iodide per day or more increases the risk of fetal goiter. Thioamides may cause fetal goiter but dose can be adjusted to minimize this effect.</p>	<p>Quality of available information: good. Fetopathic effect of iodides and antithyroid drugs involves metabolic block, decreased thyroid hormone synthesis and gland development.</p>
Tocolytics	<p>There are no reports of adverse fetal outcome resulting from exposure to therapeutic doses of terbutaline, ritodrine, or magnesium sulfate.</p>	
Toluene	<p>Intrauterine growth retardation; craniofacial anomalies; microcephaly. It is likely that high exposures from abuse or intoxication increase the risk of teratogenesis and abortion. Occupational exposures should present no increase in the teratogenic or abortigenic risk. The magnitude of the increased risk for teratogenesis and abortion in abusers is not known because the exposure in abusers is too variable.</p>	<p>Quality of available information: poor to fair. Neurotoxicity is produced in adults who abuse toluene; a similar effect may occur in the fetus.</p>

Valproic acid	<p>Malformations are primarily neural tube defects and facial dysmorphism. The facial characteristics associated with this drug are not diagnostic. Small head size and developmental delay have been reported with high doses. The risk for spina bifida is about 1% but the risk for facial dysmorphism may be greater. Because therapeutic exposures increase the incidence of neural tube defects, one would expect a slight increase in the incidence of abortion.</p>	<p>Quality of available information: good. Anticonvulsant; little is known about the teratogenic action of valproic acid.</p>
Vitamins	<p><i>Biotin:</i> No adverse fetal effects for the usual therapeutic regimen</p> <p><i>Cyanocobalamin:</i> No adverse fetal effects for the usual therapeutic regimen.</p> <p><i>Folic acid:</i> The efficacy of folic acid supplementation for reducing the risk of neural tube defect recurrence may be limited to a select portion of the population. There are no adverse fetal effects for the usual therapeutic regimen.</p> <p><i>Vitamin A:</i> The same malformations that have</p>	<p>Used for treatment of multiple carboxylase deficiency</p> <p>Used for treatment of vitamin B₁₂- responsive methylmalonic acidemia</p> <p>Used for reduction in recurrence of neural tube defects</p> <p>Quality of available information: good. High concentrations of retinoic acid are cytotoxic; it may interact with DNA to delay differentiation and/or inhibit protein synthesis. Quality of available information: poor. Mechanism is</p>

been reported with the retinoids have been reported with very high doses of vitamin A (retinol). Exposures below 10,000 IU. present no risk to the fetus.

Vitamin A in its recommended dose presents no increased risk for abortion.

Vitamin D: Large doses given in vitamin D prophylaxis are possibly involved in the etiology of supra-aortic stenosis, elfin faces, and mental retardation.

There is no data on the abortifacient effect of vitamin D.

likely to involve a disruption of cell calcium regulation with excessive doses.

Aminopterin and Methotrexate

Aminopterin and methotrexate (methylaminopterin) are folic acid antagonists that inhibit dihydrofolate reductase, resulting in cell death during the S phase of the cell cycle (55). Aminopterin-induced therapeutic abortions have resulted in malformations (hydrocephalus, cleft palate, meningomyelocele and growth retardation) in some of the abortuses (56,57,58). Three case reports of children exposed to aminopterin *in utero* included observations of growth retardation, abnormal cranial ossification, high-arched palate, and reduction in derivatives of the first branchial arch (59). The pattern of malformations associated with exposure to either compound has been referred to as the fetal aminopterin/methotrexate syndrome (60). Key

P.239

features of this pattern of malformations include prenatal growth deficiency, abnormal cranial ossification, micrognathia, small low set ears, and limb abnormalities. There have also been three case reports to date of severe developmental delay in children with methotrexate syndrome (61,62,63). Methotrexate is used therapeutically as an abortifacient, treatment of rheumatoid arthritis and other autoimmune disorders, and as an antineoplastic agent. Skalko and Gold demonstrated a threshold effect and a dose-dependent increase in malformations in mice exposed to methotrexate in utero (64). Although malformations were induced in rats at doses exceeding those used in humans (65), smaller doses than those used in humans have resulted in malformation in rabbits (66). Analysis of human data indicate a critical period of exposure to methotrexate from 6-8 weeks from conception at a dose above 10 mg per week for the development of aminopterin/ methotrexate syndrome (67). The risk of adverse effects as a result of aminopterin in the usual therapeutic range is not known precisely but appears to be moderate to high (58).

Androgens

Masculinization of the external genitalia of the female has been reported following *in utero* exposure to large doses of testosterone, methyltestosterone, and

testosterone enanthate (68,69,70). The masculinization is characterized by clitoromegaly with or without fusion of the labia minora and no indication of nongenital malformations. Affected females experience normal secondary sexual development at puberty (71).

Many animal models show the masculinizing effects of androgens. Well-known studies were performed by Greene and coworkers in the rat, Raynaud in the mouse, Bruner and Witschi in the hamster, Jost in the rabbit, and Wells and Van Wagenen in the monkey (72,73,74,75,76). These studies demonstrated the masculinization of the urogenital sinus, its derivatives, and the external genitalia, although there was little effect on the mullerian ducts, and ovarian inversion did not occur. Based on experimental animal studies of altered sexually dimorphic behavior in female guinea pigs, rats and monkeys (77,78,79,80,81,82), behavioral masculinization of the female as a result of prenatal exposure to androgens in the human will be rare. The available literature indicates that the effects of androgens on the fetus are dependent on the dose and stage of development during which exposure occurred.

Angiotensin Converting Enzyme Inhibitors

The first angiotensin converting enzyme (ACE) inhibitor, captopril, was introduced in 1981 for the treatment of severe refractory hypertension. Since then the number of ACE inhibitors has increased and now includes enalapril, lisinopril, quinapril, perindopril, fosinopril, ramipril, and cilazapril (83). Their relative effectiveness, combined with a paucity of side effects as compared to other antihypertensives, have made these drugs extremely popular for the treatment of all types of hypertension and congestive heart failure and diabetic nephropathy.

ACE inhibitors are competitive inhibitors of ACE, a carboxypeptidase that forms an integral part of the renin angiotensin system (83). ACE catalyses the conversion of angiotensin I to angiotensin II, one of the most potent vasoconstrictors known. It is the same enzyme as kininase II, and also catalyses the breakdown of bradykinin. A vasodilatory peptide itself, bradykinin stimulates the release of other vasodilatory substances including prostaglandins and endothelium derived relaxation factor (84). Both mechanisms of action contribute to the decrease in blood pressure resulting from ACE inhibition (85).

Although they are considered relatively safe for the treatment of hypertension, the use of ACE inhibitors during pregnancy has been associated with adverse fetal outcomes in both humans and experimental animals. The first case of adverse fetal outcome in humans was reported in 1981 (86). In that report, treatment with captopril began on the 26th week of gestation, oligohydramnios was detected 2 weeks later, and a cesarean section was performed the following week. The child was anuric and hypotensive and died on day 7. The kidneys and bladder were morphologically normal but hemorrhagic foci were found in the renal cortex

and medulla. Numerous cases of severe and often lethal adverse fetal effects associated with ACE inhibitor use during pregnancy have since been reported (87,88,89). The most consistent findings have been associated with a disruption of fetal renal function resulting in oligohydramnios and neonatal anuria accompanied by severe hypotension (87,89). Intrauterine growth retardation, pulmonary hypoplasia, hypocalvaria, persistent patent ductus arteriosus, and renal tubular dysgenesis have also been reported (89,90,91). Some of these effects may also result from the condition for which ACE inhibitors were prescribed (87). These effects have been associated with ACE inhibitor treatment only during the second and third trimester. There are no reports of adverse fetal outcome associated with ACE inhibitor use during the first trimester (89,91). As ACE inhibitors do not appear to affect organogenesis in either humans or in animal studies, it is not a classical teratogen. For this reason Pryde and associates (89) have proposed the term ACE inhibitor fetopathy to describe the characteristic syndrome that results from ACE inhibitor use during pregnancy.

The majority of adverse fetal effects associated with ACE inhibitor use during pregnancy result from the direct therapeutic action of ACE inhibitors on the fetus. ACE inhibitors readily cross the placenta in which they inhibit fetal ACE activity (89,92). The decreased renal blood flow caused by vasodilation of renal efferent arterioles results in a loss of glomerular filtration pressure leading to fetal anuria and oligohydramnios (92,93). This in turn may result in other adverse fetal outcomes, such as pulmonary hypoplasia. Fetal urine production and tubular function does not begin until approximately 9-12 weeks of gestation

P.240

and probably explains the lack of adverse fetal effects when ACE inhibitor treatment is discontinued in the first trimester. Renal dysplasia, in particular a lack of renal proximal tubule differentiation, has also been noted in some effected fetuses (90,93,94).

Exposure to ACE inhibitors during pregnancy has also resulted in several cases of hypocalvaria, an ossification defect of the membranous bones of the skull that leaves the fetal brain inadequately protected (89,90). Although the pathogenesis is still unknown, inadequate perfusion of developing bone as a result of fetal hypotension combined with pressure from uterine muscles as a result of oligohydramnios may explain this defect (90,91). It has also been suggested that ACE inhibitors may affect ossification by acting on osteoblast-derived growth factors (90).

Despite consistent reports of adverse ace inhibitor fetopathy, there are no controlled studies available to assess the risks associated with the use of ACE inhibitors during pregnancy. Because there is no reported incidence of adverse fetal effects as a result of ACE inhibitor use during the first trimester of pregnancy, there is no contraindication to ACE inhibitors in women of reproductive age. If the woman becomes pregnant therapy is then changed to an alternative

antihypertensive that represents less risk to the fetus.

Antibiotics

The incidence of intraamniotic infection is about 1% of all pregnancies but 3%-40% of women with ruptured membranes for 24 hours or more (95).

Intraamniotic infection is associated with increased morbidity in the newborn including pneumonia, and sepsis. There is also a significant increase in perinatal mortality associated with intraamniotic infection although this is in part related to prematurity.

Increased neonatal mortality and morbidity, especially from group B streptococcal infection, can be largely prevented by intrapartum chemoprophylaxis. Neonatal sepsis is also significantly reduced if mothers receive intrapartum antibiotics. With few exceptions (such as streptomycin) acute exposure to antibiotics in usual therapeutic doses poses little significant risk to the fetus, especially in comparison to the potentially devastating effects of neonatal sepsis.

Aminoglycosides

This class of antimicrobials includes gentamicin, tobramycin, streptomycin and kanamycin. The only drug in this category with confirmed developmental toxicity is streptomycin. Based on case reports, there appears to be a small increased risk of sensorineural deafness in offspring of women treated with streptomycin for tuberculosis during pregnancy (96,97). Other congenital anomalies have not been associated with in utero exposure to streptomycin in the human (98). Because of the risk for ototoxicity, streptomycin should not be given during pregnancy. However, other aminoglycosides, such as kanamycin, appears to have minimal risk of causing similar adverse effects (99,100).

Anti-Tuberculosis Therapy

Drugs prescribed for the treatment of tuberculosis include aminoglycosides, ethambutol, isoniazid, rifampin, and ethionamide. The ototoxic effects of streptomycin are the only proven adverse effects of these drugs on the fetus. Neither ethambutol nor rifampin have been associated with an increase in the incidence of growth retardation, premature birth or malformations (96,97,101,102).

Early reports did not associate therapeutic exposures to isoniazid with an increased risk of malformations (96,97) but there is an unconfirmed association with CNS dysfunction (103,104). There was one attempted suicide involving 50 tablets of isoniazid per day during the 12th week that resulted in a stillbirth with arthrogryposis multiplex congenita syndrome (105). Isoniazid may have small increased risk for adverse effects on the CNS but there is no apparent increase in

risk for congenital malformations or abortions with therapeutic exposures. Only one report associated ethionamide with an increased risk of teratogenic effects (106). However, this association is tenuous and not supported by other case reports (107).

As a general observation, the antituberculosis drugs produce adverse effects on the fetus of experimental animals in greater doses than those equivalent to therapeutic exposures and not in all species. Embryotoxicity can be demonstrated for streptomycin in the mouse, kanamycin in the guinea pig, isoniazid in the rat, rifampin in the rat, and ethionamide in the rabbit (108,109,110). While this does not eliminate the possibility of adverse effects on the fetus following exposure to the other prescribed tuberculostatic medications discussed, therapeutic exposures appear to represent a very small risk of teratogenesis and even less risk of abortion.

Cephalosporins

Cephalosporins are frequently prescribed during pregnancy. Examples include cephalexin (Keflex), cefixime (Suprax), and cefaclor (Ceclor). Although generally considered safe for use in pregnancy, epidemiological studies examining the effects of this class of antibiotics on the developing fetus are scarce. However, available data indicate that, although a small risk cannot be completely excluded, a high risk of congenital anomalies resulting from in utero exposure in the first trimester is unlikely (111).

Macrolides

This category includes erythromycin, azithromycin, and clarithromycin (Biaxin). Erythromycin does not readily cross the placenta and is generally considered safe for use in pregnancy. There is less available data on azithromycin and clarithromycin however existing data indicate that any potential risk is minimal. As is the case with other sexually transmitted diseases, chlamydia infection is on the increase. The infant most likely acquires chlamydial infection during parturition

P.241

at an incidence of approximately 50%. Erythromycin is an effective prenatal treatment.

Metronidazole

Metronidazole (Flagyl) is used most frequently to treat trichomoniasis, various other protozoan and anaerobic bacterial infections, and to help prevent preterm labor. Administration is given orally, rectally and parenterally. Vaginal absorption occurs readily but plasma levels achieved are much lower than those achieved by other routes. There are a large number of studies examining the risk of exposure

during pregnancy to the developing fetus. Epidemiological studies, and the majority of animal studies have not revealed an increased risk of congenital anomalies with exposure during the first trimester (112,113,114,115,116,117), or when used to prevent preterm labor in the third trimester (118,119). Based on these studies therapeutic use of metronidazole during pregnancy is generally considered safe. Although some bacterial test systems indicated mutagenicity, there is no evidence for increased chromosomal abnormalities in human cells (120,121,122).

Penicillin

The most frequently prescribed drugs in this category include penicillin, ampicillin, and amoxicillin. Newer agents may also contain an agent to enhance effectiveness against resistant microbials such as the use of amoxicillin with clavulanic acid (Augmentin). There are no adverse fetal effects reported for any penicillins. Among other uses penicillin is used in pregnancy to treat *Treponema pallidum* in pregnant women.

Quinolones

Fluoroquinolones (ciprofloxacin, norfloxacin, ofloxacin), are used to treat urinary infections. Reports of use in early pregnancy have not revealed any teratogenic or developmental risk (123,124,125,126,127,128,129,130). Studies in immature dogs and rodents revealed a potential for arthropathy and cartilage erosion (131). Musculoskeletal dysfunction was not noted in a multicenter prospective controlled study of 200 women exposed to fluoroquinolones during pregnancy (124). Effects on cartilage and bone would be unlikely in the first trimester and there are few studies addressing long term effects with late pregnancy exposure. Based on available evidence quinolone antibiotics do not appear to pose a risk to the fetus at therapeutic doses however more studies are needed to address the potential for osteotoxicity in the neonate and juvenile.

Sulfonamides

Sulfonamides are usually combined with other antibiotics, such as in trimethoprim-sulfamethoxazole (Bactrim). Due to the possibility of jaundice in the newborn, sulfonamides should not be used during the last trimester of pregnancy, or during nursing. Trimethoprim is a folate metabolism antagonist and thus has potential for adverse embryonic and fetal effects (see Trimethoprim below).

Tetracyclines

This class of antibiotics includes tetracycline and doxycycline. Tetracycline crosses the placenta but is not concentrated by the fetus. Tetracyclines complex with

calcium and the organic matrix of newly forming bone without altering the crystalline structure of hydroxyapatite (132). Although tetracycline has been shown to discolor teeth without affecting the likelihood of developing caries (133,134), very high doses may depress skeletal bone growth. No congenital malformations of any other organ system have been associated with antenatal tetracycline exposures (98). Several case reports of limb reduction defects in human embryos exposed to tetracycline are not supported by epidemiological studies or animal studies. Therapeutic doses of tetracycline are associated with no or minimal increased risk of congenital malformations but they are likely to result in some degree of dental staining, which does not appear to have a deleterious effect on the offspring.

Untreated *Neisseria gonorrhoeae* can lead to serious consequences for the infected woman. Treatment with ceftriaxone plus doxycycline has no reported adverse effects on the fetus.

Trimethoprim

Trimethoprim is an inhibitor of microbial dihydrofolate reductase, and is usually combined with a sulfonamide for treatment of urinary tract infections. Early studies did not report an association between exposure to trimethoprim during pregnancy and congenital anomalies (135,136,137,138). However, more recent studies using much larger study populations have reported increases in the incidence of neural tube defects, orofacial clefts and cardiovascular defects among infants exposed to trimethoprim during the first three months of pregnancy (139,140,141,142). Use of a vitamin supplement containing folic acid during treatment resulted in a reduced risk in these studies.

Trimethoprim was not teratogenic in rodents using less than 10 times the human therapeutic dose for treatment of urinary tract infections, and caused malformations and intrauterine death at high doses (>16 times therapeutic doses) (143,144,145). The relevance of these findings to human risk at therapeutic doses is unclear.

Due to the potential for adverse effects on folate metabolism in the pregnant woman and fetus, trimethoprim should be avoided during pregnancy.

Antihypertensives (Excluding Angiotensin Converting Enzyme Inhibitors)

Clonidine

Clonidine exerts its hypotensive effect by a direct alpha adrenergic agonistic action in the CNS. It is used to treat

hypertension and may also be given epidurally with epidural anesthesia. It appears to be relatively safe during pregnancy but there are few available data regarding effects of exposure during the first trimester of pregnancy. When used during labor with epidural anesthesia there are reports of a small but increased frequency of fetal bradycardia (146,147) and, even less commonly, transient neonatal hypotension (148,149).

Hydralazine

Hydralazine is a vasodilator often used in combination with methyldopa for the treatment of preexisting hypertension in pregnancy and is considered to be safe. Although there is one report of fetal thrombocytopenia (150), over 120 normal pregnancies have been reported (151). Additionally there have been reports of an increased frequency of fetal distress in neonates born to women treated with hydralazine near term (152,153,154).

Methyldopa

Methyldopa is currently the safest antihypertensive drug available for use during pregnancy (155). Methyldopa is a centrally acting adrenergic antagonist with no reported adverse effects on the fetus or on mental and physical development.

Nifedipine

Nifedipine is a calcium channel blocker used for the treatment of preterm labor with no reported adverse effects. The potential for adverse effects with its long term use in the treatment of hypertension is unknown.

Propranolol

Propranolol is a β -blocker useful in treating preexisting hypertension during pregnancy. There have been no reports of associations with use in the first trimester and congenital anomalies (156). However, prolonged use may cause intrauterine growth retardation (157,158,159,160,161,162,163). Moreover, there have been several reports of difficulties in perinatal adaptation associated with maternal treatment late in pregnancy and shortly prior to delivery including apnea and respiratory distress (159,160,164,165,166).

Aspirin

Aspirin acts principally by inhibiting prostaglandin synthesis by irreversibly acetylating and inactivating fatty acid cyclooxygenase. Low-dose aspirin (60-150

mg per day) is used clinically in the prevention or treatment of a variety of conditions that affect maternal and fetal health. For instance, aspirin is used for the treatment of systemic lupus erythematosus, antiphospholipid syndrome, and preeclampsia.

Of obvious concern is the potential for increased fetal and maternal bleeding associated with low-dose aspirin use near the time of delivery or higher doses used to treat preterm labor. Jankowski and associates reported a study involving 25 women threatened with premature delivery who were given 3.6 g of oral aspirin per day for 4 successive days within 10 days prior to delivery (167). They and others have found no adverse effect on maternal bleeding at delivery, fetal hemorrhage, or circulatory disorders.

There is some evidence that aspirin combined with dipyridamole may prevent or ameliorate intrauterine growth retardation associated with idiopathic uteroplacental insufficiency. Fetal growth was also improved with aspirin (150 mg per day) alone in fetuses with high, but not extreme, umbilical artery systolic/diastolic ratio. Third trimester exposure to low daily doses of aspirin were not associated with adverse fetal outcome in these studies (168,169).

High fetal losses are associated with lupus anticoagulant antibodies, anticardiolipin antibodies and systemic lupus erythematosus. Surviving fetuses experience an increased incidence of growth retardation, fetal distress, and preterm delivery. Low-dose aspirin (60-80 mg per day) in combination with prednisone (20-80 mg per day) improves pregnancy outcome and greatly reduces thrombosis (170).

Case reports suggest that 75 to 300 mg of aspirin per day in combination with dipyridamole might reduce the risk of late fetal loss in patients with arterial thromboembolism, thrombotic thrombocytopenia purpura, and idiopathic or essential thrombocythemia (170).

Although doubts concerning the safety of aspirin during pregnancy have been expressed, aspirin use during the first trimester is not associated with an increased teratogenic risk (171). Third trimester exposure to 80 mg per day or less are not associated with an early constriction of the ductus arteriosus (172). Much larger doses of aspirin during the third trimester have been associated with an increased length of gestation, duration of labor, frequency of postmaturity and blood loss at delivery (173) and justify careful fetal surveillance.

Benzodiazepines

The benzodiazepines, such as chlordiazepoxide (Librium), diazepam (Valium), xanax, and meprobamate, are widely used as tranquilizers during pregnancy and, therefore, it is not surprising that they have been associated with congenital malformations in some publications.

Chlordiazepoxide was associated with various anomalies after exposure during

early pregnancy but no syndrome was identified (98,174). Other studies were inconclusive or found no association (175,176,177). Chlordiazepoxide appears to have a minimal risk for congenital anomalies and no increased risk for abortion at therapeutic doses. Higher exposures are likely to increase the risk of adverse effects on the fetus but the magnitude of the increase is not known.

Some studies reported an association between diazepam and increased incidence of congenital malformations

P.243

(177). However, a follow-up study found no associations (178). The majority of studies of fetal outcome following *in utero* exposure to diazepam are negative (112,175,176,177,178,179,180). Behavior alterations have been reported in infants exposed to benzodiazepines, mostly diazepam (181), but this observation must be confirmed and the long-term developmental outcome evaluated before it can be appropriately interpreted. Although third trimester exposure to diazepam can reversibly affect the fetus and neonate (182) there is minimal increased risk of congenital malformations and no demonstrated increased risk of abortions from therapeutic exposures.

Meprobamate has been weakly associated with a variety of congenital malformations (183,184). Other studies found no associations (98,176). Because of inconsistencies, the data are not sufficient to confirm or rule out a small increase risk of malformations as a result of exposures early in pregnancy.

Benzodiazepines appear to have minimal increased risk of malformations at therapeutic ranges; higher exposures may increase the risk. The risk for abortion is unknown but given the widespread use of these drugs, it is unlikely that a significant abortigenic effect would have gone unnoticed.

Caffeine

Caffeine is a methylated xanthine, which acts as a CNS stimulant. It is contained in many beverages including coffee, tea, and colas, and chocolate. Caffeine is also present in many over-the-counter medications, such as cold and allergy tablets, analgesics, diuretics, and stimulants; the latter lead to relatively minimal population intakes. Caffeine containing food and beverages are consumed in large quantities by most of the human populations of the world. The per capita consumption of caffeine from all sources is estimated to be about 200 mg/day, or about 3 to 7 mg/kg per day (185). Consumption of caffeinated beverages during pregnancy is quite common and is estimated to be approximately 144 mg per day (186).

Current evidence, does not appear to implicate the usual exposure of caffeine as a human teratogen, however, associations between maternal coffee drinking during pregnancy and miscarriage or poor fetal growth have been reported in

epidemiological studies (187,188,189,190,191). In many instances these associations are largely attributable to confounding effects of maternal cigarette smoking or other factors. Some of these studies (192) have serious methodological limitations. If maternal consumption of caffeine-containing beverages in conventional amounts during pregnancy does have an association with the rate of miscarriage or fetal growth retardation, the effect appears to be relatively small.

In other studies no association has been found between caffeine consumption during pregnancy and congenital defects (98,193,194). For instance, Rosenberg and associates analyzed six selected birth defects in relation to maternal ingestion of more than 8 mg/kg per day of tea, coffee, or cola (195). The defects were inguinal hernia, cleft lip/cleft palate, cardiac defects, pyloric stenosis, cleft palate (isolated) and neural tube fusion defects. None of the point estimates of relative risk was significantly greater than unity, suggesting that caffeine was not a major teratogen, at least for the defects evaluated.

Interpretation of the available information pertaining to the animal and human studies regarding the teratogenicity of caffeine leads us to conclude that the usual exposure of caffeine does not present a measurable risk in the human for any one malformation or group of malformations. There is a clear indication that the consumer must ingest a substantial amount of caffeine to have an effect on the developing embryo or fetus; total consumption of 300 mg/day may be a safe upper daily limit. Most reviewers and investigators concluded that there is a threshold, below which caffeine does not exert a detrimental effect, and the usual human consumption falls in this nontoxic range. The quantity of caffeine consumed in an average cup of coffee, about 1.4 to 2.1 mg/kg (196), is believed to be below the amount that induces congenital defects in animals. Quantities of caffeine in tea and soft drinks would be even less.

Carbamazepine

Although epidemiological and case report studies have not yielded consistent results, exposure to carbamazepine has been associated with minor craniofacial defects, fingernail hypoplasia, developmental delay (197,198), reduced birthweight, length and head circumference (199) and neural tube defects (200). Confounding the issue is the possibility that epilepsy itself may increase the risk for malformations (201). However, an attempted suicide involving carbamazepine produced blood levels of 27-28 µg/mL (the therapeutic range is 8-12 µg/mL) during what was estimated to be 3-4 weeks postconception (202). The fetus was later determined to have myeloschisis with carba-mazepine the only known exogenous risk factor. This suggests that carbamazepine has the potential to produce neural tube defects at about two- to three-fold the therapeutic level. It appears that the risk for minor defects is significant but the risk for all teratogenic effects is not known. The risk for abortion is also not known but appears to be

small.

Cocaine

Cocaine (benzoylecgonine) is one of the most commonly used illicit drugs by women of reproductive age. Reported estimates for cocaine use during pregnancy range from 3% to 17%, the highest rates occurring in inner city populations (203). Because of its widespread use during pregnancy and the growing cost of caring for cocaine exposed neonates, there has been increasing concern over the risks associated with prenatal cocaine use to maternal and fetal health. Yet despite numerous clinical studies linking prenatal cocaine use with a variety of adverse maternal

P.244

and fetal effects, methodological limitations in these studies have made it difficult to establish a causal relationship between these alleged effects and maternal cocaine use. Not only are the timing, frequency and dose of cocaine use hard to determine, but adverse effects as a result of low socioeconomic status, poor nutrition, multiple drug use, infections, and a lack of prenatal care are difficult to dissociate from effects as a result of cocaine use alone (203). As such the issue of how much risk to the fetus is associated with cocaine use during pregnancy is unresolved. Nonetheless a growing body of literature supports the concept that cocaine is a developmental toxicant. Adverse effects attributed to prenatal cocaine exposure include a higher incidence of spontaneous abortion, placental abruption, still birth, prematurity, low birth weight, growth retardation, decreased head circumference, intracerebral hemorrhage, congenital defects, neurobehavioral abnormalities, and a possible association with increased risk of sudden infant death syndrome (SIDS) (203,204). These effects are reduced but not eliminated in mothers receiving appropriate prenatal care. Like other developmental toxins, outcome is dependent on dose and time of use.

The majority of adverse effects associated with cocaine use during pregnancy appear to be as a result of high levels of cocaine abuse in later stages of gestation rather than in the first trimester or organogenesis (205). Moderate usage of cocaine only in the first trimester does not appear to result in adverse fetal outcome and may not pose an increased risk to the fetus (206).

Adverse fetal outcomes associated with maternal cocaine use are thought to primarily result from the vasoconstrictive effects of cocaine on both the maternal and fetal vasculature (205). Vasoconstriction of the uterine arteries, which are normally fully dilated during pregnancy, may compromise fetal growth and development. Studies in animals have confirmed that cocaine reduces uterine artery and placental blood flow leading to reduced oxygen and nutrient supply to the fetus (207). Fetal cardiovascular effects resulting from uterine vasoconstriction include hypertension, tachycardia, hypoxia and an increase in

cerebral blood flow (207,208). Cocaine also crosses the placenta in which it has a direct effect on the fetal vasculature flow (207). Fetal hypertension combined with increased cerebral blood flow may result in intracerebral hemorrhage or infarction, which has been reported to occur in cocaine exposed fetuses in both human and animal studies (209,210,211).

Disruption of uterine and fetal vasculature may also lead to a variety of congenital anomalies that have been associated with cocaine abuse. A significant association between cocaine use and an increased incidence of genitourinary tract malformations has been found (209,211,212). Other defects reported include limb reduction defects, nonduodenal intestinal atresia, cardiac anomalies, hypospadias, prune belly syndrome as a result of urethral obstruction, hydronephrosis and crossed renal ectopia (208,209,211). Two cases of limb-body wall complex have also been reported (213) With the exception of genitourinary tract malformations, the sample size in these clinical studies has not been sufficient to determine a statistically significant relationship between cocaine use and these congenital anomalies (214).

Coumarin Derivatives

Nasal hypoplasia following exposure to several drugs, including warfarin, during pregnancy was reported by DiSaia (215). Kerber and associates (216) were the first to suggest warfarin as the teratogenic agent. Coumarin anticoagulants have since been associated with nasal hypoplasia, calcific stippling of the secondary epiphysis, and CNS abnormalities. Warfarin embryopathy has been described and an overview of the difficulties in relating a congenital malformation to an environmental cause and has been published (217,218). There is an estimated 10% risk for affected infants following exposure during the period from the eighth through the fourteenth week of pregnancy, although this risk has been reported to be much lower in some series, and other factors besides dose and gestational stage seem to play a role (218). Low-dose warfarin (5 mg/day or less) throughout pregnancy did not result in any adverse effects in 20 offspring (219).

Coumarin inhibits the formation of carboxyglutamyl residues from glutamyl residues, decreasing the ability of proteins to bind calcium. The inhibition of calcium binding by proteins during embryonic/fetal development, especially during a critical period of ossification, could explain the nasal hypoplasia, stippled calcification, and skeletal abnormalities of warfarin embryopathy (218). Microscopic bleeding does not seem to be responsible for these problems early in development (217).

One case report was unique in that the time of exposure to warfarin was between 8 and 12 weeks of gestation, and the infant presented Dandy-Walker malformation, eye defects, and agenesis of the corpus callosum (220). This case report is the clearest evidence for a direct effect of warfarin on the developing

CNS rather than an effect mediated by hemorrhage, because the exposure is well defined and occurs before the appearance of vitamin K-dependent clotting factors. Further supportive evidence for a direct pathogenic role of warfarin is the report of an infant with an inherited deficiency of multiple vitamin K-dependent coagulation factors whose congenital anomalies were similar to warfarin syndrome without exposure to warfarin (221). The risk of stillbirths and spontaneous abortions is increased in pregnant women treated with warfarin but the risk may be less if the exposure is in the last half of pregnancy. The risk of adverse effects as a result of hemorrhaging increases later in gestation.

Cyclophosphamide

Cyclophosphamide, a widely used antineoplastic agent, is also used in severe rheumatic disease. Cyclophosphamide is likely to be teratogenic in the human but the magnitude of

P.245

the teratogenic risk is uncertain. The reported defects include growth retardation, ectrodactyly, syndactyly, cardiovascular anomalies, and other minor anomalies (222,223,224). Ten normal pregnancies have been reported after cyclophosphamide exposure (225).

The mechanism of cyclophosphamide teratogenesis was reviewed by Mirkes (24): cytochrome P-450 monooxygenases convert cyclophosphamide to 4-hydroxycyclophosphamide, which in turn breaks down to phosphoramidate mustard and acrolein. Phosphoramidate mustard may produce teratogenic effects by interacting with cellular DNA in an as yet undefined manner although acrolein acts in a different manner, possibly by affecting sulfhydryl linkages in proteins (226). Tissue sensitivity to phosphoramidate mustard and acrolein is thought to be related to such processes as detoxification and cellular repair.

Diethylstilbestrol

The first abnormality reported following exposure to diethylstilbestrol (DES) during the first trimester was clitoromegaly in female newborns (227). Herbst and associates (228,229) and Greenwald and associates (230) later reported an association of vaginal adenocarcinoma in female offspring following first trimester exposures. DES is the only drug with proven transplacental carcinogenic action in the human. Almost all of the cancers occurred after 14 years of age and only in those exposed before the 18th week of gestation. There is a 75 percent risk for vaginal adenosis for exposures occurring before the ninth week of pregnancy; the risk of developing adenocarcinoma is about 1:1,000 to 1:10,000 (231). While the incidence of vaginal adenosis was related to the amount of DES administered, the incidence of vaginal carcinoma does not appear to be related to the maternal dose.

Although there does not appear to be an adverse effect on menstrual cycle functioning or on the rate of conception, the anatomic abnormalities of the uterus and cervix induced by intrauterine exposure to DES, including T-shaped uterus, transverse fibrous ridges and uterine hypoplasia, cause the increased incidence of ectopic pregnancies, spontaneous abortions and premature delivery in pregnancies of women exposed to DES *in utero* (232,233,234,235).

There have been reports that males exposed to DES *in utero* exhibited genital lesions and abnormal spermatozoa (236,237). Other studies reported no increase in the risk for the male for genitourinary abnormalities or infertility (238). An association between *in utero* exposure to DES and testicular cancer in male offspring has been suggested but the data are not conclusive (238,239). The controversial nature of the effects of DES exposure on the male may be attributable to study design or, more likely, to the fact that dose levels varied greatly according to different regimens: exposures during the first half of pregnancies varied from 1.5 to 150 mg per day with total doses from 135 mg to 18 g (231).

DES is a potent nonsteroidal estrogen and, as in the case of steroidal estrogens, must interact with the receptor proteins present only in estrogen-responsive tissues before exerting its effects by stimulating ribonucleic acid (RNA), protein, and DNA synthesis. The carcinogenic effect of DES is most likely indirect: DES exposure results in the presence of columnar epithelium in the vagina, and this misplaced tissue may have a greater susceptibility to developing the adenocarcinoma, much as teratomas and other misplaced tissues are more susceptible to malignant degeneration.

Digoxin

Digoxin is used to correct fetal tachyarrhythmias with no substantiated adverse fetal effects (240). However, the possibility of any adverse side effects must be balanced with the fetal prognosis if the dysrhythmia persists or is likely to lead to fetal cardiac failure.

Diphenylhydantoin

Hanson and Smith (241) characterized the fetal hydantoin syndrome in infants whose mothers were treated for epilepsy with hydantoin anticonvulsants. Chronic exposure to diphenylhydantoin has been suggested to present a maximum of 10% risk for the full syndrome and a maximum of 30% risk for some anomalies (242,243,244,245). Although cleft lip and palate, congenital heart disease, and microcephaly have been reported, hypoplasias of the nails and distal phalanges are possibly more common malformations in the exposed fetuses (246,247). Hanson and associates noted that, although the hydantoin syndrome is observed in 11% of the subjects in their study, three times that number exhibit mental

deficits (31,248). Prospective studies demonstrate a much lower frequency of effects, and some do not demonstrate any effect; thus, the overall prospective risk may be much lower for the classically reported effects.

Factors associated with epilepsy may contribute to the etiology of these malformations (249). Based on the United States Collaborative Perinatal Project and a large Finnish registry, the incidence of malformations was 10.5% when the mother was epileptic, 8.3% when the father was epileptic and 6.4% when neither parent was affected (250).

Cleft lip and palate, skeletal anomalies, and cardiac defects have been produced in rabbits (31,251) mice (252,253,254,255), and rats (256,257), and the malformation rate was dose-dependent (253,258).

Glucocorticoids

Glucocorticoids (dexamethasone, betamethasone, hydrocortisone, methylprednisone) are effective in reducing the incidence of respiratory distress syndrome in premature newborns by inducing early lung maturation as first hypothesized by Liggins (259). Endogenous glucocorticoids mediate normal pulmonary maturation. Exogenous glucocorticoids are used to stimulate the production of surfactant. The adverse fetal effects observed in experimental

P.246

animals exposed to pharmacological doses are not seen in humans at therapeutic levels (260,261,262).

Dexamethasone is used to suppress the fetal adrenal gland in cases of congenital adrenal hyperplasia (263). 21-Hydroxylase deficiency impairs the conversion of cholesterol to cortisol and results in excess 17-hydroxyprogesterone which in turn results in excess levels of androgens. The masculinization of female fetuses with congenital adrenal hyperplasia varies from clitoral hypertrophy to formation of a phallus. Maternal replacement doses of dexamethasone suppress both the maternal and fetal adrenal glands and prevent masculinization in most patients (264).

Glucocorticoids are also used in the treatment of rheumatic diseases, other acute and chronic inflammatory diseases, and organ transplantation. Although some studies have reported increased frequency of perinatal death, prematurity and intrauterine growth retardation with chronic therapy, women in these studies typically had severe autoimmune or other diseases, or history of fetal loss requiring treatment, thus these findings cannot be attributed to the glucocorticoid therapy itself (223,265,266,267,268,269,270,271). Dexamethasone poses minimal or no teratogenic risk at therapeutic doses in humans and the benefits of glucocorticoid treatment, particularly dexamethasone, for prevention of masculinization as a result of congenital adrenal hyperplasia, and betamethasone

for the prevention of the respiratory distress syndrome in premature infants, and potentially other complications arising from prematurity are clear (272,273,274,275,276).

Indomethacin

Oral administration of the prostaglandin synthetase inhibitor, Indomethacin, is a prostaglandin synthetase inhibitor that is used as an analgesic, an antiinflammatory, and an antipyretic agent. Indomethacin is also effective in the treatment of polyhydramnios that is either idiopathic or related to maternal diabetes mellitus. Administration of indomethacin during the first trimester has not been shown to increase the frequency of congenital malformations (112). Late in pregnancy maternal administration of indomethacin may cause oligohydramnios, constriction of the ductus arteriosus (prostaglandins are necessary to maintain the patency of the fetal ductus arteriosus), fetal hydrops and persistent pulmonary hypertension in the newborn, potentially serious side effects of indomethacin that warrant careful fetal and neonatal surveillance (277,278,279,280). The risk for premature closure of the ductus arteriosus increases with treatment after 32 weeks (281,282,283). Indomethacin may also be used to prevent preterm labor or intraventricular hemorrhage; however its efficacy when used for this purpose is controversial. Indomethacin may also predispose the neonate to necrotizing enterocolitis when used as a tocolytic (284,285).

Lithium Carbonate

Lithium carbonate, widely used for treatment of manic-depressive disorders, was first associated with human congenital malformations in 1970 (286,287). The malformations described include heart and large-vessel anomalies, Epstein's anomaly, neural tube defects, talipes, microtia, and thyroid abnormalities (288,289,290). Lithium readily crosses the placenta (291), and appears to be a human teratogen at therapeutic dosages but it presents a small risk. Although early reports suggested a strong association of prenatal lithium exposure with cardiac defects, in particular Epstein's anomaly, more recent evidence from controlled epidemiological studies suggests that the risk for malformations is much lower than initially thought (292,293). The results of a retrospective study suggest that lithium may also increase the risk for premature delivery (294), but again the magnitude of the risk is likely to be small. Only one follow-up study has been published examining long-term effects of lithium on early development. In this study children exposed prenatally to lithium with no congenital abnormalities at birth did not show any signs of developmental delay at 7.3 years follow-up (295). Fetal toxicity has been associated with late gestational maternal lithium use with and without obvious maternal toxicity. One reported side effect is nephrogenic diabetes insipidus (296,297,298) and associated polyhydramnios

which may increase the likelihood of premature labor (294,297). Transient toxic effects have also been reported in neonates exposed late in pregnancy. These include hypothyroidism, lethargy, hypostomia, cardiac murmur, renal toxicity, persistent fetal circulation and diabetes insipidus (299,300,301,302). To prevent lithium intoxication in the neonate the lithium dosage of the patient should be adjusted to avoid high serum levels in the second and third trimester (293).

Lithium can induce abnormal development in several laboratory animals, but the mechanisms of the teratogenic action of lithium is not known (303,304,305). The neurotropic activity of lithium suggests that CNS malformations may result from cell membrane disturbances which affect neural tube closure (306).

Because of the value of lithium carbonate for treating manic-depressive psychosis, the risk associated with psychiatric relapse on removing the drug may be more important clinically than the teratogenic risk. Moreover, the risk of alternative pharmacological agents for treatment of bipolar disorder may exceed the risk from lithium carbonate (307).

Methylene Blue

Methylene blue has been used clinically for a variety of purposes including the identification of anatomic structures, the treatment of methemoglobinemia, and to mark the amniotic cavity during amniocentesis. Use of methylene blue in late gestation to detect rupture of fetal membranes has been associated with adverse fetal effects including hyperbilirubinemia, hemolytic anemia and staining of the skin (308,309,310,311). There is currently not enough data to determine whether respiratory distress in these infants may also result from late gestation methylene blue exposure (312).

P.247

There have been several reports of an increased prevalence of small intestinal atresia in twins with intraamniotic exposure to methylene blue. Twinning itself results in an increased prevalence of intestinal atresia, increasing from approximately 2 to 2.5 per 10,000 in singletons to 5 to 7.3 per 10,000 amongst twins (313). However, in twins exposed to midgestational amniocentesis in which methylene blue was used to mark the amniotic cavity the prevalence of small intestinal atresia has been reported as high as 9.6% (314). The strongest evidence indicating that methylene blue is a teratogen is a retrospective study from Amsterdam. In this study methylene blue was injected into one amniotic cavity of 86 twin pregnancies undergoing midgestation amniocentesis. Jejunal atresia occurred in 17 infants, each from different pregnancies (314). In 15 of these cases it was possible to determine which twin was exposed to methylene blue, and in each case the twin exposed to methylene blue had jejunal atresia. Based on this evidence and several other reports there appears to be a significant risk of small intestinal atresia associated with exposure to methylene blue during

midgestation amniocentesis (311,313,315,316,317,318,319). Intraamniotic exposure to methylene blue has not been associated with any other malformation (312). Whether midgestation exposure to methylene blue increases the incidence of fetal death has not been clearly established (320,321). In rats, intraamniotic injection of methylene blue increased fetal loss (322).

Misoprostol

Misoprostol is a synthetic prostaglandin E1 methyl analogue used for the prevention of gastric ulcers induced by nonsteroidal antiinflammatory drugs. It has known, but not very effective, abortifacient properties. Gonzalez and associates (323) recently reported seven newborns with vascular disruptive phenomena (limb reduction defects, Moebius syndrome) whose mothers used misoprostol early in pregnancy in an attempt to induce abortion. Although there is evidence that misoprostol is used illegally by thousands of pregnant Brazilian women as an abortifacient (324,325,326), controlled cohort or case control epidemiological studies of the fetal outcome of failed abortions are not available. Although the data available are not conclusive, the uterine bleeding produced by misoprostol and type of malformations produced suggest a vascular disruption mechanism for misoprostol induced teratogenesis.

If one is looking for vascular disruption, it will more likely be produced later in gestation. Therefore, classical animal teratology experiments will not detect the vascular disruptive effect of drugs or chemicals unless they are exposed beyond the period of early organogenesis (327). Furthermore, it has become clear that if an agent produces vascular disruption, it is a rare event and therefore large populations would need to be studied before the effect may be discovered (328).

Previous case reports are also of little assistance. Collins and Mahoney (329) reported an infant with hydrocephalus and attenuated digital phalanges after exposure intravaginally to 15-methyl F2alpha prostaglandin five weeks after conception. Schuler and associates (330) reported that 29% of women who used misoprostol in Brazil as an abortifacient failed to abort. Seventeen children who failed to abort were observed to have no malformations. Wood and associates (331) reported an infant exposed to oxytocin and prostaglandin E2 for the purpose of termination to have hydrocephaly and growth retardation. Schonhofer (332) and Fonesca and associates (333) reported five Brazilian infants with defects of the skull and overlying scalp who were exposed to misoprostol in utero. These case reports indicate the low risk of misoprostol exposure and the possibility that some of the features reported may or may not be as a result of misoprostol (334). It is too early to know the extent of the effects of misoprostol, but it is biologically plausible that they should include all of the features of vascular disruption.

Oxazolidine-2,4-diones (Trimethadione, Paramethadione)

Trimethadione and paramethadione are antiepileptic oxazolidine-2,4-diones that distribute uniformly throughout body tissues and exert their effects by means of the action of their metabolites. These drugs affect cell membrane permeability and vitamin K-dependent clotting factors, but their primary mode of action is unknown.

Zackai and associates (335) described the fetal trimethadione syndrome characterized by developmental delay, V shaped eyebrows, low-set ears with anteriorly folded helix, high arched palate and irregular teeth. Clinical observations of these and other associated findings, such as cardiovascular, genitourinary and gastrointestinal anomalies, have been reviewed (335,336,337,338). The incidence of miscarriage, stillbirth and infant death was also increased. There are wide variations in reported risk, with estimates as high as 80% for major or minor defects. Because the number of exposures is small, the actual risk could vary considerably from these figures. Although there are variations in incidences reported amongst studies, the risk of malformation or other adverse fetal effects is considered high, therefore the drug should not be used in pregnant women.

D-Penicillamine

D-Penicillamine has been used in the treatment of rheumatoid arthritis and cystinuria. D-Penicillamine is a copper chelator and copper deficiency appears to be the mechanism for teratogenicity (339). Exposure to D-penicillamine can induce a connective tissue defect including generalized cutis laxa, hyperflexibility of the joints, varicosities and impaired wound healing (340,341,342). The exposure must be long enough to induce a copper deficiency sufficient to inhibit collagen synthesis and maturation. However, the condition appears to be reversible and the risk is low, 5% or less.

P.248

Phenobarbital

Phenobarbital is used as a sedative and anticonvulsant. Risk of congenital anomalies is unlikely with occasional exposure to phenobarbital in therapeutic doses during pregnancy. Use of phenobarbital for long term treatment of seizure disorders such as epilepsy may be associated with a small to minimal risk of increase in congenital malformations such as cleft palate and congenital heart defects (177,250,343,344,345,346,347). Some of these effects may relate directly to the disease being treated itself, rather than to phenobarbital (348). The

risk appears to be greater in cases in which phenobarbital was combined with other drugs such as phenytoin (344,346,349,350,351). Some studies report no increased risk for congenital anomalies with use of phenobarbital for treatment of epilepsy. However, other studies report an increased incidence of minor congenital anomalies with phenobarbital monotherapy with a characteristic pattern of minor dysmorphic features, termed the "fetal anticonvulsant syndrome" including nail and midface hypoplasia and depressed nasal bridge (345,352,353,354).

In two prospective, studies of patients in high risk groups for neonatal intraventricular hemorrhage, intravenous phenobarbital administered antenatally resulted in a significant reduction in the incidence of severe cases of intraventricular hemorrhage by increasing cerebral vascular resistance (355). Phenobarbital reduces peak arterial blood pressure, thereby reducing the risk for intraventricular hemorrhage, one of the leading complications of the very low birth-weight preterm infant (356). Initiation of intravenous phenobarbital in the early neonatal period is probably too late to derive the potential benefits of this therapy.

Progestins

It is often overlooked that, although various progestins utilized therapeutically as progestational agents act by means of similar receptors, their potential androgenic effects can differ markedly. This point is critical to the evaluation of the virilizing effects of these compounds in the human. It has been shown, for example, that the pharmacokinetic parameters that estimate steroid bioavailability and metabolism show great variability among subjects and between steroids conveniently grouped together, such as "progestins" (357). One must assume that these differences in bioavailability and metabolism reflect differences in the biological activity of these steroids in humans.

In contrast to progesterone and 17α -hydroxyprogesterone caproate, high doses of some of the synthetic progestins have been reported to cause virilizing effects in humans. Exposure during the first trimester to large doses of 17α -ethinyltestosterone has been associated with masculinization of the external genitalia of female fetuses (358). Similar associations result from exposure to large doses of 17α -ethinyl-19-nortestosterone (norethindrone) (358) and 17α -ethinyl-17-OH-5(10)estren-3-one (Enovid-R) (68). The synthetic progestins, like progesterone, can influence only those tissues with the appropriate steroid receptors. The preparations with androgenic properties may cause abnormalities in the genital development of females only if present in sufficient amounts during critical periods of development. In 1959, Grumbach and associates (68) pointed out that labioscrotal fusion could be produced with large doses if the fetuses were exposed before the thirteenth week of pregnancy, whereas clitoromegaly could be produced after this period, illustrating that a specific form of maldevelopment can be induced only when the embryonic tissues are in a susceptible stage of

development.

The World Health Organization (359) reported that there is a suspicion that combined oral contraceptives or progestogens may be weakly teratogenic but that the magnitude of the relative risk is small. In a large retrospective study, Heinonen and associates (360) reported a positive association between cardiovascular defects and in utero exposure to female sex hormones. A reevaluation of some of the base data by Wiseman and Dodds-Smith, (361) however, did not support the reported association. Another retrospective study conducted by Ferencz and associates (188) did not find a positive association between female sex hormone therapy and congenital heart defects. Although neither study disproved the positive association reported by Heinonen and associates (360) their findings made the association less likely.

Epidemiological studies have reported an association between exposures to female sex hormones, oral contraceptives or progestogens, and congenital neural tube defects (362) and limb defects (363). Further studies and reevaluations have not supported either of these associations (9,21,22).

Further support for the absence of a nongenital effect of progestins comes from (a) a negative correlation between sex hormone usage during pregnancy and malformations, (b) no increased incidence in malformations following progesterone therapy to maintain pregnancy, and (c) no increased incidence in malformations following first trimester exposure to progestogens (mostly medroxyprogesterone) administered to pregnant women who had signs of bleeding. The Food and Drug Administration has recognized that the evidence does not support an increased risk of limb reduction defects, congenital heart disease, or neural tube defects following exposure to oral contraceptives or progestins (364).

It is generally accepted that the actions of steroid hormones are mediated by specific steroid (365) and therefore only those tissues with the specific receptors can be affected by steroid hormones.

Retinoids, Systemic Administration (Isotretinoin, Etretinate)

Vitamin A congeners, including retinol, retinal, all-trans-retinoic acid (tretinoin) and 13-cis-retinoic acid (isotretinoin), are all teratogenic in numerous species. Both isotretinoin (Accutane, Roche Laboratories), marketed for treating severe

P.249

acne, and etretinate (Tigason, Sautier Laboratories), marketed for treating psoriasis, contained warnings by the manufacturers against exposure during pregnancy. Unfortunately, exposures occurred. Analyses of the resulting malformations have been reviewed (366,367). Human malformations include CNS,

cardioaortic, microtia, clefting defects and, more controversially, limb defects. Isotretinoin has a serum half-life of 10 to 12 hours; there is no apparent risk to the fetus if maternal use is terminated before conception (368). However, the risk for malformations and subnormal results on standard intelligence tests is high for offspring of women who were treated with therapeutic doses of isotretinoin in the first 60 days after conception (369).

Etretinate exposure during the first 60 days of pregnancy is associated with a high risk of malformations. Etretinate persists in the body for up to 2 years (370,371). Whether the lower concentrations of etretinate remaining in the mother's circulation over these extended periods increases the risk of malformations is not known but, if there is an increased risk, it is likely to be low.

Experimental evidence suggests that endogenous retinoic acid may act as a natural morphogen. Exogenous retinoids act either directly, resulting in cytotoxicity, or via receptor-mediated pathways to interact with DNA and alter programmed cell death (372,373). It is likely that different specificities of retinoid binding proteins (374) account for the variations in placental transfer. Although retinoids can influence many types of cells, Lammer (366) emphasized that neuroectodermally derived cells of the rhombencephalon are particularly sensitive and that the resulting neural crest cell abnormality differs from that resulting in oculoauriculo-vertebral dysplasia or Goldenhar syndrome. The susceptibility of specific cell types to the effects of the retinoids may be determined by the intracellular concentration of cellular retinoic binding protein (366).

Retinoids, Topical Administration (Tretinoin)

There have been a number of case reports of congenital malformations occurring in the offspring of mothers who used topical tretinoin during their pregnancy. The United States Food and Drug Administration received adverse reaction reports involving approximately seventeen infants who were born from mothers who used topical tretinoin during pregnancy, with a higher than expected representation of holoprosencephaly (Rosa, F., personal communication). While there has not been an abundance of epidemiological studies involving topical tretinoin, there are three reports. Using Michigan Medicaid data, the incidence of birth defects in 147 pregnancies exposed to topical tretinoin was compared to the incidence of birth defects in 104,092 nonexposed; the relative risk was 0.8 in the exposed population (Rosa, F., personal communication). A relative risk of 0.7 for birth defects was determined in 215 pregnancies exposed to topical tretinoin as compared with 430 nonexposed mothers in data from Group Health of Puget Sound (375). De Wals and associates (376) evaluated the association of the occurrence of holoprosencephaly with topical tretinoin exposure. Among 502,189 births there were 31 infants with holoprosencephaly. Eight patients had an abnormal karyotype and 16 had a normal karyotype. None of the patients with a normal karyotype were exposed to topical tretinoin during pregnancy.

Since all teratogens that have been appropriately studied have a no-effect dose, it would be paramount that topical administration of a known teratogen such as tretinoin must be absorbed and produce teratogenic concentrations in the blood. At conventional doses, the blood levels from topical administration are far below the teratogenic dose. It would appear that prudent use of this topical medication presents no risk to the embryo, because there would be no teratogenic exposure. The pharmacokinetics, animal studies and human studies support this conclusion.

Rh Immune Globulin

After exposure to Rh(D)-positive red cells, usually resulting from a fetal transplacental hemorrhage that occurs to some degree in 75% of pregnancies, (377) the Rh(D)-negative mother becomes Rh immunized. Rh immunization during a previous pregnancy results in brain damage of various degree or death in an Rh(D)-positive newborn in approximately 50% of cases (377). Once maternal Rh immunization has developed, it cannot be treated effectively, but it can be prevented by antenatal prophylaxis with 300 ug of RhIg at 28 weeks' gestation (377). No adverse fetal effects to immunoprophylaxis have been reported.

Smoking and Nicotine

Approximately 30% of all women of childbearing age smoke, and about 25% of all women will continue to smoke after they become pregnant (378). The evidence in humans indicates that smoking affects the fetus directly in a dose-related manner and probably involves more than one component of smoke (379). Placental lesions and fetal growth retardation have been consistently reported in epidemiological studies involving pregnant women who smoke cigarettes (380,381,382). Fetal death is 20%-80% higher among women who smoked cigarettes although pregnant (382). However, despite suggestions that smoking during pregnancy may increase the risk of limb anomalies, there is no proven relationship between smoking and specific malformations or malformations in general (383,384,385). Because of the large number of pregnant women who smoke and the documented effects of smoking on the fetus, one can conclude that smoking presents a significant risk to the fetus for growth retardation and abortion.

Thalidomide

Lenz and Knapp (386) were the first to associate thalidomide exposure during pregnancy with limb reduction defects and other features of the thalidomide syndrome. Limb defects resulted from exposure limited to a 2-week period from the 22nd to the 36th days postconception:

exposures from the 27th to the 30th days most often affected only the arm, whereas exposures from the 30th to the 33rd days resulted in both leg and arm abnormalities (387,388). Although there was no association of mental retardation, brain malformations, or cleft palate, other abnormalities included facial hemangioma, microtia, esophageal or duodenal atresia, deafness, and anomalies of the eyes, kidneys, heart, and external ears and increased incidence of miscarriages and neonatal mortality (386,387,389,390). A high proportion, about 20%, of the fetuses exposed during the critical period were affected. The current use of thalidomide in Brazil for the treatment of leprosy has resulted in more recent cases of embryopathy including at least 29 children born with thalidomide syndrome (391,392). Although the mechanism of teratogenic action for thalidomide is not yet defined, the subject has been critically reviewed by Stephens (393).

Thyroid: Iodides, Antithyroid Drugs (Thioamides)

There are several case reports of congenital goiter as a result of *in utero* exposures to iodide-containing drugs (394). Maternal intake of as low as 12 mg per day may result in fetal goiter (394). Iodinated diagnostic x-ray contrast agents used for amniocentesis have been reported to affect fetal thyroid function adversely (395).

Thioamides are antithyroid drugs used to treat fetal thyrotoxicosis. Fetal thyrotoxicosis is induced by thyroid-stimulating immunoglobulins produced in euthyroid or hypothyroid women. The adverse fetal effects, e.g., craniosynostosis, intellectual impairment and increased mortality, are caused by excess fetal thyroid hormone production. The thioamides block thyroid hormone synthesis by inhibiting the oxidation of iodide or iodotyrosyl. Unlike other thioamides, propylthiouracil also inhibits the peripheral deiodination of thyroxine to triiodothyronine. All thioamides are associated with a significant risk of fetal goiter and teratogenesis (290). However, in the case of propylthiouracil, the fetal goiter can be reduced with intraamniotic injections of thyroxine (396) which also prevents other abnormalities caused by inhibition of fetal thyroid function.

Tocolytics

Fetal distress can result from uterine hypertonus, umbilical cord compression, premature rupture of the fetal membranes, oligohydramnios, placental abruption, and uteroplacental insufficiency. In some cases of severe fetal hypoxemia or acidosis, prompt delivery may be recommended. However, if immediate surgery is not feasible, tocolytics may help to reduce fetal distress until delivery is possible.

In cases of hypoxemia as a result of reduced blood flow to the fetus, inhibiting uterine activity should increase the delivery of oxygen to the fetus by increasing

uterine and intervillous perfusion. In addition to inhibiting uterine activity, β -adrenergic agonists both increase maternal cardiac output and dilate uterine vessels resulting in a further increase in placental perfusion.

Ritodrine, a β 2-adrenergic receptor agonist, may be administered as an intravenous bolus for acute fetal distress (397). Ritodrine's mechanism of action leads to a reduction in the intracellular calcium available for smooth muscle contraction.

Terbutaline sulfate, a nonspecific beta-adrenergic agonist, is associated with a higher incidence of cardiovascular side effects than ritodrine with prolonged use.

When the use of β -adrenergic agonists is contraindicated in cases of intraamniotic infection, uncontrolled maternal thyroid disease, diabetes mellitus, and cardiovascular disease, magnesium sulfate may be used as a tocolytic agent. Although its mechanism of action is unknown, it results in an uncoupling of the actin-myosin interaction in smooth muscle (398). An advantage of magnesium sulfate tocolysis is the absence of cardiovascular side effects.

The data concerning the fetal effects of tocolytic agents are restricted to case reports, but, there are no reports of adverse fetal outcome resulting from exposure to therapeutic doses of terbutaline (399), ritodrine (400), or magnesium sulfate (401).

Toluene

Although occupational exposure to toluene has not been associated with congenital malformations in offspring, there are case reports of malformations resulting from the abuse of toluene. The first description of an infant with features similar to FAS born to a chronic abuser of toluene appeared in 1979 (402). This case and 22 additional cases have been described in detail (403). Thirty-nine percent of the toluene-exposed infants were born prematurely and 9% died in the perinatal period. In the surviving infants, 52% exhibited growth deficiency, 67% were microcephalic, and 80% exhibited developmental delay. Craniofacial features similar to those in the FAS were observed in 89%. An increased incidence of prematurity, perinatal death, growth and developmental delay and phenotypic features similar to FAS were reported in 35 pregnancies of 15 toluene abusers (404). Pearson and associates (403) suggest that the clinical and experimental data can be interpreted to imply that alcohol and toluene may have a common mechanism of facial teratogenesis. Toluene appears to have the potential for developmental toxicity in the human but the magnitude of the risk is minimal for usual occupational exposures, although it may be moderate to high in inhalation abusers.

Tranquilizers

The minor tranquilizers as a group are probably the most frequently prescribed therapeutic agents. Within this group, the propanediol carbonates and the benzodiazepines, the two most widely used classes, have been associated with teratogenic effects (290). The strongest association has been between diazepam and cleft lip with

P.251

or without cleft palate but even this association is not likely to be causal (405). Since these drugs are widely used, even a small increased risk would be expected to result in more reported adverse effects than has been the case. Continued surveillance is warranted because so many pregnancies are exposed to these drugs.

Valproic Acid

Valproic acid (dipropylacetic acid) is used for the treatment of various types of epilepsy. Dalens and associates (406), were the first to report the association of valproic acid and congenital malformations in the human. Although other reports followed, Robert and colleagues (407) described the associated malformations, consisting primarily of neural tube defects, and their incidence in detail. The neural tube defect observed is usually spina bifida in the lumbar or sacral region and increased risk appears to be correlated with higher serum levels (350,408). Other anomalies include postnatal growth retardation, microcephaly, midface hypoplasia, micrognathia and epicanthal folds. Therapeutic dosages during pregnancy present a teratogenic risk for spina bifida of about 1% (409) but the risk for facial dysmorphism may be greater. Valproic acid crosses the human placenta (410) but the fetal serum concentrations are not known.

Vitamins

Biotin

Biotin-responsive multiple carboxylase deficiency is an inborn error of metabolism in which there is a severe reduction in the activities of the mitochondrial biotin-dependent carboxylase enzymes. Affected individuals exhibit dermatitis, severe metabolic acidosis and a characteristic pattern of organic acid excretion.

Metabolism in these patients is restored to normal levels by biotin supplementation. Prenatal administration of 10 mg per day of oral biotin initiated during the third trimester prevented neonatal complications with no adverse fetal effects (390).

Vitamin A

Case reports have associated congenital defects in humans with massive vitamin

A ingestion during pregnancy (411). Although effects similar to those produced by vitamin A congeners, namely CNS, cardioaortic, microtia and clefting defects (see discussion of Retinoids above), may be predicted, no pattern of anomalies has emerged. Another fourteen infants of women who ingested high doses of vitamin A (25,000 IU or more) during pregnancy had no congenital anomalies, although three additional pregnancies ended in miscarriage (412).

A review of literature concerning retinoids and birth defects entitled "Recommendations for Vitamin A Use During Pregnancy" was published by the Teratology Society (411). Supplementation of 8,000 IU vitamin A per day should be the maximum during pregnancy and high dosages (25,000 IU or more) are not recommended. Beta-carotene as a source of vitamin A is likely to be associated with a smaller risk than an equivalent dose of vitamin A as retinol (411).

Vitamin B12

Ampola and associates (413) were the first to report prenatal treatment of a vitamin-responsive inborn error of metabolism. Their report involved a fetus with a vitamin B12-responsive variant of methylmalonic acidemia, a metabolic disease involving a functional deficiency in the coenzymatically active form of vitamin B12. Oral cyanocobalamin, 10 mg per day, initiated at 32 weeks gestation resulted in only a slight increase in maternal serum B12 level. Oral therapy was therefore stopped at 34 weeks' gestation and 5 mg per day of intravenous cyanocobalamin was initiated. This regimen produced a progressive increase in maternal serum B12 and a decrease in urinary methylmalonic acid excretion. The infant had no acute neonatal complications after delivery at 41 weeks.

Vitamin D

There have been no large-scale studies examining the effects of ingestion of large doses of vitamin D during pregnancy. In several small studies no increased risk of malformations was seen in offspring of women who took large doses of vitamin D during pregnancy (414,415). There have been some reports that huge doses of vitamin D administered for rickets prophylaxis in pregnant women resulted in a marked increased incidence of a syndrome consisting of supra-aortic stenosis, elfin facies, and mental retardation similar to Williams syndrome in the human (416,417). However, more recent studies have demonstrated that Williams syndrome is caused by a gene deletion in most cases (418,419). Animal studies and additional clinical reports suggest that the teratogenic risk of therapeutic doses of vitamin D is none to minimal.

Chapter 16

Obstetric Anesthesia and Analgesia: Effects on the Fetus and Newborn

Judith Littleford

Many drugs and various techniques have been used to provide anesthesia and analgesia for surgery during pregnancy, for labor and delivery, and for breastfeeding. The following quote, which refers to the first administration of inhalational analgesia in childbirth, is as relevant to the practice of obstetric anesthesia today as it was in 1847, "It will be necessary *to ascertain anesthesia's precise effect, both upon the action of the uterus and on the assistant abdominal muscles; its influence, if any, upon the child; whether it has the tendency to hemorrhage or other complications*" (1). Between the mid-1800s and 1950s, descriptive reports of the presumed effect of maternally administered medication on the fetus and newborn appeared sporadically in the literature. Two developments eventually encouraged physicians to acknowledge the potential problems associated with placental transmission of anesthetic drugs:

- Recognition that morphine, a popular ingredient of patent medicines, was addictive, and that signs of withdrawal could be identified in the fetus (violent fetal movements and/or sudden fetal death) when the mother's heavy opioid use was decreased.
- Confirmation of the structure and dynamic function of the placenta and demonstration of the presence of chloroform in the umbilical blood of neonates.

In 1952 the pioneering work of anesthesiologist Virginia Apgar converted an intangible phenomenon, the clinical condition of a newly born baby, into a formally defined measurement (2). Thereafter, the well-being of the infant became a major criterion for evaluation of the obstetric and anesthetic management of pregnant women.

This chapter introduces the neonatal practitioner to the clinical aspects of obstetric anesthesia and analgesia and examines their effects on the fetus and newborn.

EVALUATION OF WELL-BEING

Several methods of evaluation have been adopted into common usage as anesthesiologists attempt to separate out the fetal/neonatal effects of their interventions from concomitant medical and nursing management, and from the influence of preexisting maternal conditions.

The Apgar Score

The Apgar score is a convenient method of reporting the status of the newborn and the effectiveness of resuscitation. It rates each of five physical signs traditionally used by anesthesiologists to monitor a patient's condition: heart rate, respiratory effort, muscle tone, reflex irritability, and color. Apgar demonstrated that her score was sufficiently sensitive to detect differences among newborns whose mothers had received spinal versus general anesthesia (GA) for cesarean section (2).

Elements of the score are partly dependent on the physiologic maturity of the infant. Likewise, neonatal conditions such as bradyarrhythmias affect heart rate, while infection, neuromuscular conditions, and certain medications affect respiratory effort and tone. Additional information is required to interpret Apgar scores meaningfully in infants receiving ongoing resuscitation.

Wider application has resulted in incorrect use of the Apgar score to evaluate infant morbidity/mortality and to predict the occurrence of intrapartum events and long-term disability. Apgar scores at 1 and 5 minutes correlate poorly with both cause and neurologic outcome. A joint statement from the American Academy of Pediatrics (AAP) and American College of Obstetricians and Gynecologists emphasizes the appropriate use of the Apgar Score (3).

When used as originally intended, the Apgar score remains a valuable tool to assess the condition of the infant at birth (4), but it is not specific for the effects of anesthesia on the newborn.

Umbilical Cord Blood Gas Analysis

Cord blood gas analysis is the gold standard for assessing fetal acid-base status and uteroplacental function at birth. Umbilical artery pH, base excess, and $p\text{CO}_2$ reflect fetal and immediate neonatal condition whereas umbilical vein values reflect maternal acid-base status and placental function.

“Normal” values vary depending on the definition of normality and the influence of factors (e.g., altitude, parity, breech vaginal delivery, and duration of labor) on the population studied (5). Helwig and associates (6) retrospectively examined the records of 15,000 vigorous newborns with a 5-minute Apgar score of >7 . Median umbilical artery values, with the 2.5th percentile value in parentheses, were pH 7.26 (7.10) and base excess -4 mmol/L (-11 mmol/L). The means ± 2 standard deviations were similar. The generally accepted lower limit of normal umbilical artery pH extends to 7.10 and base excess to -12 mmol/L (5,7).

Values for pH, $p\text{CO}_2$, and base excess also vary with differences in sampling technique. Preanalytical error can be introduced if the cord is not clamped immediately, there is an excess quantity of heparin in relation to the amount of blood collected, air is present in the syringe, or the sample is kept at room temperature for longer than 15 minutes (8).

The supply of oxygen and the removal of volatile (CO_2) and fixed (e.g., lactate) acids by the placenta for excretion by the maternal lungs and kidneys, respectively, allow the fetus to maintain acid-base balance within a narrow range. Interruption of these processes can lead to acidemia in the fetus. In general, respiratory acidosis alone is not associated with newborn complications; rather, it reflects a sudden decrease in uteroplacental or umbilical perfusion such as placental abruption or cord prolapse immediately preceding delivery. Base excess values have greater usefulness than pH values because base excess does not change significantly with respiratory acidosis and demonstrates linear, rather than logarithmic, correlation to the degree of metabolic acidosis. Umbilical artery base excess is the most direct measure of fetal metabolic acidosis. Human and animal studies have confirmed normal values before and during labor and rates of base excess change in relation to events causing fetal hypoxemia (maternal hypoxemia, umbilical cord occlusion, and reduced uterine blood flow) (7).

The process of normal labor and delivery without anesthetic intervention stresses the fetus such that mild acidosis develops in almost all labors (9). Reynolds and associates (10) recently completed a meta-analysis comparing epidural with systemic opioid analgesia to determine the effect of these anesthetic interventions on acid-base status at birth. They concluded that epidural analgesia was associated with an improvement in base excess, suggesting that placental exchange is well preserved in association with this technique.

While umbilical artery pH, base excess, and $p\text{CO}_2$ are considered sensitive and objective indicators of fetal hypoxia during labor, the results represent a “snapshot” of fetal status and depict the mixed effluent of all fetal tissues. Cord gases do not distinguish between primary fetal pathologic conditions, fetal effects of maternal conditions (e.g., acid-base disorders), or the influence of inadequate placental blood flow. They also do not indicate in which direction the condition of the fetus is moving, or at what rate, nor do they reflect events that occurred remote from delivery.

Fetal Scalp Blood Gas Analysis

This method is advocated to improve the specificity of fetal heart rate monitoring (11) but has not been used by anesthesiologists to measure the fetal effects of their interventions.

Evaluation of Newborn Neurobehavior

Brazelton, Scanlon, and Amiel-Tison assessed the effect of anesthetic medications on the neurobehavior of term, healthy newborns (12,13,14). Their belief was that central nervous system depression from drugs administered to the mother during labor and delivery could be distinguished from effects associated with perinatal asphyxia and trauma at birth. Several review articles have described these tests in detail and compared the Brazelton Neonatal Behavioral Assessment Scale (NBAS) (12) and Early Neonatal Neurobehavioral Scale (ENNS) (13) to

the Neurologic and Adaptive Capacity Score (NACS) (14).

Researchers in obstetric anesthesia have tended to favor the NACS. It emphasizes muscle tone, avoids aversive stimuli, can be completed quickly, and is considered easier to learn than the NBAS and ENNS. The 20-item instrument is organized into two scales, adaptive capacity and neurologic assessment. The latter is further divided into four subscales, passive tone, active tone, primary reflexes, and general neurologic status assessment. A systematic review of the literature regarding use of NACS in obstetric anesthesia research concluded that reliability and validity evaluations of the tool were lacking, and it was unclear whether NACS could detect the existence of subtle neurobehavioral effects (15). The topic was the subject of an editorial that examined the widespread acceptance of this test notwithstanding the criticism that surrounded its initial publication (16). Subsequently, it has been determined that NACS has poor reliability when used to detect the effects of intrapartum drugs and other interventions on the neonate (17).

The NBAS is a much more detailed examination that may be more sensitive to environmental influences on behavior and reflect more accurately the capabilities of the neonate (18). Early studies involving concentrated epidural solutions tended to show that babies delivered to medicated mothers were less alert, had poorer muscle tone, and had difficulty habituating to repeated stimuli. This finding

P.262

is much less likely to occur with modern obstetric analgesia (19), where emphasis is placed on administering the lowest effective dose of medication or combination of medications needed to achieve the desired maternal effect and reduce the likelihood of adverse influences on the fetus/newborn.

Electronic Fetal Monitoring

Electronic fetal monitoring, one technique in the overall strategy of intrapartum fetal surveillance (20,21), aims to improve outcomes by identifying fetuses with hypoxic acidemia at a point when the process is still completely reversible by intrauterine resuscitation or expedited delivery. The fetal heart rate (FHR), including variability, accelerations, and decelerations, if any occur, is recorded electronically on a paper trace. A reactive (normal or reassuring) cardiotocogram (CTG) is defined by the presence of accelerations. Baseline FHR normally ranges between 110 and 160 beats per minute. Reduced variability and the presence of decelerations are abnormal findings.

A systematic review of studies comparing the efficacy and safety of routine continuous electronic fetal monitoring versus intermittent auscultation (IA) of the FHR reveals the former to be associated with a significantly higher rate of cesarean and operative vaginal delivery (22). In the antecedent Cochrane review of this same topic, the incidence of GA to facilitate obstetric intervention was also increased. This aspect of management was not examined in the current review. The only significant benefit of the use of routine, continuous fetal monitoring was in the reduction of neonatal seizures; otherwise, neither IA nor continuous monitoring has been shown to decrease morbidity or mortality (22).

Difficulty in the visual interpretation of CTG patterns during labor can result in unnecessary operative intervention, while some significant changes go unrecognized. Computerized CTG systems, which do not rely on observer reading of the FHR tracing, are more accurate and reliable. Evaluation of the FHR pattern is given online continuously, and warnings are displayed if there is signal loss, reduction in fetal movements, or an abnormally flat or decelerative trace (23). Retrospective analysis of several thousand records enabled investigators to conclude that the most reliable single parameter of fetal condition was variability (short- and long-term). Absence of accelerations, presence of decelerations, decrease in the number of movements, and changes in baseline FHR all occurred occasionally in normal fetuses (24).

Recently, automatic ST segment and T-wave analysis of the fetal electrocardiogram (recorded continuously from the fetal scalp electrode used for FHR measurement) has been combined with conventional CTG. Elevation or depression of the ST segment occurs when the fetus is exposed to a hypoxic stress. When CTG is accompanied by computerized analysis of the ST segment, the number of operative deliveries for the indication of "fetal distress" can be reduced without jeopardizing fetal outcome (24). This technique of fetal surveillance improves the practitioner's ability to identify cases of significant fetal hypoxia necessitating obstetric intervention, thus reducing the risk of an umbilical cord arterial metabolic acidosis at birth (25).

Anesthesiologists have used continuous fetal CTG recordings to evaluate the effect of maternal analgesia on FHR and variability. Solt and associates (26) demonstrated that intrapartum intravenous (IV) administration of meperidine (pethidine) 50 mg and promethazine 25 mg resulted in decreased variability and fewer accelerations

on computerized CTG for the duration of their 40-minute recording. It is unclear whether the effect can be attributed to one of the two drugs or the combination, although this is a typical fetal response to systemic maternal opioid administration.

A randomized study was conducted to examine the effect of continuous epidural anesthesia with or without narcotic on intrapartum FHR characteristics as measured by computer analysis. The narcotic epidural consisted of an initial bolus of 10-12 mL 0.125% bupivacaine with fentanyl 50 µg, followed by continuous bupivacaine 0.125% with fentanyl 1.7µg/mL infusion. The nonnarcotic epidural was initiated with a bolus of 10-12 mL bupivacaine 0.25% and followed by a bupivacaine 0.125% infusion. Investigators found no difference in pre- and postepidural baseline FHR, accelerations, or variability between the groups (27). These solutions are considerably less concentrated than those used 10-20 years ago and are in keeping with modern obstetric anesthesia practice, which aims to reduce motor block by using dilute local anesthetic (LA) plus narcotic epidural solution combinations.

In a double-blind randomized study of bolus epidural opioid effect on FHR variability, butorphanol 2 mg, fentanyl 50 µg, sufentanil 15 µg, or saline in combination with bupivacaine 0.25% did not change FHR short- or long-term variability (28).

FHR decreases in response to compression of the fetal head during passage through the birth canal and in response to umbilical cord compression or reduced uterine blood flow secondary to maternal hypotension or prolonged uterine contraction. This bradycardia is vagally mediated.

Biophysical Profile Score

This ultrasound-based method combines measures of acute biophysical variables, fetal breathing, heart rate accelerations, gross body movements, and fetal tone with amniotic fluid volume (29). The first four variables reflect acute fetal condition, whereas the last variable reflects chronic fetal condition. The observation period lasts 30 minutes because fetuses are known to sleep for intervals lasting approximately 30 minutes. When normal (≥ 8 out of a possible 10), the biophysical profile score (BPS) is a direct, reliable, and accurate measure of normal tissue oxygenation. A normal score is never associated with an abnormal fetal pH. Scores $\leq 6/10$ during routine antepartum evaluation indicate the amount of oxygen

P.263

delivered to target organs is insufficient to maintain function. The lower the score, the greater the likelihood that central acidemia is present (30).

Placental transfer to the fetus of maternally administered intramuscular (i.m.) narcotic medication (diamorphine 10 mg or morphine 10 or 15 mg administered with dimenhydrinate) resulted in transiently reduced fetal activity and, consequently, a lower BPS for the duration of the drug effect (31,32). A small dose of IV fentanyl (50 µg) given in early labor was associated with abolishment of fetal breathing at 10 minutes postdosing, fewer body movements, and reduced variability (33). The effect lasted approximately 30 minutes, in keeping with the pharmacodynamic profile of fentanyl. This should be taken into account when fentanyl is administered close to the time of delivery. In this study, none of the neonates required resuscitation, and all had umbilical artery pH values >7.2 .

Fetal Pulse Oximetry

Fetal oxygen saturation monitoring by pulse oximetry (SpO_2) is poised to become the most significant advance for intrapartum fetal assessment in recent years. It relies on established, noninvasive technology and is based on the following assumptions: fetal well-being is dependent on perfusion of vital organs with oxygenated blood; SpO_2 correlates with saturation as measured by blood gas analysis; and a critical threshold for SpO_2 exists, above which the fetus will be nonacidemic and below which, acid-base decompensation may occur (34).

Based on animal and human data, fetal SpO_2 values $\geq 30\%$ can be considered reassuring, whereas SpO_2 values $<30\%$ may be associated with acidosis. Low SpO_2 values warrant further assessment if they persist for periods of >2 minutes and necessitate intervention (intrauterine resuscitation or expedited delivery) if they persist for >10 minutes (34,35). The predictive value of intrapartum fetal SpO_2 compares favorably with fetal scalp blood analysis (36). The former has the advantage of being a continuous monitoring technique.

The United States Food and Drug Administration approved the Nellcor N-400/FS14 fetal pulse oximeter for

clinical use in 2000 as an adjunct to electronic fetal monitoring in the presence of a nonreassuring tracing (Fig. 16-1). At present, this technology is limited to singleton, term fetuses in the vertex position.

Results of studies designed to investigate the effects on fetal oxygen saturation of administering epidurals to healthy parturients are beginning to appear in the literature. Neither an initial epidural bolus of 15 mL of ropivacaine 0.1% with sufentanil 10 µg or intermittent repeat plain ropivacaine boluses affected SpO₂ in healthy fetuses (37). In a study designed to account for the possible influence of maternal position, diastolic blood pressure, and preexisting FHR pattern, SpO₂ values were not affected by boluses of dilute epidural infusion solutions but did decrease with bolus administration of more concentrated LA at epidural insertion or top-up (38). Other than to comment on the variety of combinations and strengths of analgesic agents, details of the epidural solutions were not contained in the report. Further clinical trials are needed to assess and characterize the effect of all types of anesthetic intervention on fetal SpO₂ during normal and abnormal labor, in addition to various maternal conditions associated with fetal compromise (e.g., pregnancy-induced hypertension).

Fetal Doppler

Flow velocity waveforms from maternal vessels (uterine arteries), placental circulation (umbilical arteries), and fetal systemic vessels (e.g., middle cerebral artery), collectively known as Doppler evaluation, provide prognostic and diagnostic detail about placentation and fetal adaptation (39).

Regulation of the circulation is a complex fetal behavior, influenced by gestational age and the maternal environment. Under normal circumstances, the reduction in sympathetic tone created by epidural analgesia does not affect Doppler flow characteristics of either the uterine or umbilical artery vessels because the spiral arterioles are maximally dilated and the fetoplacental circulation is stable and tolerant of environmental changes. However, epidural analgesia has been shown to improve uteroplacental perfusion and effectively reduce maternal blood pressure in laboring patients with pregnancy-induced hypertension (40). This offers potential benefits for both the fetus and mother: when uteroplacental perfusion improves, fetal oxygenation and acid-base balance improve, and when blood pressure is restored to normal levels, the risk of vascular accidents and organ damage is reduced.

Static Charge-Sensitive Bed

A new method for long-term monitoring of respiration, heart rate, cardiac function, and body movements in newborn infants was presented in 1984, and possible clinical

P.264

applications were discussed (41). The technology has been used to evaluate neonatal sleep states following unmedicated vaginal delivery or elective cesarean section delivery under spinal anesthesia (42) and, in combination with SpO₂ and ECG recording, to examine the influence on the newborn baby of maternal fentanyl analgesia in labor (43).

In the first study, mode of delivery did not affect sleep state distribution during the first day of life (42). Vaginally born neonates had fewer body movements and more episodes of SpO₂ <95% in the first 24 hours after birth. This result surprised the investigators since babies born by cesarean section are known to develop respiratory problems more often than infants who are delivered vaginally. In the second study, fentanyl (50 µg of IV bolus q5min until pain relief, then fentanyl patient-controlled analgesia) was compared with paracervical block (10 mL of bupivacaine 0.25%) in a prospective, randomized fashion. The trial was interrupted after enrolment of the twelfth healthy, term newborn because there was a significant decrease in SpO₂ to 59% in one of the babies. Interestingly, the SpO₂ improved with naloxone administration even though later analysis showed the concentration of fentanyl in the umbilical vein to be below the detection limit of the assay. Intrapartum electronic fetal monitoring did not reveal any difference in variability or heart rate between groups. As well, Apgar scores and analyses of umbilical artery pH were similar. The SpO₂ values were lower and the percentage of minimum SpO₂ values between 81% and 90% were more prevalent in the fentanyl group. The static charge-sensitive bed (SCSB) method proved sensitive enough to detect lower heart rates and less quiet sleep in the fentanyl group, suggesting a salutary effect of the opioid on delivery stress (43).

Summary

The nature of the association of anesthetic medications and interventions is complex and can be confounded by a myriad of factors. As yet, there is no one test that clearly separates effects on the fetus/newborn, if any, of maternally administered medication during labor and delivery, although newer technologies show some promise.

PAIN MANAGEMENT

For most women, childbirth is likely one of the most painful events in their lifetimes. There are both physiologic and psychologic aspects to pain and its management (44).

Labor pain evokes a generalized neuroendocrine stress response that has widespread physiologic effects on the parturient and fetus (45). The neuroendocrine model, presented in Figure 16-2, examines the potential detrimental consequences of untreated pain. The sequelae of hyperventilation, secretion of stress-related hormones, and increased oxygen consumption can be prevented, obtunded, or abolished by central neuraxial blockade (epidural or spinal anesthesia).

Research in humans supports elements of this model (46), but studies are not necessarily designed to consider the effects of simultaneously occurring care practices on these same physiologic responses. "This critique is needed because it is somewhat counterintuitive that the procreative physiologic process of labor and birth would by nature have detrimental effects on a healthy mother and fetus" (47). An example of a concurrent care practice is the administration of isotonic "sport drinks" versus water only during labor (48). Sports drinks were shown to prevent the development of maternal ketosis without increasing gastric volume, although there was no difference between the groups in neonatal outcome.

Labor Pain: Implications for the Fetus

Neural pathways and neurochemical systems involved in pain perception are functional from mid-gestation and are well developed by the third trimester (49,50). Gitau and associates (51) conducted a parallel study of the fetal and maternal hormonal responses to fetal blood transfusion. They confirmed that the fetus mounts a hypothalamic-pituitary-adrenal response to transfusion via the intrahepatic vein, which involves piercing the fetal trunk, but not to transfusion in the umbilical vein at the placental cord insertion, which has no sensory innervation. The rise in fetal cortisol and endorphin occurred independently of the maternal reaction. Pretreatment of the fetus with fentanyl for this same procedure attenuated the rise in β-endorphin (52).

Hormonal stress responses do not provide a direct index of pain. While it is true that a rise in cortisol and endorphin is seen as a consequence of painful stimuli in children, other nonpainful situations (e.g., exercise) are also associated with an increase in the levels of these hormones. Nonetheless, editorial review of Fisk's fentanyl pretreatment study suggests that fetal analgesia should be given during invasive *in utero* procedures (53).

At present, there is no literature on fetal "pain" during labor or delivery.

Labor and Delivery Pain: Implications for the Mother

Visceral pain predominates during the first stage of labor. Nociceptive information arising from uterine contractions, distention of the lower uterine segment, and cervical dilation is relayed in C afferent fibers to the dorsal horn of the spinal cord at the T10 to L1 levels. As labor progresses, a mixture of visceral and somatic (A-delta fibers) pain results from traction on the pelvic floor structures surrounding the vaginal vault, and eventually from distention and stretch of the vagina and perineum (L2-S1). Delivery pain (Stage II) is somatic in nature and transmitted along the pudendal nerve (S2-4). Synaptic input at the dorsal horn, mediated by neurotransmitters and chemicals (e.g., excitatory amino acids), is relayed via the spinothalamic tract to higher centers including the reticular formation, hypothalamus, and limbic system. Dorsal horn neurons also initiate segmental spinal reflexes. Descending spinal tracts, endogenous opioids, and other inhibitory systems modulate

P.265

nociception centrally in the spinal cord. The neural mechanism of labor shares features with other forms of acute pain (54).

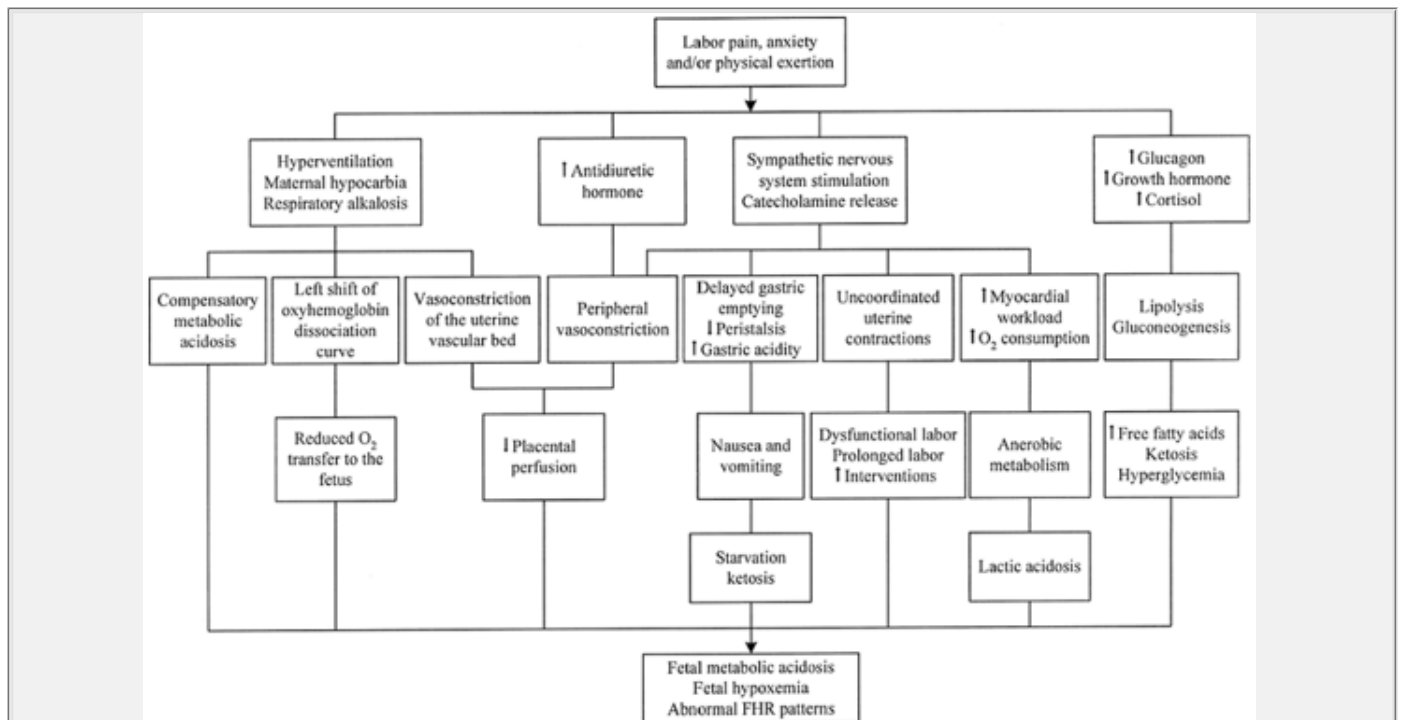

Figure 16-2 Potential adverse effects of untreated maternal pain on the fetus. (Modified from Brownridge P, Cohen SE, Ward ME. Neural blockade for obstetrics and gynecologic surgery. In: Cousins MJ, Bridenbaugh PO, eds. *Neural blockade in clinical anesthesia and management of pain*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 1998:557-604, with permission.)

To view labor pain only as a neuroendocrine, sensory experience is limiting and undermines the complexity of this phenomenon (47). Pain is just one component of the totality of the labor and birth experience. Assisting women to cope with the affective or distress components of labor and birth in a supportive environment has been shown to reduce the need for pain-relieving drugs, decrease the incidence of operative delivery, result in higher Apgar scores, and improve breastfeeding success (44,55).

Practice guidelines, including a section devoted to specific analgesia techniques, have been developed to enhance the quality of anesthetic care for obstetric patients (56). For the obstetrician, analgesia options are outlined in a practice bulletin that was written to facilitate communication with patients and anesthesia and neonatology colleagues (57).

The management of pain and anxiety in labor is a worthwhile goal whether the techniques used are nonpharmacologic, pharmacologic, or include a combination of both. The choice depends on patient preferences, medical status of the mother and fetus, progress of labor, and resources available at the facility for pain management and treatment of potential complications.

ANALGESIC TECHNIQUES FOR LABOR: EFFECTS ON THE FETUS AND NEWBORN

Analgesia refers to pain relief without loss of consciousness. Regional analgesia denotes partial sensory blockade in a specific area of the body, with or without partial motor blockade. The term neuraxial analgesia pertains to the administration of pain-relieving medications using caudal, spinal, and/or epidural techniques.

Not all methods of pain relief are available or desirable in all centers, and certain methods are more popular in different parts of the world (58).

Nonpharmacologic Methods

Proponents of nonpharmacologic methods claim that these methods reduce requirements for analgesia during the first stage of labor. This does not necessarily imply that women who use these techniques have less pain, rather that they are able to cope with labor using less analgesia.

In a systematic review of comfort measures, Simkin and O'Hara (59) commented on five methods scientifically evaluated for their effectiveness in reducing indicators of labor pain. This review also mentioned pain-related outcomes

P.266

such as obstetric interventions and duration of labor. *Continuous labor support* was associated with a decrease in duration of labor, requests for analgesia, rates of instrumental and cesarean deliveries, and occurrence of lower Apgar scores. The use of *baths* offered temporary pain relief and was considered safe provided water temperatures were maintained at or below maternal body temperature and that immersion duration was controlled. Perinatal morbidity and mortality did not increase, even if membranes were ruptured. The authors concluded that there had been insufficient study to provide clear conclusions regarding *touch/massage*, although emotional and physical relief was demonstrated with this intervention. *Intradermal water blocks* were effective in reducing severe back pain, and one randomized study reported a decrease in cesarean deliveries. Lastly, *maternal movement and positioning* was reported to impact pain relief in labor and impact several variables related to fetal and neonatal well-being. In this systematic review, no trials compared a policy of freedom to move spontaneously with a policy of restriction to a bed for outcomes such as comfort, labor progress, or fetal welfare. Mechanisms by which dystocia may be prevented or corrected through the use of maternal positioning have been discussed elsewhere (60).

Systemic Opioids

From the maternal perspective, efficacy and incidence of side effects with systemic opioid analgesia is largely dose- rather than drug-dependent. There is little evidence to suggest one agent is intrinsically superior. Most often, the choice is based on institutional tradition or personal preference.

Opioids may affect the fetus directly as a result of placental transfer and/or indirectly, for example, by altering maternal minute ventilation or uterine tone. As a group, these low-molecular-weight drugs are lipid-soluble weak bases (61) that readily cross the placenta. This implies that maternal to fetal concentration gradients are important; only free, not protein-bound, drug is available for transfer. The amount of "free" drug delivered to the placenta depends on placental blood flow and the degree of maternal protein binding. The amount of drug available to the fetus depends on the degree of placental uptake, metabolism, and clearance (62). In single-dose drug studies, key factors influencing umbilical vein/maternal drug ratio are lipid solubility and transit time through the placental bed. In multidrug dosing (e.g., patient-controlled narcotic analgesia [PCA] delivery systems), key factors influencing fetal drug levels are the degree of ionization and degree of fetal protein binding (Fig. 16-3).

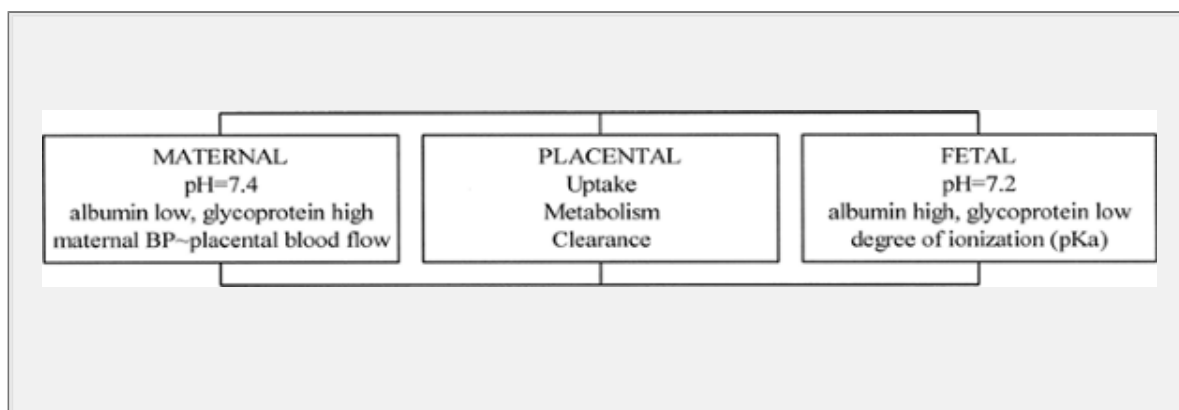

Figure 16-3 Factors influencing fetal drug levels with PCA narcotic administration.

Fetal pH is lower than maternal pH; consequently, the fraction of opioid (and other basic drugs) existing in the ionized state is higher in the fetus than in the mother. Ionization results in drug trapping. The degree of ionization depends on the drug's pKa; the effect is greater for meperidine (pKa ~8.5) than morphine (pKa ~8.0), and more significant when the fetus is acidotic. This is a simplistic, albeit true, application of opioid pharmacokinetics, a complex, difficult to predict, and incompletely evaluated topic.

All opioids have the potential to decrease baseline FHR and reduce variability, making interpretation of fetal CTG recordings potentially problematic. It has been documented from observational studies that parenteral narcotics can be associated with neonatal respiratory depression, decreased neonatal alertness, inhibition of sucking, and delay in effective feeding. When evidence related to the use of parenteral opioids for labor pain relief was subjected to a systematic review (63), it was noted that none of the studies was sufficiently powered to address the primary outcome measure of neonatal resuscitation, a measure of safety. Intramuscular opioid was compared to placebo, different i.m. opioid, same i.m. opioid but different dose, and same opioid given intravenously; IV opioid was compared to different IV opioid and same IV opioid but different modes of administration. There was insufficient pooled information to draw conclusions regarding any of the secondary outcome measures, including fetal distress administration of naloxone, Apgar score <7 at 5 minutes, baby death, admission to a special care setting, feeding problems, and problems with mother-baby interaction.

The concept of genetic imprinting at birth for opiate or amphetamine addiction in later life has been associated with systemically administered pain-relieving labor medications (narcotics, barbiturates, or nitrous oxide) (63). The original studies that led to this conclusion were criticized regarding the matching of controls and the imprinting hypothesis proposed to explain the finding (64). Although a more recent study of drug-abusing subjects confirmed the phenomenon, these results will be considered controversial until there is more confirmatory evidence.

Meperidine is the most commonly used opioid for labor analgesia worldwide. It has been shown that, as the time increases from administration of single-dose, i.m. meperidine 1.5 mg/kg during labor to delivery of the baby, so too does the level of meperidine in the fetus (65). Maximum fetal concentrations reach a plateau between 1 and 5 hours after dosing; therefore, babies born within 1 to

P.267

5 hours after meperidine is given to the mother have the greatest chance of narcotic-induced depression. In contrast to single-dose studies, multiple doses of meperidine administered over many hours lead to accumulation of meperidine's metabolite, normeperidine, in the mother and fetus (66). Half-lives of 17-25 hours for this metabolite are common in the mother, whereas the half-life exceeds 60 hours in the fetus/newborn. Normeperidine is associated with respiratory depression, not reversible by naloxone, and seizures. Because of concerns about meperidine, research has focused on the newer, shorter-acting opioids with no active metabolites as alternatives.

Fentanyl has been available clinically for more than 20 years. It offers prompt analgesia coupled with a short duration of action and no active metabolites. Both maternal and fetal drug levels decline in a parallel fashion following a single dose of the drug (67). In the first report of its administration to laboring patients, fentanyl (50 to 100 µg IV q1h) was compared with meperidine (25 to 50 mg IV q2-3hr) (68). More mothers were nauseated and sedated and more babies required naloxone in the meperidine group.

Sufentanil is the most lipid soluble (octanol:water partition coefficient 1778) of the commonly used opioids (61). This feature should enhance placental transfer after a single dose, but transfer is impeded by the extent of maternal plasma protein binding (α 1-acid glycoprotein) and uptake by the placenta. Sufentanil concentration in the fetus rises slowly, reaching a plateau between 45 and 80 minutes postadministration (69). It is a useful maternal analgesic for pain relief during second stage, when fetal delivery is imminent (<45 minutes).

Remifentanil is a novel, ultra-short-acting opioid. It has the most rapid onset of peak effect (~1 minute), shortest context-sensitive half time (~3-5 minutes), and greatest clearance (40 mL/kg/min) of the commonly used opioids (61). Although the maternal cardiovascular and side effect profiles are similar to other fentanyl congeners, remifentanil is chemically distinct because of its ester linkages. This ester structure renders it susceptible to hydrolysis by red cell- and tissue-nonspecific esterases, resulting in rapid metabolism. Remifentanil concentration decreases by 50% within 3 to 5 minutes of stopping drug administration, regardless

of the duration of the infusion (61).

Labor pain occurs at intervals and increases in intensity over time. Rapid recovery between contractions and after delivery is desirable. Therefore, the most effective means of administering remifentanyl to the laboring patient, taking advantage of the drug's characteristics, is via PCA with a background infusion. Bolus dose, lockout time, and rate of infusion can be titrated (70). The drug rapidly crosses the placenta and is quickly metabolized by fetal esterases (71). Maternal oxygen desaturation and sedation and reduced FHR variability have been observed (72). Newborns exposed to remifentanyl *in utero* up until the time of delivery have been vigorous. There have been no reports of lower Apgar scores, unacceptable umbilical cord gas analyses, or respiratory depression necessitating naloxone use. (70,71,73)

Naloxone is used to reverse respiratory depression in narcotic-exposed newborns. It is contraindicated for infants of narcotic-dependent mothers, as administration may precipitate acute withdrawal and seizures. Naloxone has never been shown to reduce the need for assisted mechanical ventilation or reduce admission rates to special-care nurseries (74). No studies have evaluated the effect of naloxone on time to spontaneous effective respiration or long-term outcome. Naloxone use in adults has been associated with reports of hypertension, pulmonary edema, arrhythmias, and cardiac arrest (61).

Agonist-Antagonist Opioids

Nalbuphine is commonly used as a systemic analgesic during labor. Reports of severe perinatal cardiovascular and respiratory depression prompted Nicolle and associates (75) to carry out a study designed to delineate placental transfer and disposition of nalbuphine in the neonate. The estimated half-life was 4.1 hours (versus 0.9 hour in infants and 2 hours in adults). Given that the liver extensively metabolizes nalbuphine, the authors speculated that the slower neonatal plasma disappearance rate compared to the infant or adult could be due in part to immature hepatic function or bypass of the liver via the ductus venosus. All 28 babies had 5-minute Apgar scores of 10. Fifty-four percent of the FHR tracings showed reduced variability lasting 10-35 minutes after maternal injection.

One potential use for this class of drugs is in the treatment of opiate-dependent pregnant women. Babies born to mothers on a buprenorphine maintenance program showed little or no clinically measurable neonatal abstinence syndrome in contrast to findings with methadone, morphine, or heroin maintenance programs (76).

Nitrous Oxide

Nitrous oxide (N_2O) is an odorless inhalational agent that exerts weak but prompt analgesic activity. It is a relatively insoluble gas at room temperature, and therefore equilibrates rapidly between the alveoli, blood, and brain. To be fully effective, inhalation needs to be timed with contractions such that the patient begins to breathe the gas about 10 to 15 seconds in advance of the next contraction. This synchronizes the peak effect of N_2O with the zenith of pain, assuming the average contraction lasts 60 seconds and peaks at the midpoint. N_2O is combined with oxygen in a 50:50 mixture for obstetric use and is self-administered by the patient through a specialized breathing circuit equipped with a demand valve. The negative pressure generated at the onset of inspiration opens the valve, which remains open during inspiration and closes when the patient begins to exhale. Inhalation analgesia with N_2O during labor and delivery by itself, as a coanalgesic, or as a temporizing measure pending other forms of pain relief is less common in the United States than in other developed countries.

Any patient at risk of vitamin B12 deficiency (e.g., pernicious anemia or vegetarian) should not use N_2O as it

P.268

irreversibly oxidizes vitamin B12, reducing the activity of methionine synthetase (necessary for myelin formation) and other B12-dependent enzymes. Many countries have set maximal environmental limits for N_2O , which necessitates the use of ventilation systems that allow exhaled gas to be scavenged.

N_2O readily crosses the placenta. The maternal-fetal concentration ratio reaches 0.8 within 15 minutes of continuous inhalation. It has no effect on uterine contractions or FHR. It is not metabolized and is eliminated quickly and entirely by the lungs with the onset of respiration at birth. This is true whether the mother inhales N_2O for 5 minutes or 5 hours. N_2O does not affect Apgar scores or sucking behavior (77).

Paracervical Block

This peripheral block provides a therapeutic alternative for first-stage labor pain when central neuraxial blockade is contraindicated or unavailable. The technique involves transvaginal injection of LA on either side of the cervix to interrupt pain transmission at the level of the uterine and cervical plexuses (located at the base of the broad ligament). Paracervical block (PCB) is relatively easy to perform and, when effective, it provides good to excellent analgesia that lasts 1-2 hours.

Since the introduction of PCB in the 1940s, reports of serious adverse sequelae, including injection of LA directly into the uterine arteries or fetal head, fetal death, and profound bradycardia, have resulted in modification of the injection technique and changes to the concentration and type of LA used. There are statements cautioning against employing this block in situations of uteroplacental insufficiency or nonreassuring FHR tracings.

Overall, in current practice the incidence of fetal bradycardia postblock is about 15% (78), with the onset beginning 2 to 10 minutes after injection and the bradycardia lasting 15 to 30 minutes. The exact etiology is unknown; however, a recent investigation comparing epidural with PCB using Doppler flow velocity waveforms of the maternal femoral and uterine arteries, and umbilical and fetal middle cerebral arteries has shed some light on this phenomenon (79). PCB was associated with a small but significant increase in uterine artery impedance, indicating uterine artery vasoconstriction. In this study, Apgar scores and umbilical arterial and venous pH determinations were within the normal range in both groups.

Neuraxial Analgesia

Spinal, epidural, and combined spinal-epidural (CSE) techniques are commonplace for managing childbirth pain. They are used to administer opioids, LAs, and other pain-modulating adjuvants. Collectively, these methods are considered the most effective forms of pain relief available to laboring women.

Although spinal anesthesia has been in use since 1899, spinal analgesia only became a viable possibility in the 1970s following the discovery of specific opioid receptors in the brain and spinal cord. From a practical standpoint, however, it was not an option for laboring women at that time for two reasons: there was an unacceptably high incidence of postspinal headache (also known as postdural puncture headache) in the young female population; and a single injection technique could not be relied upon to provide analgesia for more than 1 to 2 hours. The advantage of having an epidural catheter in place, either for subsequent bolus dosing or for continuous infusion, is the provision of uninterrupted analgesia between placement of the catheter and delivery of the baby.

The (re-)introduction of fine-gauge, pencil-point, atraumatic (noncutting) spinal needles in the late 1980s fostered a renewed interest in subarachnoid (intrathecal) injection (80). With the advent of CSE equipment and "needle-through-needle" technique, single-level subarachnoid injection, followed immediately by epidural catheter placement at the same site, became possible (81). The CSE procedure has become synonymous with subarachnoid injection of opioid (\pm a small dose of LA) and simultaneous initiation of a low-dose epidural infusion. The perceived advantages of CSE compared with more traditional methods continue to be debated, along with the consequences of routine dural puncture (81,82,83).

Epidural catheter analgesia alone has been popular for many years. Depending on the choice of agents used, it provides superior pain relief during the first and second stages of labor and can be extended, if necessary, for cesarean section, instrumented vaginal delivery, manual placental removal, or episiotomy repair.

Neuraxial Opioids

Opioids injected into the lumbar intrathecal space distribute between nerve tissue and cerebrospinal fluid (CSF) on the basis of their partition coefficients (lipid solubility). Opioids injected into the epidural space first diffuse across the dura to reach the subarachnoid space, and then behave as their intrathecal counterparts. Morphine, the least lipid soluble of the commonly used opioids, diffuses slowly from the CSF into the substantia gelatinosa of the dorsal horn to activate opioid receptors. This accounts for its delayed onset and prolonged duration of action. Morphine also spreads rostrally, moving by bulk flow with CSF to reach vasomotor, respiratory, and vomiting centers in the brainstem. In contrast, the highly lipophilic fentanyl and sufentanil penetrate nerve tissue quickly. They have a faster onset of activity coupled with a shorter duration of action. Remifentanyl is not approved for use in the intrathecal space because it contains a glycine preservative.

All opioids have some minor intrinsic LA properties, but these effects are marked with meperidine (61), allowing it to be used as the sole agent, even for cesarean section, in the rare event of amide LA allergy. Intrathecal

meperidine produces significant sympathetic and motor blockade as well as typical opioid side effects such as pruritus. It has little value as an adjunct to regional analgesia for labor.

The purported advantages of using opioid drugs alone to induce neuraxial analgesia for labor include:

- Preservation of motor function, sustaining the ability to ambulate during first stage and to push during second stage
- Avoidance of LA-induced sympathectomy which can be associated with undesirable cardiovascular sequelae such as hypotension
- Reduction in the systemic side effects of opioids themselves, given the receptor-specific route and minute amount of drug needed to exert an effect. Less total opioid means less chance of drug transfer to the fetus and fewer unpleasant maternal side effects such as nausea, vomiting, pruritus, urinary retention, and sedation.

Fetal bradycardia may develop following administration of intrathecal opioid, although its occurrence can follow any type of effective labor analgesia (84). While technique-specific etiologies can occur (e.g., maternal hypotension or fetal LA toxicity), uterine hypertonus as the mechanism inciting the transient but profound drop in heart rate was first reported in 1994 (85). This topic has been the subject of study (86) and systematic review (87).

Pain relief can affect uterine function. Hunter (88) reported in 1962 that bilateral lumbar sympathetic block for first-stage labor pain caused abnormal uterine contraction patterns to normalize and previously normal patterns to become hyperactive. Although there is likely more than one mechanism, the etiology is thought to be related to a change in the balance of circulating catecholamines occurring with the advent of analgesia, favoring α - over β -activation of smooth muscle receptors (46,89). Uterine muscle tone and vascular resistance increase as a result of the contraction-inducing norepinephrine influence predominating over the contraction-relaxing epinephrine effect. FHR decreases because of a reduction in uteroplacental blood flow. The effect may be more pronounced in the face of oxytocin stimulation.

From an anesthetic perspective, any block that includes segments T10 to T12 (uterine afferent pain fibers enter the spinal cord at the T10-L1 level) will affect efferent nerves to the adrenal medulla (46). There is a temporal relationship between the speed of onset of labor pain relief and the appearance, if any, of bradycardia. It occurs faster with spinal analgesia (<10 minutes) and more slowly with epidural analgesia (15 to 30 minutes) (84). However, as Van de Velde and associates (86) point out, speed of onset of labor pain relief cannot be the only factor at work. Nonreassuring FHR tracings did not occur after CSE using a mixture of bupivacaine and sufentanil (1.5 μ g) when compared to a larger dose of intrathecal sufentanil (7.5 μ g) alone, despite equally fast pain relief. Metanalysis performed during a well-conducted systematic review of this topic revealed a significant increase in the risk of fetal bradycardia due to intrathecal opioid (odds ratio 1.8, 95% confidence interval 1.0 to 3.1) (87).

The clinical implications are not obvious because the occurrence of FHR changes in response to labor analgesia has not prompted an increase in the rate of interventional delivery (87). The hypertonus usually lasts less than 10 minutes and can be relieved by administration of a nitric oxide donor such as nitroglycerin (50 to 100 μ g IV), or a β 2 agonist such as terbutaline (125 to 250 μ g IV), in cases of prolonged fetal bradycardia. The observed changes in FHR have not correlated with observable clinical differences in neonatal outcome, including Apgar scores, cord pH, prevalence of cord pH <7.15, or admission rate to a neonatal intensive care unit (86).

Despite the utility of opioids as neuraxial agents during labor, their use without LAs is confined to early labor; by themselves, they do not provide adequate relief as labor progresses and pain intensifies (81,90).

Neuraxial Local Anesthetics

LAs exert their effect by penetrating the epineurium and neural cell membrane in the lipid-soluble (un-ionized) base form to reach the axoplasm. Cellular integrity and metabolism are unaffected. Once inside the cell, the molecules revert to ionized and un-ionized forms in equilibrium. The charged form blocks sodium channels,

thereby disrupting sodium conductance and preventing depolarization. This interaction between LA and channel is reversible and ends when the concentration of LA falls below a critical minimum level.

There are several factors that influence the choice of LA agent and concentration employed for epidural or caudal analgesia. These include the delivery system used (intermittent bolus, continuous infusion, or patient-controlled epidural bolus \pm background infusion), desired speed of onset, nature of the pain, progress of labor, degree of motor block tolerable for the patient and anesthesiologist, local practice and experience, and cost. In general, when LA is used alone, concentrated solutions are required to afford pain relief. Since block density is dose dependent, the more concentrated the solution used, the greater the degree of motor block expected; this has been implicated in pelvic muscle relaxation-induced fetal malposition, maternal inability to push, and need for instrumental delivery (91). In a recent meta-analysis comparing randomized clinical trials of techniques using epidural LA alone with intrathecal opioid alone (92), the authors were unable to find sufficient information to comment on either similarities or differences in maternal and fetal outcomes. This study was accompanied by an insightful editorial that will assist readers to critically interpret the results of this and other systematic reviews and meta-analyses (93).

LAs alone are not normally used for spinal analgesia, and use of the caudal technique for pain relief in labor is uncommon.

Combining Opioids, Local Anesthetics, and Pain-Relieving Adjuvants

When spinal, epidural, and CSE techniques involve combinations of pain-modulating drugs (sodium channel-blocking

P.270

agents, opioid-receptor agonists, α -adrenergic agonists, and/or acetylcholinesterase inhibitors) acting by different mechanisms, there is potential to afford analgesia with minimal motor blockade and other relevant side effects (19,83,94). Lower doses of individual agents in combination often result in at least additive and, at times, synergistic analgesic effect.

Labor Epidurals and Outcome

An erudite and interesting historical review of anesthesia for childbirth by Caton and associates (95) provides the foundation for a discussion of the controversies and unresolved issues surrounding the influence of epidural analgesia on maternal outcomes that affect the fetus and newborn.

There have been five systematic reviews (63,96,97,98,99) comparing epidural to nonepidural analgesia methods. All focused in some manner on the clinical dilemma of balancing the alleviation of maternal pain with the possible increase in side effects and/or adverse outcomes for the mother and baby. The search strategies, choice of inclusion and exclusion criteria, assessment of individual trial validity, primary and secondary outcomes, and approach to the synthesis of information differed. Commentary about two of the reviews that were conducted in parallel is thought provoking (100).

The following is a simplified summary of the information provided by the reviews:

- Epidural solution concentration and technique varied tremendously over the 38-year timespan covered. As a result, there were some qualitative differences in the effects of treatment (heterogeneity).
- All reviewers concluded that there was insufficient evidence to support an increased incidence of cesarean section with the use of epidural analgesia.
- Data on babies were scanty, apart from gross measures such as Apgar scores and results of umbilical cord blood gas analysis. Some issues remained unproven; e.g., the suggestion that "epidural analgesia is associated with less naloxone use and higher one-minute Apgar scores." No consistent picture emerged about the incidence of neonatal adverse effects associated with epidural. There was little evidence regarding the effects of epidural on fetal physiologic mechanisms.
- Epidural analgesia was associated with (not necessarily a causal relationship):

- longer second-stage labor (approximately 14 minutes)
- more fetal malposition (occiput posterior), possibly due to failure to rotate or because laboring with a fetus in this position results in more pain, which brings about the request for epidural analgesia
- higher rate of instrumental vaginal deliveries
- maternal fever
- increased use of oxytocin augmentation. This serves as an example of the “association versus causation” debate (101). Active labor management protocols, including the routine use of oxytocin, may simply be associated with a higher demand for epidurals.

Halpern and associates noted (96) that the quality of the clinical trials included in their review improved with time; all trials after 1995 reported outcomes with patients grouped by intent to treat. Analysis conducted in this way (i.e., by groups to which patients were randomized) is vital because women who choose epidurals differ demographically from those who choose other methods of labor analgesia. The former are more likely to be nulliparous, be admitted to the hospital earlier in labor with higher fetal head positions, have slower rates of cervical dilation, bear heavier babies, and need oxytocin augmentation more frequently. All of these factors and degree of maternal pain independently predict the need for cesarean delivery for dystocia (“failure to progress” or prolonged labor) (102).

In the five reviews cited above, the nonepidural analgesia “control methods” primarily consisted of i.m. or IV administration of opioids. More recently, continuous infusion epidural has been compared to CSE (103) and patient-controlled epidural analgesia (104). These publications serve to highlight epidural technique modifications, such as choice of drug, dosage (volume and concentration), and method of administration, that have taken place over time.

Obstetric management practices have an important role to play in terms of the progress and outcome of labor (91). For instance, the presence of an epidural block may sometimes decrease the obstetrician's threshold for performing instrument-assisted deliveries, as well as for allowing instrument-assisted delivery for the purpose of teaching residents. Active management of labor (routine oxytocin augmentation and/or artificial rupture of membranes), delayed pushing in second stage, and promotion of ambulation have all been suggested as methods to reduce obstetric intervention and increase the number of spontaneous vaginal births (94).

Instrumental Vaginal Delivery

Attempts at operative vaginal delivery (vacuum extraction or forceps) put the baby at risk of injury, including hemorrhagic morbidities such as subgaleal hematoma and cerebral hemorrhage (105). Forceps use is also associated with facial nerve and brachial plexus injury (106). In a study comparing use of forceps and vacuum extractors, babies delivered by vacuum extraction showed a higher incidence of cephalohematomas, although need for resuscitation at birth, admission to a neonatal intensive care unit, and neonatal death rate were not different (107).

Epidural analgesia has been associated with a higher rate of operative vaginal deliveries (96,97,98,99). Recently, the “Comparative Obstetric Mobile Epidural Trial” (COMET) study group (108) showed that there was a decreased incidence of instrumental vaginal delivery when lower doses of medication (CSE, low-dose LA plus opioid infusion) were used in labor compared to conventional doses of LA (bupivacaine 0.25%). The presumed mechanism is the preservation of motor tone and bearing-down reflex. Mild neonatal

depression necessitating neonatal resuscitation was more common among babies whose mothers were in low-dose LA plus opioid epidural infusion group, most likely due to the cumulative effect of the opioid over time. Neither the Apgar scores at 5 minutes nor the rates of admission to a neonatal intensive care unit differed between groups.

Newer methods of epidural analgesia offer the best chance of spontaneous delivery with satisfactory pain control (109).

Delayed Pushing

The "Pushing Early or Pushing Late with Epidural" (PEOPLE) study, a multicenter, randomized, controlled trial, compared conventional early pushing commencing at full cervical dilation with pushing late, ≥ 2 hours after full dilation. Operative delivery was reduced with delayed pushing; however, umbilical arterial pH < 7.10 occurred more frequently among babies whose mothers were in the delayed pushing group. The two groups had similar rates of neonatal morbidity, including asphyxia. Protocols advocating delayed pushing result in longer second stages and increased incidences of maternal fever (110).

Maternal Fever

Mothers who choose epidural are more likely to develop a fever during labor (111). The link between epidural analgesia, maternal fever, and the purported increase in neonatal septic work-ups is less clear (111,112,113,114); the concern is that babies are more likely to be treated with antibiotics since it is not currently possible to distinguish between maternal fever from infectious and noninfectious causes during labor. Many investigators believe the association of an epidural with fever is probably attributable to noninfectious causes, e.g., altered thermoregulation resulting from epidural analgesia. Neonates born to mothers who receive epidural analgesia do not have an increased risk of sepsis (91,111).

Breastfeeding

A succinct and thorough review of this topic concludes that intrapartum epidural analgesia does not adversely affect a baby's or mother's ability to breastfeed (115). The most critical factors for breastfeeding success are support of and education for the mother.

SURGERY DURING PREGNANCY

Urgent surgery during pregnancy requires modification of anesthetic and surgical approaches to address the safety of the mother and her fetus (116,117,118). Anesthetic considerations include:

- Management of maternal risk factors resulting from physiologic adaptation to the demands of a growing fetus and ongoing support of the placental unit
- Maintenance of the pregnant state
- Optimization of uteroplacental perfusion and fetal oxygenation, and maintenance of a stable intrauterine environment
- Attention to the direct and indirect actions of maternally administered medications on fetal well-being

The choice of anesthetic technique is guided by maternal indications, taking into account the site and nature of surgery. Efforts are made to reduce fetal drug exposure and, with reassurance, allay maternal anxiety. When possible, regional techniques are preferred because managing the airway of a pregnant patient poses unique challenges. Edema, weight gain, and increased breast size make intubation of the trachea technically difficult. Decline in functional residual capacity coupled with increased oxygen consumption predisposes the mother to rapid desaturation during induction of GA. Lower esophageal sphincter laxity leads to reflux of stomach contents, increasing the risk of aspiration once protective airway reflexes are abolished. Most abdominal procedures, however, require GA to provide sufficient muscle relaxation to facilitate surgical exposure.

Approximately 2% of pregnant women require surgery during pregnancy (117). The procedure may be directly related (e.g., cervical cerclage), indirectly related (e.g., ovarian cystectomy), or unrelated (e.g., appendectomy) to pregnancy. Semielective procedures should be delayed until the second trimester. Surgery at this time avoids

the vulnerable period of organogenesis (approximately 15- to 60-day gestation) and technical difficulties of maneuvering around a large, gravid uterus or managing the maternal airway in an advanced stage of pregnancy. Special techniques, including laparoscopy, cardiopulmonary bypass, transplantation, and induced hypothermia have all been performed safely during pregnancy (116).

Premature labor represents the greatest risk to the fetus in the perioperative period. Neonatal mortality in the developed world is approximately 50% at 25 weeks, dropping to about 10% at 30 weeks (119). Postponing surgery during this period of rapid fetal maturation should weigh the advantages to the fetus against the hazards that delay poses to the mother. There is no evidence to suggest that any anesthetic agent, dose, or technique influences the risk of preterm labor (117). Rather, it is more likely to be related to the surgery itself, manipulation of the uterus, or the underlying condition of the mother (e.g., infection). The more advanced the pregnancy, the greater the probability of uterine irritability. Certain medications can be used as part of the anesthetic technique to promote uterine quiescence (e.g., magnesium sulfate, inhalational anesthetic agents, or β_2 agonists), and surgical strategies can be employed to avoid handling the uterus. IV, sublingual, or transcutaneous administration of nitroglycerin is usually reserved for uterine relaxation during brief procedures or to manage refractory uterine activity (120).

The decision to monitor the fetus during surgery necessitates that someone be available for ongoing interpretation

P.272

of fetal well-being and that there be a plan for intervention should fetal distress be diagnosed or suspected. Indicators of fetal distress are often indistinct because technical limitations at various gestational ages eclipse data acquisition, and FHR variability is reduced or eliminated by certain anesthetic drugs. Intervention may include delivery, reassessment of anesthetic depth, or a more aggressive approach to maximize uterine blood flow, tocolysis, and/or maternal oxygenation (116). If delivery of the fetus is planned to occur at the same time as surgery, a coordinated team approach involving anesthesia, obstetrics, surgery, nursing, respiratory therapy, and neonatology is vital.

The well-being of the fetus is dependent on the adequacy of the maternal blood supply to the placenta, which is mainly derived from the uterine arteries (121). Uterine artery blood flow increases during pregnancy and approaches 500 to 800 mL/min (10% to 15% of maternal cardiac output) at term. The uterine vascular bed is a low-resistance system, not capable of further dilatation and devoid of autoregulation. Therefore, placental blood flow varies directly with net perfusion pressure (uterine artery pressure - uterine venous pressure) across the intervillous space and inversely with uterine vascular resistance. When faced with maternal hypotension, to preserve uteroplacental perfusion in a "pressure-passive" system, a more aggressive approach to management (rapid fluid loading, vasopressor therapy, Trendelenburg and left lateral positioning) is required compared to strategies for the nonpregnant patient (118). Hypotension may be due to many different etiologies but commonly results from aortocaval compression in the supine position, general or high spinal anesthesia, or hemorrhage. Bleeding from the uterine vessels can be very brisk and can quickly lead to life-threatening hemorrhage. Left lateral decubitus positioning prevents aortocaval compression in the second and third trimesters. This can be accomplished by having the mother lie on her left side or by elevating the right hip with a wedge, as illustrated in Figure 16-4. Maintaining homeostasis in the intrauterine environment also requires attention to maternal oxygenation, temperature, and acid-base balance (respiratory and metabolic).

Most anesthetic agents are not known to be teratogens. When evaluating the possibility of teratogenicity from maternally administered anesthetic medications, points to be considered include (116,122):

- The incidence of congenital anomalies in the developed world is 3%.
- Human teratogenicity studies are impossible to perform for ethical reasons.
- Extrapolation from animal studies may not be valid.
- Hypoxemia and hypotension cause physiologic derangement that may be teratogenic.

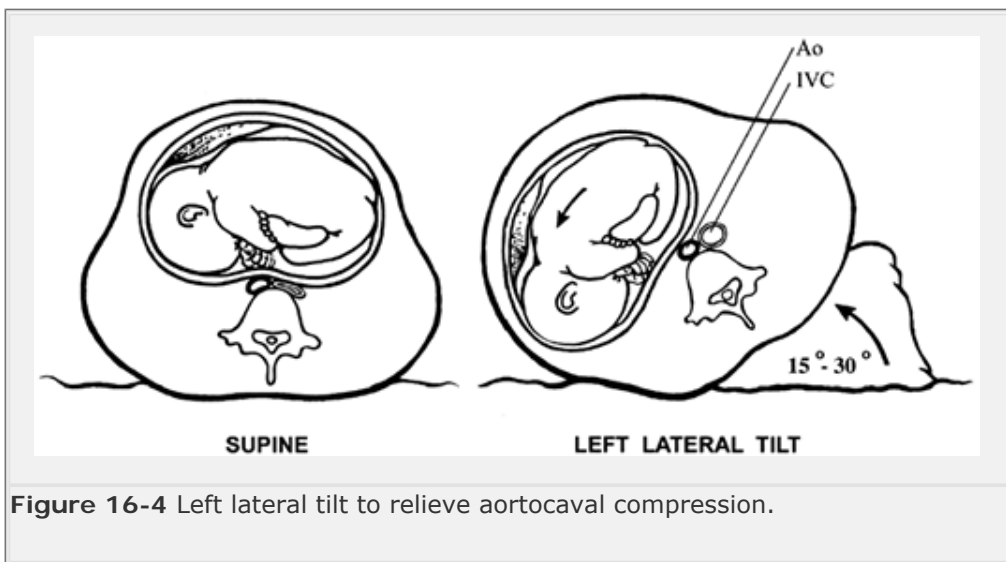

Figure 16-4 Left lateral tilt to relieve aortocaval compression.

Drugs that are usually avoided during anesthesia for long surgical procedures in early pregnancy include N₂O and benzodiazepines. N₂O is avoided because it causes oxidation of vitamin B12, rendering it incapable of functioning as a cofactor for methionine synthetase, an enzyme necessary for DNA synthesis in humans. Benzodiazepines are avoided because epidemiologic studies have shown a link to the development of congenital inguinal hernia (122).

Postoperative pain management may include plexus blocks or epidurals, when appropriate, to limit fetal exposure to drugs. Opioids and acetaminophen are used widely. Prolonged use of nonsteroidal antiinflammatory drugs (NSAIDs) is avoided due to concerns about premature constriction of the ductus arteriosus and development of oligohydramnios.

Fetal Surgery

Fetal surgery is defined as "the performance of procedures on the fetus or placenta designed to alter the natural history of a fetal disease that is diagnosed *in utero*" (123). Surgery can vary from minimally invasive percutaneous procedures, facilitated by local, spinal, or epidural anesthesia, to direct fetal operations following a hysterotomy incision. The latter requires maternal GA and attention to the possibility of inflicting pain on the fetus (124). Anesthetic considerations are identical to those for nonobstetric surgery during pregnancy. Once again, care needs to be

P.273

provided to two patients simultaneously, although the fetus is the primary patient in these circumstances.

Fetal sedation by placental transfer of maternally administered medication is not reliable and does not ensure an anesthetized or immobile fetus. Given enough time and subject to their individual solubilities, inhalation anesthetic agents used for maternal GA and uterine relaxation equilibrate in fetal tissues. Deep maternal inhalation anesthesia may result in progressive fetal acidosis by an uncertain mechanism. Fetal blood pressure, heart rate, oxygen saturation, and base excess can decrease due to direct impairment of fetal myocardial contractility, redistribution of fetal blood flow, or changes in uterine perfusion. Fetal distress and response to maneuvers can be recognized and managed by measuring heart rate, blood pressure, and umbilical blood flow, and by monitoring pH, pCO₂, pO₂, base deficit, glucose, and electrolytes. Vascular access facilitates this and the administration of fluid, blood products, and/or drugs (125).

Additional fetal anesthesia can be provided by direct i.m. or intravascular (via the umbilical vein) administration of opioids and neuromuscular blocking agents. Pancuronium is often chosen for fetal paralysis because of its long duration and vagolytic properties, which help elevate the FHR and maintain cardiac output. Fentanyl, in relatively large doses (12.5 to 25 µg/kg estimated fetal weight), attenuates the autonomic and hormonal stress response during potentially painful procedures (52,125). In the face of intense uterine tocolysis, maintenance of maternal blood pressure may require concomitant vasopressor therapy.

The ex utero intrapartum treatment (EXIT) procedure was developed for fetuses that have a predictably compromised airway, either because of prior *in utero* surgery (e.g., to treat congenital diaphragmatic hernia) or due to an obstructing mass, such as cystic hygroma or thyroid goiter. Delivery occurs by planned cesarean section with an anesthetic approach that maintains uterine relaxation. A hysterotomy incision is made with a

device that limits uterine bleeding, and the fetus is partially delivered through the incision. The surgeon performs laryngoscopy or tracheotomy and secures the airway (endotracheal tube or tracheotomy tube) while the fetus is still attached to the umbilical cord and maintained on uteroplacental perfusion. Attention is paid to avoiding fetal hypothermia. The fetal lungs are expanded and surfactant administered if the infant is premature. The cord is then clamped and the remainder of the cesarean section proceeds as usual. Fetal well-being and operating conditions have been maintained for up to 2 hours during EXIT procedures (123,125).

Whether the fetus feels pain, and from what gestational age, has been the subject of vigorous debate (124,126,127). Prior to 22 weeks, the fetus does not have the neuro-anatomic pathways in place to feel pain; between 22 and 26 weeks, thalamocortical fibers, considered to be crucial for nociception, are forming; and after 26 weeks, the fetus has the necessary neurologic development to feel pain. Investigators have used surrogate end points, including fetal "reflex" movement away from and biochemical stress response to noxious stimuli in an attempt to define markers of pain. Hormonal and circulatory stress responses to invasive procedures are observed by 20 weeks (49,50,51,52,53). Further definition of the neuroanatomic and neurophysiologic maturation of sensory pathways involved in pain transmission in the human fetus may provide more direct information about the fetal pain experience.

RESUSCITATION ISSUES DURING PREGNANCY

Intrauterine Resuscitation of the Compromised Fetus

The term "fetal distress" is used to identify a state of progressive fetal asphyxia with hypoxia and acidosis, which, if not corrected, results in decompensation and permanent organ damage. It is diagnosed or suspected when characteristically "abnormal" features emerge in one or more of the tests used to evaluate fetal well-being.

Intrauterine resuscitation consists of a series of maneuvers designed to reverse treatable causes of fetal asphyxia, restore fetal oxygenation, and correct fetal acidosis. These maneuvers are fundamental to the practice of obstetric anesthesia and are summarized, using an evidence-based template, by Thurlow and Kinsella (128). The circumstances surrounding the onset of fetal distress direct the order of application and determine which aspects of intrauterine resuscitation are appropriate for a particular patient. The goals and measures are:

- Increase blood flow to the placenta
 - treat maternal hypotension aggressively by administering a nonglucose-containing crystalloid/colloid IV fluid bolus, stopping the epidural infusion, and giving vasopressor therapy
 - alleviate aortocaval compression by changing the mother's position until an improvement in FHR occurs (left lateral, followed by right lateral, and finally knee chest position)
 - reverse uterine artery vasoconstriction induced by hypocapnia from maternal hyperventilation by managing pain and providing verbal reassurance
- Relax uterine muscle
 - stop oxytocin infusion
 - administer a tocolytic such as 50 to 100 µg of IV nitroglycerin
- Increase fetal oxygenation
 - administer 100% oxygen to the mother by face mask
 - relieve umbilical cord compression by changing the mother's position or, if oligohydramnios is

present, consider amnioinfusion

- Rule out umbilical cord prolapse or, if present, provide manual elevation of the presenting part per vagina, maintaining warmth and moisture for the cord until emergent delivery
- Confirm fetal asphyxia by an alternate test
- Prepare for emergent delivery

P.274

Maternal Cardiac Arrest

The management of cardiac arrest in pregnancy is outlined in the *Guidelines 2000 for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care* (129). Acute cardiac life support protocols are modified in pregnancy, but the standard adult algorithms for medication, intubation, and defibrillation still apply.

The key to resuscitation of the fetus is resuscitation of the mother. Relief of aortocaval compression is paramount. Chest compressions are performed higher on the sternum to adjust for the shift of abdominal contents toward the head. Consideration of arrest etiologies unique to pregnancy (e.g., amniotic fluid embolism) and diagnoses exacerbated by the physiologic changes of pregnancy (e.g., peripartum cardiomyopathy) is important if response to resuscitative efforts is lacking. All medication infusions such as magnesium sulfate, oxytocin, or epidural are discontinued and early intubation is encouraged to reduce the risk of aspiration. Fetal surveillance monitors (e.g., scalp electrode lead) must be discontinued prior to defibrillation. The decision to perform open-chest cardiac massage or emergent cesarean section should occur earlier rather than later if circulation is not restored by usual measures. Perimortem cesarean section has the highest chance of improving outcome for both mother and baby when uterine size is >20 weeks (some would say >24 weeks) and delivery occurs within 5 minutes of the onset of the arrest (130).

Perimortem Cesarean Section

Perimortem cesarean section refers to emergent operative delivery of the fetus through a midline, classical uterine incision in situations in which the mother is moribund or pulseless and is being actively resuscitated. Emptying the uterine cavity increases maternal cardiac output (contraction of the myometrium results in autotransfusion of blood previously directed to the uterus and improved preload secondary to relief of inferior vena cava compression) and lung volume and makes it easier to perform effective chest compressions.

Accurate data regarding the incidence and outcome of this procedure for the mother or neonate are difficult to obtain. For example, the British Confidential Enquiry does not report deliveries during which the mother has been successfully resuscitated (131). There have been several case reports of expedient cesarean delivery during which both mother and baby have survived fully intact. Perimortem cesarean section is an established part of the resuscitation process in near-term pregnant women (129). In the largest series to date, Katz and associates (132) reviewed the literature from 1900 to 1985 for papers in which time from cardiopulmonary arrest to delivery was listed. Most fetal survivors were delivered within 5 minutes. The general consensus is that the likelihood of perimortem cesarean section resulting in a living and neurologically normal baby is related to the interval between onset of maternal cardiac arrest and delivery. Also, the chances of normal survival are good following delivery if the fetus lives past the first few days (131). For this technique to be an option, it must be considered in the context of immediately available staff and equipment to perform the cesarean section, and staff and equipment to conduct the neonatal resuscitation.

ANESTHETIC TECHNIQUES FOR CESAREAN SECTION: EFFECTS ON THE FETUS AND NEWBORN

General Anesthesia

GA is a reversible state characterized by loss of consciousness and lack of pain with or without skeletal muscle

relaxation. Going to "sleep", staying "asleep", and "waking up" are known as induction, maintenance, and emergence. The state of GA is achieved through the use of drugs administered in a specific order, namely, induction agents (possibly including narcotics), neuromuscular blockers, inhalation agents, analgesics, and reversal agents.

Given enough time, all medication administered to the mother crosses the placenta and enters the umbilical vein, so gauging drug administration during the induction and maintenance phases of GA is important. An important factor affecting neonatal outcome is the elapsed time between the induction of anesthesia and clamping of the umbilical cord, as this represents the time of fetal exposure to maternally administered medication. A second factor is the time from uterine incision to delivery of the baby. A long incision-to-delivery time is associated with an increased incidence of fetal acidosis, presumably caused by uteroplacental vasoconstriction. If possible, induction-to-clamp time should be <10 minutes and uterine incision-to-delivery time <3 minutes (133).

The three determinants of placental transfer of drugs to the fetus include the physical-chemical properties of the drug, characteristics of the maternal, placental, and fetal circulations, and placental anatomy and physiology. Fetal and neonatal pharmacologic effects of anesthetic agents given to the mother during a cesarean section conducted under GA depend on the amount of drug reaching the fetus. Estimating this is not an easy task.

There are difficulties associated with human *in vivo* studies of placental transfer during pregnancy (134). The fetoplacental unit is inaccessible *in situ*, and there are ethical considerations in conjunction with maternal and fetal safety. *In vivo* studies are most commonly performed at birth by collecting maternal venous and umbilical cord arterial and venous blood samples. It is difficult to draw conclusions based on one set of measurements. Likewise, the applicability of animal placentas as models for the human placenta is limited because the structure and function of the placenta is species specific. Many studies of anesthetic pharmacology to date have been conducted using animal models. The alternative is to use a human *ex vivo* placental perfusion model. Ala-Kokko and associates

P.275

(134) make a strong case for the human placental perfusion model as the best method available for studying transplacental passage of drugs.

It will take time to study anesthesia drugs using this methodology. The conclusions reached in most of the studies cited in the following discussion derive from animal and *in vivo* blood sampling data.

The standard method by which anesthesia is induced for cesarean section is rapid sequence induction. The process consists of giving 100% oxygen by mask, IV administration of an induction agent \pm narcotic and neuromuscular-blocking drug followed by application of cricoid pressure and intubation of the trachea. The induction agents used to initiate GA include sodium thiopental, methohexital, ketamine, propofol, and midazolam. Keta-mine is usually reserved for situations involving maternal hemodynamic instability because it preserves sympathetic outflow. The others have been studied and compared (135,136,137). Midazolam and propofol have been associated with longer induction times, a lighter plane of maternal anesthesia (as measured by electroencephalogram), and lower Apgar scores. Both sodium thiopental and methohexital are highly lipid soluble. They share pharmacokinetic properties with thiamylal, another barbiturate that peaks in umbilical arterial plasma at 3 to 5 minutes and declines rapidly until 11 minutes (133,137). Induction to umbilical cord clamp times of approximately 10 minutes coincide with declining fetal levels of these agents and therefore little neonatal depression.

Neuromuscular-blocking drugs share a structural similarity, a quaternary ammonium ion, which slows but does not eliminate transfer of these drugs across the placenta (133). Succinylcholine is the only depolarizing drug available for clinical use. In the normal parturient, it is degraded so rapidly by plasma cholinesterase that virtually none reaches the fetus, whereas the percentage of nondepolarizing neuromuscular-blocking drug (e.g., rocuronium, pancuronium, and atracurium) that crosses the placenta ranges from 7% to 22%, depending on the drug. The literature is vague with respect to effects on the neonate. However, in the setting of high-dose nondepolarizing neuromuscular blockade (e.g., EXIT procedures), it may be necessary to support neonatal ventilation for a period of time or to administer reversal agents.

Inhalation anesthetics (not including N₂O) are also known as volatile agents. Halothane, enflurane, isoflurane, and the newer desflurane and sevoflurane are examples of drugs used to maintain anesthesia during cesarean section. Achieving adequate depth of inhaled anesthesia depends on how quickly partial pressures of a particular volatile agent equilibrate in alveolar, blood, and brain compartments. The less soluble the agent, the faster a deep plane of anesthesia is attained. Desflurane and sevoflurane are much less soluble than the other agents so

theoretically they would be expected to cross the placenta and equilibrate in fetal tissues more rapidly than their more soluble counterparts, potentially resulting in a more depressed neonate. Equally expected, however, once the newborn establishes ventilation, is that the lungs more quickly would excrete ("blow off") these relatively insoluble drugs. Desflurane is more pungent and irritating to the airway and may result in laryngospasm. This should be considered when suctioning the neonate whose mother has received desflurane (133). When compared with isoflurane 0.5%, sevoflurane 1% (equianesthetic concentration) was found to produce similar maternal and neonatal results (138). Cord blood gases and Apgar scores were equivalent. Desflurane in a subanesthetic dose (3%), mixed with N₂O-O₂, was considered safe and effective for cesarean section in healthy parturients when compared to enflurane 0.6%. Higher doses of desflurane delayed time to sustained respiration in the newborn (139).

Administration of GA to a parturient is demanding and dissimilar in terms of the drugs and techniques used to achieve the same state in an elective surgical patient. With the exception of a planned, elective cesarean section, circumstances surrounding labor and delivery are difficult to control. Consequently, the obstetric patient rarely comes to the operating room in optimal condition. Combine this with the effect on the parturient of the physiologic changes of pregnancy, add in the fact that mother and baby have unrelated anesthetic needs, and even a healthy woman becomes a high anesthetic risk.

Complications of GA for cesarean section remain the leading cause of anesthesia-related mortality. The case fatality ratio for GA versus regional anesthesia (RA) during obstetric delivery for the period 1991 to 1996 was 6.7:1 (140). In parturients who die from complications of GA, airway problems (failed intubation or aspiration) represent the most frequent cause of death (141). The incidence of failed intubation in obstetric patients is 1:250 to 1:280 compared with 1:2,230 for provision of GA in the main operating room (140,141); thus, the anesthesiologist working in the labor and delivery suite is seven times more likely to encounter failed intubation. The use of GA for cesarean section is declining in favor of RA techniques (142,143), prompting concern over the number of opportunities remaining for trainees to learn, and anesthesiologists to maintain, their obstetric airway management skills (144).

GA continues to be indicated in certain situations including, but not limited to, expedited delivery, technically impossible or failed RA, coagulopathy, cardiovascular instability, anticipated hemorrhage, tethered spinal cord, and patient preference.

Regional Anesthesia

RA is the loss of all sensation, motor function, and reflex activity in a specific area of the body. The surgical conduct of cesarean section under RA requires a sensory block to the fourth to sixth thoracic dermatome levels (T4-T6). Although the incision is most commonly in the lower abdomen, traction on the peritoneum ± uterine exteriorization can cause discomfort unless the area extending from mid-thoracic to sacral levels is blocked. Either an epidural or spinal approach will suffice, but larger doses of

P.276

LA and opioid medications are required than when the same techniques are used to provide analgesia in labor. As a result, the fetus/neonate may be affected directly by placental transfer of LAs and opioids, or indirectly by sympathetic blockade, with resultant alterations in uteroplacental perfusion (133).

LA toxicity manifests systemically as a progressive continuum of symptoms beginning with tongue numbness and tinnitus, moving to visual disturbance and muscle twitching, and finally escalating into convulsions, coma, arrhythmias, and respiratory arrest. Toxic LA levels are most often produced by inadvertent IV injection; however, toxicity can result through absorption from the epidural space, particularly given the large dose of LA required to produce T4 blockade. The search for LAs with low "toxic" profiles has led to four modern-day agents: lidocaine, bupivacaine, ropivacaine, and levobupivacaine (145,146). Lidocaine is subject to tachyphylaxis and is often mixed with low-dose epinephrine to delay its otherwise rapid absorption from the epidural space. Its toxicity profile includes central nervous system rather than cardiac hyperactivity. Bupivacaine is marketed as a racemic mixture. In the 1970s and early 1980s epidural anesthesia with higher concentrations of this drug was associated with lethal ventricular arrhythmias and cardiovascular collapse. It became apparent that the R-enantiomer was responsible. Bupivacaine is still in widespread use today, but much smaller doses are employed for labor analgesia and it is not commonly used in the epidural space to provide anesthesia for cesarean section. Ropivacaine and levobupivacaine are single enantiomer (L-form) LAs. Evidence from a variety of experiments in several species supports a reduction in toxicity (145,146).

Labor epidural analgesia can be extended and made denser if the parturient is delivered by cesarean section.

Under normal maternal and fetal conditions, skillfully conducted GA and RA are almost equivalent with respect to neonatal well-being (147,148). Nevertheless, given the risks to the mother and the association of lower Apgar scores with GA, RA for elective, and sometimes emergent, cesarean section is preferred (19,142,149,150). A compromised fetus may even benefit from anticipatory maternal epidural catheter placement in labor when there is a high risk of cesarean section (151) or primary epidural or spinal anesthesia for elective cesarean section (150,152). RA results in less neonatal exposure to drugs (especially when the spinal technique is used), allows the mother and her partner to participate in the birth of their baby, and provides better maternal postoperative pain relief (143).

For all the advantages of spinal anesthesia such as simplicity of technique, rapid onset, reduced risk of systemic toxicity, density of anesthetic block, and postoperative pain relief afforded by neuraxial morphine, the potential for hypotension with this technique poses the greatest threat to the mother and fetus (19). The incidence of hypotension is similar between epidural and spinal anesthesia but occurs earlier and more rapidly with the spinal approach. Hypotension results from temporary sympathectomy, an inevitable but undesirable component of mid-thoracic blockade. Reduced preload (increased venous capacitance and pooling of blood volume in the splanchnic bed and lower extremities) and reduced afterload (decreased systemic vascular resistance) lower maternal mean arterial pressure (MAP), leading to nausea, lightheadedness and dysphoria, and reduced uteroplacental perfusion. When maternal MAP is maintained, maternal symptoms are averted and uteroplacental perfusion improves.

In their epidemiologic study of 5,806 cesarean deliveries, Mueller and associates (153) concluded that fetal acidemia was significantly increased after spinal anesthesia and maternal arterial hypotension was by far the most common problem encountered. The prevalence of fetal acidemia with RA for cesarean section has been confirmed in another study (150). However, isolated acidemia does not correlate with Apgar scores and is a poor indicator of outcome. Low umbilical artery pH reflects both the respiratory and metabolic components of acidosis, whereas base excess reflects only the metabolic component. It is base excess that correlates with neonatal outcome, values more negative than -12 mmol/L having an association with moderate to severe newborn encephalopathy (7). However, prevention of hypotension is advantageous to minimize any influence on neonatal acid-base status.

The routine measures used to maintain uteroplacental perfusion include left lateral tilt position, lower leg compressive stockings, and IV fluid loading (121,154). Vasopressor therapy is reserved for the treatment of hypotension. Prophylactic use of ephedrine in one study (155) and therapeutic use in another (150) possibly contributed to fetal acidemia. Likewise, ephedrine use was associated with lower umbilical arterial pH values when compared with phenylephrine in a systematic review (156). The literature is replete with debate regarding which vasopressor, a mixed $\alpha\beta$ agonist (e.g., ephedrine) or a pure α agonist (e.g., phenylephrine), would be more appropriate for the management of hypotension during spinal anesthesia for cesarean delivery (157,158,159,160). The controversy revolves around the etiology of fetal acidemia: Is it due to the metabolic effects of β -stimulation in the fetus or insufficient maintenance of uteroplacental perfusion by failure to reclaim sequestered blood from the splanchnic bed to augment preload? Regardless, the choice of vasopressor drug is perhaps less important than the avoidance of hypotension (161).

Fetal Effects of Maternal Oxygen Administration

Providing supplemental oxygen to the parturient during cesarean section is common clinically, whether the procedure is elective, urgent, or emergent (162). This practice has been justified by the belief that raising the oxygen reserve of the mother is universally beneficial for the fetus. Since the advent of SpO₂, patients who may benefit from oxygen therapy are more easily identified and clinicians can be more selective about administering oxygen therapeutically.

P.277

For example, SpO₂ readings obtained during elective cesarean section conducted under spinal anesthesia showed that maternal saturation was well maintained on room air, and administration of 35% oxygen by facemask failed to significantly change umbilical vein pH or partial pressure of oxygen (163). This finding was further substantiated in a study by Cogliano and associates (164).

Oxygen given to the mother does not increase fetal oxygenation to the same extent because of usage during intermediary placental metabolism. In comparison, neonatal oxygen therapy has the potential to raise newborn PaO₂ substantially. There is a growing body of clinical and experimental evidence that seems to indicate that the practice of routine supplemental oxygen during neonatal resuscitation may be injurious (165,166,167).

Oxidative stress is implicated as a common underlying mechanism in several neonatal conditions, including necrotizing enterocolitis, retinopathy of prematurity, periventricular leukomalacia, and chronic lung disease (168,179). It occurs when free radical generation exceeds the body's antioxidant defense mechanisms, and it is not exclusive to newborns; free radicals and antioxidants also play a role in adult diseases (170,171). The interest in free radicals as harbingers of disease prompted investigators to explore potential fetal effects of giving oxygen to mothers. Accordingly, the process of routine oxygen supplementation for healthy parturients undergoing elective cesarean delivery with RA has been questioned. (172).

Free radicals have a brief lifespan, making their detection difficult. Therefore, studies investigating oxidative stress usually measure surrogate markers, namely products of the attack by free radicals on lipids, proteins, and nucleotides. This methodology was used to examine the effect on the newborn of administering air or oxygen-enriched air to parturients undergoing elective cesarean section (173). There was a clear difference between groups, with greater free radical activity in the babies born to mothers breathing oxygen-enriched air. The main site of free radical generation was the placenta, as evidenced by the higher concentration of free radicals in the umbilical vein compared to the artery. As Backe and Lyons point out, "at present, we have no means of linking free radical formation with neonatal outcome following elective cesarean section.... in a low-risk situation such as [this], a favorable outcome is unlikely to be influenced by maternal hyperoxia" (174). "The significance of [the Khaw and associates study] relates to the use of high inspired maternal oxygen fractions ($\geq 60\%$) for the delivery of compromised and premature [babies]." There are no published trials addressing maternal oxygen therapy for fetal distress (175).

POSTPARTUM PAIN MANAGEMENT

The genesis of postpartum pain is multifactorial. Postsurgical etiologies include episiotomy, manual placenta removal, postpartum tubal ligation, and/or visceral/ incisional pain following cesarean delivery. For some women, cramping originating from uterine involution or localized pain resulting from perineal tears can result in distressing discomfort. The mother may suffer a postspinal headache as a complication of regional analgesia or anesthesia. Any method that reduces the magnitude of these painful experiences is desirable. This section is limited to pharmacologic therapy and its implications for the breastfeeding mother.

The goal of a pain management regimen is to prevent or control pain to a degree that is acceptable to the patient while facilitating activities of daily living and promoting quality of life. There are additional challenges for treating pain in women who have just given birth. New mothers are motivated to ambulate early and care for their babies, which requires them to be clear-headed and to experience minimal side effects from analgesics. Concern that postpartum analgesia could have implications for the baby may make the mother hesitant to take an analgesic, and therefore suffer unnecessarily. Breastfeeding calls for use of analgesic agents that are transferred minimally into breast milk and have little effect on the neonate (176).

The current trend is to use a balanced, multimodal approach (177,178). Additive or synergistic analgesic effects, with fewer side effects, have been demonstrated by combining agents with different mechanisms of action in smaller doses than would be required if the individual agents were used alone. This concept has become so important that, as part of the accreditation process, health care organizations are surveyed regarding pain assessment and management, looking for treatment initiatives that include a multimodal approach (179).

The act of breastfeeding results in milk production, secretion, let-down, and increased breast blood flow. Therefore, the timing of breastfeeding relative to drug administration influences the amount of drug that appears in the breast milk. Drug exposure can be minimized if the mother takes medication immediately after nursing or just before the baby is due to have a lengthy sleep, and uses short-acting medications. The neonatal dose of most medications obtained through breastfeeding is 1% to 2% of the maternal dose (122).

Breast milk content also affects the extent of drug transfer from maternal plasma. For instance, lipid-soluble drugs are less likely to accumulate in colostrum, which contains little fat. Colostrum has the same pH as maternal plasma, which is advantageous as far as narcotics are concerned. These weak bases are not sequestered in colostrum via ion trapping and therefore do not accumulate. Colostrum morphine concentrations have been measured during the first 48 hours of postcesarean IV patient-controlled analgesia (180). The milk-to-maternal plasma ratio for morphine was <1 . Morphine was seen in very small concentrations in less than half of the milk samples. The authors concluded that the amount of drug likely to be transferred to the breastfed neonate was negligible. Only small amounts of colostrum are secreted during the first few postpartum days (10 to 120 mL/day) so newborn exposure from volume is limited. Ultimately, the concentration of drug in the

baby's plasma is more important than the concentration of the drug in colostrum or breast milk. This depends on absorption across the gastrointestinal tract, volume of distribution, and extent of metabolism and excretion in the newborn. Little is known about the bioavailability of analgesics and their metabolites because of ethical issues involved in repeated blood sampling from babies.

Postcesarean section pain peaks on the second day after surgery (181), and analgesic usage begins to decline. Milk composition continues to change over the first 10 days after birth. There is a gradual increase in fat and lactose content and a reduction in protein and pH. By day 10 postpartum, factors such as high lipid solubility, low molecular weight, minimal protein binding, and the un-ionized state facilitate secretion of medications into mature breast milk (182). Women who breastfeed and require GA for surgery are usually counseled to feed their baby before the surgery and temporarily interrupt feeding postoperatively by wasting the first milk sample (express with a breast pump and discard). After that, if the mother feels well enough and there are no surgical contraindications, she is encouraged to resume feeding. Most anesthetics are rapidly cleared from the mother; some authors argue that no portion of human milk need be wasted (182).

Postdelivery analgesia should be tailored to match the changing severity of pain over time; as well, prompt recognition and treatment of side effects help to optimize pain management. Epidural or intrathecal morphine is commonly administered when neuraxial blockade is used for delivery. The analgesic effect following a single neuraxial dose can last up to 18 to 24 hours; however, in keeping with the multimodal approach, fixed regimen or "on-request" analgesics such as NSAIDs or acetaminophen (paracetamol) are usually prescribed concomitantly.

Mild analgesics (acetaminophen and NSAIDs) provide background pain relief to which opioids and/or adjuvant analgesics can be added (178,183). Fixed-dose combinations (e.g., acetaminophen plus codeine) have established efficacy and safety. They are widely used for postpartum pain management (184). Individual titration of opioids is essential. Different routes of administration, including oral, IV, and patient-controlled IV or patient-controlled epidural infusion should be available. A significant reduction in postpartum narcotic use can be achieved through implementation of a self-medication program (185). The AAP published a statement on drug transfer into human milk and possible effects on the infant or on lactation to assist prescribing practices (186). The AAP considers acetaminophen, most NSAIDs, and morphine compatible with breastfeeding.

CONCLUSION

The ideal analgesia/anesthesia for labor and delivery would meet the following criteria (82):

- Provide fast, effective, and continuous pain relief while maintaining the parturient's ability to move and ambulate throughout labor, and to push during vaginal delivery
- Not interfere with the progress of labor and possibly improve the course of a dysfunctional labor
- Be technically straightforward and devoid of unacceptable side effects, complications, or risks
- Not imperil the fetus *in utero*
- Provide satisfactory conditions for delivery
- Permit early mother-baby interaction
- Have no short- or long-term impact on neonatal outcome

Not unexpectedly, no single technique of analgesia or anesthesia meets all of these criteria. The challenge for the anesthesiologist is to balance the needs of the mother and fetus while being flexible enough to modify or change the approach as circumstances dictate.

ACKNOWLEDGEMENT

My thanks to the staff at the Neil John Maclean Health Sciences Library, University of Manitoba; to online search system developers everywhere for helping to simplify the process of identifying and retrieving journal articles; to the inventors of systematic reviews and meta-analyses; and to Mr. Hiscoke, my grade 7 science teacher, for introducing me to the thesaurus.

Chapter 17

Cardiorespiratory Adjustments at Birth

Ruben E. Alvaro

Henrique Rigatto

Respiratory physiologists and physicians have long been interested in the respiratory and cardiovascular events that occur at birth. However, apart from occasional references to the pulmonary circulation, the fetal circulation only received serious consideration in the middle of the twentieth century, when it was recognized that dramatic changes in blood flow through the lungs occurred after birth.

The first detailed description of circulation in the mammalian fetus was provided by Harvey in 1628 (1). Although he correctly described blood flow from the inferior vena cava through the foramen ovale, he thought that the blood had to enter the pulmonary veins before returning to the left atrium. He was also perplexed by how the fetus survives *in utero* without the aid of respiration. The answer to the last question came in 1799, when Scheel noted light red blood in the umbilical vein and dark red blood in the umbilical artery in the fetal sheep, as well as darkening of that color when the pregnant ewe was asphyxiated (2). However, it was Zweifel, in 1876, who categorically stated that the placenta was the lung of the fetus, describing the presence of oxyhemoglobin in the umbilical blood before any breathing had occurred (3).

The conventional belief during the nineteenth century was that the fetal pulmonary blood flow progressively increased over gestation and that it was relatively higher in the fetus than after birth (4,5). It was not until the first part of the twentieth century that the right ventricular pressure was demonstrated to fall and pulmonary blood flow to increase after the establishment of breathing (6,7). It was only 50 years ago that Dawes and colleagues (8) demonstrated by direct measurements in fetal lambs that pulmonary blood flow increased when the lungs were ventilated with air. Over these past 50 years, the developmental changes in the pulmonary circulation and in its responses to stresses of hypoxia, and increases in pulmonary arterial pressure and blood flow, have become subjects of intense investigation (9).

It is well known now that during fetal life the placenta and not the lungs serves as the organ for gas exchange. Because of this, the normal fetal circulatory pattern is arranged very differently from that observed after birth and is quite satisfactory for survival in the womb. The placental circulation is in a parallel arrangement; that is, it receives blood from the descending aorta and drains blood to the systemic venous circulation. To accomplish this, the fetal circulation depends on a series of intra- and extracardiac shunts that allows the oxygenated blood to flow from the placenta to the systemic organs and for the deoxygenated blood to return to the placenta. This blood flow distribution allows the delivery of blood with the highest oxygen content (from the placenta) to the heart and brain and blood with lower oxygen content to the lower body and placenta. Because the lungs are not required for gas exchange, pulmonary blood flow is low (approximately 10% of the combined ventricular output), yet adequate for lung growth and development. Unique only to fetal life, the blood exiting the lungs has a lower saturation than does blood entering the pulmonary circulation, and although the lungs do not participate in gas exchange *in utero*, they are metabolically active, secreting liquid into the potential air spaces and synthesizing surfactant, a substance that is vital to achieve adequate ventilation at birth. The fetal lungs are also physically active in that they simulate breathing movements.

The transition from the placenta to the lungs at birth is accomplished by three main cardiopulmonary processes: (a) onset of breathing, resulting in lung expansion with concomitant decrease in pulmonary vascular resistance and increase pulmonary blood flow; (b) increase in blood oxygen content that further decreases pulmonary vascular resistance; and (c) loss of the placental circulation with resultant increase in systemic vascular resistance leading to the closure of the fetal cardiovascular shunts and transition from fetal to neonatal circulation. Thus, to establish the lungs as the site of gas exchange after birth, significant

P.285

changes in the cardiac and pulmonary circulation as well as the initiation of pulmonary ventilation must occur. Many abnormal maternal, placental and fetal conditions may interfere with this physiologic transition and compromise the newborn infant.

The establishment of effective pulmonary ventilation at birth requires that the lungs develop to a stage where the alveoli can be inflated to provide adequate gas exchange. It also requires the lowering of the pulmonary

vascular resistance to allow for the increase in pulmonary blood flow to accommodate the entire cardiac output. The successful transition also requires that the lung liquid volume be removed from the alveolar spaces and that surfactant material be secreted into the acinus to allow for satisfactory physical expansion of the lungs after the initial postnatal breaths. Adequate neurologic drive to generate and maintain spontaneous continuous breathing is essential to maintain ventilation postnatally.

The change to pulmonary ventilation at birth increases pulmonary venous oxygenation that serves to suppress active vasoconstriction of pulmonary vessels. The result is a tenfold increase in pulmonary blood flow and a rapid decrease in pulmonary vascular resistance. The removal of the placenta after constriction of the umbilical vessels in response to increased oxygenation, contributes to a rise in systemic vascular resistance. The decline in pulmonary vascular resistance below systemic values contributes to the closure of the foramen ovale and ductus arteriosus, establishing the adult circulatory patterns.

This chapter reviews some of the most important cardiorespiratory adjustments that occur at the time of delivery allowing the fetus to achieve a successful extrauterine transition.

PULMONARY ADAPTATION

Fetal Lung Fluid

During fetal life, the internal volume of the lungs is maintained by the secretion of liquid into the pulmonary lumen. This liquid expansion of potential air spaces is essential for the growth and the development of normal lung structure before birth, which, in turn, may influence lung function after birth (10).

TABLE 17-1 COMPOSITION OF LUNG LUMINAL LIQUID, AMNIOTIC LIQUID, AND PLASMA OF FETAL LAMBS

	Lung Liquid	Amniotic Liquid	Plasma
pH	6.27 ± 0.01	7.07 ± 0.22	7.34 ± 0.04
Osmolality	300 ± 6	257 ± 14	291 ± 8
Na ⁺ (mEq/L)	150 ± 1	113 ± 6	150 ± 1
Cl ⁻ (mEq/L)	157 ± 4	87 ± 5	107 ± 1
HCO ₃ ⁻ (mEq/L)	3 ± 1	19 ± 3	24 ± 1
Protein (g/dL)	0.03 ± 0.01	0.1 ± 0.1	4.1 ± 0.3

Values are mean ± SEM (standard error of mean) and are taken from the work of Adamson et al., Adams et al., and Humphreys et al.

The fluid in the fetal lung was for many years assumed to be aspirated amniotic fluid as a result of fetal breathing movements (11). In 1941, Potter and Bohlender (12) observed alveolar fluid in two human fetuses with malformations of the respiratory tract which blocked the entrance of amniotic fluid, thus establishing that the lung fluid was secreted, not inhaled. Experiments performed in other species confirmed that fetal pulmonary fluid was indeed generated within the lungs (13,14,15).

We know now that the fetal lung fluid is neither a mere ultrafiltrate of plasma nor aspirated amniotic fluid. Compared to plasma this lung fluid is rich in chloride and potassium, is significantly lower in bicarbonate and has similar sodium concentration. It is also quite different from amniotic fluid having much higher osmolality, Na⁺ and Cl⁻ concentrations, and significantly lower K⁺, protein and urea concentration (Table 17-1) (10,16,17,18). This distinctive composition of the lung liquid changes very little during gestation (17,19). The high Cl⁻ and the low protein content characteristics of the lung fluid result from active Cl⁻ secretion and tight junctions between epithelial cells respectively.

It is not known exactly when this secretory activity begins, but already during the glandular stage of lung development, at about 3 months of gestation, the lung epithelium actively secretes fluid (20,21). By this time the epithelium has developed tight junctions, which are evident by morphologic examination and also by the low protein concentration present in the lung liquid in relationship to the plasma. In fetal lambs, the volume of lung liquid increases from about 5 mL/kg of body weight at midgestation (18) to about 30 to 50 mL/kg at term (18,22,23,24,25). The secretion rate increases from about 2 mL/kg body weight at midgestation (18) to about

5 mL/kg at term (26,27). More recently, Pfister and associates (28) demonstrated that the lung liquid volume exhibited a plateau level in the near-term fetal sheep before it began to decline toward birth. They also observed that the rate of lung liquid secretion declined in two linear phases that commenced earlier than the changes in lung liquid volume (28). In fetal lambs, the amount of lung liquid in relation to lung weight remains

P.286

relatively constant at approximately 90% through much of the pregnancy (29,30). The lung liquid secretion decreases with increased luminal hydrostatic pressure induced by a prolonged obstruction of the fetal trachea and increases when luminal pressure falls below amniotic fluid pressure and when fetal breathing movements are abolished (24).

This liquid secreted by the fetal lungs flows intermittently up the trachea with fetal breathing movements. Some of this fluid is swallowed and the remainder contributes directly to the formation of amniotic fluid production, accounting for approximately 25% to 50% of the amniotic fluid turnover in the sheep fetus, with the rest being formed by the fetal urine (10). The mechanism by which amniotic fluid is not aspirated into the lungs was demonstrated by Brown and associates (31) in 1983, when they showed that the larynx acts as a one-way valve allowing only liquid outflow under normal circumstances. The continuous secretion of liquid by the lungs confronted with a flow impediment produced by the larynx and the amniotic fluid pressure creates a small but important positive intrapulmonary pressure, which is essential for normal growth and for the structural and biochemical maturation of the developing lung (10,29,31,32). Thus, in fetal sheep, unimpeded leakage of tracheal liquid decreases lung size by arresting pulmonary tissue growth, whereas prolonged obstruction of tracheal outflow leads to lung hyperplasia (32,33). Nardo and associates (34) showed that lung hypoplasia in fetal sheep can be considerably improved by short-term obstruction at the tracheal level. Conversely, pulmonary hypoplasia in humans can be observed in pathologic conditions such as diaphragmatic hernia, pleural effusion, or severe oligohydramnios (Potter syndrome) as a result of the compression of the fetal lungs and the decrease in their internal volume (35,36).

Congenital high airway obstruction syndrome (CHAOS) is a clinical condition caused by complete or near-complete obstruction of the fetal airway that results in elevated intratracheal pressure, distention of the tracheobronchial tree, and lung hyperplasia. The enlarged lungs may cause cardiac and caval compression leading to *in utero* heart failure manifested by ascites, hydrops fetalis, and placentomegaly (37,38).

The production of fetal lung liquid depends on a system of active ion transport across the alveolar type II cells of the pulmonary epithelium (10,39,40). Olver and Strang (41) demonstrated that lung liquid secretion is coupled with active transport of Cl^- toward the pulmonary lumen, generating an electrical potential difference of -5 mV (lumen negative). This chloride secretion generates an osmotic gradient that causes liquid to flow from the microcirculation through the interstitium into the potential air spaces. This chloride secretion occurs through chloride channels in the apical membrane (alveolar side) and depends largely on chloride influx at a bumetanide-sensitive $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ (NKCC) cotransporter system in the basolateral membrane (interstitial side) (42). Thus, Cl^- enters the cell on a cotransporter linked with K^+ and Na^+ down the electrochemical potential gradient for Na^+ generated by $\text{Na}^+\text{-K}^+\text{-adenosine triphosphatase}$ (ATPase) in the basolateral membrane of the cell. Consequently, Cl^- concentration increases inside the cell above its equilibrium potential, which provides an electrochemical gradient for Cl^- exit across the luminal membrane of the epithelial cell through Cl^- permeant ion channels (Fig. 17-1) (10). Addition of the loop diuretic bumetanide or furosemide (specific NKCC inhibitors) into the fetal lung liquid decreases fluid secretion by decreasing Cl^- entry into the epithelial cell through the basolateral membrane.

Figure 17-1 Lung liquid secretion. The present model for chloride secretion emphasizes the central role of basolateral Na-K-ATPase in maintaining high intracellular K^+ and low Na^+ concentrations. Na^+ re-enters the cell down its electrochemical gradient via the Na/K/2CL cotransporter on the basolateral membrane. K^+ may leave the cell through basolateral channels. The high intracellular Cl^- concentration and the negative intracellular membrane potential facilitate the rise of the Cl^- concentration to tally its electrochemical equilibrium. A further rise in intracellular Cl^- concentration will lead to opening of the apical Cl^- channels and flow of this anion into the lung lumen. Na^+ and water will follow Cl^- through a paracellular route. (Adapted from O'Brodivich HM. Immature epithelial Na^+ channel expression is one of the pathogenetic mechanisms leading to human neonatal respiratory distress syndrome. *Proc Assoc Am Physicians* 1996;108:345-355.)

Clearance of Fluid at Birth

To allow adequate postnatal gas exchange, pulmonary fluid, which is essential to fetal lung development, must be rapidly removed at birth in order (43,44,45). Thus the transition from intra- to extrauterine life requires the effective clearance of lung liquid to support air breathing and the conversion of the pulmonary epithelium in the distal air spaces from fluid secretion to fluid absorption. Disruption of this process has been implicated in several disease states, including transient tachypnea of the newborn (TTN) and hyaline membrane disease (44,46,47,48). Preterm delivery and cesarean section without prior labor result in excessive retention of lung fluid and may contribute to respiratory compromise in the newborn infant (47,49,50,51,52,53).

A complete understanding of the mechanisms by which fetal lungs are able to clear themselves of fluid is still lacking. It is clear now that the traditional explanations for fluid reabsorption which relied on Starling forces, lymphatic uptake and vaginal squeeze at the time of birth, can

P.287

only account for a very small fraction of the lung fluid clearance (54). More recently, several studies have strongly suggested that the primary mechanism of lung liquid reabsorption is the change in ion transport induced by catecholamines during labor (10,31,44,55,56,57). Although the mechanisms responsible for lung liquid clearance at birth develop gradually during the last part of pregnancy, the removal of lung liquid and the switch from fluid secretion to fluid absorption, triggered by events at birth, are probably quite rapid because in the human the functional residual capacity of the lungs rises to a near normal value of 25 to 30 mL/kg within 15 minutes after normal delivery (58).

Although there is disagreement about whether clearance begins prior to labor, or occurs entirely within labor, it is now clear that the vast bulk (>75%) of this liquid leaves the lung some time before normal term birth (59). In studies done in full-term fetal sheep, Pfister and associates (28) showed that the lung liquid volume began a gradual decline well before the onset of labor and it was mainly a result of a decrease in the secretion rate rather than active reabsorption. They also showed that this gradual decline was followed by a much more rapid decline within labor that was mainly a result of active reabsorption of fluid driven by active Na^+ transport through the pulmonary epithelium. This last process is stimulated by the catecholamine surge that occurs just before the onset of labor (31). Other authors, however, suggest that lung liquid volume continues to rise until the day before labor (24,25,60).

As explained in the previous section, chloride secretion across the distal lung epithelium results in the production of lung liquid which is necessary for proper lung development in fetal life. In contrast, sodium absorption allows for fluid reabsorption and is critical for efficient oxygenation in the newborn.

The movement of sodium across the pulmonary epithelium from the alveolar lumen to the interstitium with subsequent absorption into the vasculature can be considered a two-step process. In the first step, sodium passively enters the apical membrane of the alveolar type II cell through amiloride-sensitive epithelial Na^+ channels (ENaCs). Thus, intraluminal instillation of amiloride delays lung fluid clearance in fetal life (61,62,63,64,65,66,67) and induces severe respiratory distress and a persistence of fetal lung fluid postnatally (68). In the second step, sodium is actively pumped out of the cell into the interstitium through the basolateral membrane by the ouabain inhibitable Na^+ - K^+ -ATPase. Thus, Na^+ - K^+ -ATPase pump inhibition with ouabain consistently reduces liquid clearance in various species (62,66,69,70,71,72). To equilibrate the osmotic pressure, generated by the movement of Na^+ , water diffuses from the alveolar to the interstitial space either through specific water channels (aquaporins) or through the paracellular junctions (Fig. 17-2) (44,73,74). Although recent data demonstrate that aquaporin-4 messenger RNA (mRNA) in the perinatal epithelium is developmentally regulated and peaks at birth (74,75) there is no evidence that these channels regulate fluid clearance (Fig. 17-2) (10,44,55,72,73,76,77,78). The mechanisms of Na^+ absorption through the pulmonary epithelium have been confirmed by isolation and culture of fetal alveolar type II cells (68,79,80,81,82).

Figure 17-2 Lung liquid absorption. At birth, to offset Cl^- secretion Na^+ channels on the epithelial cell are activated, establishing conduit for the osmotically active Na^+ ion. Basolateral membrane Na^+ - K^+ -ATPase generates the gradient for apical Na^+ entry into the epithelial cell and switches the distal lung epithelium from a secreting to an absorbing organ. The net movement of Na^+ to the basolateral direction induces a parallel movement of Cl^- and fluid through the paracellular route or the transcellular pathway, using specific water channels, that is, aquaporins. Amil insens, amiloride insensitivity. (Adapted from O'Brodoovich HM. Immature epithelial Na^+ channel expression is one of the pathogenetic mechanisms leading to human neonatal respiratory distress syndrome. *Proc Assoc Am Physicians* 1996;108:345-355.)

The gene for the amiloride-sensitive epithelial sodium channel has been cloned; it consists of three homologous subunits called α -, β -, and γ -ENaC. The α subunit is a prerequisite unit for any channel activity. The expression of the three subunits is necessary for maximum ion transport (83). The α -ENaC (84) and the β - and γ -ENaC subunits (85) were detected in early midtrimester on the apical domain of human airway cells suggesting that sodium absorption might begin significantly before birth, even if secretion is still dominant. The three subunits increased sharply around the time of birth, were highest shortly after birth, and declined in parallel with endogenous plasma epinephrine concentration during the first week of life. The importance of the ENaC was confirmed by studies showing that α -ENaC knockout mice were unable to clear lung liquid from the alveolar spaces after birth resulting in death from respiratory failure (86). Mice with β - or γ -ENaC null mutations had delayed liquid clearance but had near-normal lung water content 12 hours after birth (86,87).

It is well known now that net alveolar fluid clearance occurs at a rapid rate late in gestation and that this clearance is driven by elevations of endogenous epinephrine. The critical link between β -adrenergic stimulation and lung fluid clearance was made in 1978 by Walters and Olver who found that intravenously infused epinephrine caused rapid absorption of lung fluid in near-term fetal lambs and that this response could be

immediate and reversible increase in luminal electronegativity by stimulating the active transport of Na^+ out of the lung lumen (55). In the absence of adrenergic stimulation the amiloride-sensitive Na^+ channels remain closed (secretory state). Thus, the opened or closed state of the Na^+ channels determines whether the fetal lungs, at any particular time, are secretory or reabsorptive (10). The epinephrine stimulation of amiloride-sensitive alveolar fluid clearance is mediated by cyclic adenosine monophosphate (cAMP) and Ca^{2+} likely acting as an intracellular second messenger (89,90).

The induced reabsorption with epinephrine increases strikingly with advancing gestational age and can be induced by pretreatment of fetal sheep with the combination of corticosteroids and triiodothyronine (91). These two hormones are required to switch the effect of β -adrenergic stimulation from net chloride and liquid secretion to net sodium and liquid absorption (30,56,57,92,93). Consistent with *in vivo* observations, α -ENaC mRNA is increased by glucocorticoids in the primary cultures of alveolar type II cells FDLE, while the expression of β - and γ -ENaC mRNA is unaffected by glucocorticoid (94).

Another factor that appears to be particularly important in the switch of transepithelial liquid flow from secretion to absorption is the sharp increase in alveolar pressure of oxygen ($\text{P}_{\text{A}}\text{O}_2$) that occurs at birth. It was recently shown that fetal PO_2 favored the development of fluid filled cyst-like structures while the rise of PO_2 to postnatal levels reduced fluid in the cysts (95). The effect of oxygen seems to be the result of an increase in $\text{Na}^+\text{-K}^+$ -ATPase activity and the response is also enhanced by glucocorticoids and thyroid hormones. Thus, at birth, epinephrine, oxygen, glucocorticoid and thyroid hormones interact to produce a permanent switch from secretion to absorption in the distal epithelium.

Although the switch from Cl^- secretion to sodium absorption is the critical mechanism for lung fluid clearance at the time of delivery, other passive factors play a role in clearing the residual liquid present in potential air spaces at birth. The first is transient and peaks early and relates to enlarged transepithelial pores produced by spontaneous ventilation (22,29,47,51). Thus air inflation, by passive reabsorption down the transpulmonary pressure gradient associated with ventilation, shifts residual liquid from the lung lumen into the interstitium around distensible perivascular spaces of large pulmonary blood vessels and airways. These perivascular cuffs progressively diminish in size as the fluid is removed by small pulmonary blood vessels and lymphatics. Bland and associates (96,97) showed that the pulmonary circulation absorbs most of the residual liquid present in potential air spaces at birth and that elevated left atrial pressure or reduction of plasma protein concentration slows the rate of liquid clearance in mature animals. Although there is a small and transient increase in lymph flow after postnatal breathing begins, the amount of excess liquid drained postnatally by pulmonary lymphatics is only approximately 11% of the residual liquid in the lungs at birth (98). The second mechanism is the transvascular protein gradient that facilitates the movement of fluid from the essentially protein-free lung fluid into the interstitium, followed by passage of liquid into the bloodstream.

RESPIRATORY ADAPTATION

Fetal Breathing

The discovery of fetal breathing in the late 1960s immediately stimulated interest in the factors that control breathing *in utero* (99,100,101). Although of unknown purpose, because no gas exchange is involved, fetal breathing may represent preparation *in utero* for a vital function important in life. Shortly after its discovery, the Oxford group (102) showed that, although fetal breathing was influenced by fetal behavior, occurring essentially in rapid eye movement (REM) sleep, it was clearly regulated by other chemical factors, such as carbon dioxide and oxygen concentration. Subsequent work confirmed and expanded these findings by recording the electrical activity of the diaphragm and clearly demonstrating the central origin of the respiratory output in utero (103,104,105,106,107). Using ultrasonographic technology, breathing movements were also identified in the human fetus, being present approximately 40% of the time during late pregnancy, a figure similar to that in sheep (108,109,110,111).

The discovery of fetal breathing not only stimulated the development of the area of fetal assessment but it also brought a new dimension to the events occurring at birth. What has been traditionally called "the initiation of breathing at birth" must now be called "the establishment of continuous breathing at birth." Breathing begins long before birth. The question is not what determines the appearance of breathing at birth, but what makes it

continuous. From another angle, what makes fetal breathing episodic in late gestation and present only during low-voltage electrocortical activity? The answer to this question remains unknown.

Fetal breathing in sheep is mostly continuous in early gestation (90 to 115 days) but becomes episodic in late gestation, primarily occurring during periods of low-voltage electrocortical activity (99,101,107,112,113). During high-voltage electrocortical activity there is no established breathing present, but occasional breaths may surface after episodic, generalized, tonic muscular discharges associated with body movements (Fig. 17-3) (107). During low-voltage electrocortical activity, breathing is irregular, the diaphragmatic electromyogram (EMG) being characterized by an abrupt beginning and end. The physiologic mechanism responsible for the occurrence of fetal breathing only during low-voltage electrocortical activity is unknown.

Modulation of Fetal Breathing by CO₂, O₂, and Neurochemicals

Many studies clearly show that the fetal breathing apparatus is capable of responding well to chemical stimuli and other agents known to modify breathing postnatally. Thus it

P.289

became clear that the fetus responds to an increase in arterial carbon dioxide pressure (PaCO₂) with an increase in breathing (102,108,114,115,116,117,118). The increased breathing activity is prolonged into the transitional high voltage electrocortical activity but does not continue into the established (Fig. 17-4) (118). There is much evidence suggesting that the actions of CO₂ are central.

Administration of low oxygen to the fetus by having the ewe breathe hypoxic mixtures abolished fetal breathing; this was associated with a decrease in body movements and in the amplitude of the ECoG (102,119,120). Transection of the brain at the upper level of the pons prevents the inhibitory action of hypoxia and induces continuous breathing. Conversely, increase in arterial PO₂ to levels above 200 mm Hg through the administration of 100% O₂ to the fetus via an endotracheal tube stimulated breathing and induced continuous breathing in 35% of the experiments in fetal sheep (121). These findings suggest that low partial tension of O₂ in the fetus at rest may be a normal mechanism inhibiting breathing *in utero*.

A comprehensive review of the effects of various neurochemicals agents on fetal breathing has been published (122). In general, fetal breathing is inhibited by muscimol (123), a γ -aminobutyric (GABA) agonist, pentobarbiton (124), and diazepam (125) acting at the GABA_A receptor complex (126). Other endogenous inhibitors include adenosine, prostaglandin E₂ (PGE₂) (see next subsection), and endorphins, which may be present at high levels in the fetal circulation. Agents that stimulate fetal breathing movements include prostaglandin inhibitors such as indomethacin, meclufenamate, morphine, caffeine, pilocarpine, and 5-hydroxy-tryptophan (5-HTP). Fetal breathing is inhibited by maternal hypoglycemia whereas it is stimulated after maternal meals and hyperglycemia.

Figure 17-4 Fetal breathing during control and during CO₂ rebreathing. Note the increase in tracheal pressure and diaphragmatic activity during CO₂ rebreathing. Fetal breathing was prolonged into the transitional low- to high-voltage ECoG, but stopped in established high-voltage ECoG. (From Rigatto H. Regulation of fetal breathing. *Reprod Fertil Dev* 1996;8:23-33, with permission.)

Establishment of Continuous Breathing at Birth

The traditional view has been that labor and delivery produce a transient fetal asphyxia that stimulates the peripheral chemoreceptors to induce the first breath. Breathing would then be maintained through the input of other stimuli, such as cold or touch (127,128). More recent observations have questioned this general view. First, the denervation of the carotid and aortic chemoreceptors does not alter fetal breathing or the initiation of continuous breathing at birth (Fig. 17-5) (129,130). Second, continuous breathing can be established *in utero*, with manifestations of arousal, by raising fetal PO₂ and occluding the

P.290

umbilical cord (Fig. 17-6) (121). These observations during administration of high O₂ or cord occlusion suggest that the fetus can be made to resemble a neonate *in utero* without the transient hypoxemia to stimulate the peripheral chemoreceptors and without any of the sensory stimuli, such as cold, once thought to be important for the establishment of continuous breathing at birth.

Figure 17-5 Delay in minutes from opening of the window to () the appearance of the first breath and to () sustained breathing. There were no significant differences between the sham-operated and the chemodenervated groups. (From Rigatto H. Regulation of fetal breathing. *Reprod Fertil Dev* 1996;8:23-33, with permission.)

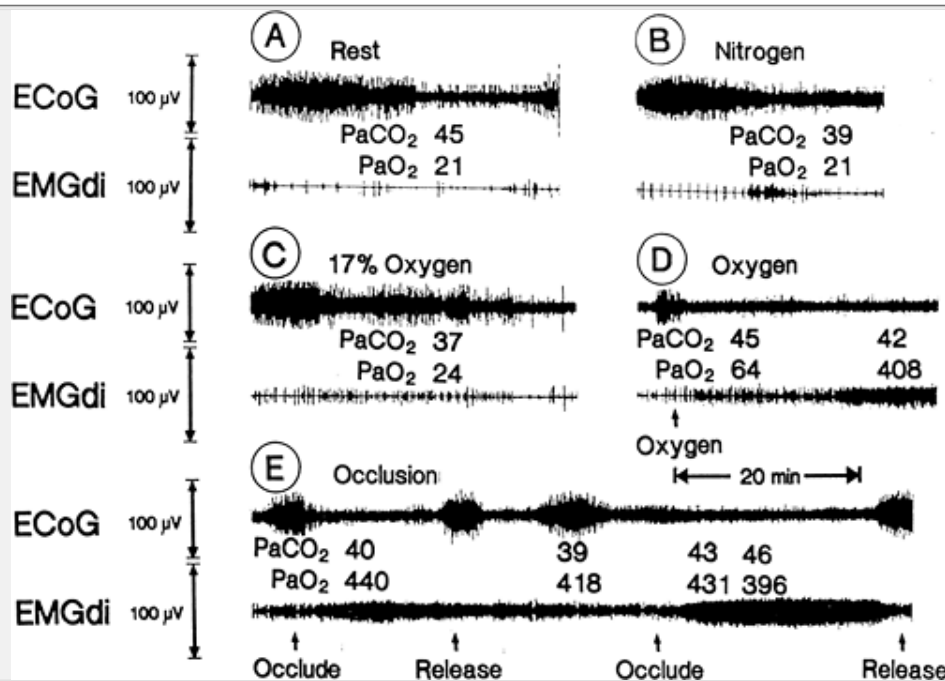

Figure 17-6 Representative tracing showing the effect of fetal fraction of inspired oxygen (FiO_2) on fetal breathing and electrocortical activity. **A:** Control cycle showing little breathing in fetus in early labor at 143 days of gestation. **B:** Lung distention (mean airway pressure 30 cm H_2O) and inspired N_2 does not affect baseline tracing. **C:** Seventeen percent O_2 also does not alter breathing. **D:** One hundred percent O_2 induces continuous breathing. **E:** Occlusion on two occasions induces more forceful breathing than that observed with O_2 alone. Note that continuous breathing was elicited despite preventing the rise of $PaCO_2$ by ventilating the fetus with high-frequency ventilation (15 Hz, stroke = 7 cm H_2O). ECoG, electrocortical activity; EMGdi, electromyogram of the diaphragm. (From Rigatto H. Regulation of fetal breathing. *Reprod Fertil Dev* 1996;8:23-33, with permission.)

Thus, the physiologic mechanism responsible for the inhibition of fetal breathing and the establishment of continuous breathing at birth remains unknown. It has been debated whether the key factors in inducing these changes are intrinsic to the fetal brain or are in the placenta. Because placental separation at birth is associated with the onset of continuous breathing, we, together with others, have hypothesized that placental factors might be responsible for the inhibition of fetal breathing (131,132,133,134,135). This line of thinking is based on the assumption that the release of a factor by the placenta into the fetal circulation prevents fetal breathing from being continuous, with inhibition during high-voltage ECoG, and present only during periods of reticular activation as it occurs during low-voltage ECoG. In the absence of this factor from the placenta at birth, after cord clamping, the state-related inhibition observed during high-voltage ECoG is insufficient to disrupt continuous breathing. Teleologically, it is interesting that nature may have delegated to the placenta the important role of providing the fetus with gas exchange and nutrients and it is conceivable that it may also have endowed the placenta with some form of chemoreceptor

P.291

activity regulating fetal breathing and behavior by the secretion of chemical substances into the fetal circulation.

More direct evidence for a placental role has been present since Dawes (127) and Harned and Ferreiro (128) showed that only after clamping the umbilical cord does the newborn lamb start breathing and behaving like a neonate. Subsequently, Adamson and associates (133) induced breathing in the fetus with umbilical cord occlusion and supply of O_2 via an endotracheal catheter. On release of the cord, breathing ceased immediately, before any change in blood gases or pH, suggesting that a factor from the placenta might be involved. In our laboratory, we were able to induce continuous breathing and wakefulness in fetal sheep by occluding the umbilical cord, as long as we provided a gas exchange area for the fetus via an endotracheal tube (132,136,137,138). These experiments suggest the origin in the placenta of a compound that inhibits fetal breathing and fetal activity.

In trying to prove the hypothesis that a factor is released by the placenta, we injected the fetal sheep with a placental extract (juice of cotyledons acutely dissected, sliced, and immersed in Krebs solution) after continuous

breathing was induced by cord occlusion (Fig. 17-7) (132). In all experiments the placental extract decreased or abolished breathing. The infusion of the placental extract into the fetal circulation also inhibited spontaneous fetal breathing present during low-voltage electrocortical activity without inducing significant changes in blood gas tensions, pH, heart rate, and blood pressure (139). This factor appeared specific to the placenta because the breathing response was absent with extracts from other tissues, such as liver, muscle, or blood. We have demonstrated that this factor in the placental extract is likely a prostaglandin, because treatment of the extract with indomethacin/acetylsalicylic acid (ASA), which significantly reduced the concentration of prostaglandins, eliminated the activity of the extract (Fig. 17-8) (140).

Indirect evidence that placental prostaglandins, especially PGE₂, are the mediators responsible for the inhibition of breathing in fetal life has been provided by Kitterman and associates (141) and Wallen and associates (142) who showed that infusion of PGE₂ into the circulation of the fetal sheep induced a prompt and complete cessation of breathing movements. In addition, the incidence of fetal breathing movements was inversely correlated with both the PGE₂ dose and the mean PGE₂ concentration. Conversely, intravenous infusion of prostaglandin synthetase inhibitors, such as indomethacin or meclofenamate, induces continuous breathing for many hours in the fetus (141,143,144). Thus, the rate of placental prostaglandin production, plays a significant role in setting the level of fetal breathing activity by producing a sleep-related inhibition in the fetal brainstem.

Figure 17-7 Representative tracing showing the effects of different placental infusates on fetal breathing and ECoG. The whole placental extract and the subfraction 3-5 to 10 kDa decreased or abolished breathing in all cases, and when given in low-voltage ECoG, this was associated with a switch to high voltage. No significant effects were seen with infusates having molecular mass greater than 10 kDa or less than 1 kDa. ECoG, electrocochleography; EMGdi, electromyogram of the diaphragm. (From Rigatto H. Regulation of fetal breathing. *Reprod Fertil Dev* 1996;8:23-33, with permission.)

It is unlikely, however, that prostaglandins are involved in the inhibition of fetal breathing observed during hypoxia, because this inhibition persists after the administration of prostaglandin inhibitors. Several studies show that adenosine is the likely mediator of the respiratory depression observed during hypoxia because intravascular administration of adenosine inhibits fetal breathing and eye movements (145) and the infusion of adenosine receptor antagonists blunts this inhibition (145,146). Also, brain disruptions that eliminate hypoxic inhibition of breathing also abolish the depressant effects of adenosine (147). Koos and associates (148) have shown that hypoxia inhibits fetal breathing through activation of central adenosine receptors, specially the A(2A) subtype.

Mechanics of the First Postnatal Breaths

Although the neural and chemical control mechanisms responsible for establishment of continuous breathing at birth are not completely understood, the mechanical processes responsible for inflating the lungs at birth are in some detail accepted.

It is well known that a sufficient force (opening pressure) must be generated across the lungs with the first inspiration to overcome the viscosity of the fluid in the

airways, as well as the forces of surface tension and tissue resistance (149). As we described in the subsection

“Clearance of Fluid at Birth” in preparation for lung ventilation at birth, the volume of pulmonary fluid in the fetus decreases during late gestation, especially during initiation of labor, as a result of reduction in the rate of secretion and an increase in reabsorption of fluid in response to catecholamines. Pfister and associates (28) found large negative intrapulmonary pressure in fetal sheep during labor, which implied that the lung volume was less than functional residual capacity. The findings of a negative intrapulmonary pressure near the end of labor may in part explain reports that the first inspiration in human infants does not require diaphragmatic contraction. The elastic recoil of the chest wall after delivery would tend to rebound to the resting position causing a small passive inspiration of air.

Figure 17-8 Incidence of fetal breathing movements during the infusion of placental extracts. The regular placental extracts () induced a profound inhibition of fetal breathing that progressively recovered upon discontinuation of the infusions. This effect disappeared when the extracts were treated with indo-methacin/ acetylsalicylic acid (ASA) (). Values are mean ± standard error (SE). * p. <0.05.

Although most of the lung fluid is reabsorbed during labor and delivery, a small but significant amount of fluid is still present in the lungs at the time the newborn infant is ready to take the first postnatal breath. A pressure of about 60 cm H₂O is required to make this fluid flow through the airways with the first inspiration (150).

However, a much higher opening pressure would be needed to overcome the high surface tension forces if the airways were not partially distended with this fluid (Fig. 17-9) (151). According to the Laplace equation for a cylinder state, the pressure required to overcome surface tension is directly proportional to the surface tension and indirectly proportional to the radius of curvature ($P = t/r$). If the airways were not partially distended by liquid, the opening pressure in the terminal airway would be very large because of the small radius of curvature. Thus, the normal fluid content of the lung at birth facilitates the first breath by lowering the opening pressure, and ensuring a more homogeneous filling of the lung with air. A significant reduction in the volume of fetal pulmonary fluid, as seen sometimes in postterm deliveries, may not be beneficial at birth. First, greater pressures would be required to inflate the air sacs in fluid-free lungs, and second, the distribution of inspired air during the first breath may not be as uniform. Faridy (151) showed that the highest opening pressure is seen in fluid-free lungs and the lowest in lungs containing fluid of approximately 25% of maximum lung volume.

The opening pressure of the lungs at birth also depends on the compliance of the alveolar tissue and the surface forces at air-fluid interface. During labor and birth, a massive release of surfactant in pulmonary fluid facilitates lung opening by lowering the opening pressure through the decrease in surface forces and the improvement of lung compliance (151,152,153,154). Thus, as seen in Fig. 17-10, the first postnatal breath (I) begins with no air volume in the lungs

and no transpulmonary pressure gradient. As the chest wall expands, the transpulmonary pressure increases until it overcomes the surface tension of small airways and alveoli. At this point, actively inspired air begins to enter the lungs and, according to the Laplace equation, as the radius increases, the distending pressure required to open up those units decreases.

Figure 17-9 Pressure-volume curves after air versus liquid expansion of the lung. (From Radford EP. In: Remington JW, ed. *Tissue elasticity*. Washington, DC: American Physiological Society, 1957, with permission.)

Figure 17-10 Pressure-volume curves of the first three extrauterine breaths. (From Smith CA, Nelson NM. *Physiology of the newborn infant*, 4th ed. Springfield, IL: Charles C. Thomas, 1976:125, with permission.)

Although the first inspiratory effort is extremely important for lung opening, the creation of functional residual capacity (FRC) at the end of the first expiratory effort is essential for the normal pulmonary adaptation at birth. It is obvious that if all the air that entered the lung were to leave the lung, every breath would necessarily resemble the first breath (155). This FRC can only be created if the pulmonary surfactant is present allowing for the stabilization of the peripheral air spaces. The near-zero surface tension and the bubble formation produced by surfactant allows for retention of large volumes of air at the end of the first expiration. When surfactant is deficient, the consequences are a tendency to airlessness with each expiration and the application of high inspiratory pressures to maintain respiration. This leads to the marked retractions so commonly associated with atelectasis and hyaline membrane disease (HMD) as seen in preterm infants with surfactant deficiency.

Mortola and associates (156) showed that in healthy term infants born by cesarean section, the amount of air exhaled after the first breath was less than the inhaled volume representing the formation of the FRC. This FRC continued to rise after the first breath in a very irregular fashion from a mean of about 10 mL/kg at birth to 30 mL/kg by the second day of life (157). The first breaths are actively exhaled by the high negative transpulmonary pressures (see Fig. 17-10). These expiratory breaths are also associated with interruptions in the expiratory flow ("braking of the expiration"), likely as a result of closure in the pharyngeal/laryngeal region, as indicated by the radiographic studies of Bosma and associates (158). The resulting positive pressure in the airway generated by this respiratory pattern would not only facilitate liquid absorption, but it would also improve air retention at the end of expiration, as well as increase lung compliance. Boon and associates (159) showed that the formation of FRC in asphyxiated neonates born by cesarean section was associated with a stepwise increase in tidal volume presumably indicating that the physical characteristics of the lungs had changed sufficiently to allow the lungs to remain inflated. Although vaginally delivered infants have not been extensively

studied, it is likely that they require similar pressures for the first inflation as cesarean-delivered infants. In both vaginal- and cesarean-delivered infants, the major sources of resistance to inflation (surface forces caused by air-liquid interface and the frictional forces caused by the movement of the column of liquid in the airway) may be very similar and yield comparable inspiratory volume and FRC of the first breath (156).

CIRCULATORY ADAPTATION

Fetal Circulation

A combination of preferential flow and streaming through structural shunts in the liver (ductus venosus) and heart (foramen ovale and ductus arteriosus), allows the highest oxygen content blood coming from the placenta to be delivered to the heart, brain, and upper torso (Fig. 17-11). This relative parallel flow contrasts with the flow in series and without shunts of the adult circulation. Thus, the volume of blood in the fetal heart ventricles is not equal. In fact, the right ventricle ejects approximately two-thirds of total fetal cardiac output (300 mL/kg per minute), whereas the left ventricle ejects only a little more than one third (150 mL/kg per minute) (160).

Placenta blood is delivered to the fetus through the umbilical vein. Approximately 50% of this umbilical blood flow passes through the ductus venosus directly into the inferior vena cava and mixes with the systemic venous drainage from the lower body. The other 50% of the umbilical blood flow joins the hepatic portal venous system and passes through the hepatic vasculature (161). Preferential streaming allows the well-oxygenated blood derived from the ductus venosus to travel through the dorsal and leftward wall of the inferior vena cava (162). A tissue flap called the *eustachian valve*, located at the junction of the inferior vena cava and right atrium, serves to direct the highly oxygenated blood from the ductus venosus across the foramen ovale into the left atrium and then the left ventricle and ascending aorta (162,163,164). The less-oxygenated anterior stream (mainly blood from the lower body and the hepatic circulation) joins the oxygen-poor blood from the superior vena cava (which drains the head and upper body) and the coronary sinus (which delivers venous return from the myocardium) at the right atrium,

P.294

directing the blood through the tricuspid valve into the right ventricle (Fig. 17-11).

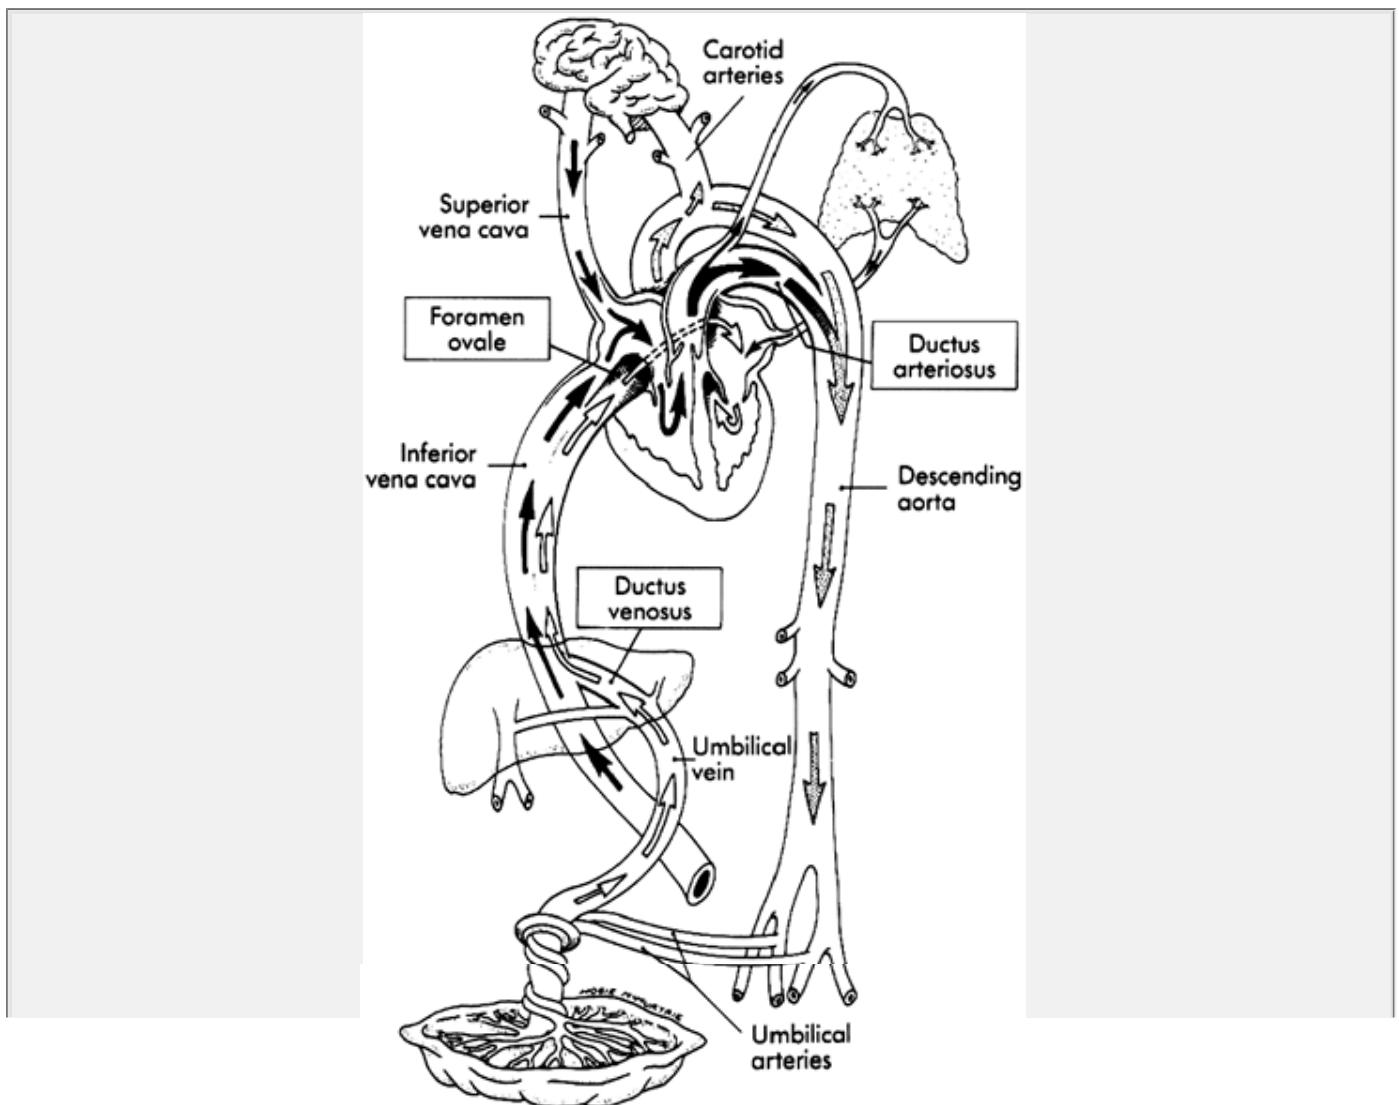

Figure 17-11 Fetal blood circulation. (From Bloom RS. Delivery room resuscitation of the newborn. In: Fanaroff AA, Martin RJ, eds. *Neonatal and perinatal medicine: diseases of the fetus and infant*, 5th ed. St. Louis: Mosby-Yearbook, 1992:302, with permission.)

Because the placenta is responsible for gas exchange *in utero*, very little blood flow is sent to the lungs. The pulmonary circulation is a high-resistance, low-flow circuit that receives less than 10% of the ventricular output. Instead of entering the pulmonary arteries, most of the right ventricular blood is diverted away from the lungs through the widely patent ductus arteriosus to the descending aorta, reaching the placenta for oxygenation through the umbilical arteries.

The well-oxygenated blood coming across the foramen ovale joins the small amount of blood returning from the lungs via the pulmonary veins in the left atrium and traverses the mitral valve into the left ventricle. This blood is then ejected across the aortic valve into the ascending aorta bringing well-oxygenated blood to the myocardium, brain, head, and upper torso (see Fig. 17-11).

Regulation of Fetal Pulmonary Vascular Resistance

There is a close association between pulmonary arterial development and airway development. As gestation progresses, synchronization of airway and vessel branching occurs, suggesting they may be regulated by common mediators or exchange messenger molecules (165,166). The embryonic endothelial channels later acquire a smooth-muscle layer and thus the ability to regulate vascular tone and blood flow.

During early gestation, pulmonary blood flow is limited by the paucity of pulmonary vessels. However, although the number of small blood vessels per unit of lung volume increases tenfold during the last trimester, pulmonary blood flow remains low because of a high pulmonary vascular resistance (Fig. 17-12). In addition to the mechanical compression of pulmonary vessels by the fluid-filled, atelectatic lungs and the lack of rhythmic distention, this high-resistance low-flow state is probably maintained in part by vasoconstriction because the fetal pulmonary vascular bed responds readily to vasodilators.

Sympathetic tone does not appear to be responsible for the high pulmonary vascular resistance of the fetus,

P.295

because neither sympathectomy nor α -adrenergic blockade decreases the resistance (167,168,169). Although arachidonic acid and its cyclooxygenase products, prostaglandin $F_2\alpha$ and thromboxane A_2 are vasoconstrictors in the fetal and newborn lung, their blockade does not decrease vascular resistance (170,171,172).

Figure 17-12 Representative changes in the pulmonary hemodynamics during transition from the late-term fetal circulation to the neonatal circulation. P pulmonary vascular resistance (PVR) decreases progressively during later gestation as a consequence of lung growth and increased cross-sectional area for flow. PVR decreases dramatically at birth as a consequence of the vasodilating effect of lung aeration. PVR continues to fall more gradually over the first 6 to 8 weeks of life. Pulmonary blood flow remains at relatively low levels during fetal growth, then increases abruptly with lung expansion and the rapid fall in PVR. Mean pulmonary artery pressure falls rapidly immediately after birth because the pulmonary vasodilation causes PVR to fall more than pulmonary blood flow increases. (Adapted from Rudolph AM. Fetal circulation and cardiovascular adjustment after birth. In: Rudolph AM, Hoffman JIE, Rudolph CD, eds. *Rudolph's pediatrics*, 19th ed. Norwalk, CT: Appleton & Lange, 1991:1309-1313, with permission.)

The discovery that the effects of some vasodilator agents, such as acetylcholine, bradykinin, and histamine, were dependent on release of an endothelium-derived relaxing factor (EDRF), later shown to be nitric oxide (NO) (173,174), led to the exploration of its possible role in the perinatal decrease in pulmonary vascular resistance. Nitric oxide, an inorganic, gaseous free radical discovered in the late 1980s, is produced by the endothelial cells from the terminal nitrogen of L-arginine by nitric oxide synthase (NOS). NOS can be stimulated by pharmacologic agents such as acetylcholine or bradykinin, and by birth, shear stress, and oxygen. Nitric oxide activates soluble guanylate cyclase, which produces smooth-muscle relaxation by activation of protein kinase C (Fig. 17-13) (175). Hydrolysis of cyclic guanosine monophosphate (cGMP) is accomplished by phosphodiesterases that control the intensity and duration of cGMP signal transduction (176). In fetal life, NO production is also stimulated by activation of adenosine triphosphate (ATP)-dependent K⁺ channels. A maturational increase in NO-mediated relaxation has been documented during the late fetal and early postnatal period, which parallels the dramatic fall in pulmonary vascular resistance at birth (177,178,179,180,181). In fetal lambs, inhibiting NO synthesis increases resting pulmonary vascular resistance and inhibits the ventilation-induced fall in pulmonary vascular resistance. Increased oxygen tension increases both basal and stimulated NO release and inhibition of NO blocks virtually the entire increase in fetal pulmonary blood flow caused by hyperbaric oxygenation without ventilation (182,183,184). Shear stress resulting from increased pulmonary blood flow and rhythmic distention of the lung without changing oxygen tension also induces endothelial NOS gene expression and contributes to pulmonary vasodilatation at birth (185,186).

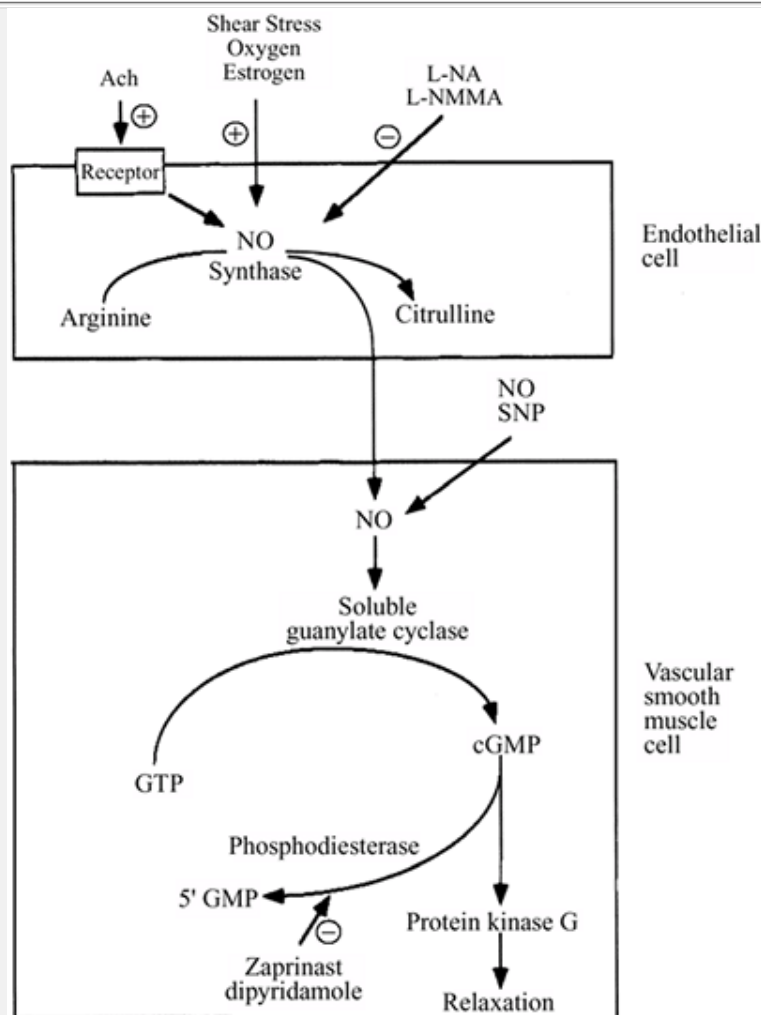

Figure 17-13 The proposed mechanism of synthesis and action of nitric oxide. Nitric oxide (NO) is produced in the endothelium from the terminal guanido nitrogen of L-arginine by NO synthase. NO synthase can be stimulated by pharmacologic agents such as acetylcholine (Ach) or bradykinin, and by birth, shear stress, and oxygen. Endothelial production of NO can be blocked by arginine analogues that have modifications of the guanido nitrogen of the molecule. Nitric oxide activates soluble guanylate cyclase, increases cyclic guanosine monophosphate (cGMP) concentrations in vascular smooth muscle, and initiates the cascade resulting in smooth-muscle relaxation. The magnitude and duration of the effect of cGMP is controlled by its inactivation by specific phosphodi-esterases. GMP, guanosine monophosphate; GTP, guanosine triphosphate; L-NA, nitro-L-arginine; L-NMMA, N^G-mono- methyl-L-arginine. (From Lakshminrusimha S, Steinhorn R. Pulmonary vascular biology during neonatal transition. *Clin Perinatol* 1999;26(3):601-619, with permission.)

Endothelin-1 (ET-1), a 21-amino acid peptide also produced by vascular endothelial cells, has potent vasoactive activities (187). Although ET-1 appears to play an important and active role in mediating pulmonary vascular resistance, *in vivo* studies indicate that the effects of exogenous endothelin are complex and depend on the site, developmental

P.296

age, and tone of the vascular bed (188,189,190). Consequently, exogenous ET-1 predominantly vasodilates the fetal and newborn pulmonary circulations by acting on the ET_B receptors located on the endothelial cells but causes vasoconstriction in the adult pulmonary circulation by acting on the ET_A receptors located in the smooth muscle cells (191,192). Increasing data also suggest that endogenous NO and ET-1 participate in the regulation of each other through an autocrine feedback loop. Thus, ET-1 stimulates the release of NO, and NO inhibits the ET-1 system (193,194).

The low oxygen tension in fetal life is a physiologic stimulus for the pulmonary vasculature to be constricted. This hypoxic pulmonary vasoconstriction develops over the period of gestation when the cross-sectional area of the vascular bed is increasing rapidly. Decreasing oxygen tension in the fetus at 103 days of gestation does not increase pulmonary vascular resistance, but in the 132- to 138-day fetus it doubles the resistance. Conversely, increasing oxygen tension before 100 days of gestation does not decrease pulmonary vascular resistance, but by

135 days it decreases resistance markedly and increases pulmonary blood flow to normal newborn levels. Its mechanism of action may be in part through regulation of activity and gene expression of voltage-gated K⁺ channels (195), nitric oxide synthase and/or endothelin (196,197).

Unlike the mature pulmonary circulation, the fetal pulmonary vasculature appears to regulate flow through a myogenic response. The fetal pulmonary vasculature exhibits a time-limited vasodilation in response to dilating stimuli, including shear stress, oxygen, and many pharmacologic vasodilators, with return to the constricted resting state despite continued exposure to the vasodilating stimulus. This unique mechanism limits pulmonary blood flow and preserves placental perfusion and gas exchange.

Transition to Extrauterine Circulation

At birth, a number of complex events must take place so that the fetal circulation that depends on the placenta for gas exchange and intracardiac and extracardiac shunts to deliver oxygenated blood to the heart and brain, switches to the neonatal circulation in which the gas exchange is transferred to the lungs and the fetal shunts are eliminated. A rapid and sustained decrease in pulmonary vascular resistance during the first breaths facilitate this adaptation. Although this normal pulmonary vascular transition occurs spontaneously and quickly in most neonates, failure of the pulmonary circulation to undergo this changes results in persistent pulmonary hypertension of the newborn (PPHN). This condition, which carries significant morbidity and mortality, develops when the pulmonary vascular resistance fails to decrease adequately during the transition to extrauterine life. Altered intrauterine environment producing structural changes in the pulmonary circulation or hypoxemia, acidosis and/or hypercarbia secondary to meconium aspiration, surfactant deficiency, or pneumonia at birth abnormally constricts the transitional pulmonary circulation. In this condition, right-to-left shunts at the atrial and ductus arteriosus levels continue secondary to the high pulmonary vascular resistance, producing significant hypoxemia, which, in turn, causes an increase in pulmonary vasoconstriction. Thus, two major hemodynamic events must occur at delivery to allow for a normal transition from fetal to neonatal circulation.

Pulmonary Vasodilatation

At birth, pulmonary arterial blood flow increases eight- to tenfold and pulmonary vascular resistance (PVR) decreases by 50% within the first 24 hours, as the lung assumes the function of gas exchange (Fig. 17-14) (198,199,200,201,202). This decrease in PVR is brought about by active vasodilation which is regulated by a complex and incompletely understood interaction among metabolic, hormonal, and mechanical factors, triggered by a number of birth-related stimuli. Three main factors contribute to the increase in pulmonary blood flow during this transition: (a) ventilation of the lungs, (b) increased oxygenation, and (c) hemodynamic forces such as increased shear stress. The effects of these factors on pulmonary circulation at birth appears to be mediated primarily by the release of NO from the vascular endothelium which results in smooth muscle relaxation via activation of the intracellular cGMP-dependent protein kinase (203). The initial partial increase in pulmonary vasodilation may be independent of oxygenation and may be caused by physical expansion of the lungs and the production of prostaglandins (204). The next component is maximal pulmonary vasodilation associated with oxygenation, which may be mainly caused by NO synthesis. The increased shear forces related to the rise in pulmonary blood flow may stimulate endothelial cells to produce NO, which helps maintain pulmonary vasodilation (Fig. 17-14).

Figure 17-14 Pulmonary vascular conductance increases with the onset of ventilation. Separate curves depict the contributions of gaseous inflation, increased PO₂, and decreased PCO₂. (Adapted from Strang LB. The lungs at birth. *Arch Dis Child* 1965;40:575, with permission.)

Ventilation of the Lungs

It has long been known that the initiation of rhythmic breathing causes vasodilation, even in the absence of increase in oxygen tension (see Fig. 17-14) (8,199). However, physical expansion of the lungs alone produces only partial increase in pulmonary blood flow and a decrease in PVR. A small proportion of this relates to the mechanical distention of the lungs and the establishment of an air-liquid interface, as alveolar fluid is replaced by gas, which increases vessel radius by exerting a negative dilating pressure on the small pulmonary arteries and veins (205,206). Ventilation of the lung also releases vasoactive substances such as prostacyclin (PGI₂) from vessel walls, which increases pulmonary blood flow and decreases PVR (207). Cyclooxygenase inhibition, which blocks PGI₂ production, prevents the normal decrease in PVR with lung expansion, but not the changes that occur with oxygenation (207,208,209,210). Other prostaglandins, such as PGD₂ and histamine released by the mast cells during lung expansion, may also contribute to the initial postnatal pulmonary vasodilation (211). NOS and K_{Ca} channel inhibition also blunt ventilation-induced pulmonary vasodilatation (212,213).

Increased Oxygenation

Oxygen is a potent stimulus for pulmonary vasodilation. Even in the absence of ventilation, increased oxygen tension reduces PVR. Ventilation plus increased oxygen tension produces complete pulmonary vasodilation and both are particularly crucial in the normal transition to postnatal circulation and pulmonary gas exchange (see Fig. 17-14) (199). Although the mechanisms of oxygen-induced pulmonary vasodilation are not completely understood, several factors appear to contribute to this response. It is known that K⁺ channels are the major regulators of resting membrane potential in pulmonary arterial smooth muscle cells and that hypoxia decreases K⁺ current by repressing K⁺ channel gene expression (214,215). Gosche and associates (216) have found that K_{voltage} but not K_{Ca} or K_{ATP} channel activation contributes to the oxygen-induced vasodilation in isolated third-generation pulmonary arterioles from term fetal rats. Whether K⁺ channels function as sensors of, or effectors for, oxygen-induced changes in pulmonary vascular tone is unknown. Thus, changes in K⁺ channel activity may occur via a direct effect of oxygen tension on the K⁺ channel (217) or, alternatively, K⁺ channels may open in response to changes in the concentration of a second messenger substance like NO (218,219). Many studies show that the effect of oxygen on perinatal pulmonary circulation appears to be mediated primarily by the effects of NO on K⁺ channels in arterial smooth muscle cells either directly or through a cGMP-sensitive kinase (220,221,222,223). Endothelium-derived nitric oxide modulates pulmonary vascular tone under basal conditions in the fetus and during transition of the pulmonary circulation at birth. Several studies show that the *in utero* increase in pulmonary blood flow observed in response to either ventilation with oxygen or maternal hyperbaric oxygen exposure can be markedly attenuated with inhibition of NO synthesis (219). It has also been shown that the maturational rise in NO production seen from late gestation to 4 weeks postnatally is modulated by oxygen. Thus, the sudden increase in oxygen tension that occurs at birth appears to enhance NO synthesis and NOS inhibition blunts the oxygen-induced decrease in PVR. Although it is assumed that oxygen may act directly on endothelial cells to increase NO production, it is possible that it stimulates release of another agent, such as bradykinin, calcitonin gene-related peptide, or adrenomedullin, which, in turn, stimulates NO production (224,225).

Oxygen could also increase plasma and red blood cell ATP, which releases NO from endothelial cells and is a potent fetal pulmonary vasodilator (226). It is known that the release of NO from cultured human vascular endothelial cells is stimulated by ATP and that the inhibition of NOS by N-nitro-L-arginine attenuates the vasodilation caused by ATP and its metabolites in the fetal circulation. Konduri and associates (227) suggested that an increase in oxidative phosphorylation and a release of ATP can also mediate the endothelium-dependent pulmonary vasodilation that occurs in response to oxygen exposure.

Other studies show that NO release and pulmonary vasorelaxation can also be mediated by endothelial α₂-adrenoreceptors activation (228,229,230). Magnenant and associates suggested that α₂-adrenoreceptors are

involved in the control of basal pulmonary vascular tone and in the pulmonary vasodilator effect of norepinephrine during fetal life through activation of the NO-dependent pulmonary vasodilation (231).

Recent studies also support the hypothesis that hypoxia causes ET_A-mediated inhibition of a K⁺ channels, which leads to vessel depolarization and calcium influx, resulting in vasoconstriction (232,233,234,235). Goirand and associates (236) showed that ET_A receptor blockade opposes hypoxic pulmonary vasoconstriction in the rat isolated perfused lung through the suppression of the inhibition of K⁺ channels by endogenous ET-1. Thus, the increase in oxygen, together with the perinatal decrease in ET_A receptor message, probably contributes also to decreased hypoxic pulmonary vasoconstriction observed at birth.

Increased Shear Stress

Partial or complete compression of the ductus arteriosus *in utero* increases pulmonary blood flow and causes a progressive fall in pulmonary vascular resistance in response to flow- or shear stress-induced pulmonary vasodilation (237,238). The initial increase in pulmonary blood flow that occurs with lung expansion and oxygenation at birth raises shear stress in the pulmonary vascular endothelium, causing further pulmonary vasodilation (239). This blood flow-dependent pulmonary vasodilation is mainly caused by nitric oxide, which is produced by an increase in shear stress of vascular endothelium (240,241,242). The released of NO from arterial and venous endothelial cells contributes to the maintenance of the physiologically low basal pulmonary vascular tone. Stepwise elevations in flow

P.298

increased exhaled NO and nonselective inhibition of NOS completely blocks the shear stress-induced pulmonary vasodilation (240,242). This NO shear stress-induced vasodilation is mediated by activation of both voltage- and Ca²⁺-dependent K⁺ channels (241,242,243,244). Ralevic and associates (245) showed that vascular endothelial cells also release ATP when they are exposed to shear stress. Inhibition of receptors for ATP attenuates the pulmonary vasodilation that occurs in response to stepwise increases in flow (246).

Loss of the Placental Circulation and Closure of the Fetal Shunts

At birth, the umbilical circulation is abolished as the vascular smooth muscle of the umbilical cord go into spasm in response to the abrupt longitudinal stretching and the increased oxygenation (247). The removal of the low-resistance bed of the placenta produces much of the increase in systemic vascular resistance at birth. Without umbilical venous flow, the ductus venosus receives little blood flow and a passive, as well as active, constriction begins. Complete closure of the ductus venosus usually occurs by the end of the first week of life. The reasons for closure of the foramen ovale after birth are twofold. First, the occlusion of the umbilical cord decreases the volume of blood flowing up the inferior vena cava decreasing the right-left atrial pressure difference. Second, the increase in pulmonary venous return to the left atrium in response to the marked increase in pulmonary blood flow increases left atrial pressure. The reverse pressure difference across the foramen ovale pushes the foramen ovale flap against the atrial septum, closing the shunt. The foramen ovale remains patent, with no flow through it for weeks or months. The closure of the third fetal shunt, the ductus arteriosus, depends predominantly on the net balance between vasodilators, mainly oxygen, prostaglandins, and other vasoactive substances (248,249). Increased oxygen tension is known to be a potent stimulant of ductal smooth muscle constriction after birth (249). Prostaglandins, mainly PGE₂, are major mediators of ductal relaxation pre- and postnatally. The rapid fall in circulating prostaglandins at birth, caused by increased lung metabolism (from increased pulmonary blood flow) and the loss of placental prostaglandins, facilitates the constrictive effects of oxygen on the ductal tissue. Although functional closure of the ductus arteriosus occurs in the first 72 hours of life (250), permanent or anatomical closure takes several days and weeks and is achieved by endothelial destruction, subintimal proliferation, and connective-tissue formation (251). When the ductus arteriosus fails to close or reopens in the first days of life, as is frequently observed in small preterm infants, a significant left-to-right shunt may occur. The incidence of reopening is inversely related to birth weight. The closure of the patent ductus arteriosus effectively separates the pulmonary and systemic circulations and establishes the normal postnatal circulatory pattern.

CONCLUSION

The transition from fetal to neonatal life represents one of the most dynamic and difficult periods in human life

cycle. Dramatic neurohormonal, metabolic, and cardiorespiratory adjustments must occur over hours to days around the time of delivery to insure the smooth and successful transition to extrauterine life. These changes are invoked by a variety of processes, including perinatal surges in hormones, labor, delivery, gaseous ventilation and oxygenation of the lungs, cord occlusion, and decrease in environmental temperature. Intensive research over the last century has significantly improved our understanding of the normal development of the cardiorespiratory system that allows the fetus to rapidly and efficiently adapt to air breathing at birth. This transitional period is characterized by removal of the lung liquid volume from the alveolar spaces and by the secretion of surfactant material into the acinus for satisfactory physical expansion of the lungs after the initial postnatal breaths. To maintain adequate ventilation and oxygenation the newborn infant must also switch from intermittent fetal breathing to continuous breathing at birth, a process that it is still not completely understood. The switch from placental to pulmonary gas exchange also requires the elimination of the fetal shunts and a rapid and sustained decrease in pulmonary vascular resistance to allow a significant increase in pulmonary blood flow. Thus, the circulation changes from one characterized by a relatively low combined ventricular output, right ventricular dominance, and pulmonary vasoconstriction, to a circulation in series with a high cardiac output equally divided between the two ventricles, and a greatly dilated pulmonary vascular bed. Many factors can disrupt this physiologic process causing significant morbidity and mortality.

Chapter 18

Delivery Room Management

Virender K. Rehan

Roderic H. Phibbs

Although more than 90% of neonates undergo smooth fetoneonatal transition, of the 10% who require some resuscitative assistance during delivery, a small minority requires extensive resuscitative efforts (1,2). More importantly, because the need for resuscitation can come as a complete surprise, at every delivery there should be at least one person whose primary responsibility is the management of the newly born and who is capable of initiating resuscitation. Either this person or someone else who is immediately available should be skilled in all aspects of neonatal resuscitation. However, if the need for resuscitation is anticipated, additional skilled personnel should be called on before delivery. Furthermore, because many high-risk deliveries occur in nonteaching and smaller hospitals, all personnel involved in delivery room care of the newborn should be trained adequately in all aspects of neonatal resuscitation. All necessary resuscitation equipment should be checked and in working order before each delivery.

There is a high risk of asphyxia, defined as a combination of hypoxemia, hypercapnia, and acidosis, during labor, delivery, and in the first minutes after birth. This is because the newborn infant must successfully inflate his or her lungs and make adaptations to the circulation immediately after birth. Failure of either to occur leads to asphyxia. The key changes during fetoneonatal transition are the establishment of effective ventilation and perfusion of the lungs to raise partial pressure of arterial oxygen (PaO_2) from the normal low levels of the fetus to the normal, relatively higher level of the neonate, together with the shutting down of the fetal circulatory pathways, which include the right-to-left shunts through the foramen ovale and the ductus arteriosus. Skillful resuscitation of infants with impaired transition can prevent brain damage and minimize subsequent morbidity and mortality. An understanding of the physiologic changes in the respiratory and circulatory systems that occur normally as the newborn infant adapts to extrauterine life is essential for a rational and effective approach to resuscitation.

RESPIRATORY ADAPTATION

At birth, the lungs must transition rapidly to become the site for gas exchange or else hypoxia and cyanosis (see Color Plate) will rapidly develop. For the lungs to exchange gas adequately after birth, the airways and the alveoli must be cleared of fetal lung fluid, and an increase in pulmonary blood flow must occur. *In utero*, fetal pulmonary vascular resistance is high and the fetal systemic vascular resistance is low; most of the cardiac output is shunted away from the lungs and is directed to the placenta where fetoplacental gas exchange occurs. Within minutes of delivery, the newborn's pulmonary vascular resistance may decrease eight- to tenfold, causing a corresponding increase in neonatal pulmonary blood flow. Effective transition requires that the lung fluid be expelled or quickly absorbed to allow effective gas exchange. In fact, the decrease in lung fluid begins during labor (3). As a consequence of increased catecholamine levels, during labor, there is also an increase in lymphatic drainage. The absence of these physiologic events accounts for the increased incidence of transient tachypnea of the newborn after a cesarean section without labor. The first breath must generate a high transpulmonary pressure to overcome the viscosity of the lung fluid and the intraalveolar surface tension. It also helps to drive the alveolar fluid across the alveolar epithelium. Lung expansion and aeration also stimulate surfactant release with the resultant establishment of an air-fluid interface and development of functional residual capacity

(FRC) (4). Normally, 80% to 90% of FRC is established within the first hour of birth in the term neonate with spontaneous respirations.

CIRCULATORY ADAPTATION

At birth, the clamping of the umbilical cord increases the systemic vascular resistance with a resultant increase in left ventricular and aortic pressures. Lung aeration and subsequent

P.305

gas exchange result in increased PaO₂ and pH, which result in pulmonary vasodilation. These physiologic changes increase flow of blood to the left atrium via the pulmonary veins, so that left atrial pressure exceeds right atrial pressure, resulting in functional closure of foramen ovale. When pulmonary vascular resistance decreases to a level lower than the systemic vascular resistance, the ductus arteriosus closes functionally. As a result of the cessation of umbilical venous return, clamping of the umbilical cord also leads to the closure of the ductus venosus.

Asphyxia has the potential to set in motion a series of responses that can not only impair the normal fetoneonatal transition, but may, in fact, reverse this process and lead to the persistence of the fetal circulatory state. Hypoxia keeps the ductus arteriosus open and causes pulmonary vasoconstriction leading to right-to-left flow across the ductus. Tissue hypoxia causes metabolic acidosis worsening the pulmonary vasoconstriction. The pulmonary hypertension leads to tricuspid insufficiency, raising right atrial pressure, which leads to right-to-left shunting of blood through the foramen ovale, causing further tissue hypoxia. However, in the majority of instances, with timely and appropriate resuscitation, the changes leading to a persistent fetal circulation like state can be reversed quickly.

PATHOPHYSIOLOGY OF INTRAPARTUM ASPHYXIA AND RESUSCITATION

Asphyxia occurs when the organ of gas exchange fails. When this happens, arterial carbon dioxide partial pressure (PaCO₂) rises, and PaO₂ and pH fall. Despite the low PaO₂, tissues continue to consume O₂, although at a lower rate in some organs. When the PaO₂ is very low, anaerobic metabolism sets in, producing large quantities of metabolic acids. These are buffered partly by the bicarbonate in the blood (5).

The human infant is particularly vulnerable to asphyxia in the perinatal period. During normal labor, transient hypoxemia occurs with uterine contractions, but the healthy fetus tolerates this well. There are five basic events that lead to asphyxia during labor and delivery:

- Interruption of umbilical blood flow (e.g., cord compression);
- Failure of gas exchange across the placenta (e.g., placental abruption);
- Inadequate perfusion of the maternal side of the placenta (e.g., severe maternal hypotension);
- An otherwise compromised fetus who cannot further tolerate the transient, intermittent hypoxia of normal labor (e.g., the anemic or growth-retarded fetus); and

Failure to inflate the lungs and complete the changes in ventilation and lung perfusion that must occur at birth. This failure may occur because of airway obstruction, excessive fluid in the lungs, or weak respiratory effort. Alternatively, it may occur as a result of fetal asphyxia from one of the other four events, because fetal asphyxia often results in an infant who is acidotic and apneic at birth.

The umbilical cord blood pH, partial pressure of oxygen (PO_2), partial pressure of carbon dioxide (PCO_2), and calculated base excess are standard measures of fetal asphyxia (6,7,8). With fetal acidosis, the pH can vary over a wide range. Consequently, it is important to remember that pH is a logarithmic function of hydrogen ion concentration. A decrease of 0.3 pH units from 7.40 to 7.10 indicates only a 40 nmol/L increase in hydrogen ion (i.e., from 40 to 80 nmol), whereas a 0.3 decrease from 7.10 to 6.80 indicates an increase of 80 nmol/L (i.e., from 80 to 160 nmol). The gradient in blood gas tensions between umbilical artery and vein gives some indication of placental perfusion at the time of birth. The slower the flow of fetal blood through the placenta, the more complete the equilibration of gas tensions between fetal and maternal blood. For example, an arterial PO_2 of 25 mm Hg with a venous PO_2 of 32 mm Hg suggests good placental blood flow. An arterial PO_2 of 12 mm Hg with a venous PO_2 of 45 mm Hg suggests very slow flow. Metabolic acidosis suggests asphyxia, although some of the increased lactic acid in the blood may be a result of reduced uptake of lactate by the asphyxiated liver rather than increased lactate production from anaerobic metabolism (6,9). If asphyxia occurred just before birth, there may be lactic acid in the tissues that has not yet reached the central circulation. This will be detected only by blood gas measurements a few minutes after birth. If the fetus was asphyxiated an hour before delivery and recovered, that event may not be reflected in the umbilical cord blood gases at birth. Other indicators of asphyxia include plasma hypoxanthine, which increases because of lack of aerobic metabolism, plasma erythropoietin, which increases in response to fetal hypoxia, increased plasma levels of several lipid mediators, such as platelet-activating factor, and increased cerebrospinal fluid levels of several proinflammatory cytokines such as interleukin (IL)-1 β , IL-6, and IL-8 (10,11,12).

Asphyxia in the fetus or newborn infant (including a preterm infant) is a progressive and reversible process. The speed and extent of progression are highly variable. Sudden, severe asphyxia can be lethal in less than 10 minutes. Mild asphyxia may progressively worsen over 30 minutes or more. Repeated episodes of brief, mild asphyxia may reverse spontaneously but produce a cumulative effect of progressive asphyxia. In the early stages, asphyxia usually reverses spontaneously if its cause is removed. Once asphyxia is severe, spontaneous reversal is unlikely because of the circulatory and neurologic changes that accompany it. Other sources provide a more detailed review of these phenomena (13,14).

Figure 18-1 schematically represents the sequence of pathophysiologic changes that accompany asphyxia. Although there are some quantitative differences between the changes that occur in the fetus and those in the newborn infant, the scheme generally applies to both. It is useful to consider the changes in both fetus and newborn infant together, because many cases of neonatal asphyxia

P.306

begin in the fetus and continue after birth. Cardiac output is maintained early in asphyxia, but its distribution changes radically. Selective regional vasoconstriction reduces blood flow to less vital organs and tissues such as gut, kidneys, muscle, and skin (15). Blood flow to the brain and myocardium increases, thereby maintaining adequate oxygen delivery despite reduced oxygen content of the arterial blood. Other organs and tissues must depend on increased oxygen extraction to maintain oxygen consumption (16,17). Pulmonary blood flow is low in the fetus. It is

decreased further by hypoxia and acidosis (18). As a consequence of these adaptations, fetal oxygen consumption decreases (19).

Early in asphyxia, newborns make vigorous attempts to inflate their lungs. If successful, the lungs become adequately ventilated and perfused, but the mere presence of gasping does not ensure that this will happen. As asphyxia becomes more severe, the respiratory center is depressed, and the chances of an infant spontaneously establishing effective ventilation and pulmonary perfusion diminish.

If asphyxia progresses to the severe stage, oxygen delivery to the brain and heart decreases. The myocardium then uses its stored reserve of glycogen for energy. Eventually, the glycogen reserve is consumed and the myocardium is exposed simultaneously to progressively lower values of PO_2 and pH. The combined effects of hypoxia and acidosis lead to decreased myocardial function and decreased blood flow to the vital organs (20,21). Brain injury begins late during this phase (13,14).

This sequence of cardiovascular events is manifested by changes in heart rate and aortic and

central venous pressures (see Fig. 18-1), all of which are measured easily in the newborn immediately after birth. The early bradycardia and hypertension are caused by the reflexes that shunt blood away from nonvital organs. Early in asphyxia, central venous (i.e., right atrial) pressure may rise slightly, owing to pulmonary hypertension and constriction of systemic capacitance vessels. As the myocardium fails, central venous pressure rises further, aortic pressure decreases, and heart rate is reduced further.

The initial adaptations of the systemic circulation to asphyxia are mediated by various physiologic reflexes (22). There also are major hormonal responses to asphyxia, including elevations in plasma corticotrophin, glucocorticoids, catecholamines, arginine vasopressin, renin, and atrial natriuretic factor, and a decrease in insulin (23,24). Some of these are important in maintaining the circulatory adaptations to asphyxia. Catecholamines, which come mainly from the adrenal medulla, maintain myocardial function in the presence of asphyxia, thereby increasing survival (25,26). Arginine vasopressin helps maintain the hypertension, bradycardia, and redistribution of systemic flow (27). Increased hepatic glycogenolysis helps maintain plasma glucose concentrations (9).

The physiology of resuscitation is essentially a reversal of the pathophysiology of asphyxia. In Fig. 18-1, which illustrates both processes, asphyxia proceeds from left to right, and resuscitation from right to left. It is crucial to determine where the infant is in this sequence of pathophysiologic events when resuscitation is started. If asphyxia has proceeded to myocardial failure, resuscitation must include restoration of cardiac output as well as establishment of effective ventilation and perfusion of the lungs. Generally, myocardial failure does not occur until both pH and PaO₂ are extremely low, approximately 6.9 and 20 mm Hg, respectively. Cardiac output is reestablished through rapid correction of the severe hypoxia and acidosis. Until this is done, output must be maintained by cardiac massage. As soon as pH is raised to approximately 7.1 and PaO₂ to 50 mm Hg, the myocardium responds rapidly, heart rate rises, aortic pressures rise, and pulse pressure widens, whereas central venous pressure falls. These changes indicate that cardiac massage can be stopped. At this point, the infant may be hypertensive because the vasoconstriction in nonvital organs is still present. This vasoconstriction is relieved only by continued adequate oxygenation and correction of acidosis. Pressures then will fall toward normal. The vasoconstriction also is manifested by intense pallor of the skin. As the vasoconstriction is relieved, the skin becomes pink and well perfused, with rapid capillary refilling (i.e., less than 2 seconds) when blanched by pressure. As peripheral flow improves, lactic

P.307

acid sequestered in these tissues enters the central circulation and a large base deficit, which may have been corrected earlier, now reappears.

If asphyxia is only moderately severe, resuscitation begins in the middle of the sequence depicted in Fig. 18-1. There is hypertension, indicating that the myocardium has not yet failed. Effective ventilation of the lungs with a high oxygen concentration may correct acidosis by lowering the PaCO₂, oxygenating the blood, and adequately dilating the pulmonary vascular bed. If significant acidosis persists after alleviation of the hypercarbia, alkali might be needed to correct the metabolic component of the acidosis, relieve pulmonary vasoconstriction, and establish good pulmonary perfusion. Generally, raising pH to 7.25 is sufficient for this purpose, but there are some important exceptions (discussed below) in which a higher pH is needed to dilate the pulmonary vascular bed.

When the effects of asphyxia are alleviated, spontaneous respiratory efforts return. The duration between the onset of resuscitation and reappearance of spontaneous respiratory efforts is directly proportional to the amount of brain injury that has occurred (13).

Onset of spontaneous respiratory efforts is not necessarily an indication to withdraw assisted

ventilation. Often, there is residual atelectasis and the infant does not have strong, regular respiratory efforts. PaCO₂ may be normal, and PaO₂ may rise to a high level with assisted ventilation. But when assisted ventilation is withdrawn, effective ventilation may decrease and the whole process of asphyxia recurs. Therefore, assisted ventilation and supplemental oxygen should be only gradually withdrawn.

The blood volume of the asphyxiated infant may be abnormal. Asphyxia during labor usually shifts blood from the placenta to the fetus. There are certain situations, however, in which the infant's blood volume may be reduced. The most obvious of these is hemorrhage from the fetoplacental unit, which is manifested by vaginal bleeding. Three other conditions that shift blood volume from the fetus to the placenta are compression of the umbilical cord, in which umbilical venous flow is reduced selectively more than arterial flow; severe hypotension in the mother; and asphyxia occurring only at the end of labor (28).

Initially, it may be difficult to determine whether or not blood volume is adequate in the asphyxiated newborn. There are two reasons for this. First, many of the circulatory responses to asphyxia are similar to those associated with loss of blood volume. Either asphyxia or hypovolemia may cause bradycardia, metabolic acidosis, poor peripheral perfusion indicated by pallor and slow capillary filling, and a large difference between core and skin temperature. A low aortic pressure could be a result of either the end stage of asphyxia or to shock. Only changes in central venous pressure are in the opposite direction, and even here the coexistence of the two processes can have offsetting effects. Second, the circulatory changes during asphyxia and resuscitation may determine the adequacy or inadequacy of the circulating blood volume. If an infant is moderately asphyxiated and has systemic and pulmonary vasoconstriction (see Fig. 18-1, *center*) and a small blood volume, aortic and central venous pressures will be nearly normal. Administration of a blood volume expander at this point would only overload the circulation. The effects of volume expansion would be even worse if the asphyxia were more severe and myocardial failure were present. Correction of asphyxia (see Fig. 18-1, going from right to left) relieves the vasoconstriction of resistance and capacitance vessels, and the small blood volume now becomes inadequate to support the circulation. Reperfusion of asphyxic and ischemic tissues also increases loss of intravascular water from these capillary beds, leading to edema and reduced plasma volume.

During recovery from asphyxia, several metabolic abnormalities appear. There may be hypoglycemia caused by depletion of carbohydrate reserves during the asphyxia. Hypoglycemia must be prevented because it can cause myocardial failure in a heart recently subjected to asphyxia (29). Hyperglycemia caused by excessive glucose administration similarly is dangerous during asphyxia because it worsens the acidosis by increasing lactic acid production (30). Hypocalcemia also develops, possibly as a result of increased calcitonin release during asphyxia (31), and can lead to myocardial failure.

Hyperkalemia occurs during asphyxia, when, in the process of buffering acidosis, H⁺ enters the erythrocytes and K⁺ is displaced from them. Although this increases plasma K⁺ while the patient is asphyxiated, total body K⁺ decreases as some of the K⁺ is excreted by the kidney. On relief of asphyxia, the buffering processes are reversed and K⁺ leaves the plasma and reenters the erythrocytes, leading to hypokalemia.

HIGH-RISK PREGNANCIES

Certain situations during pregnancy, labor, or delivery carry an increased risk of intrapartum asphyxia. If these high-risk deliveries are identified before birth, their progress during labor and delivery should be closely monitored and resuscitation can be initiated at birth. Tables 18-1 and 18-2 list some of the factors that alert the physician to a high-risk delivery. Optimal management of these cases requires good communication between the obstetrician, anesthesiologist, and

RESUSCITATION OF THE ASPHYXIATED INFANT

If a severely asphyxiated infant is expected, a resuscitation team must be present at delivery. In the majority of instances, good communication between the obstetrician and pediatrician will provide timely notice of the impending delivery of an asphyxiated infant. The actual extent of resuscitation needed can be determined only after someone with considerable clinical experience evaluates the infant's condition. It is helpful to assign the responsibility of each member of the resuscitation team before delivery.

P.308

The following is an example of outlining the responsibilities of each member of the resuscitation team.

TABLE 18-1 SOME FACTORS THAT PLACE THE NEWBORN AT HIGH RISK FOR ASPHYXIA		
Maternal Conditions	Labor and Delivery Conditions	Fetal Conditions
Diabetes mellitus	Forceps delivery other than low-elective or vacuum-extraction delivery	Premature delivery Postmature delivery
Preeclampsia, hypertension, chronic renal disease	Breech or other abnormal presentation and delivery	Acidosis determined by fetal scalp capillary blood
Anemia (i.e., hemoglobin <10 g/dL)	Cephalopelvic disproportion: shoulder dystocia, prolonged second stage	Abnormal heart rate pattern or dysrhythmia
Blood type or group alloimmunization	Cesarean section	Meconium-stained amniotic fluid
Abruptio placentae, placenta previa, or other antepartum hemorrhage	Prolapsed umbilical cord	Oligohydramnios Polyhydramnios
Narcotic, barbiturate, tranquilizer, psychedelic drug use or alcohol intoxication	Cord compression (e.g., nuchal cord, cord knot, compression by aftercoming head in breech delivery)	Decreased rate of growth: uterine size or fetal size determined by ultrasonography
History of previous perinatal loss	Maternal hypotension or hemorrhage	Macrosomia Immaturity of pulmonary surfactant system
Prolonged rupture of membranes		Fetal malformations determined by sonography
Lupus		Hydrops fetalis
Maternal heart disease		Low biophysical profile
Maternal fever or other evidence of amnionitis		
Abnormal umbilical artery Doppler velocity		Multiple birth; in particular, discordant, stuck, or monamniotic

Member A:

- Assess infant.
- Manage airway and intubate the trachea, if needed.
- Provide positive-pressure ventilation.
- Secure endotracheal tube (ET).

Member B:

- Listen for heart rate and, if needed, give cardiac massage.
- Auscultate chest to be sure ET is in proper position and gas exchange is good.
- Catheterize umbilical vessel or vessels and maintain patency of catheters.
- Measure intravascular pressures, assess perfusion, sample blood for pH, PO₂, and PCO₂, and draw blood cultures.
- Administer fluids and drugs.
- Continue assessment of infant.

TABLE 18-2 FETAL HEART RATE PATTERNS ASSOCIATED WITH FETAL AND NEONATAL DISTRESS	
Heart Rate Pattern	Fetal or Neonatal Problems
Severe (i.e., <80 beats/min), sustained bradycardia, with loss of variability	Fetal hemorrhage, fetal asphyxia
Sustained tachycardia, uncomplicated by other abnormal patterns	Infection, often with apnea
Late decelerations with loss of variability	Asphyxia
Severe, recurrent variable decelerations, with loss of variability	Asphyxia and possible hypovolemia
Sinusoidal	Severe anemia with asphyxia

Member C:

-

Blot baby dry; apply electrocardiograph (ECG) monitor leads, radiant monitor servocontrol, and transcutaneous oxygen sensor.

- Keep timed, written record of resuscitation and vital signs and assign the Apgar scores at 1 and 5 minutes and every 5 minutes thereafter until the score is 7 or greater; time and record the rate and volume of infusions such as alkali and blood volume expanders.
- Assist member A by providing ET suction, adjusting the fraction of oxygen inspired (FiO_2), and helping to secure ET.
- Help member B by providing medications and blood volume expanders in sterile syringes; B is working in a sterile field early in resuscitation.
- Monitor baby's temperature and capillary blood glucose.

Resuscitation Equipment and Supplies for Optimal Resuscitation (Modified from Reference 1)

All resuscitation equipment (listed below) should be checked before each delivery and should be fully operational.

- Resuscitation table with heat source
- Suction equipment
- Bulb syringe
- Mechanical suction and tubing
- Suction catheters: 5 Fr, 6 Fr, 8 Fr, 10 Fr, and 12 Fr
- 8 Fr feeding tube and 20 mL syringe
- Meconium aspirator
- Bag and mask equipment
- Neonatal resuscitation bag with a pressure-release valve or pressure manometer (the bag must be capable of delivering 90% to 100% oxygen)
-

Face masks, newborn and premature sizes (cushioned-rim masks preferred)

- Oxygen source with flowmeter (flow rate up to 10 L/min) and tubing
- Intubation equipment
- Laryngoscope with straight blades: No. 00 (very-low-birth-weight infant); No. 0 (preterm infant); and No. 1 (term infant)
- Endotracheal tubes, 2.5-, 3.0-, 3.5-, 4.0-mm internal diameter (ID)
- Stylet (optional)
- Scissors
- Tape or securing device for ET
- Alcohol sponges
- CO₂ detector (optional)
- Laryngeal mask airway (optional)
- Medications
- Epinephrine 1:10,000 (0.1 mg/mL)-3-mL or 10-mL ampules
- Isotonic crystalloid (normal saline or Ringer lactate) for volume expansion: 100 or 250 mL
- Sodium bicarbonate 4.2% (5 mEq/10 mL)-10-mL ampules
- Naloxone hydrochloride 0.4 mg/mL-1-mL ampules or 1.0 mg/mL-2-mL ampules
- Dextrose 10%, 250 mL
- Normal saline for flushes
- Feeding tube, 5 Fr (optional)
- Umbilical vessel catheterization supplies

- Sterile gloves
- Scalpel or scissors
- Povidone-iodine solution
- Umbilical tape
- Umbilical catheters, 3.5 Fr, 5 Fr
- Three-way stopcock
- Syringes: 1, 3, 5, 10, 20, and 50 mL
- Needles: 25, 21, and 18 gauge, or puncture device for needleless system
- Miscellaneous
- Gloves and appropriate personal protection
- Radiant warmer or other heat source
- Firm, padded resuscitation surface
- Clock (timer optional)
- Warmed linens
- Stethoscope (neonatal head preferred)
- Tape: ½ or ¾ inch
- Cardiac monitor and electrode or pulse oximeter and probe
- Oropharyngeal airways (0, 00, 000 sizes or 30-, 40-, and 50-mm lengths)
- Arterial and venous pressure monitor with waveform displays; transducers can be connected to the catheters beforehand so that aortic pressure is displayed as soon as the umbilical artery catheter is inserted, and the venous waveform can be used to localize the catheter tip in the thoracic inferior vena cava (32)

- Indirect blood pressure monitor
- Tube thoracostomy tray with instruments and catheters from 10 to 14 Fr
- Blood gas electrodes with a trained operator of the blood gas machines close enough to the resuscitation area so that results are available in less than 5 minutes

In selected situations (see the section "Special Problems"), it is useful to have present in the delivery room a unit of whole blood or packed erythrocytes that have been cross-matched against the mother; this blood can be kept in a cold pack and returned to the blood bank if not used.

Clinical Assessment of Severity of Asphyxia

The Apgar score was the first attempt at a systematic assessment of birth asphyxia (6,33). There is a loose correlation between low Apgar scores and umbilical cord blood gases. However, some infants with severe acidosis have normal Apgar scores, and some with normal blood gases and pH have very low scores (34,35). Maternal anesthetics, sedatives, maternal drugs, fetal sepsis, and central nervous system pathologic conditions can lower the Apgar score; extremely premature infants often have low scores without any other evidence of asphyxia (36,37). Regardless of the cause, an Apgar score that remains low calls for action. The clinical significance of the Apgar score increases with time. Scoring should continue every 5 minutes until the score increases to 7 or above. The length of time it takes to reach a score of 7 is a rough indication of severity of asphyxia. Umbilical cord blood gases, discussed previously, are useful measures of fetal asphyxia, but this information will not be available until a few minutes after birth, and resuscitation must be started before that. Thus, their main value is in guiding subsequent management of the infant.

It is important to point out that the term *perinatal asphyxia* should be used with caution because an inaccurate use of this term may have medicolegal ramifications. It should be reserved in the clinical context of damaging hypoxemia and metabolic acidosis. A neonate who suffers from hypoxemia proximate to delivery that is severe enough to result in hypoxic encephalopathy will show other evidence of hypoxic damage, including severe metabolic or mixed acidemia (pH <7.00) on an umbilical cord arterial sample; persistence of an Apgar score of 0 to 3 for longer than 5 minutes; neonatal neurologic sequelae, for example, seizures, coma, hypotonia; and evidence of multiorgan system dysfunction. However, because neonatal neurologic problems may be attributed to factors other

P.310

than those involving labor and delivery, the term *neonatal depression* should be used when cause is uncertain.

The following resuscitation approach is based mostly on the recommendations of the American Academy of Pediatrics and the American Heart Association for neonatal resuscitation (1). However, it must be pointed out that most of these recommendations are based on anecdotal experience and a review of the available literature, but have not been rigorously tested. It is expected that in the future some of these recommendations will undergo close scrutiny and possible change.

Initial Steps in Resuscitation

Initial assessment, performed within a few seconds of delivery, dictates the extent of resuscitation needed. Initial assessment includes determining whether or not the infant is breathing, if there is

good muscle tone, if the color is pink, and whether the infant looks term or preterm. If the infant is term, vigorous, without any known risk factors, and born through clear amniotic fluid, the infant need not be separated from the mother to receive initial care. Thermal care can be given by putting the infant on the mother's chest (direct skin-to-skin contact), drying the infant, and covering the infant with dry linen. If the infant is apneic, gasping, has decreased muscle tone, or is cyanotic, immediate resuscitation is needed. Place the infant under a radiant warmer; quickly towel dry the baby; open the airway by laying the infant in the sniffing position; suction the mouth first and then the nose; provide tactile stimulation (by gently slapping or flicking the soles of the feet or by gently rubbing the back); and, if necessary, give oxygen. In the majority of instances, with these initial steps, the infant will start breathing adequately and demonstrate a color change to pinkish. If the infant starts breathing adequately, but continues to have central cyanosis, provide free-flow 100% oxygen. However, if the infant does not start breathing adequately or has a heart rate of less than 100 beats per minute, positive pressure ventilation (PPV) should be instituted immediately. The entire process up to this point should not take more than 20 to 30 seconds.

Positive Pressure Ventilation

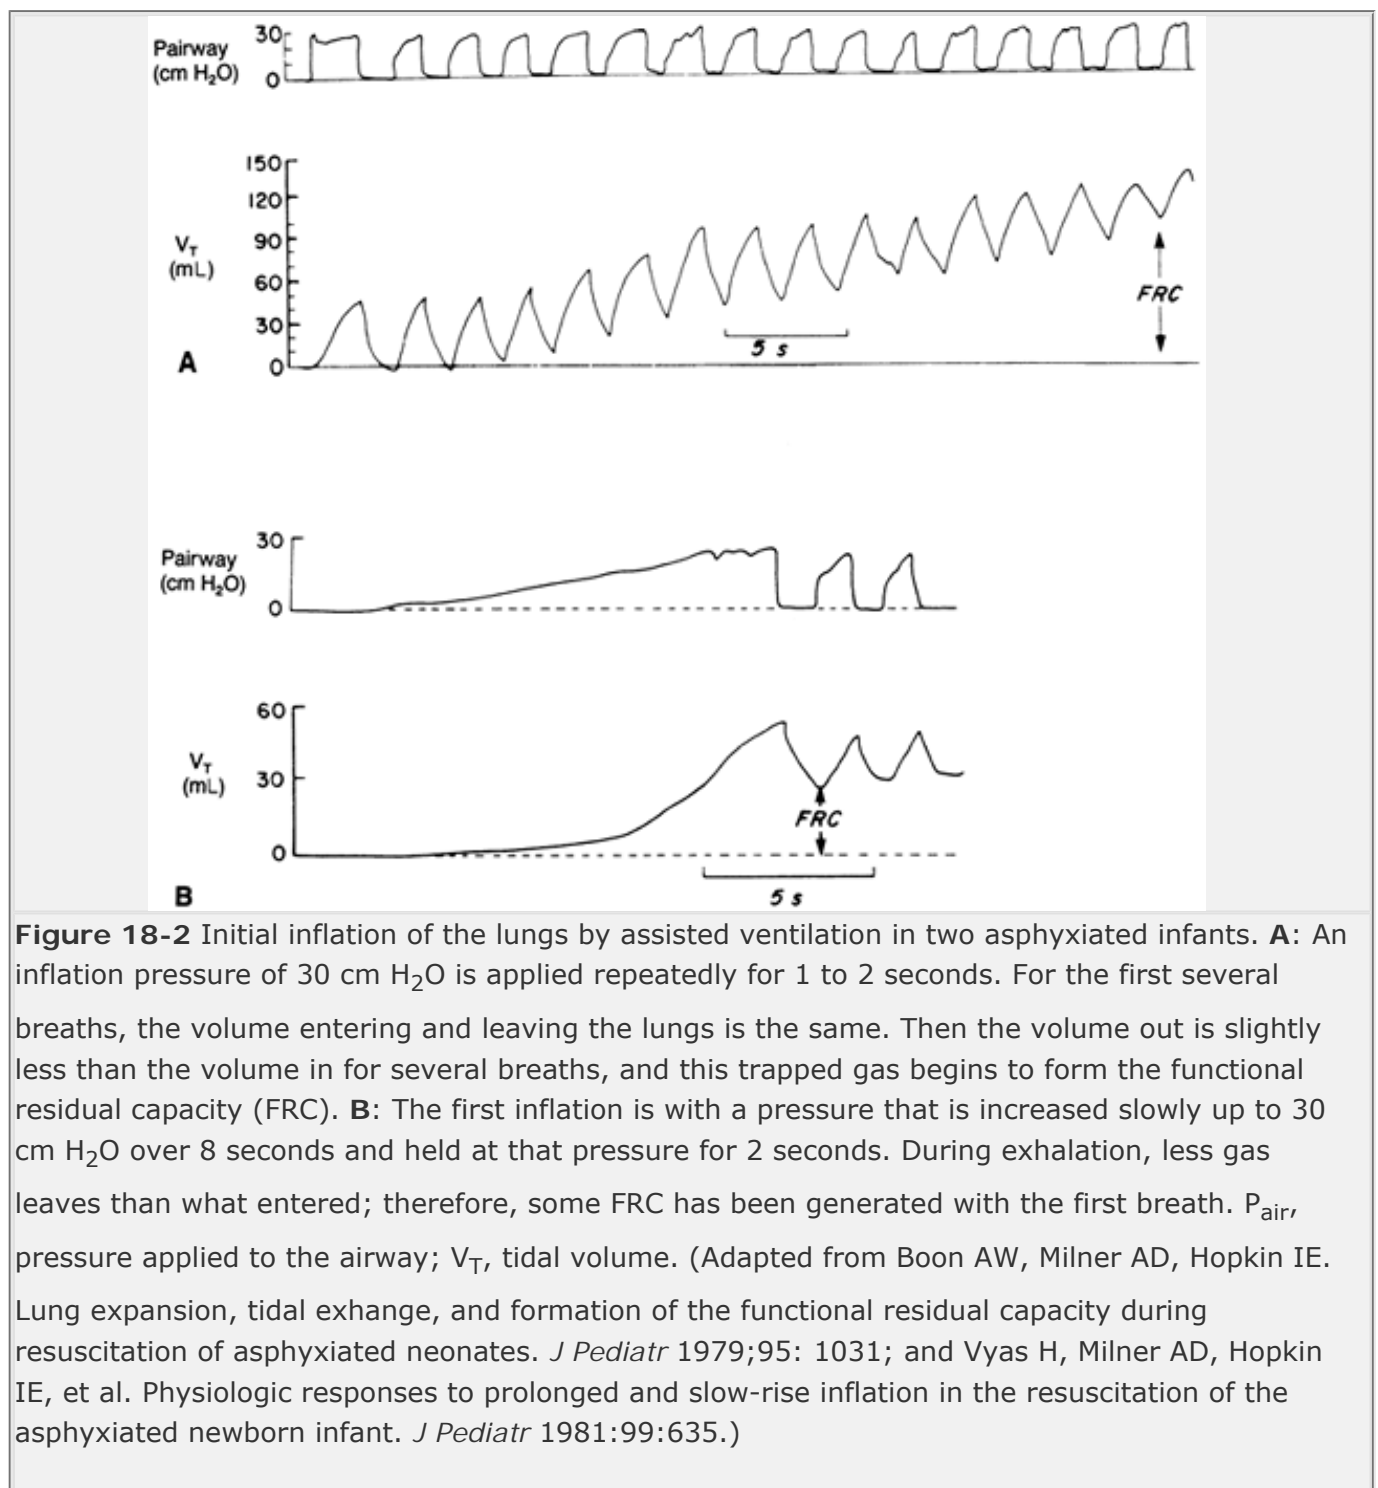

Ensuring adequate ventilation is the single most important step in the cardiopulmonary resuscitation of the compromised newborn infant (38). Indications for initiating PPV include (a) apnea or gasping breaths; (b) heart rate of less than 100 beats per minute (bpm); and (c) persistent central cyanosis despite the provision of free-flow 100% oxygen. Initial PPV can be provided by either a flow-inflating bag (also called an anesthesia bag) or a self-inflating bag. Each type has its own advantages and disadvantages, and the resuscitator should be familiar with the type of bag used in his or her institution. If PPV is needed for a term infant, provide bag-and-mask ventilation at a rate of 40 to 60 breaths per minute with initial pressures of as high as 30 to 40 cm H₂O. Subsequently, however, one should ventilate with the lowest pressures required to produce a gentle chest rise. Begin ventilation by slowly applying a pressure of 20 to 30 cm H₂O. Maintain this inflating pressure for 1 to 2 seconds, then ventilate at a rate of 40 to 60 breaths per minute, using an inflation time of 0.3 to 0.5 seconds and enough pressure to provide a visible rise of the upper portion of the chest. Repeat the application of the initial inflating pressure pattern three to four times over the first 2 minutes. These prolonged breaths inflate regions of the lungs that were gasless and create necessary FRC (39). Figure 18-2 illustrates this process. Care must be taken to avoid rapid inflation or overdistension of the lungs.

It is important to realize that infants respond to initial lung inflation by eliciting a variety of physiologic responses. The infant may respond by the "rejection response," in which the infant responds to PPV with a positive intraesophageal pressure to resist the inflation, that is, the infant actively resists attempts to inflate the lungs by generating an active exhalation. This response acts to not only reduce lung inflation, but also may cause high transient inflation pressures. Another response is "Head's paradoxical response" in which the neonate responds to PPV with an inspiratory effort, causing a negative intraesophageal pressure. This inspiratory effort, with the resultant negative pressure produces a fall in inflation pressures but results in a transient increase in tidal volume. Of course, the neonate may demonstrate no response to the inflation attempt, that is, not generating any change in intraesophageal pressure during the positive pressure inflation, and passive inflation subsequently results. It is important to recognize that these physiologic responses to positive pressure inflation in the delivery room may cause large variability in the tidal volume and intrapulmonary pressures, despite constant delivery of inflation pressure.

The very premature infant with a very small lung volume and a surfactant-deficient lung presents special problems for initial ventilation that are discussed later (see section "Special Problem"). Whether low tidal volume ventilation starting in the delivery room, in an attempt to avoid lung

injury and hypocapnia in premature infants, can be safely delivered, and whether it is as efficacious as normal tidal volume ventilation remains to be seen.

In the majority of instances, provision of appropriate PPV is followed by an increase in heart rate, improvement in color, and spontaneous breathing. Rate and pressures of PPV should be gradually reduced before deciding to see if the infant will tolerate its discontinuation. Free-flow oxygen may be continued as long as necessary to keep the infant pink. Some of the factors determining the success of PPV using a bag and mask include choosing the correct size mask, proper positioning of the infant, achieving tight seal between the face and the mask, and using adequate inspiratory pressure. If despite correct bag-and-mask PPV the infant fails to improve or continues to deteriorate, consider beginning chest compressions and bag-and-endotracheal-tube ventilation.

Chest Compressions

Chest compressions are infrequently needed during neonatal resuscitation. However, infants who have a heart rate of less than 60 bpm, despite 30 seconds of effective PPV, need immediate chest compressions (Fig. 18-3) Chest compressions can be provided by either the thumb technique or the two-finger technique, the thumb technique being preferred. Chest compressions are performed by placing thumbs or finger on the sternum immediately above the xiphoid and compressing at a rate of 90 per minute with an accompanying breath rate of 30 per minute (chest-compressions-to-ventilation ratio = 3:1). To provide effective chest compressions, one should ensure that the depth of compressions is one-third the depth of the chest, thumbs or fingers remain in contact with the chest at all times, the duration of the downward stroke of the compression is shorter than that of the release, compressions are well coordinated with ventilation, and there is adequate chest movement during ventilation. Continue chest compressions until the heart rate is greater than 60 bpm

P.312

and ventilate until heart rate is greater than 100 bpm, at which point the infant's own respiratory effort is assessed for adequacy. Ventilation can then be discontinued if heart rate remains above 100 bpm and the infant continues to breathe spontaneously. However, if the heart rate remains below 60 bpm despite effective chest compressions and ventilation, ET intubation (if it has not been already done) and administration of medications may be needed. However, it is important to realize that the most important reason for continued bradycardia during resuscitation is failure to establish effective postnatal ventilation rather than perinatal asphyxia. Therefore, it is important to make every effort to optimize ventilation before chest compressions and medication administration are considered.

Figure 18-3 Resuscitation and cardiac massage were performed on a 2.1-kg infant who was delivered by cesarean section because of signs of fetal asphyxia at 34 weeks of gestation. The infant was intubated and ventilated with 60% oxygen beginning 30 seconds after birth. An electrocardiogram was begun at 1 minute, and at 2.5 minutes an umbilical artery catheter connected to a pressure transducer and a recorder was passed into the descending aorta. Note persistent bradycardia despite assisted ventilation and low aortic pressure with narrow phasic pressure. Cardiac massage raised heart rate and pressure. When briefly discontinued after 1 minute, pressure and heart rate fell. After another minute of massage and assisted ventilation, good cardiac output had returned. This was manifested by a sustained higher heart rate and higher blood pressure with wider phasic pressure when massage was discontinued a second time 5 minutes after birth. By 8.5 minutes, the infant was still acidotic, but there was adequate oxygenation and aortic pressure continued to rise. PaCO₂, arterial carbon dioxide partial pressure; PaO₂, arterial oxygen partial pressure; SaO₂, saturation of arterial blood hemoglobin with oxygen.

Endotracheal Intubation

Endotracheal intubation is probably the most difficult step in neonatal resuscitation and the one that requires constant practice to maintain sharp skills in this technique. Someone experienced in endotracheal intubation should be available to assist at every delivery. Therefore, if the resuscitator is not comfortable with endotracheal intubation, he/she should focus on providing effective ventilation via bag and mask until somebody experienced in endotracheal intubation arrives. Indications for endotracheal intubation include (a) to suction meconium; (b) to improve ventilation when bag-and-mask ventilation is ineffective; (c) to coordinate ventilation and chest compressions; (d) to administer medications such as epinephrine; (e) when prolonged ventilation is needed, for example, extreme prematurity; (f) to administer surfactant; and (g) when congenital diaphragmatic hernia is suspected (probably the only absolute indication for endotracheal intubation).

The correct size laryngoscope blade is No. 1 for a term and No. 0 for a preterm infant. For a very-low-birth-weight (VLBW) infant, a size 00 blade may be used. The ET should be of uniform internal diameter as tubes with shoulders may obstruct the line of vision during insertion and are more likely to cause trauma to the vocal cords. The choice of ET is based on the infant's weight or gestational age: for infants weighing less than 1000 g (<28 weeks' gestational age), use a 2.5-mm internal diameter (ID) tube; for infants weighing 1000 to 2000 g (28 to 34 weeks' gestational age), use a 3.0-mm ID tube; for infants weighing 2000 to 3000 g (34 to 38 weeks' gestational age), use a 3.5-mm ID; and for larger infants, a 3.5- to 4.0-mm ID tube may be used. To minimize the risk of vocal cord trauma and the subsequent development of laryngeal stenosis, one should make sure that the inserted ET is not too tight a fit in the larynx. In general, gas should leak from the space between the ET and the trachea when 15 to 30 cm H₂O pressure is applied to the airway. Cutting the tube at the 13- to 15-cm mark prior to insertion makes it easier to handle during the procedure, decreases the chances of inserting the tube too far, and decreases the resistance to airflow. The use of a stylet during ET insertion is optional. If a stylet is used to stiffen the ET, it should be ensured that its tip is approximately 0.5 cm above from the tip of the tube and does not protrude from the end or the side hole of the ET. In addition, the stylet should be well secured so that it does not advance farther into the ET during intubation. If the stylet extends beyond the tip of the ET, it could traumatize the airway.

For intubation, stabilize the infant's head in the sniffing position, slide the laryngoscope into the mouth and advance it gently beyond the base of the tongue, lift the blade, and look for landmarks, suctioning if necessary. Once the vocal cords are visualized (as an inverted letter V [Λ] within the glottis), insert the ET gently until the vocal cord guide is at the level of the vocal cords. Application

of downward pressure on the cricoid may facilitate intubation. Preoxygenating the infant before attempting intubation, delivering free-flow oxygen during intubation, and limiting actual intubation attempts to no longer than approximately 20 seconds minimizes hypoxia associated with intubation. If intubation is unsuccessful in 20 seconds, ventilate the infant by bag and mask for at least 1 minute before again attempting intubation. Other complications of intubation include apnea and bradycardia; contusion or laceration of the tongue, gums, or airway; perforation of the trachea or esophagus; infection; and pneumothorax. With all these complications possible, intubate gently.

If the ET is inserted to aspirate meconium, immediately connect a meconium aspirator and apply suction as the tube is gradually withdrawn. Repeat the procedure as necessary until little additional meconium is suctioned or until the infant's heart rate indicates that PPV is required. If the ET is inserted to ventilate the infant, after insertion, immediately ensure that the ET is in the trachea by observing the chest rise with each breath, listening for good breath sounds with each breath, the absence of breath sounds over the stomach, and observing vapor condensation on the inside of the tube during exhalation. If there is still any doubt whether the tube is in the esophagus or trachea, a color change on a CO₂ detector attached to the ET may be helpful. However, be aware that extremely premature infants and infants with very poor cardiac output may exhale insufficient CO₂ to be detected reliably by CO₂ detectors. Correct placement of the ET within the trachea is guided by the lip-to-tip distance in centimeters (6 + the infant's body weight in kilograms), which places the ET tip midway between the vocal cords and the carina. Correct placement is further suggested by listening to equal air entry on both sides of chest, in the axillae. If the breath sounds are louder on the right side of chest, the ET is likely to be in the right main stem bronchus and should be slowly pulled back until equal breath sounds are heard over both sides of chest before it is taped in place. If the ET is to be left in place beyond initial resuscitation, final confirmation of appropriate placement should be made through a chest radiograph.

Medications

More than 99% of infants requiring resuscitation improve with timely and skillful implementation of initial steps of

P.313

resuscitation and establishment of effective ventilation. Only a small fraction of infants require medications during resuscitation (2). Each delivery area should have a chart displaying the appropriate dosages and concentrations of all medications used in neonatal resuscitation. All medications needed for resuscitation can be administered via the ET or via an umbilical venous or an arterial catheter.

Epinephrine is usually the first drug administered during resuscitation. It is indicated when the heart rate remains less than 60 bpm after 30 seconds of adequate PPV and another 30 seconds of chest compressions and PPV. It is administered either via an ET or umbilical vein (40). Administration via the umbilical route is probably more effective, but is often delayed because of the time required to establish an umbilical venous access. Therefore, during neonatal resuscitation, administration via an ET is generally the most rapidly accessible and practical route for epinephrine administration. The recommended dose is 0.1 to 0.3 mL/kg of a 1:10,000 solution, given rapidly. In addition to its β_1 effect on the heart, it also has a peripheral α_1 effect that results in peripheral vasoconstriction and increased blood flow to the heart and brain. The heart rate should increase promptly after epinephrine has been administered; if it does not, epinephrine can be repeated every 3 to 5 minutes. Epinephrine should not be given before establishing adequate ventilation, because in the absence of available oxygen it may cause myocardial damage by increasing the workload and oxygen consumption of the heart muscle. One area of controversy is the use of high-

dose epinephrine during neonatal resuscitation. Because of the theoretical risks of higher doses coupled with lack of any human data proving its added advantage, higher doses are not currently recommended for neonatal resuscitation.

If the infant looks pale and there is evidence of blood loss, administration of a volume expander is indicated. Although it is most commonly given through the umbilical vein, the intraosseous route can be used (41). The recommended solution for treating hypovolemia during neonatal resuscitation is an isotonic crystalloid solution (normal saline or Ringer lactate at 10 mL/kg). Whether albumin can be given safely in this situation, and whether it is as effective as normal saline is not known. O-negative blood crossmatched with the mother's blood (if available) can be transfused. This should be prepared before delivery if low fetal blood volume is suspected antenatally. A volume expander can be repeated if the infant shows minimum improvement after the first dose and evidence of hypovolemia persists (persistent pallor despite adequate oxygenation, weak pulses, and poor response to adequate resuscitation). Although hypovolemia should be corrected fairly quickly, there is concern that too rapid infusion of the volume expander may result in intracranial hemorrhage, especially in the preterm infant. Therefore, each infusion should be given over 5 to 10 minutes.

The use of sodium bicarbonate (NaHCO_3) during resuscitation is controversial. The current recommendation is to use NaHCO_3 if the infant has undergone all other steps of resuscitation appropriately and has failed to respond. Although there is a lack of data documenting its benefit, if the pH is less than 7.05 as a consequence of a mixed acidosis, or the base deficit is 15 mEq/L or more, correction of the metabolic component of the acidosis with an infusion of NaHCO_3 may be helpful. The immediate objectives are twofold: to reverse the myocardial failure and low cardiac output that occurs from acute metabolic, but not respiratory, acidosis (22,42,43); and to relieve the intense pulmonary vasoconstriction that occurs with severe acidosis, particularly in full-term infants (19,44,45). The degree of pulmonary vasoconstriction is approximately the same for metabolic and respiratory acidosis (46). The recommended dose is 2 mEq/kg [4 mL/kg of 4.2% solution, osmolarity = 900 mOsm/L] given slowly (no faster than 1 mEq/kg per minute). Some studies suggest that there is an association between rapid infusions of large volumes of concentrated NaHCO_3 and intracranial hemorrhage in preterm infants. The hemorrhages might be caused by transient hypernatremia from too rapid an infusion, by an acute rise in PaCO_2 from inadequate ventilation during the NaHCO_3 infusion, which would cause cerebral vasodilation, or by the asphyxia for which the NaHCO_3 was given. However, infusion of NaHCO_3 into the inferior vena cava at the rate of 1 mEq/kg per minute, for a total dose of up to 5 mEq/kg, causes only a slight transient increase in the arterial sodium concentration.

The ability of NaHCO_3 buffer to raise pH depends on the ability of the lungs to eliminate the CO_2 produced by the buffering process, as determined by the following equation:

Consequently, NaHCO_3 should not be given unless ventilation is adequate and PaCO_2 is low, normal, or declining toward normal. Continue ventilation during bicarbonate therapy to eliminate the excess CO_2 produced. CO_2 is highly diffusible, so even if ventilation is adequate, some of the CO_2 produced by buffering could enter cells and transiently increase acidosis. The implications of this intracellular acidosis following sodium bicarbonate infusion are not known, and remain to be studied.

Tris(hydroxymethyl)-aminomethane (THAM acetate), although generally not used during resuscitation, may also be helpful in correcting metabolic acidosis. It has the dual advantage of reducing PaCO_2 and buffering metabolic acid. It is most useful for treating infants with severe

mixed metabolic and respiratory acidosis and for situations of severe asphyxia with suspected extreme acidosis in which blood gas measurements are not available. It may cause respiratory depression, and so should be used only in situations in which ventilation already is assisted. Also it may cause hypoglycemia. Further, it should not be used in patients who are anuric or uremic. An earlier preparation was very hyperosmolar, highly alkaline and tended to cause sclerosis of blood vessels. These problems have been corrected by the use of the 0.3 mol/L preparation (can be used without dilution), which also is adjusted to pH 8.6. Figure 18-4 illustrates correction of a severe mixed acidosis.

P.314

Figure 18-5 shows how the cardiovascular effects of an infusion of alkali differ depending upon the severity of the asphyxia.

If the infant's respiratory depression is suspected to be caused by maternal narcotics (e.g., morphine, meperidine, or butorphanol tartrate), administered within 4 hours prior to delivery, administration of naloxone hydrochloride (Narcan), a narcotic antagonist should quickly reverse the respiratory depression. However, prompt and adequate ventilatory support should always precede the administration of naloxone and should be continued until the infant is breathing normally. As the duration of action of narcotics often exceeds that of naloxone, continued close observation is necessary and repeated doses of naloxone may be required. Because naloxone can precipitate an acute withdrawal reaction, it should not be given to the infant of a mother who is suspected of being addicted to narcotics or is on methadone maintenance. The recommended dose of naloxone hydrochloride is 0.1 mg/kg (1.0 mg/mL solution). It should be given preferably endotracheally or intravenously; however, intramuscular and subcutaneous routes are also

acceptable, although they have a delayed onset of action.

Infants who have had severe asphyxia and who do not respond promptly to adequate resuscitation are likely to have myocardial depression with decreased cardiac output and hypotension. These infants may respond to dopamine starting at 5 µg/kg per minute and increasing to 15 to 20 µg/kg per minute, as needed. Rarely, dobutamine might need to be added (starting at 5 µg/kg per minute and increasing to 15 to 20 µg/kg per minute). During vigorous resuscitation it is useful to monitor heart rate and oxygen saturation electronically and have ECG electrodes applied.

Figure 18-5 Changes occurred in heart rate, aortic blood pressure, and arterial blood gas tensions during the first 45 minutes after birth of a 1.2-kg premature infant with severe asphyxia complicated by bilateral pleural effusions. The child's trachea was intubated immediately after birth, and he was manually ventilated with 100% oxygen throughout this time. Note the severe mixed acidosis in the first blood gas measurement at 11 minutes after birth. Administration of NaHCO₃ at this point would have been inappropriate and ineffective because assisted ventilation had not yet achieved adequate elimination of CO₂. NaHCO₃ was given only after adequate CO₂ elimination was achieved. Note that there was no rise in the arterial carbon dioxide partial pressure (PaCO₂) after this, indicating that all the CO₂ produced during the buffering process was eliminated, and the only change was a reduction in base deficit from -14 to -5 mEq/L, which raised the pH from 7.06 to 7.22. Note the high initial aortic pressure, which was due to the vasoconstriction of asphyxia, indicating that myocardial failure had not yet developed. As asphyxia was relieved, aortic pressure fell to normal. (BE, base excess; PaO₂, arterial oxygen partial pressure.)

Umbilical Vessel Catheterization

Catheterization of umbilical vessels is invaluable during neonatal resuscitation. The umbilical vein is readily accessible in the newborn and can be quickly catheterized. It is most often used for the administration of medications and volume expanders. For these purposes, the catheter should be inserted only 3 to 5 cm, or until free flow of blood is established, to avoid placing the tip in the portal circulation. The umbilical artery can be catheterized to obtain blood for arterial blood gas and other samples as well as to monitor blood pressure. The umbilical arterial catheter can be connected to a precalibrated pressure transducer, so that blood pressure can be monitored

continuously. Alternatively, it can be connected to the transducer ahead of time and the blood pressure displayed as soon as the catheter is passed into the aorta. This also reduces the risk of accidentally injecting air bubbles through the catheter into the infant's circulation while the catheter is being connected to the transducer.

It is important to obtain quickly a measurement of pH and PaCO₂ to determine that ventilation is neither inadequate nor excessive and to detect metabolic acidosis. Although a venous blood gas analysis is not as representative as an arterial one, it will suffice as an initial measurement to detect severe acidosis and to determine whether or not PaCO₂ is near the normal range. Venous PaCO₂ is about 6 mm Hg higher and pH is about 0.03 units lower than in arterial blood (32).

Other aspects of infant's care that need to be closely followed are discussed in the following sections.

Hematology

Consumption of coagulation factors may complicate severe asphyxia. This is almost always a transient process rather than continuing disseminated intravascular coagulation.

Thrombocytopenia is the most consistent finding. In extreme cases, clinical bleeding occurs and requires replacement of platelets and plasma clotting factors. Other hematologic changes include a transient rise in the number of granulocytes, including immature forms, and in erythroid precursors in the peripheral blood. These can rise to very high levels and could be misleading when considering diagnoses such as infection and hemolytic anemia. If the changes are secondary to asphyxia, however, they will disappear in a day or so.

Glucose

When hypoxia and acidosis have been relieved, begin a continuous infusion of 10% dextrose in water at 3 mL/kg per hour to maintain a normal concentration of blood glucose. This provides 5 mg of glucose per kg per minute. Begin screening for hyperglycemia and hypoglycemia with repeated testing of capillary blood. Hypoglycemia can be corrected by a bolus infusion of 10% dextrose (2 mL/kg over 2 to 3 minutes) and by temporarily increasing the infusion rate to 5 mL/kg per hour (8.4 mg/kg per minute), which is sufficient in all but the most extreme cases of asphyxia-induced hypoglycemia. Rapid infusions of more concentrated solutions of dextrose can be dangerous because of their hyperosmolarity and their tendency to produce serious vascular injury.

Fluid and Electrolytes

Asphyxia causes renal ischemia, which may persist after birth and resuscitation (47). Many asphyxiated infants are oliguric for the first day of life and have a rising serum creatinine (48,49). Very high serum creatinine concentrations in the first days of life, however, are not caused by renal failure but are caused by tissue necrosis after severe asphyxia. When urine output increases, there is transient hematuria and polyuria. With extreme asphyxia, corticomedullary hemorrhagic necrosis occurs and the renal failure is more severe. As renal function returns, sodium, potassium, and chloride can be added to parenteral fluids. As acidosis is corrected, extracellular potassium shifts back into cells and postasphyxial infants with good renal function may become hypokalemic. The usual maintenance amounts of electrolytes may be adequate to maintain serum electrolyte concentrations, but in many cases renal losses of electrolytes are very high during this diuresis, so it will be necessary to administer higher concentrations of electrolytes. When planning sodium requirements, consider the sodium given as NaHCO₃ during resuscitation and the NaCl in catheter-

flush solutions. Infants who are asphyxiated often become hypocalcemic by the first day after birth (31). Serum ionized calcium should be measured and supplemental calcium given as needed.

Gastrointestinal Function

During asphyxia, blood flow to the small and large bowel is reduced. *Severe* asphyxia may cause serious ischemic injury to these organs and gastrointestinal blood flow may remain abnormal for up to 3 days after delivery and resuscitation (47). Because of this, it may be advisable to continue intravenous fluids and delay enteral feedings for several days. Occasionally, acute necrotizing enterocolitis occurs when severely asphyxiated infants are fed in the first day or two after birth. This is particularly important in infants who also have suffered hypovolemic shock, because shock severely compromises intestinal blood flow.

Central Nervous System

Severe asphyxia can lead to hypoxic ischemic encephalopathy. Because the homeostatic responses to asphyxia tend to preserve oxygen delivery to the brain at the expense of other organs, asphyxial encephalopathy tends to occur in infants with evidence of multiorgan injury (47,49). However, there are situations in which encephalopathy appears in isolation. A significant portion of the damage to the brain is reperfusion injury, which occurs some time after recovery from asphyxia (50,51). This interval raises the potential for treatment that could prevent this portion of the injury. Several forms of therapy that might provide such neuroprotection are under investigation, but none has been shown to be effective (50). However, there are some lessons from these studies that are applicable to clinical care. Many studies point to hypocarbia as a contributor to neurologic injury (50,52). Closely monitoring PaCO₂ and adjusting ventilation to avoid hypocarbia has been discussed previously. There is much conflicting information about the beneficial versus the harmful effects of hyperglycemia in the asphyxiated infant. So it seems prudent to keep the blood glucose concentration in the physiologic range. Recent experimental studies have shown that moderate cerebral hypothermia initiated as soon as possible in the latent phase, before the onset of secondary injury, and continued for 48 hours or more, is associated with potent, long-lasting neuroprotection. There are several recently published and ongoing randomized clinical trials to test the safety and efficacy of whole-body hypothermia and selective head

P.316

cooling (53,54). Current data suggest that whole-body cooling is feasible in term neonates, with no life-threatening adverse events, but improvements are needed to maintain stable hypothermia for prolonged periods, and its impact on long-term outcome remains to be seen (55).

DISCONTINUATION OF RESUSCITATION

Discontinuation of resuscitation in an infant with cardiorespiratory arrest should be strongly considered, and may be appropriate, if despite all the steps of resuscitation, heartbeat remains absent after 15 minutes. Current data support the position that after 10 minutes of asystole, a newborn infant is very unlikely to survive, and if it survives, is likely to have severe neurologic compromise (1,56,57,58). Of course, parents should have a major role in determining the care of their newly born infant and the extent of resuscitation offered. Based on the data at hand, every effort should be made to plan the resuscitation approach before delivery, with the provision that the plan may change according to the infant's condition at delivery and the infant's response to resuscitative efforts.

Situations When Noninitiation of Resuscitation is Reasonable

In recent years there has been considerable debate over the concept of the lower limit of viability and other circumstances when noninitiation of resuscitation can be recommended. Although there are still no clear answers to such a sensitive subject, noninitiation of treatment may be appropriate for infants with confirmed gestation of less than 23 weeks or a birthweight of less than 400 g, anencephaly, or confirmed trisomy 13 or 18. Present data support the position that despite resuscitation these infants are very unlikely to survive, or if they do survive, it will be with severe disability. However, in situations of uncertain prognosis, including uncertain gestational age (antenatal prediction of gestational age is variable; see Chapter 11), resuscitation options may include a trial of resuscitation, noninitiation, or discontinuation of resuscitation following assessment of the infant. If after initial assessment, there is still any doubt, full resuscitation and continuation of life support can allow time to obtain more complete clinical information and the family's viewpoint, and will allow for counseling to the family regarding continuation versus withdrawal of support. Then, if agreed on, withdrawal of support may be appropriate. In general, it is a bad idea to decide initially not to resuscitate and then, many minutes later, change the decision to aggressively resuscitate.

Continuing Supportive Care After Resuscitation

After adequate ventilation and circulation have been established, the infant may still be at risk for deterioration. Consequently, continuing close monitoring of heart rate, respiratory rate, blood pressure, arterial oxygen saturation, blood gas analysis, blood glucose, and the administered oxygen concentration may be indicated.

Monitoring Respiratory Status

During this time, the infant should be closely monitored for complications of assisted ventilation. The ET may be dislodged from the trachea and advance into the esophagus. Alternatively, the tube may advance into the right main bronchial stem, leading to nonventilation of the entire left lung and the upper lobe of the right lung. This is the most common serious complication of endotracheal intubation. Clinical suspicion may need to be confirmed by a repeat chest radiograph. Examine the abdomen for distension that may elevate the diaphragm and interfere with ventilation. This usually is a consequence of assisted ventilation via a face mask and can be relieved by an orogastric tube.

Following successful resuscitation, pulmonary function may change rapidly, leading to several complications. First, PaO_2 will rise as ventilation and perfusion become better matched and may reach levels that are dangerously high in the very premature infant. Hyperoxia is better managed initially by reducing the inspired oxygen concentration rather than by withdrawing ventilatory assistance. Second, improved ventilation may lead to acute hypocarbia, which will reduce cerebral and myocardial blood flow (59,60,61). Correct the hypocarbia by reducing the rate of assisted ventilation and inspiratory pressure. Figure 18-6 illustrates these changes. Third, as lung compliance increases, the ventilatory pressure that was appropriate initially will become excessive. If the excess pressure is mild, the result will be hyperventilation and hypocarbia. If it is extreme, however, there will be tamponade of the pulmonary circulation and right-to-left shunting of blood at the atrial and ductal levels and low systemic blood flow. This phenomenon is manifested by a low aortic pressure, wide fluctuations in blood pressure in phase with the positive-pressure ventilation, and arterial hypoxemia. This situation can be detected by briefly disconnecting the ET from the ventilation system. Aortic pressure will rise within 5 seconds. If this occurs, restart ventilation using lower airway pressures. The hypoxia caused by the shunting of blood from right

to left will decrease quickly as the lungs are ventilated with lower pressures.

Tension pneumothorax may occur during spontaneous or assisted ventilation of any infant. A tension pneumothorax of small or moderate size may restrict ventilation and cause hypoxia and hypercarbia. Pneumothorax must be suspected whenever PaO_2 decreases despite a ventilation system that is functioning properly. Sometimes the diagnosis of pneumothorax is difficult to make by physical examination alone. Breath sounds may be unequal bilaterally, but often they are equal. The upper portion of the affected side of the chest tends to lag behind the unaffected side during inflation of the lungs. Transillumination with a cold fiberoptic light may cause the affected side to glow brightly; however, the absence of this sign does not rule out pneumothorax, particularly in the larger infant with a

P.317

thicker chest wall. The diagnosis of pneumothorax can be made best by a chest radiograph, but this often is difficult to obtain quickly in the resuscitation area. The arterial and central venous pressures may not change with small pneumothoraces. If hypoxia and hypercarbia become severe, it may be necessary to perform a diagnostic thoracentesis with a small-gauge angiocatheter and syringe before there is time to obtain a radiograph. The situation changes when a pneumothorax is large and under tension. Venous return to the heart and cardiac output may fall precipitously to extremely low levels. If blood pressure, PaO_2 , and PaCO_2 are being measured, this critical situation will be diagnosed easily because the onset of hypoxia and hypercarbia will be accompanied by severe hypotension rather than the hypertension of asphyxia (see Fig. 18-1) (62). This situation warrants intervention, which is as urgent as in cardiac arrest. One cannot wait for a confirmatory radiograph. Figure 18-7 illustrates the diagnosis and successful treatment of such a case. Satisfactory decompression of a tension pneumothorax usually requires insertion of a thoracostomy tube and continuous suction applied to the tube through an underwater suction system. Aspiration with a needle and syringe usually gives only very brief relief. While assembling equipment for decompression of the pneumothorax, however, insert a 22-gauge Angiocath connected to a three-way stopcock and a 30-mL syringe. This is a convenient and relatively safe method for temporary decompression of the pneumothorax.

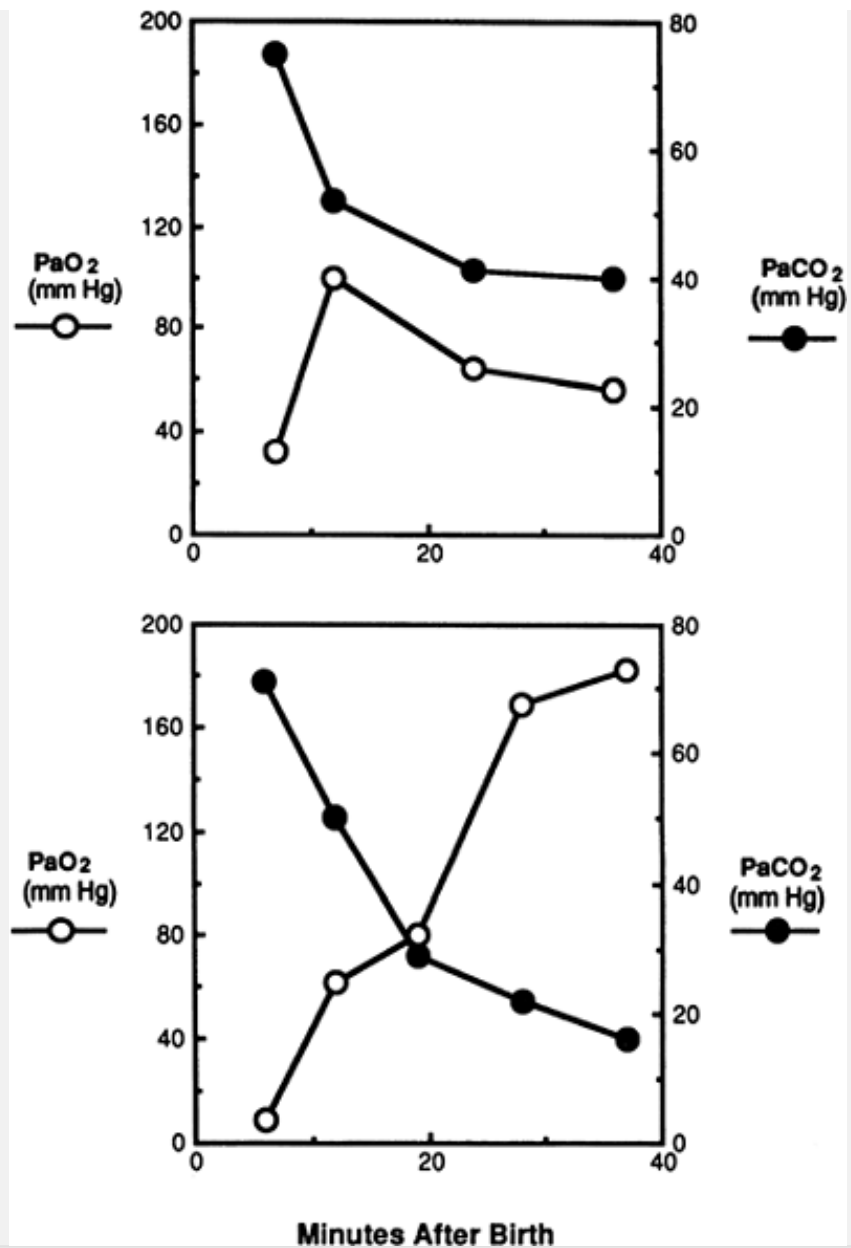

Figure 18-6 Changes in arterial blood gas tensions occurred during the resuscitation of two very-low-birth-weight infants. Each was intubated immediately after birth, and in each the umbilical artery was catheterized before 10 minutes after birth to allow frequent measurements of blood gasses. Both were hypoxic and hypercarbic at the first measurements at 6 and 7 minutes after birth. As ventilation and oxygenation improved, ventilation pressures, rates, and inspired oxygen concentration were reduced. In the baby in the *upper panel*, this led to normal blood gas tensions. In the baby in the *lower panel*, adjustments were made too slowly, leading to hyperoxia and extreme hypocarbia. PaCO₂, arterial carbon dioxide partial pressure; PaO₂, arterial oxygen partial pressure.

Figure 18-7 Aortic blood pressure of a premature, 1.5-kg infant at 32 gestational weeks of age during development of a tension pneumothorax. This is a continuous tracing at 2 hours of age. Because the patient's condition was rapidly worsening, as shown by hypotension, a narrow pulse pressure, and rapidly worsening, as shown hypotension, a narrow pulse pressure, and rapidly increasing cyanosis despite assisted ventilation with 100% oxygen, thoracentesis of the right pleural cavity was done (*arrow*) before radiologic confirmation of the pneumothorax was obtained. About 50 mL of air escaped when the pleural cavity was opened. The patient's color improved, and blood pressure promptly returned to normal.

Pulmonary function will improve rapidly in many infants as compliance improves with absorption of lung water. Pulmonary perfusion will increase in response to a rising pH and PaO₂. On the other hand, if ischemia has caused more severe asphyxia with lung injury, there may be continued respiratory distress that is indistinguishable from early hyaline membrane disease. This will require continued ventilatory assistance. Unlike hyaline membrane disease, however, this form of respiratory failure usually begins to improve within a few hours after birth (63), whereas hyaline membrane disease as a result of immaturity of the surfactant system worsens over the first day after birth. When a fetus with immature lungs has suffered significant intrapartum asphyxia, the ensuing hyaline membrane disease generally will be more severe (64). Figure 18-8 illustrates these divergent courses of respiratory distress.

Infants with early onset hyaline membrane disease should be given exogenous surfactant as soon as the condition is apparent and the ET is in proper position with its tip above the carina. Early treatment with surfactant is more effective than treatment that has been delayed several hours (65). At this early stage in the infant's course, it often is impossible to distinguish between hyaline membrane

disease, postasphyxial respiratory distress, and congenital pneumonia. This is not a reason to withhold surfactant treatment, because it has virtually no adverse effects (under proper monitoring) and may be of some benefit in some infants with other pulmonary diseases (66,67).

Figure 18-8 The course of respiratory distress is characterized by changes in mean airway pressure in three groups of infants: those with severe perinatal asphyxia but no hyaline membrane disease; those with perinatal asphyxia plus hyaline membrane disease; and those with no perinatal asphyxia but hyaline membrane disease. In both groups with hyaline membrane disease, the disease worsens, as indicated by the increased mean airway pressure required over the first 24 hours. Those who also had asphyxia had more severe disease. Those with severe asphyxia but no hyaline membrane disease had a completely different course, with progressive improvement over the first 24 hours of life. ^, No respiratory distress syndrome—severe acidosis; ^, respiratory distress syndrome—severe acidosis; , respiratory distress syndrome—mild or no acidosis. (From Thibeault DW, Hall FK, Sheehan MB, et al. Postasphyxial lung disease in newborn infants with severe perinatal acidosis. *Am J Obstet Gynecol* 1984;150:393.)

Monitoring Circulatory Status

Asphyxia disrupts the newborn's ability to compensate for the loss of large amount of blood volume (68). However, most asphyxiated infants have a normal or greater-than-normal blood volume; only a few have a low blood volume (28). Consequently, hypovolemic shock does not develop in most asphyxiated infants. Of the few infants in whom hypovolemic shock develops in the first hours after birth, however, almost all have had intrapartum asphyxia (69). Blood volume expansion is essential for the infant who is in hypovolemic shock, but may be harmful for the asphyxiated infant who has a normal blood volume.

Because some circulatory changes caused by asphyxia may either mimic or mask hypovolemic shock, it is impossible to identify those infants who need blood volume expansion until resuscitation has produced adequate oxygenation of arterial blood and a normal PaCO₂. Acute hypocarbia causes systemic hypotension, and severe overventilation may reduce systemic blood flow (see above). Neither of these states requires blood volume expansion.

Signs that suggest an inadequate blood volume include low aortic pressure and a narrow and abnormal aortic waveform (Fig. 18-9 and Fig. 18-10), falling hematocrit, persistent metabolic acidosis, low central venous PO₂ (i.e., <30 mm Hg) after correction of arterial hypoxia, cold extremities, and delayed (i.e., >3 seconds) filling of capillaries in the skin after they have been blanched under pressure, provided that core temperature is normal. Tachycardia often is absent in the early stages of severe shock and may be present from too many other causes to be a reliably useful sign (70,71).

Aortic blood pressure during first 12 hours after birth

Figure 18-9 Mean aortic blood pressure was obtained from an umbilical artery catheter. The *dashed line* is the average blood pressure at each birth weight, and the *solid lines* are the 95% confidence limits of this relationship. Blood pressure values below the lower confidence line are hypotensive. (From Versmold HT, Kitterman JA, Phibbs RH, et al. Aortic blood pressure during the first twelve hours of life in infants with birth weights 610-4220 grams. *Pediatrics* 1981;67:607).

If some findings suggest shock but the diagnosis is uncertain it is useful to directly monitor the central venous pressure through the umbilical venous catheter with the tip positioned in the inferior vena cava or right atrium (32). Central venous pressure may be low or normal during hypovolemic shock, but it will be high with circulatory tamponade from excessive PPV, tension pneumothorax, or postasphyxial myocardopathy. The findings of low or normal central venous pressure in combination with signs of

P.319

poor systemic perfusion support a trial of volume expansion. Low central venous oxygen content is a very sensitive, but nonspecific, indicator of increased oxygen extraction in the microcirculation in response to inadequate oxygen delivery from any cause. It is one of the earliest changes during hypovolemic shock (72).

Figure 18-10 Changes in aortic blood pressure during rapid hemorrhage in a newborn lamb. Blood pressure falls and pulse pressure (i.e., systolic minus diastolic) narrows. Note the difference in waveform before and after hemorrhage. Before the hemorrhage, pressure continues to decrease after the dicrotic notch, indicating continued systemic flow during diastole. This disappears after hemorrhage, indicating little or no systemic flow during diastole. Heart rate has not yet increased but will do so later.

Hypovolemic shock is best treated with repeated small infusions of whole blood that has been crossmatched against the mother before delivery and is available in the resuscitation area at birth. Group O Rh-negative blood given to newborns without crossmatching against the mother's serum occasionally has produced fatal transfusion reactions caused by incompatibility in minor blood groups and should not be used. If only packed erythrocytes are available, give equal volumes of cells and a plasma substitute, such as isotonic saline. If no erythrocytes are available, use normal saline for initial resuscitation, then give packed cells as soon as they are available. However, this is less effective than giving blood initially. The objective of therapy is prompt restoration of adequate tissue perfusion. This must be done rapidly enough to avoid the cumulatively harmful effects of prolonged underperfusion of tissues. The latter can lead to the secondary effects of shock, including increased capillary permeability and pulmonary disease, which make therapy more difficult. Excessive speed in volume replacement is also dangerous, however. Some vascular beds, such as that of the brain, vasodilate in response to systemic hypotension. If treatment produces an abrupt rise in systemic pressure, there is not enough time for the vasculature to partially constrict, and as a result the higher pressure is transmitted to the capillaries, where it may cause capillary injury, edema, or hemorrhage. In some instances, with the initial correction of hypovolemia, systemic vasoconstriction is relieved, and pressure falls again, requiring further volume expansion provided other signs of poor perfusion persist. Occasionally, when there has been massive hemorrhage, volume may have to be replaced more rapidly. In such a case, monitor aortic pressure continuously to avoid abrupt rises in pressures. Figure 18-11 shows the course of successful treatment during the first hour of life in an infant who lost approximately 50% of his blood volume during delivery and also suffered asphyxia. Figure 18-12 shows the course in an infant in whom hypovolemia did not become evident until assisted ventilation relieved asphyxia and unmasked hypovolemia.

Figure 18-11 Heart rate, aortic blood pressure, and blood volume replacement were monitored during the first hour after birth in a 2.8-kg infant who suffered massive blood loss when the anteriorly placed placenta was incised deeply at cesarean section delivery. The *shaded area* shows the cumulative volume of whole blood given expressed as mL/kg body weight. The final volume, which produced a normal aortic blood pressure and relieved signs of poor perfusion, was 40 mL/kg: approximately one-half the total blood volume for a normal newborn infant. The blood was given as a series of small transfusions guided by the changes in blood pressure. Note that the heart rate is not elevated at first, despite the extreme hypotension, and that subsequently heart rate does not consistently change in the opposite direction of blood pressure changes.

Transient myocardial failure of 1 to 2 days of duration can occur after asphyxia (29,73). The resulting circulatory failure is differentiated from that caused by hypovolemic shock by an elevated central venous pressure. Postasphyxial cardiomyopathy responds to a continuous infusion of dopamine with improved systemic perfusion and decreased central venous pressure. Start with a dose of 5 $\mu\text{g}/\text{kg}$ per minute and increase the dose as needed to obtain adequate systemic perfusion pressures. If possible, correct hypoxia and acidosis to improve myocardial function before starting dopamine. If pulmonary vasoconstriction and hypertension coexist with systemic hypotension caused by myocardial failure, venous-to-arterial shunting of blood through the foramen ovale and ductus arteriosus often occurs. This leads

P.320

to additional systemic hypoxemia and worsening metabolic acidosis. When correcting acidosis in this situation, it is important to avoid hyperventilation, because hypocarbia constricts the coronary circulation and causes systemic hypotension (60,61). Some infants of poorly controlled diabetic mothers have a particularly severe form of cardiomyopathy. The antecedents of this cardiomyopathy are asphyxia plus hypoglycemia plus hypocalcemia, and all of these must be corrected to improve myocardial performance.

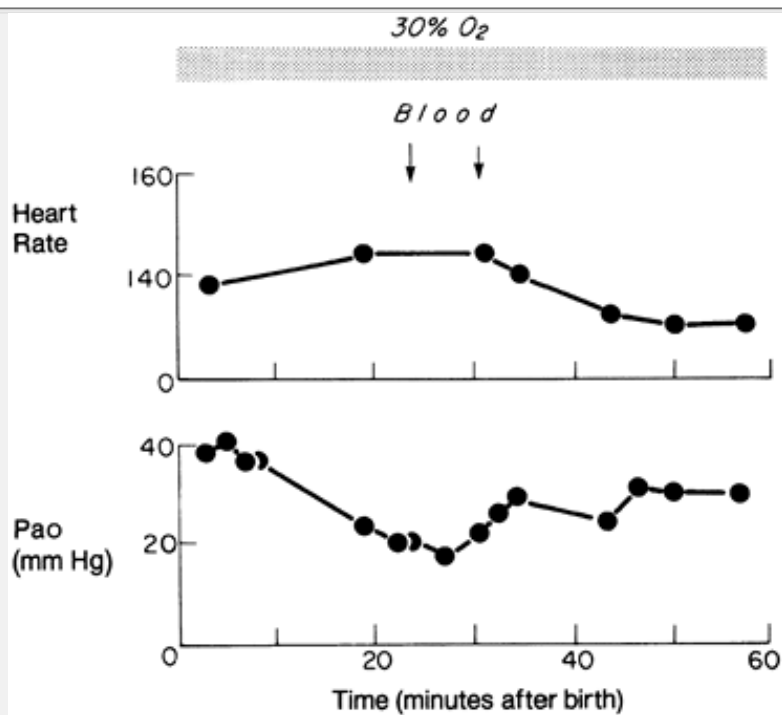

Figure 18-12 Heart rate, aortic blood pressure (Pao), and therapy were monitored during the first hour after the birth of a 1.5-kg second twin delivered by cesarean section. There had been a large abruption of the placenta. Initially, the infant was hypoxic and acidotic, and aortic pressure was normal. As blood gas tensions normalized, aortic pressure fell and the infant continued to appear pale and poorly perfused. This probably is an example of the intense vasoconstriction of asphyxia keeping blood pressure at a normal level despite a subnormal blood volume. Relief of the asphyxia allowed sufficient vasodilation to unmask the hypovolemia.

Additional Measures

These may include treatment of hypoglycemia, suspected infection, or seizures. Complete documentation of all observations, resuscitative actions, and timings of these actions is absolutely essential not only for good clinical care but also for medicolegal purposes. Postresuscitation may also be the first time to meet the family in situations where there has not been the opportunity to meet the family before delivery. The family should be informed about the infant's condition at the earliest opportunity, the resuscitative measures that have been taken, why they were necessary, and, in fact, parents should be encouraged to interact with the newly born as soon as possible.

SPECIAL PROBLEMS

Meconium-Stained Amniotic Fluid

Meconium staining of amniotic fluid occurs in 10% to 15% of all deliveries (74,75). Mature fetuses pass meconium in response to various stimuli, including asphyxia. Meconium staining diminishes with decreasing gestational age and is rare before 34 weeks of gestation, whereas it is quite common in postmature fetuses. The proportion of infants admitted to the neonatal intensive care unit (NICU) is several-fold higher among infants born through meconium-stained amniotic fluid (MSAF) than in those born through clear amniotic fluid (76,77). Furthermore, meconium-stained infants are 100-fold more likely to develop substantial respiratory distress than those born through clear amniotic fluid (78). Meconium can be aspirated into the airway by gasping, which may occur *in utero* in response to a variety of stimuli, including hypoxia, or, by inhalation after delivery. Aspiration of meconium can cause pulmonary disease both by plugging of the airways or by

producing a chemical pneumonitis. Clinical pulmonary disease is more likely if meconium staining occurs before the second stage of labor, if meconium-stained fluid is thick with particulate matter, if infant is depressed at delivery, and if there is meconium below the vocal cords (76). However, a significant proportion of infants with meconium aspiration syndrome (MAS) are born through thin consistency meconium staining of amniotic fluid or are vigorous at birth (79,80).

In many instances, infants with meconium aspiration demonstrate symptoms immediately after birth. However, sometimes, infants are clinically well at birth and manifest symptoms of MAS during the first few hours after birth. Severe disease nonetheless can develop in infants with this more gradual onset of symptoms. Pulmonary air leaks are ten times more likely to develop in infants with meconium aspiration than in infants without meconium staining; this air leak often occurs during resuscitation. Infants with meconium aspiration are at a great risk of developing hypoxemia, acidosis, hypercapnia, and the resultant persistent pulmonary hypertension of the newborn (PPHN). Approximately one-third of infants with MAS have PPHN, and two-thirds of infants with PPHN are associated with MAS (78,81).

When MSAF is identified before delivery, personnel trained in all aspects of neonatal resuscitation must be present in the delivery room. On delivery of the head, the infant's nasopharynx and nares should be suctioned with a catheter or a bulb syringe before delivering the shoulders. Previous recommendations included that after suctioning at the perineum, suctioning via ET intubation should immediately follow if the amniotic fluid is stained with thick meconium versus thin meconium, irrespective of infant's general condition. However, no study documents the efficacy of this approach. In fact, a multicenter, prospective, randomized, controlled trial demonstrated that, regardless of the consistency of meconium, there was no increase in the incidence of respiratory distress or MAS when vigorous infants were not intubated and suctioned following delivery (80). Consequently, present recommendations include ET intubation and suctioning soon after delivery only if the infant is *nonvigorous*, that is, if the infant has depressed respirations, depressed muscle tone, and/or heart rate less than 100 bpm. To avoid initiation of breathing, vigorous stimulation and drying should be delayed until intubation and suctioning are performed in these infants. Endotracheal intubation and suctioning should be repeated until little additional meconium can be recovered or until the infant has significant bradycardia and requires positive pressure ventilation or chest compressions. Therefore, during endotracheal suctioning, a second person should monitor heart rate continuously. Furthermore, to avoid hypoxemia, free-flow oxygen should be provided throughout the suctioning procedure. Other procedures to prevent meconium aspiration such as squeezing baby's chest, chest physiotherapy, or inserting a finger in baby's mouth, which are sometimes performed, have not been rigorously tested and may actually be harmful. These procedures are not recommended, and should be strongly discouraged.

Preterm Infants

Preterm (<37 weeks' gestation) infants constitute a special group because of the special needs and problems encountered in the resuscitation of these infants. As a group premature infants make up the largest proportion of infants requiring resuscitation after delivery. The majority of infants born at less than 28 weeks' gestation require some degree of resuscitation. The immature respiratory system in these infants makes it extremely hard for them to spontaneously achieve adequate lung inflation and create an adequate FRC. As lung inflation stimulates surfactant release from the type II alveolar cells, the majority of extremely premature

P.321

infants do require some ventilatory assistance beginning in the delivery room. Further, there is a large body of evidence suggesting that the pathogenesis of bronchopulmonary dysplasia begins during the first few minutes of life, with aggressive ventilation that results in volutrauma and hypocapnia (82). Therefore, initial ventilation requires special attention in the extremely preterm infant with a small lung volume and surfactant deficiency. Ventilating such lungs with very large

tidal volumes even for a very brief period can do serious lung damage. In premature lambs, as few as five sustained inflations of 35 to 40 mL/kg leads to the release of proinflammatory cytokines and gross histopathologic changes (83). The large inflating breaths recommended earlier in this chapter for resuscitation of larger infants may not be appropriate for extremely premature infants. Therefore, it has been suggested that a gentler and noninvasive mode of supporting ventilation, that is, starting continuous positive airway pressure (CPAP) in the delivery room may be an effective strategy to prevent the development of bronchopulmonary dysplasia (84). However, there are no convincing data as yet to support this notion. Whether low-tidal-volume ventilation starting in the delivery room, in an attempt to avoid lung injury and hypocapnia in premature infants, could be safely delivered and whether it is as efficacious as normal-tidal-volume ventilation remains to be seen. As pulmonary function improves and these smallest infants are weaned from assisted ventilation, it is important to remember that many of them cannot maintain an adequate FRC, even in the absence of lung disease, and progressive atelectasis will gradually develop unless end-expiratory distending pressure is applied to their lungs.

As with the prevention of volutrauma, special emphasis should also be given to prevent oxygen-induced lung injury by providing the lowest level of oxygen supplementation that maintains adequate delivery of oxygen to tissues. This requires not only keeping vigilance on the oxygen concentration provided but also optimizing cardiac output and hemoglobin concentration. Continuous monitoring of oxygen saturation starting in the delivery room is likely to reduce overall oxygen exposure (85). Further, recent data suggest that resuscitation with 100% oxygen may generate oxygen free radicals that may cause tissue damage, particularly to the brain. Some clinical studies suggest that resuscitation with room air may be both effective and possibly even safer than with 100% oxygen, but no large, randomized, controlled trial has tested the efficacy of using room air versus 100% oxygen for resuscitation (86,87,88,89). Such a trial is eagerly awaited, but until then, the recommendation is to continue to use 100% oxygen for resuscitation. However, if supplemental oxygen is unavailable, and PPV is indicated, use of room air may be acceptable.

Although clinical trials have proven that surfactant therapy is effective in improving the clinical outcome of premature newborns, it is unclear whether preventive (prophylactic or delivery room administration) or therapeutic (selective or rescue administration) strategy is better. A recent meta-analysis suggests that prophylactic surfactant administration to premature infants judged to be at risk for developing respiratory distress syndrome, compared to selective use of surfactant in infants with established respiratory distress syndrome (RDS), improves clinical outcome (90). However, it remains unclear as to exactly which criteria should be used to judge "at risk" infants who require prophylactic surfactant administration. A reasonable approach is to administer surfactant to the infant delivered at less than 28 weeks' gestation born to a mother who did not receive antenatal steroids. The disadvantages of this approach include that the infant has to be intubated and a significant number of infants may not develop RDS, and would receive surfactant unnecessarily. As more and more infants are being treated with CPAP in the delivery room, it has been speculated that transient intubation of the infant solely for the purpose of surfactant administration and continuation of CPAP may be a more cost-effective way of managing RDS in preterm infants (91).

Because of the relatively larger surface area-to-body mass ratio, thin permeable skin, decreased amount of subcutaneous fat, and diminished metabolic response to cold stress, premature infants are at great risk of developing hypothermia. Hypothermia, especially in extremely preterm infants, may result in adverse outcomes; therefore, during the delivery of premature infants, especially those of 28 weeks or less of gestation, preventing heat loss should be a top priority. One should take all the necessary steps to reduce heat loss, even if these infants do not initially appear to require resuscitation. The radiant heat required to maintain normal body temperature during resuscitation evaporates water from the infant's skin. This can produce very high insensible water

losses from very premature infants. Once the ET and the umbilical catheter are in place and secured and other emergency procedures are completed, cover the infant with a clear plastic wrap to reduce insensible water loss. One study suggests that wrapping premature infants in polyethylene immediately after delivery prevents heat loss (92). This practice needs to be further evaluated to determine its potential value in changing the outcome of extremely preterm infants.

Furthermore, preterm infants have a very fragile network of capillaries in the germinal matrix of their brains and, therefore, are at high risk of developing intraventricular bleeds and lifelong neurodevelopmental problems. Both periventricular leukomalacia and intraventricular hemorrhage are linked to birth asphyxia, need for resuscitation, hemodynamic instability, early significant hypocarbia, and metabolic acidosis (93). To avoid the rupture blood vessels in the germinal matrix, preterm infants should be handled very gently, and too rapid administration of blood and volume expanders should be avoided.

Newborn with Airway Compromise

The management of a newborn with a compromised airway can be challenging and requires careful identification of the source of the airway obstruction. In mild situations, appropriate positioning of the infant's head and neck or provision of short-term positive pressure ventilation is all that may be needed. However, in infants with severe airway

P.322

obstruction or with multiple problems, laryngeal mask airway, intubation (either oral or nasal) requiring fiberoptic endoscopy, or emergent tracheostomy may be required. If the problem is known prenatally, it may require a team approach involving the obstetrician, neonatologist, anesthesiologist, and otolaryngologist. In some situations, an *ex utero* intrapartum tracheloplasty (EXIT) following a planned cesarean section in which the maternal-fetal placental circulation can be prolonged for several minutes following delivery can be lifesaving. Laryngeal mask airway may be a useful temporizing device until a more definitive intervention for the compromised airway can be arranged. It is particularly helpful when tracheal visualization is impaired because of glossoptosis, macroglossia, hypoplastic mandible, or cervical immobility. However, its use requires considerable practice (94).

Newborn with a Surgical Condition

The general principles of stabilization for any infant also apply to an infant requiring surgical intervention during the initial care. These include establishment of airway patency and adequate ventilation, effective circulation, correct fluid and electrolyte balance, paying careful attention to thermoregulation, and providing appropriate antibiotic coverage. However, specific early management will depend on the underlying surgical condition. In infants with gastroschisis or omphalocele, avoidance of both direct and ischemic trauma to the eviscerated viscera by appropriate infant positioning, keeping up with the infant's excessive fluid and heat losses from the exposed viscera, and preventing infection of the exposed abdominal contents are the biggest challenges. In an infant with a suspected diaphragmatic hernia, the greatest emphasis during the initial management should be on avoiding bag and mask ventilation and immediate endotracheal intubation. Insert an orogastric tube into the stomach and aspirate its contents immediately. This reduces the risk of regurgitation and aspiration, which can occur despite the presence of an ET. This also prevents the compression on the already hypoplastic lungs in these patients. If the diagnosis is not known prenatally, a scaphoid abdomen and difficulty in achieving adequate ventilation suggest a diaphragmatic hernia. Furthermore, because invariably there is accompanying pulmonary hypertension, strategies such as sedation, paralysis, correction of acidosis, avoidance of systemic hypotension, and selective pulmonary vasodilation might be required from the outset.

Hydrops

Resuscitation and delivery room management of a newborn with hydrops fetalis pose a unique set of problems for the neonatologist. Usually, the diagnosis is known before delivery. Every effort should be made to establish the cause of hydrops before delivery to help with preparations for resuscitation at delivery. With improvements in prenatal care, hydrops because of Rh alloimmunization has considerably decreased and now hydrops because of nonimmune causes is much more frequent. More personnel are needed for resuscitation of infants with hydrops than for a routine resuscitation. Have whole blood or packed erythrocytes crossmatched against the mother in the resuscitation area, even if the hydrops is not caused by Rh disease or other alloimmune hemolysis, because many infants with nonimmune hydrops are also anemic at birth. In addition to the usual supplies for resuscitation, supplies needed for a partial exchange transfusion, thoracentesis, and paracentesis, plus tubes required for diagnostic studies must be on hand. Two umbilical vessel catheters should be connected to pressure transducers and a recorder with one channel calibrated for arterial pressures and the other for venous pressure. Blood should be obtained from the umbilical cord at birth to measure hematocrit or hemoglobin immediately.

An ultrasonography examination should be done just before delivery to assess for the presence and size of pleural effusions and ascites. On many occasions, drainage of large pleural effusions and ascites may be needed before delivery to facilitate delivery as well as to facilitate postnatal gas exchange (95). Similarly, postnatal drainage of pleural effusions and ascites is often required in the delivery room (96). Lung inflation and ventilation often are difficult in hydropic infants because the lungs are compressed by the diaphragm, which is elevated by ascites and by large pleural effusions. There is also low compliance because of excessive lung water. Resuscitation usually requires immediate endotracheal intubation and ventilation with oxygen at high pressures. If paracentesis needs to be performed because of abdominal distension due to ascites, it should be performed in the flank region to avoid puncturing a potentially large liver or spleen. Remove just enough fluid so that the abdomen becomes soft and the diaphragm moves easily upon inflation. If ventilation remains difficult and there are pleural effusions, these should be reduced to allow ventilation. Even after fluid is removed from the abdomen and chest, many of these infants continue to require high pressures to provide adequate ventilation because of excess lung water, surfactant deficiency, and in some cases of long-standing hydrops, pulmonary hypoplasia.

While the infant is being ventilated and the effusions are being reduced, catheterize the umbilical vein and artery and measure venous and arterial pressures, blood gas tensions and pH to assess the state of circulation. Anemia compromises tissue oxygenation, and anemic hydropic infants usually do not respond well to resuscitative measures until the hematocrit is at least 30% to 35% (97). Transfused blood is virtually 100% hemoglobin A, which transports oxygen much more efficiently after birth than hemoglobin F. How the anemia is corrected depends on the state of the circulation. Most infants with hydrops caused by alloimmune disease have low or normal blood volumes (98). The blood volume of infants with nonimmune hydrops of various causes is unpredictable. If intravascular pressures indicate that blood volume is adequate, do a partial exchange transfusion and keep the blood volume constant. If there is evidence

P.323

of hypovolemia, infuse more blood than is withdrawn until the intravascular pressures are normal. Alternately, infuse a bolus of packed erythrocytes, as is done for the treatment of hypovolemic shock. In most cases, evidence of hypovolemia does not appear until asphyxia is relieved (97). The most common scenario is a partial exchange transfusion that keeps blood volume constant while raising the hematocrit, and then repeated small infusions of packed erythrocytes or fresh-frozen plasma to support the circulation. Fresh-frozen plasma may partially correct the coagulation defects that are often present in these infants (99). Most infants with alloimmune hydrops have

very low concentrations of serum albumin and a low plasma oncotic pressure (97,100). About one-half of those with nonimmune hydrops are also hypoalbuminemic. There is no evidence, however, that albumin infusion or correction of hypoproteinemia is beneficial (96). Moreover, there is concern that giving albumin and fresh frozen plasma to these infants during resuscitation may raise plasma oncotic pressure enough to draw excessive volumes of fluid into the circulation and worsen pulmonary edema. If this occurs, appropriate adjustments to ventilatory support are needed. Pulmonary vasoconstriction is particularly common in infants with hydrops (96,101). Anticipate and promptly correct metabolic derangements such as acidosis and hypoglycemia. Surfactant deficiency and hypoplastic lungs may be associated with hydrops, and are managed accordingly. Therefore, if pulmonary perfusion does not improve during resuscitation, correction of metabolic acidosis may be required. After resuscitation is complete, there usually is pulmonary disease that requires assisted ventilation. This may be transient respiratory distress, hyaline membrane disease, pulmonary hypoplasia, or some combination of these.

Multiple Births

The three features of multiple births that complicate delivery room management are the following:

- Increased incidence of preterm labor and delivery. This affects management only by increasing the number of personnel needed for resuscitation. The risk of intrapartum asphyxia is somewhat increased in the second-born twin.
- Increased incidence of congenital anomalies in monozygotic multiple births.
- Increased risk of intrauterine growth retardation because the placenta may be unevenly shared among the fetuses. This results in the usual problems associated with intrauterine growth retardation, for example, intrapartum asphyxia, polycythemia, hypoglycemia, and pulmonary hemorrhage (see Chapter 11). Twin-to-twin syndrome with the most severe form being "stuck twin syndrome."

The twin-to-twin transfusion syndrome, which occurs in at least 5% of multiple pregnancies, results from vascular anastomosis between the circulations of monozygotic twins, primarily with a monochorionic placenta. Both the degree of transfusion from one fetus to the other and the time course are quite variable and determine the clinical presentation at birth. Transfusion may have been relatively recent or may have begun in the second trimester and been long-standing at the time of birth. If the transfusion is primarily in one direction, the donor twin becomes anemic and the recipient twin polycythemic. With ongoing transfusion, the recipient grows normally while the donor becomes progressively smaller for gestational age. As the process becomes more severe, polyhydramnios develops in the recipient fetus and oligohydramnios in the donor. Ultimately, either twin may become hydropic, one from volume overload and the other from anemia. In severe cases, the donor twin may die (102).

When twins suffering from this syndrome are delivered, management during resuscitation can be extremely complicated. Findings in the mother should lead to close ultrasonographic surveillance of the fetuses and prenatal recognition of the unidirectional twin-to-twin syndrome. The polycythemic infant might need to have his or her hematocrit reduced. Management of the anemic donor is less straightforward. Recent blood loss requires the same management as in any other hypovolemic infant (see above). More often, the anemia is prolonged and severe, so the donor circulation may be compromised and may not tolerate blood volume expansion. In this situation, proper therapy is

partial exchange transfusion with packed cells to raise the hematocrit to a normal level. Both arterial and central venous pressures should be monitored beginning immediately after birth to assess the circulatory status and make the correct adjustments in both hematocrit and intravascular volume. Rapidly measure hematocrit or hemoglobin in each twin and begin appropriate therapy.

In monochorionic twins, the vascular anastomoses may be multidirectional, so that the direction of flow is determined at least in part by the difference in circulatory resistance between the twins. Such twin-to-twin transfusions are not diagnosed so easily, nor are the hemoglobin measurements necessarily different at birth even when the blood volumes are.

The "stuck twin syndrome" is a poorly understood phenomenon in monochorionic twins. There is discordant growth with oligohydramnios in the growth restricted fetus and polyhydramnios in the appropriate-for-gestational-age fetus. The growth-restricted fetus becomes impacted into a small volume within the uterus. Lung growth is often restricted, which leads to pulmonary hypoplasia that is lethal, if severe. If mild, it requires positive-pressure ventilation at high pressures and rates. In some cases, there is marked myocardial dysfunction in one or both twins, which can be detected antenatally by echocardiography. Preparations for delivery are the same as for any other severe twin-to-twin transfusion syndrome.

Birth Injury

Severe birth injury and intrapartum asphyxia often occur together. The main problem for delivery room management

P.324

in these infants is significant hemorrhage from the traumatized tissues, which complicates the resuscitation. The blood loss almost always is internal and, therefore, not immediately evident. Moderate blood loss can occur in fractured limbs or into the perineum in a difficult breech delivery. Sites for major blood loss include intracranial, mediastinal, and intraabdominal (e.g., ruptured spleen, hepatic subcapsular hematoma). A subgaleal hematoma can produce a massive loss of blood volume because of the extremely large potential space. Any of these hematomas can contain several hundred milliliters of blood and are particularly dangerous because they can consume large quantities of coagulation factors and lead to generalized bleeding that perpetuates the hypovolemia. In severe cases, only early and aggressive therapy can bring the situation under control. Treatment includes replacement of the lost blood volume and erythrocyte mass and, if there is depletion of clotting factors, treatment with fresh-frozen plasma, platelets, and, occasionally, cryoprecipitate.

Early detection of internal hemorrhage from birth trauma is crucial. Abdominal distention and discoloration suggest intraabdominal bleeding, which may need to be verified by abdominal ultrasonography, computed tomographic scanning, magnetic resonance imaging, or needle aspiration. Control of intraabdominal bleeding may require surgery. Intracranial hemorrhage sufficient to cause hypovolemia usually is manifested by a bulging fontanelle and can be confirmed by ultrasonography. Small intracranial hemorrhages also may cause circulatory instability through their effects on the autonomic nervous system. A mediastinal hematoma does not declare itself by the physical signs, but a chest radiograph often suggests its presence when the mediastinum is widened. If suspected, it can be diagnosed quickly by an ultrasonographic examination of the mediastinum. Early swelling of the back of the neck from a subgaleal hematoma may be hard to recognize, but an expanding subgaleal hemorrhage pushes the ears laterally and forward. This often is the earliest sign of this condition. Subgaleal hemorrhage, too, can be confirmed by ultrasonography.

Overall, remarkable progress has been made since the first publication of the neonatal

resuscitation guidelines by the American Academy of Pediatrics and American Heart Association in 1985. However, many recommendations for neonatal resuscitation still are based on accepted practice rather than research data. Many of these are being questioned, and are now being rigorously tested. Undoubtedly, based on the analysis of new data, novel recommendations will emerge. Fortunately, with skillful intervention, resuscitation of a newborn infant is usually successful, in contrast to resuscitation attempts in an older child or an adult.

ACKNOWLEDGMENTS

We are extremely grateful to Nik Phou for his help in the preparation of the manuscript, and to M. Vasudeva Kamath, MD, MPH, for helpful suggestions.

Chapter 19

Physical Assessment and Classification

Michael Narvey

Mary Ann Fletcher

The approach to the newborn examination differs in several ways from that of the adult patient. It is imperative that one seizes opportunities as they arise, rather than force an unwilling infant to an assessment based on the examiner's preferred order. Such forcing often culminates in the infant crying, which although informative may render a complete examination impossible at that time. Instead, during a quiet moment, one may appreciate the heart sounds or the clarity of breath sounds. Similarly during an awake, active period, simple observation may yield a plethora of information regarding the neurologic status of the infant. In the acutely ill infant, delaying the complete examination until such time that the infant may be handled safely is prudent. Inspection, palpation, percussion, and auscultation are all important tools for examination at any age and are incorporated into the neonatal assessment. It is important to provide a thorough systematic assessment of the newborn, but flexibility must be inherent in the approach.

Antenatal ultrasound screening and more recently the evaluation of fetal abnormalities by MRI have provided physicians with the capability of preparing for the delivery of newborns with anticipated problems. For example, antenatal discovery of congenital diaphragmatic hernia allows planned delivery in a tertiary care hospital with neonatal staff present at delivery. Despite improvements in triaging of deliveries, the physical examination at birth remains a critical tool in the management of all newborns. In the above example, assessment of vital signs, work of breathing, color, and the presence of other anomalies at birth determine subsequent management, not just the diagnosis itself. In other cases, significant anomalies may be present but their impact on the newborn not appreciated until examination after birth.

Physical assessment in neonates serves to determine anatomic normality for the first time in a new life and the state of health in someone unable to describe their symptoms. A challenge is to determine which findings will be transient or are merely variations of normal and which are markers of major malformations or syndromes. Most of the clinical descriptions of specific syndromes are made of findings that become typical only after there has been sufficient growth and maturation. An example is the subtlety or absence of obvious findings in aborted fetuses or extremely premature infants with Down syndrome.

Because many of the physical signs of early disease also present as part of the normal physiologic changes occurring at birth or in the newborn period, differentiating the markers of subtle illness from transitional variations is a particular challenge in neonatal physical diagnosis. Additionally, there are unique findings that appear quite dramatic but carry little medical significance. Once the examiner has determined that findings represent a disease process, he or she then has to decide just how sick that infant is, or is likely to become. To that end, there have been devised a number of acuity of illness scores that range from the very simple to complex systems that include physiologic monitoring and laboratory values (1,2,3,4,5). The primary advantage of such scoring systems is in forcing a systematic and quantitative assessment that can be compared among observers and over time. Such scores have been used as indicators of mortality risk (5).

The first neonatal examination occurs immediately after birth in the assigning of Apgar scores at 1 and 5 minutes of age and every 5 minutes thereafter until the total is above 7. The scores summarize encapsulated assessments of the cardiopulmonary and neurologic systems after inspection for color, heart rate, respiratory efforts, tone, and muscle activity and assigning a value of 0, 1, or 2 for each of the five observations. Also part of this first examination is inspection for designation of gender and a cursory inspection for major anomalies. Any obvious abnormality merits more immediate evaluation, but the definitive examination in healthy infants should take place after initial transition and the first bath.

P.328

The first complete examination ordinarily occurs within the first 24 hours after birth, but if any portion of an assessment is deferred or abnormal at that time reexamination prior to discharge is warranted. For infants discharged before 48 hours after delivery, an examination should take place within 48 hours of discharge by a health professional competent in newborn assessment (6).

During the first outpatient visit, the physician should fully reevaluate the infant, especially those systems not as

easily assessed immediately after birth, e.g., the eyes, and those that undergo the greatest changes during transition, e.g., the cardiovascular and hepatobiliary systems. The areas emphasized with subsequent well-baby examinations include neuromuscular and sensory development, the heart, and the hips, as well as parameters of growth including head circumference, length, and weight.

This chapter is a brief discussion of the steps for assessing the newborn infant and interpreting some of the findings. A thorough textbook on how to perform and interpret the physical examination in neonates is available (7).

NEWBORN HISTORY

It is tempting to start the physical examination of neonates before reviewing the history and available laboratory information of the mother. If a newborn is critically ill, the clinician should initiate therapy for stabilization after a cursory examination and before obtaining the complete history, but too much delay can lead to missed or partial diagnoses. Historic information is just as important for neonates as for any other patient. Even if it is more practical to examine an apparently healthy newborn before obtaining the history, a complete evaluation includes all available information. Knowledge of certain historic details may increase one's vigilance for signs of drug withdrawal in a baby born to a drug abuser, for instance. A key part is the mother's pregnancy history as well as her prior medical and social history. Other essential elements include general family history, postnatal history, and information about the placental examination.

Maternal history includes the mother's age, gravidity, parity, time and type of previous fetal losses, general fertility issues, and premature births and their outcomes; maternal illness before or during pregnancy; extent and location of prenatal care; results of any prenatal laboratory tests, especially those for hepatitis, human immunodeficiency virus (HIV), and sexually transmitted diseases; labor and delivery history including duration, assessments of fetal well-being, anesthesia, and route of delivery, drug, alcohol, and tobacco use; prescription and nonprescription medication use; and her vocation. The general family history includes current or significant past medical illnesses in other family members, including siblings; physical traits or appearance, including birth weights of other siblings; consanguinity; social information, educational levels, and vocations; and ethnic or racial background. Helpful information about the newborn period of siblings includes success in breast-feeding, infections, congenital anomalies, genetic conditions, jaundice, and other concerns. To include the postnatal course as part of the newborn history, the clinician should review events surrounding the birth and response to resuscitation, vital signs, feeding, eliminations, and behavior. If there were any complications or requirement for anything other than routine care, this information is a key part of the total neonatal history.

Placental Information

Often more overlooked than history in evaluating neonates is information about the placenta and the clues it provides about the gestational history. Several features of the placenta and cord can be readily assessed on gross examination by anyone at the time of delivery. The placenta should be examined for size, odor, color, and the number and character of fetal membranes. In the last trimester the ratio of fresh placental weight to infant weight is normally 1:6. There should be a uniform thickness and density throughout. Depressions and adherent clots or changes in firmness on the maternal surface suggest abruption or infarction. The placenta is essentially odorless except for a slight odor of fresh blood. Malodor may indicate the presence of infection although this is controversial.

The color of the fetal surface changes with gestational age (GA), but pallor or plethora suggest aberrations in fetal blood volume or hemoglobin level. Elevated bilirubin in the amniotic fluid stains the placenta bright yellow. Meconium will discolor the fetal surface greenish-brown but so too can old blood. If either meconium passage or bleeding occurred more than 1 day prior to delivery, it can be difficult to differentiate the two by gross examination.

The fetal surface should be examined for cloudiness of fetal membranes, which suggests an inflammatory reaction but not necessarily due to infection. Nodules on the amnion indicate prolonged, extreme oligohydramnios. Fetal pulmonary hypoplasia is highly probable in this setting and is a key finding in renal agenesis. Their presence suggests futility if resuscitation is underway.

In multiple gestations with a single placenta, the dividing membranes should be assessed. Membranes can be teased apart and counted: four layers indicate dichorionic placentation and two layers indicate a monochorionic placenta. With a dichorionic placenta or completely separate placentas and same gender twins, one cannot say if they are identical or fraternal from the placental examination. Monochorionicity has traditionally been viewed as

patho-gnomonic for identical twins; however, a recent report refutes this assertion (8). Just as monozygotic twins can have separate placentas, dizygotic twins can have tightly fused placentas that appear to be one mass. If there are any remnants of vessels seen in translucent dividing membranes held to a light, there are four membrane layers. If there is only a transparent membrane with no chorionic remnants, it is likely to contain only amnion.

GESTATIONAL AGE ASSESSMENT

For standard reporting of reproductive health statistics and as a prerequisite to determining normality, all infants should be classified by GA and birth weight (6). Ultrasonography has improved the accuracy of pregnancy dating, but discrepancies in dates, physical appearance, or size require further evaluation. If there has been no prenatal care, physical assessment remains the primary clinical determinant of GA.

GA is noted in completed weeks after the onset of the last menstrual period (LMP). For example, a fetus who is 37 weeks and 2 days is in its 38th week of gestation. A term infant is any infant whose birth occurs from the beginning of the first day of week 38 through the end of the last day of week 42 after the onset of the LMP (i.e., 260 to 294 days of gestation). A preterm infant is one born before 37 completed weeks or at 36 weeks and 6 days (259 days) or less. A postterm infant is one whose birth occurs from the beginning of the first day of week 43 (i.e., after 294 days or at 42 weeks and 1 day or more). Correct classification of GA has assumed great importance when discussing the outcome of preterm infants. GAs should never be *rounded up*. For example, a preterm infant of 24 weeks and 6 days should be considered and classified as 24, not 25 weeks. Classifying infants born at term, preterm, or postterm helps to establish the level of risk for neonatal morbidity and long-term developmental problems. The terms premature and postmature often are used clinically to connote physical or physiologic findings not always correlating with GA. Postdates is an obstetric term meaning a pregnancy that has continued to any time after the expected date of confinement but is not necessarily postterm.

Assessment Techniques

Estimation of GA by physical examination is possible because there is a predictable pattern of physical changes that occur throughout gestation. The most popular score for GA assessment was originally developed in part by Saint-Anne-Dargassies (9), Amiel-Tison (10), and Dubowitz and associates (11). These systems have been applied to infants with GAs of 22 to 27 weeks despite the fact that no infants below 28 weeks were included in their development. In these very premature infants, the GA was consistently overestimated by up to 2 weeks when compared to reliable ultrasound dates. Conversely, in postterm pregnancies they tended to underestimate the age of postterm infants (12). A further modification by Ballard and associates (13), which included infants with GAs ≥ 26 weeks, purportedly improved reliability. However, even in infant cohorts of $<1,500$ g and $<2,500$ g, the Ballard score similarly yielded a 1- to 2-week error, being greatest at lower birth weights (14,15,16,17). A final modification produced the New Ballard Score (NBS), which claimed to improve the accuracy of age assessment to within 1 week (Fig. 19-1) (18). The strength of this study was inclusion of infants ≥ 20 weeks, designed to improve accuracy because of larger numbers of extremely premature infants. However a recent study in 24- to 27-week premature infants refuted these findings, showing persistent miscalculation by up to 2 weeks (19). Some have attributed the tendency to overestimate true GA to accelerated neurologic maturity (14,18). It is likely that factors contributing to preterm birth cause stress in the developing fetus and bring about faster neurologic maturation compared to unstressed fetuses in continuing pregnancies. Using last menstrual period (LMP) or early ultrasound as the gold standard, some studies show a closer correlation between physical criteria alone and GA compared to neurologic or total Ballard score. In a multicenter study, infants who were small for their GA had consistent overestimation of their GA. (14).

Due to the inaccuracy of the NBS in extreme prematurity, one must continue to use maternal LMP and early ultrasound as the gold standard for determining GA (see Chapter 12). This becomes imperative when deciding aggressiveness of support in an infant born at 22 to 23 weeks by dates. Despite the aforementioned concerns, the NBS remains the best method available to estimate GA in the presence of uncertain dates.

Other methods for GA assessment have emerged over the years. Prior to gestation of 27 weeks, the cornea is too hazy to permit examination of intraocular structures. The vessels in the anterior vascular capsule of the lens mature in a predictable enough pattern in the last trimester to allow determination of GA with a 2-week margin of error in infants at 28 to 34 weeks of gestation. (20) The exam must be performed within the first 24 to 48 hours of life as the vessels atrophy rapidly after this time. It may prove useful when a neurologic abnormality

and uncertain dates render the NBS inadequate. As well, it has been validated in infants who are small for GA, which compromises the accuracy of the NBS (21).

One final technique is the use of changes in skin reflectance during fetal development to determine GA of infants at 24 to 42 weeks of gestation (22). A reflectance spectrophotometer at a wavelength of 837 nm obtains a measurement of skin reflectance independent of melanin, yielding an estimate of GA unaltered by skin color. Initially considered for use in black infants who were thought to be more neurologically mature at birth than other ethnic groups, the requirement for special equipment and discovery that GA assessment tools were not influenced by racial differences likely prevented widespread use of this technique (23).

Accurate estimation of GA requires experience and consideration of the infant's history and overall condition at the time of scoring; for example, maternal medications or drugs and the infant's fetal position or sleep state affect the neuromuscular response in a normal infant. Significant hypertonia or hypotonia is particularly powerful in affecting the neuromotor scores but does not affect the physical maturity score. Examination as soon as possible after initial stabilization or by 12 hours increases the accuracy in gestations shorter than 28 weeks (18). The use of NBS is particularly

P.330

attractive for neonates who are immature and instrumented because it does not require lifting the infant. Although described here separately from other components of the examination, the steps for assessing GA can be done as part of the general physical examination and can provide information for the neurologic evaluation. The neurologic examination of infants during the first year continues to use a number of these assessment elements (24,25).

Figure 19-1 Assessment of maturity by the expanded Ballard score (18).

Neuromuscular Maturity

The resting posture is that observed with the infant in a quiet unrestrained environment. Tone increases in a caudocephalad direction to a pattern of full flexion at term (Fig. 19-1).

The square window is assessed by flexing the wrist and measuring the minimal angle between the palm and flexor surface of the forearm. This angle decreases with advancing

P.331

GA. Conditions of marked intrauterine compression, such as severe oligohydramnios, increase wrist flexion. As an extremely premature newborn advances through corrected GA, he or she will not continue to develop as much wrist flexion after birth as the infant would have had he or she stayed *in utero*.

The scarf sign indicative of shoulder and superior axial tone is assessed by pulling the hand across the chest to encircle the neck as a scarf and observing the position of the elbow in relation to the midline. There is decreased range and a higher score if there is marked obesity, chest wall edema, an abnormally shortened humerus, or shoulder girdle hypertonicity. Brachial plexus injury or generalized hypotonia produces a spuriously low score.

With the infant supine and head midline, arm recoil is assessed by first flexing the elbow and holding the arm against the forearm for 2 to 5 seconds. The elbow is then fully extended and released with observation of how quickly and fully the infant resumes a flexed posture. Assessing recoil should not be done as part of testing arm traction or with forceful extension because other responses may interfere with a normal reaction. Any pathology affecting the motor strength or tone of the arm will decrease this score.

To determine the popliteal angle, one should first flex the hips with the thighs alongside the abdomen rather than over the front. With the hips held in flexion and the pelvis flat, the knee is then extended as far as possible to estimate the popliteal angle. If an infant was in frank breech presentation with legs extended, the popliteal angles would be greater than expected for age.

In the heel-to-ear maneuver, the legs are held together and pressed as far as possible toward the ears without lifting the pelvis from the table. The angle made by an arc from the back of the heel to the table decreases with maturity.

Physical Maturity

Skin in the most premature infants is gelatinous and almost transparent, allowing the abdominal vessels to be visible. It becomes opaque with maturity as it thickens and keratinizes, eventually shedding the lubricating vernix after it dries and cracks.

Lanugo, which is the fine hair evenly distributed over the body, first emerges at 19 to 20 weeks, but for a few weeks after initial emergence it is not readily apparent. Maximally apparent at 27 to 28 weeks, lanugo sheds first from the areas of greatest contact. Lanugo is distinct from the more pigmented body hair that may be quite prominent in infants of medium to dark complexion.

Assessment of the plantar surface includes measuring the foot because its length reliably corresponds to early GA. With normal muscle activity and uterine compression, creases develop in the sole, progressing from the toes toward the heel. Inappropriate sole creasing is seen in infants with serious neuromotor deficit in the lower extremities (e.g., decreased creasing or only deep vertical creasing) or with oligohydramnios (e.g., increased creasing).

The breast develops with an increase in color, stippling of the areola, and increase in the size of the breast tissue. Although the volume of the breast somewhat depends on fetal nutrition and fat deposition, areolar development with increasing GA is more consistent and independent of these factors.

Ear cartilage becomes firmer with gestation if there is no continuous, extrinsic pressure and the auricular muscles have normal anatomy and activity. Concurrently, as gestation advances, the number of ear folds increase as well. Unfusing of the eyelids can occur over several weeks, and a fused condition by itself is not a sign of extreme, nonviable immaturity. Opening starts by 22 weeks; complete unfusing is evident by at latest 28 weeks (18).

Maturity of the external genitalia is one of the more reliable individual indicators of GA (18). Due to timed descent in the third trimester, testicular progress through the canal into the scrotum is a GA marker. The testes

are usually palpable high in the scrotum at 36 weeks and fully descended by 40 weeks. For the scrotum to develop fully into a pendulous, rugose, term appearance, testicular descent must occur at some time, even if the sac is empty at the time of birth.

The appearance of term female genitalia depends on fat deposition and is abnormally immature in a poorly nourished infant. The clitoris approaches term size well before 38 weeks so it is disproportionately large in premature females (26,27). The appearance of a pigmented vertical line, the linea nigra, above the pubis toward the umbilicus suggests a GA of at least 36 weeks.

Influences on Age Assessment Results

If there is a discrepancy between expected and achieved scores, factors that influence the demonstrated findings should be sought before assigning GA.

Resting posture reflects progressive flexion into the position assumed when a term fetus occupies virtually all available intrauterine space and is no longer in a freely floating state. To minimize the volume occupied, this flexion logically progresses in a caudal to cephalic sequence. Compression from oligohydramnios accelerates flexion; it gives an artificially advanced estimate of maturity. Conversely, poor fetal motor activity over a long period spuriously decreases estimated age. Fetuses with markedly decreased motor activity and polyhydramnios have decreased plantar and palmar horizontal creasing and inappropriately immature posturing. Any condition affecting the position or activity of the lower extremities, such as frank breech presentation with hyperextended knees or myelomeningocele with paresis leads to an aberrantly lowered neuromotor score. Similarly, an infant who is hypotonic from illness or sedation has less flexion than normal for true GA.

GROWTH

Measurement Techniques

Infants weighing less than 2,500 g are low birth weight (LBW) regardless of GA; very low birth weight (VLBW)

P.332

refers to a weight less than 1,500 g, and extremely low birth weight (ELBW) indicates an infant weighing less than 1,000 g. Classification by these weight groups helps establish the level of risk for neonatal and long-term morbidity and mortality, particularly when the weight classification is coupled with an accurate GA (28).

Of all measurements, crown-heel length is the most subject to variability, because it depends on achieving full extension of an infant who is more naturally in flexion. This measurement is performed with the infant supine, neck neutral, leg fully extended, and ankle flexed to 90 degrees. If there is deviation from an expected norm, the first step in evaluation is to remeasure the infant for confirmation. Although not part of routine practice, a measuring board definitely improves accuracy.

When anomalies of the lower extremities make crown-heel length implausible, the crown-rump measurement may still be feasible. Crown-rump length is measured with the infant supine and the hips flexed 90 degrees. Congenital dwarfism may be classified as those with a short trunk, short legs, or both. These subtypes can be readily differentiated by the crown-rump to total length ratio. From 27 to 41 weeks of gestation the value is fairly consistent at 0.665 ± 0.027 (29). The ratio is normal if a condition causes proportional reductions in length of the upper and lower body; increased if the legs are shortened to a greater degree; and decreased if the trunk is foreshortened. Standards for separate lengths of upper and lower limbs are available (30,31).

The head circumference is the largest dimension around the head obtained with a tape placed snugly above the ears. This is the occipital frontal circumference (OFC). Head circumference undergoes a marked increase during the last trimester, averaging 25 cm at 28 weeks and 35 cm at term (32). The average head circumference is 0.5 cm greater in male compared with female neonates (33). Due to greater reliability of repeated measurements, paper rather than reusable cloth tape measures should be used (34). Minor changes in head circumference occur during the first week after birth as scalp edema and molding resolve. The molding seen after prolonged breech positioning can lead to an OFC that is as much as 2 cm higher than it will be after molding resolves.

The OFC predictably falls on the same percentile curve as the length. If the OFC differs from length by more than one quartile, the cause should be sought because head size in part reflects brain growth. The most frequent reason for a head percentile to exceed that of length is familial. In this situation the head circumference follows a persistently higher but consistent growth curve. In contrast, pathologic macrocephaly

tends to cross to higher percentile curves as it progresses. A decreased rate of head growth, manifested by a flat curve or by dropping to a lower percentile, may indicate poor brain growth, atrophy, or premature suture fusion (craniosynostosis [CS]). As OFC may be normal in some forms of CS, the head width index (maximal biparietal diameter divided by the OFC) and head length index (glabella to occipital prominence divided by the OFC) may be more informative (35). For example, a patient with scaphocephaly secondary to sagittal suture closure may have a normal OFC but have an abnormally small width index and excessive length index. Normal ranges for these indices are available (35). The fetal head circumference exceeds the abdominal circumference until 32 weeks. Between 32 and 36 weeks, the two circumferences are equivalent, and after 36 weeks the abdominal circumference normally is greater.

Interpretation of Growth Parameters

Interpretation of growth parameters requires plotting the measurements on percentile charts constructed from a similar race and environmental population. If birth weight falls between the 10th and 90th percentiles for a given GA, the infant is appropriate for gestational age (AGA); if less than the 10th percentile, the infant is small for gestational age (SGA); and if above the 90th percentile, the infant is large for gestational age (LGA). Some literature cites the 3rd and 97th percentiles as outer limits, but for most clinical purposes this broader range underselects for some at-risk infants, particularly in the lower sizes. Accuracy in GA assessment is critical in determining if a weight is appropriate. AGA infants born at term are at lowest risk for problems associated with neonatal mortality and morbidity (28).

Infants are considered symmetric if the three parameters of weight, length, and head circumference fall on the same curve. The infant is asymmetric if the parameters are on different curves, usually with the weight on a curve lower than those of the head circumference or length. If an infant has either a slowing of intrauterine growth rate documented by serial fetal sonography or a presumed slowing by very low weight for length measurements, he or she is classified as having intrauterine growth retardation (IUGR). All infants who fall below the 10th percentile for weight are both SGA and IUGR. Infants above the 10th percentile are AGA but may be IUGR if they did not achieve their expected growth potential. An infant who demonstrates a deceleration in growth from the 50th to the 20th percentile during the last trimester due to maternal hypertension is such an example.

Infants who are SGA, IUGR, or LGA are at risk for perinatal and long-term problems. Several of the problems encountered by LGA infants include the following:

- Iatrogenic prematurity due to overestimation of GA by late size estimates
- Increased requirement for delivery by cesarean section
- Pulmonary hypertension
- Shoulder dystocia
- Birth injuries
- Ecchymoses
 - Local fat necrosis associated with forceps applications
 - Cephalohematoma, skull fracture
 - Brachial plexus injuries
 - Paralysis of diaphragm

- Polycythemia
 - Jaundice
 - Hyperviscosity syndrome
 - Seizures
 - Renal vein thrombosis
- Increased total blood volume
- Poor feeding
- Hypoglycemia

EXAMINATION

Examination Conditions

A routine neonatal examination, normally 5 to 10 minutes, should take place in a quiet, warm environment. The room's light should be bright enough to detect skin markings and color but not so bright as to discourage open eyes. When an infant is ill, attention to optimizing the environment and recognizing the potential effect of noxious nursery surroundings on his or her state is fundamental.

Even healthy infants do not tolerate handling in extended examinations. The sicker or more immature they are, the less they tolerate manipulation and environmental assaults. For all examinations, the prime consideration must be that no harm should come by the process. In routine care situations, having one or both parents present during an examination allows discussion about physical findings and offers the opportunity to point out behaviors that can help them better understand their infant. They can address directly any questions about history or therapy at that time as well.

General Assessment

The specifics of neonatal examination are discussed in the following sections. Some systems that are discussed in more detail in other chapters are given less emphasis in this chapter than they would merit in an actual examination.

Inspection

Inspection begins before making any physical contact and from enough of a distance to encompass the infant as a whole. An immediate assessment of wellness can come from simply noting the state, color, respiratory effort, posture, and spontaneous activity. Even simple observations of spontaneous movement patterns can suggest future neurologic deficits or well-being (36).

State

Important indicators of infant well-being are the states or levels of arousal the infant achieves throughout the

examination and throughout the day as described by the parents or nursing staff. One categorization of states listed here was originally defined by Precht and Beintema (37). Modifications have been made but are not clinically important for general assessments (38,39,40,41).

- Deep sleep
- Light sleep
- Awake, light peripheral movements
- Awake, large movements, not crying
- Awake, crying

During examination, a healthy infant should demonstrate several levels of arousal. The most useful states for assessing an infant are those of light sleep and quiet awake so irritating maneuvers are held until the conclusion of the assessment. What it takes to assist an infant in moving from one state to another or how well he or she does it without assistance is noteworthy. Because the deep sleep that follows a recent feeding may give an appearance of lethargy on arousal, knowing the feeding history and pattern is prerequisite to determining aptness of state.

Newborns spend nearly two-thirds of each day in sleep (42). Each 24-hour period involves cycling between periods of active sleep (AS) and quiet sleep (QS). These periods are also known as rapid eye movement (REM) and non-REM sleep, respectively. During AS, infants demonstrate phasic limb movements, eye movements, and irregular respirations. Breathing is typically rapid and shallow interspersed between periods of more regular respiration (43). In comparison, QS is characterized by regular respirations and the absence of eye and limb movements. As GA increases, the proportion of time spent in QS increases (44). Stress during the perinatal period may alter the proportion of time spent between AS and QS as firstborns and infants born after cesarean section spend more time in AS than babies from subsequent pregnancies or vaginal deliveries (42).

Quieting an infant may require anything from simply stopping the handling to holding and talking to him or her. The amount of time spent in unstimulated crying is normally limited in the first 24 hours but may increase significantly each day thereafter. Excessive crying that requires more than routine consoling, particularly if there are no intervals of quiet alert states, indicates abnormal irritability, but other causes include a proper response to pain or to a cold environment (45,46).

Color

Color assessment includes judging perfusion and skin color for the presence of cyanosis, (see color plate) jaundice, pallor, plethora, or any unusual pigmentation.

Respiratory Effort

The degree of respiratory effort is a primary indicator of how distressed or comfortable a newborn infant is, even if the cause of distress is not pulmonic. The examiner can observe the respiratory rate, depth of excursions, use of accessory muscles with retractions or nasal flare, any emitted sounds (e.g., grunting or wheezing), and crying pattern. Understanding the infant's pattern of respiratory

P.334

effort can suggest a specific illness and direct the examination. As the severity of a condition increases, these distinctions may be lost (Table 19-1).

TABLE 19-1 PATTERNS OF NEONATAL RESPIRATORY EFFORT^a

Conditions	Pattern Observed
Distal airway or lung parenchyma	Intercostal retractions, sternal retractions, flaring, tachypnea, grunts, increased work in breathing
Upper airway obstruction	Suprasternal retraction, subcostal retractions
Cardiac pattern	Tachypnea without effort, infant is quiet but not somnolent
Neurodepression	Poor effort compared with physiologic need, apnea
Metabolic acidosis of sepsis	Tachypnea, apnea, lethargy, whining, minimal retractions

^a Early in disease process before patterns merge with multiple system involvement.

Posture

The normal resting postures at different GAs are shown in Fig. 19-1. While observing neck position, the examiner looks for symmetry between the sides and compares the upper and lower extremities. If there is lateral asymmetry and the head is turned to one side, there may be an asymmetric tonic neck reflex with the extremities on the mental side in extension and those on the occipital side in flexion. In that case, the head should be turned to the opposite side to verify that the asymmetry reverses.

If the fetal presentation is nonvertex or unknown or there is asymmetry or deformation, it is helpful to assist the infant in assuming a position reflecting his or her intrauterine attitude. The physician can fold the extremities into the fetal position by applying moderate pressure to a relaxed infant's feet while gently shaking the infant's legs and by directing the arms toward the thorax through gentle pressure on the elbows.

Spontaneous Activity

The examiner should observe what the infant does in light sleep and awake states. Does the infant stretch, move all extremities equally, open and close hands, root and start sucking when something touches his or her face, and yawn with great facial expression, or does the infant lie quietly and move only in response to stimulation?

Premature infants spend more time sleeping but should have spontaneous activity and resting postures commensurate with their GA (47). Because they habituate and become disorganized and stressed quickly on handling, inspection before contact in a benign environment is important.

Vital Signs

Temperature

It is unusual for neonates to develop fevers except in response to increased environmental temperature. If an infant's skin temperature is above 38°C and remains elevated after the environment returns to normal, a rectal temperature should be obtained. Unless the temperature has been elevated for a prolonged time, the rectal temperature is less likely to be affected by environment, and evaluation for infectious or neurologic causes is indicated (48). Recurrent or profound hypothermia also requires additional evaluation.

In a warm environment, overbundling may cause temperature elevation into the febrile range (49). The infant's postural response to hyperthermia is arm and leg extension, decreased spontaneous activity, and increased sleep duration in order to maximally dissipate heat. Conversely, hypothermic infants assume a flexed posture to conserve heat. During the first week of life, only 30% of infants born at less than 30 weeks are capable of limb extension, but by 2 weeks this number increases to 87% (50). As such, premature infants in the first week of life and hypotonic or myopathic infants are most at risk for temperature instability because they are less capable of altering position to aid heat dissipation or conservation.

Term infants in the first day of life sweat in response to overheating, but not as efficiently as in a child or adult (51). Infants less than 36 weeks, in comparison, are incapable of sweating on the first day but do so by 2 weeks of age (52). Furthermore, the minimal temperatures required to induce sweating are higher in preterm than in term infants. The first site capable of sweating is the forehead with recruitment of other sites happening in a

caudal direction. Visible sweating at rest or on feeding in an afebrile infant is abnormal and may indicate distress, typically from cardiac disease.

Respiratory Rate and Heart Rate

The respiratory rate is obtained by looking at the upper abdomen for a full minute. As soon as an infant is touched, the respiratory rate and depth change. The normal respiratory rate is 30 to 60 inspirations per minute in a term infant, with lower rates occurring after the period of cardiopulmonary transition. When awake, some normal infants breathe shallowly and rapidly but are able to slow sufficiently to feed well.

P.335

The heart rate is 110 to 160 beats per minute (bpm) in healthy term infants, but it may vary significantly during deep sleep or active awake states. Preterm infants have resting heart rates at the higher end of the normal range. Tachycardia, with a rate persistently greater than 160 bpm, may be a sign of many conditions, including central nervous system (CNS) irritability, congestive heart failure, sepsis, anemia, fever, or hyperthyroidism. Conversely, low resting heart rates may be observed following mild perinatal asphyxia.

Blood Pressure

Measuring blood pressure is not a routine part of vital signs in most newborn nurseries but is used for infants requiring special care and for evaluating coarctation of the aorta. There are wide variations of normal at different GAs (53,54,55,56). The Committee on Fetus and Newborn of the American Academy of Pediatrics states that hypertension should be diagnosed only after three separate measurements (57).

The range of normal blood pressure in neonates depends on the method used for assessment and GA (see Appendix C-1 for blood pressure values). The values obtained by the blanching and flush methods are mean pressures and are lower than those registered by direct intravascular or Doppler monitoring. The flush method for obtaining mean pressure is easier in an active infant and requires only a sphygmomanometer (58). The Doppler methods, although providing diastolic and systolic pressures, require electronic equipment and a quieter patient. Two important elements for obtaining accurate blood pressure are a quiet infant and a properly sized cuff with a width two-thirds the length of the upper arm.

Facies

Assessment of facies includes looking for symmetry, size, shape, and the relations of all parts of the face and how the infant holds or uses them. A seemingly unusual facial appearance dictates analyzing the individual components to decide if the constellation represents malformation, deformation, a syndrome, or merely familial appearance.

Head and Neck

Inspection of the head includes assessment of the shape and size relative to the rest of the body, face distribution and character of the hair, and the underlying scalp.

Head circumference was discussed previously. Even when the OFC is normal, it is important to notice if the size of the head seems appropriate for the size of the face. The shape of the cranial vault reflects interaction of internal forces (i.e., brain anatomy, volume, intracranial pressure) against external forces (i.e., intrauterine and extrauterine molding, suture mobility). Normal intrauterine molding for a vertex presentation leads to a narrowed biparietal diameter and a maximal occipitomenal dimension. After breech presentation, there may be marked accentuation of the occipitofrontal dimension with parietal flattening, an occipital shelf, and apparent frontal prominence. This normal breech shape requires differentiation from the abnormal occipital prominence found in posterior fossa masses (e.g., Dandy-Walker malformation), frontal prominence due to increased cranial volume, or the boat-shaped scaphocephaly from synostosis of the sagittal suture. Normal molding resolves within a few weeks, but other aberrations progress. Pathologic conditions that prevent normal molding of the fetal head should be suspected in infants who failed to engage in vertex and descend in labor. These conditions are unusual but important to detect as early as possible.

Unusual head shapes are found in approximately 10% of newborns with the most common abnormality being posterior or lateral plagiocephaly (i.e., flattening) (59). Associated risk factors are primiparity, assisted delivery,

prolonged labor, and twin pregnancies (59). Right-sided flattening occurs more often than left due to the more common left occiput anterior descent during birth. It has been postulated that plagiocephaly present at birth may contribute to the development of positional plagiocephaly in infancy. Initiatives to decrease the incidence of sudden infant death syndrome through supine sleep positioning may accentuate plagiocephaly, as the infants may lay on the side of the preexisting flattening (59). Plagiocephaly and torticollis often coexist; occipital flattening with contralateral frontal prominence dictates determining range of motion for the neck. The infant's head should turn as far as the shoulder in both directions; farther if it is premature. Frontooccipital plagiocephaly may be manifested by a unilateral epicanthal fold or asymmetric positioning of the ears (60). To fully assess position, the ears should be viewed *en face* and from the top of the head.

Hair and Scalp

The hair is inspected for color, texture, distribution, and directional patterns. Although hair color may change, there should be racial concordance. For example, reddish or blond hair in a dark-skinned infant may indicate albinism. The hair color should also be fairly uniform. Random patches of white hair are familial or sporadic and inconsequential, but white forelocks with other pigment defects and anomalies are associated with deafness and retardation (61). The texture of hair at birth is relatively fine. Most of the conditions associated with abnormal textures or fragility appear some time later. With immaturity, the hair is even finer and more sparse.

The hairline may vary at the frontal margin, and normal but hirsute infants have hair well down the forehead but without synophrys (i.e., eyebrows which have grown together). The posterior hairline has a more consistent limitation, so that hair roots well below the neck creases, particularly at the lateral margins, suggest syndromes associated with short or webbed necks. Although neonatal hair initially appears quite disheveled, its growth direction normally is consistent.

P.336

In 97.5% of newborns, there is a single parietal hair whorl, located in or just to the right of the midline approximately 80% of the time (62). Nearly 90% of these whorls have a clockwise rotation. More than two, an isolated frontal or a significantly abnormally positioned whorl may be a sign of abnormal development of underlying structures. Due to hair kinkiness, whorls are identified in only 10% of black infants. Consequently, the absence of a whorl should not trigger unnecessary investigations of the CNS in this population. It is unusual for hair to be strongly upswept at the neck or forehead at birth. If there is extreme hair unruliness with multiple directions of growth, particularly with unusual facies, microcephaly, or SGA, there may be poor brain growth of early fetal onset (63). Unruliness is typical but not diagnostic of a number of genetic syndromes, including Cornelia de Lange and Down syndromes.

Superficial ecchymoses and abrasions of the scalp are common after vaginal deliveries, especially after extraction by forceps or vacuum. Incision sites for fetal scalp electrodes or blood sampling should be small and inconsequential, although some are deep enough to require closure. A small defect of the scalp, cutis aplasia, that appears coincidentally at a potential monitoring spot may be confused with an electrode lesion because it sometimes appears ecchymotic or blistered. Telangiectatic or staining lesions appear over the scalp, neck, and face, ranging from the superficial and transient flammeus nevus or stork bite to the more intense, permanent port wine stain. Scalp nodules less than 3 cm in size and covered by a port wine stain are not benign. This lesion, encircled by a long thick whorl of hair is known as the "hair collar sign." All of these nodules contain a small encephalocele and thus neuroimaging is indicated (64).

An unusual finding is scalp rugae along with a normal scalp hair pattern. The skull beneath the rugae has collapsed during fetal development and portends a very poor neurologic outcome (65).

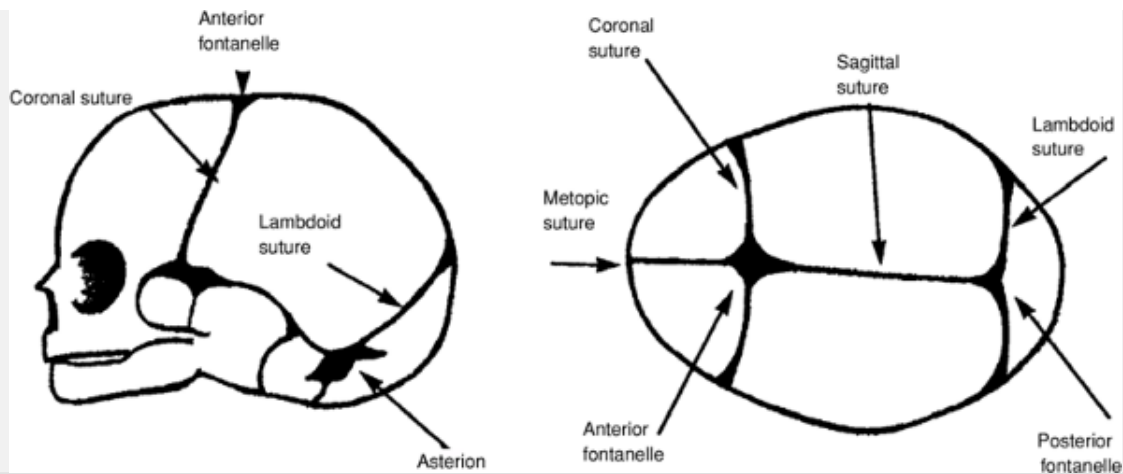

figure 19-2 Lateral and sagittal views of the cranial sutures. (From full reference citation, with permission).

Transillumination of the skull may detect large fluid collections, but the method has been supplanted by more precise diagnostic techniques. Transillumination remains an important adjunct to examining the chest, abdomen, and genitalia for fluid or air accumulations.

Palpation of the Head

Palpation detects motility and firmness of adjacent bones, size of the sutures, and bony or dermal defects. There are six bony plates to the cranial vault; one frontal, two parietal, two temporal, and one occipital. Normally at birth, these bones are separated by suture lines of which there are also six: metopic, sagittal, and paired coronal and lambdoid (Fig. 19-2). Depending on the extent and direction of molding, there is variable overlap in the sagittal, coronal, or lambdoid sutures. With CS, the fused sutures do not move freely when alternate sides are pressed. Primary CS implies that the suture fusion is present at birth whereas secondary CS occurs when poor brain growth culminates in premature closure of the sutures. This is an important distinction because while the neurologic outcome for primary CS is often normal, that of secondary CS is almost invariably poor. If secondary CS is present, one should evaluate the infant for other signs of thyrotoxicosis and exclude it as a cause (66). Sutures that are overlapping but not fused feel like a mountain cliff, with a drop-off from the overriding bone to the lower bone. Sutures that are fused feel more like a mountain range, with equal build-up on both sides. Growth of the skull plates is perpendicular to the suture lines. If the sutures fuse prematurely, growth is impaired, giving rise to the various forms of CS (Fig. 19-3). Isolated CS occurs in 0.6 of 1,000 live births, in a 2 to 3:1 male to female ratio, with affected sutures found to be metopic in 50%, sagittal in 28%, coronal in 5.5%, and lambdoid in 5.5% (67).

Any suture, particularly the metopic, may be normally widened in the absence of increased intracranial pressure;

P.337

The exception is a wide lambdoid suture, which ordinarily indicates increased pressure. Palpation of the bones adjacent to the sagittal suture may reveal a give and return similar to that felt when pressing on an aluminum can. These softer areas, indicating craniotabes, occur most often in premature infants or term gestations if the fetal head was compressed against the maternal bony pelvis for several weeks. Physiologic craniotabes resolves within a few weeks after birth (68). Pathologic craniotabes occurs in syphilis and rickets but may not be evident from these associations in the early neonatal period.

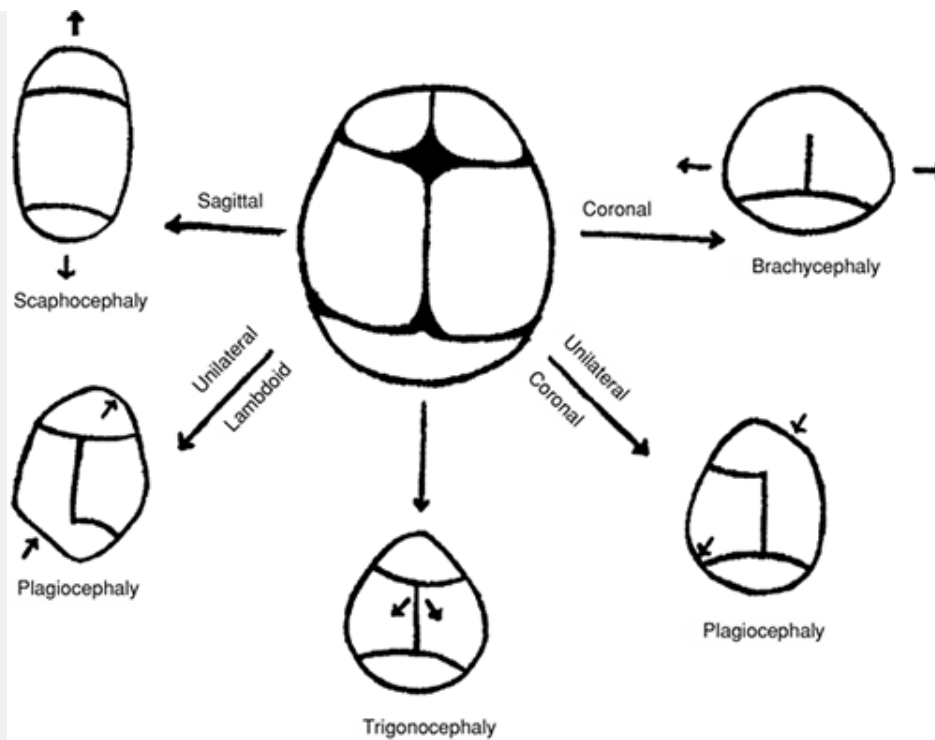

Figure 19-3 The various forms of craniosynostosis displaying lack of growth perpendicular to the prematurely fused suture line. (From full reference citation, with permission.)

The fontanelles vary in size between and within race and by GA (69,70,71,72). There is little clinical application for measurements in otherwise normal infants because head growth can occur despite apparently closed fontanelles. Regardless of size, a pulsatile bulging fontanelle is a strong indicator of raised intracranial pressure. The rate of fontanelle closure is independent of gender, growth parameters, and bone age (71,73,74). Infants with a closed posterior fontanelle at birth have smaller anterior fontanelles, and those with smaller anterior fontanelles also have smaller head circumferences (72). Although aberrantly large fontanelles are seen in genetic syndromes and metabolic or endocrine diseases, they are not pathognomonic.

There are several other palpable findings on the head unique to the neonatal period. The most frequent, caput succedaneum, presents at birth with pitting edema and initially is most prominent over the presenting area. It represents fluid accumulation within and under the scalp. Although a caput initially may be limited to overlying a single bone, it will shift to dependent regions and be more apparent in crossing sutures.

Cephalohematoma is less common and rarely is present immediately upon delivery. Any nonfluctuant swelling that is palpable in the delivery suite is more likely a caput. Typically a cephalohematoma develops after delivery and expands during the first few hours as blood accumulates between the surface of a calvarial bone and its pericranial membrane (75). The cephalohematoma is rounded and discrete with boundaries limited by suture lines. There may be pitting edema if a caput overlies a cephalohematoma, but an isolated cephalohematoma feels fluctuant. Because of periosteal reflection at the margins, there is often a false sensation of underlying bony depression. The blood contained in a cephalohematoma may take several weeks to resorb and prolong neonatal jaundice. Any resolving cephalohematoma that begins to increase in size and becomes erythematous should be aspirated to rule out infection. Unless there are neurologic indicators, radio-graphs to look for the occasional underlying skull fracture are not indicated.

The least frequent scalp injury is a subgaleal hematoma, which may feel crepitant with less pitting and more discoloration than found in caput succedaneum. Because there is little anatomic restriction to accumulation of fluid under the aponeurosis, large amounts may redistribute

and deplete total body volumes in massive subgaleal hemorrhage (76). Cephalohematomas and subgaleal hematomas occur most often after vacuum or difficult forceps extractions but may develop spontaneously even in cesarean or unassisted vaginal deliveries (77). If a subgaleal hematoma is suspected, observation for tracking of the swelling towards the nape of the neck and bluish discoloration will confirm the diagnosis. Serial measurements of OFC should be made in the first 24 hours in all cases of suspected subgaleal hemorrhage; an increasing OFC will allow for early identification and treatment of hypovolemia.

A thorough examination of the head includes auscultating for bruits over the temporal arteries and anterior

fontanelle, particularly if there are conditions involving high-output cardiac failure or neuropathology.

The neck should be extended for maximal exposure to look for branchial clefts or cysts anywhere from the ear along the anterior border of the sternocleidomastoid. The isthmus of a normal thyroid is just palpable in the sternal notch on neck extension; midline enlargements rarely represent a goiter. Other congenital neck masses include cystic hygroma, lymphangioma, and cervical teratoma (78). A teratoma will usually be found in the anterior midline with extension to the right, which differs from the more exclusively midline goiter (79). Any mass may produce feeding difficulties, torticollis, and respiratory distress if airway compression is present. Finally, a firm mass in the belly of the sternocleidomastoid is a fibroma, which may cause torticollis. If present, the head tilt is to the involved side with the chin pointing away from the involved muscle.

Eyes

Examining the eyes of a neonate requires patience and a cooperative infant. Stimulating sucking or taking the infant from a supine to an upright position and rocking gently back and forth may encourage spontaneous eye opening in dim light; however, if the infant is crying inconsolably, delaying the examination is prudent. It is inadvisable to pry the infant's eyes open as doing so will usually elicit crying and result in tighter eye closure.

The emphasis of the neonatal eye examination is on the structure and appearance of the eye and its surroundings rather than assessment of visual acuity or extraocular muscles. The examination may proceed from anterior to posterior structures: eyebrows, eyelids, eyelashes, eye socket, conjunctiva, sclera, cornea, iris, and pupils.

The eyebrows are examined for symmetry and synophrys. Synophrys may raise suspicion that the infant has a syndrome such as Cornelia de Lange or others. Do the eyelids rise and fall symmetrically? Failure of one side to elevate may indicate a congenital ptosis, which may be due to several causes. A miotic pupil on the ipsilateral side suggests the presence of congenital Horner's syndrome. Absent eyelashes may be a clue to a disorder of the ectoderm and should prompt further evaluation.

Additional observations include determining the relative size, shape, and position of the eye in its socket and demonstrating if the infant appears to have vision by reacting to light. One looks for symmetry and observes whether the eyes seem to fit their sockets; they should sit neither too deeply nor too far forward. The size and shape of the socket needs to be related to the size and shape of the surrounding skull. Marked molding with depression of the forehead may make normal eyes appear to sit too far forward unless their position relative to the cheeks is considered. Standard measurements for the eyes are available (80).

Subconjunctival hemorrhages may be present following vaginal delivery. These are transient, disappearing after a few days, and related to increased intravascular pressure during delivery.

Tearing or persistent eye crusting after the first 2 days calls for evaluation for glaucoma, infection, corneal abrasion, mass lesions with obstruction of the nasolacrimal duct, or absence of the puncta. The signs of congenital glaucoma that may be noticed during the neonatal examination include photophobia, excessive tearing, cloudy cornea, or eyes that appear large (81).

The pupillary response to light requires a relatively dark room with only a moderately bright beam to avoid stimulating reflex eye closure. The pupil diameter decreases toward term as its response to light increases. Pupil reaction occurs consistently only after 32 weeks but may develop as early as 28 weeks of gestation. Pupillary reaction and size are not affected by the presence of intraventricular hemorrhage as had been previously thought (82). Pupils of term infants are anomalously dilated if their diameter is larger than 5.4 mm or anomalously constricted if smaller than 1.8 mm (83). The pupils may appear discrepant in size (anisocoria) but if more than 1 mm in diameter different, a cause should be sought (84).

Iris color is poorly defined at birth. The iris should form a continuous circle without interruptions or unusual stretching or banding. In infants less than 28 weeks of gestation, corneal cloudiness permits only a cursory inspection of the iris and pupils.

A thorough fundoscopic examination with mydriasis is not routine, but there should be an attempt to detect cloudiness, masses, or large hemorrhages. Assessment of vision is best with an alert, quiet infant, but a startle in response to a bright light flash through closed lids even with the infant asleep indicates intact optic pathways. The corneal edema normally present in the first 2 days after birth may prevent an accurate detection of a red reflex or visualization of the fundus without mydriasis. This is especially problematic in darkly pigmented eyes. The red reflex is best visualized using a direct ophthalmoscope with the widest beam of light possible, held 30 cm from the infant such that both eyes are within the field of light (85). An abnormal red reflex indicates an

Ears

Each ear is examined for shape, size, position, presence of a canal, and any extraneous tags or pits. The ear canal should be examined, especially in the presence of an auricular abnormality. However, the presence of vernix and debris from birth may obscure visualization of the tympanic membrane until after the first few days of life. The shape of the external ear is determined in part by intrauterine forces and by the activity of extrinsic and intrinsic auricular muscles. Abnormal formation may be a sign of neuromuscular weakness or abnormalities in auricular muscles (86,87). This is quite uncommon, with a recent estimate of 0.011% having a malformed auricle at birth (86). The length of the ear roughly approximates the vertical distance from the arch of the brow to the bottom of the nose. Ear length measurements at different GAs are available (88). Posteriorly rotated or low-set ears occur when cephalad migration and anterior rotation fail to complete. Molding or deformation from the birth process may also yield an abnormal position, but this will resolve after a few days. The position at term should be similar on both sides, with at least 30% of the pinna above a line extended between the medial canthi (89). Because a line extended between the medial and lateral canthi on one eye reflects variable slanting of the eye, it is better to use a more consistently positioned marker such as the two medial canthi.

A behavioral reaction to a standardized sound excludes only gross bilateral deficits, but it should be elicited in all neonates. Assessment of hearing by brainstem-evoked potential or otoacoustic emission is specifically indicated in infants at risk for hearing deficits, particularly those with anomalies of the head and neck, a family history of childhood deafness, very low birth weight, severe asphyxia, fetal infection, meningitis, severe jaundice, and intracranial hemorrhage. Even though congenitally acquired hearing deficits may result from anomalies, infections, or other perinatal conditions, loss may not develop for months or be detectable until behavioral audiometry is feasible. Early detection of hearing deficits may improve with the institution of universal hearing screening, which is becoming standard in many institutions worldwide.

Nose

The nose is assessed for shape, size, patency, presence of swelling over the nasolacrimal duct, size of the philtrum, and definition of the nasolabial folds. It should appear appropriately sized for the face when viewed laterally and *en face*.

Nasal deformation with asymmetry of the nares and apparent deviation occurs as part of facial compression and molding. The triangular cartilage rarely may be dislocated during delivery causing septal deviation, which is best treated by surgical relocation during the first week. With depression of the tip of the nose, a dislocated septum appears even more angled within the nares but a normal septum merely compresses. After release, a dislocated septum does not return to upright nor can it be readily molded into a normal shape (90).

Nasal patency is assessed by free passage of a small catheter through both nares and into the stomach. Air flow is detected by holding a strand of thread in front of each nostril and observing fluttering with breathing.

Congenital obstruction of the nasolacrimal duct occurs in approximately 20% of newborns, 95% of whom are symptomatic within the first month of life (91). Common signs are a large tear meniscus at the lower lid, tearing without stimulation, dried mucoid residue after a nap, or a discharge during waking. A distally obstructed nasolacrimal duct is diagnosed by pressing the finger over the lacrimal sac and sliding it along the course of the duct toward the eye to express material from the puncta. Dacryocystocele is a dilation of the lacrimal drainage system due to obstruction at both ends and filling of the enclosed space. Dacryocystoceles are observed at birth as immobile, tense, sometimes blue-gray cystic swellings no more than 1 cm in length located just below the medial canthal tendon (92).

Mouth and Throat

The shape of the mouth is a marker of fetal position and neuromotor activity. For the mouth to develop properly, there must be muscle activity of the tongue against an intact hard palate. If there is a large palatal defect so the tongue does not meet superior resistance, the mandible is more receded and small. If the hard palate is intact but the tongue inactive, the hard palate may have a high arch or have prominent lateral palatine ridges.

The more common oral findings have counterparts in neonatal dermatology and are benign (Table 19-2). The mouth should be observed with the infant at rest and crying. The shape and size of the mouth is best determined by looking at the mandible and how well it fits the maxilla. It should open at equal angles bilaterally. If the head was tilted *in utero* for an extended period just before delivery, there may be mandibular deviation causing the jaw to open at an angle. This deformation resolves spontaneously, but significant oral asymmetry causes difficulty in breast-feeding on one side compared to the other. Asymmetry on crying occurs with facial nerve paresis, in which the nasolabial folds are asymmetric, or with absence of the depressor anguli oris muscle, in which the folds are symmetric (93, 94). The side with the absent muscle feels thinner.

The tongue, buccal surface, palate, uvula, and back of the mouth should be visualized. The gums and hard palate are best assessed by palpating with a gloved finger while the strengths of the suck and gag reflex also are assessed. A bifid uvula should alert one to the presence of a submucous cleft palate.

Oral cysts in various locations may be present in up to 80% of newborns (95). One to six pairs of small benign midline cysts known as "Epstein pearls" may be present at the junction of the hard and soft palates. Other cysts may be found along the maxillary or mandibular alveolar ridges or on the buccal surfaces. These cysts are benign and often

P.340

resolve by 3 months of age. Epstein pearls are always found in the midline except when there is a submucous cleft, in which case they appear as paired cysts along either side of the median raphe (95).

TABLE 19-2 NEONATAL ORAL FINDINGS

Finding	White (%)	Nonwhite (%)	Comments
Palatal cysts (e.g., Bohn nodules, Epstein pearls)	73-85	65-79	Yellow-white elevated cysts 1 mm in diameter; nests of epithelial cells in the midpalatal raphe at the fusion points of the soft and hard palates
Alveolar or gingival cysts	54	40	Appear similar to palatal cysts
Alveolar lymphangioma	0	4	Blue-domed, fluid-filled cysts in posterior regions; no more than one per quadrant; may cause discomfort during feeding if cysts are large
Alveolar eruption of cysts with or without teeth	<0.1	<0.1	Clear, fluid-filled cysts; mandibular central incisor; rates range from 1:2,500 in Hong Kong to 1:3,392 in Canada
Leukoedema	11	43	Filmy, white hue of mucosa, nonblanching; of no significance compared with thrush
Median alveolar notch	16	26	Reduces when teeth erupt or persists as notch between central incisors
Ankyloglossia	~2	~2	Male to female ratio of 3:1; lingual frenum prevents protrusion of tongue, extends to papillated surface of tongue, or causes fissure in tip
Commissural lip pits	1	3	Blind-ended pits at corners of mouth; autosomally dominant; associated with preauricular pits; medial pits more syndromic

Thrush			Adherent white plaques on tongue and buccal and palatal surfaces; will scrape off; caused by <i>Candida</i> sp.
Bifid uvula	<1	<1	Associated with submucous cleft palate
Ranula	<<1	<<1	Cyst of sublingual salivary gland
Epulis	<<1	<<1	Large, pedunculated cyst of incisor region
Data from refs. 120,121,122,123,124,125.			

Natal teeth, often in pairs, may be found most commonly along the mandibular alveolar ridge. These fairly mobile teeth are present in 1:2,000 to 3,000 live births and are often removed due to concerns of aspiration (96). Despite the probable low risk of aspiration, removal should be considered due to ulceration of the ventral surface of the tongue, which may occur if they are retained (97).

A prominent tight frenulum (ankyloglossia or “tongue tie”) has been cited as causing poor latch and nipple pain during breast-feeding. While prophylactic frenuloplasty cannot be advocated, it may be considered for the infant with severe persistent feeding problems or nipple pain unresponsive to usual therapeutic interventions (98).

Other abnormalities involving the tongue include one that is too large, preventing mouth closure, and tongue protrusion because of low oral-facial tone or small oral cavity.

Skin and Lymph Nodes

The skin is assessed for general color, presence of any extra markings or rashes, texture, turgor, edema or areas of induration, thickness of underlying fat, and maturity. Icterus progresses in a cephalocaudal pattern and is best appreciated in natural light. Detection may be improved by gently blanching the skin to remove the blood from the dermal capillaries. Levels requiring phototherapy are seldom attained if icterus is not present past the nipple line (99).

The distribution and types of pigmentation should also be noted. Areas of hypo- or hyperpigmentation such as café au lait spots are important to document as they may be associated with neurologic disorders.

A common finding is the presence of a line of demarcation with pallor above and deep erythema in the dependent area below (harlequin color change). Another frequent skin pattern is marbling of the extremities from vasoconstriction (cutis marmorata) occurring when the infant undergoes hypothermic stress.

If any mark on the skin is to be considered to be a “birth mark,” there is rarely an infant born without several. In view of the many variations of normal and the important signs of other diseases or syndromes that are manifested on the skin, understanding the common physical findings of the neonatal skin is fundamental.

Lymph nodes are palpable in more than one-third of all neonates, most commonly in the inguinal region and independent of perinatal history. These nodes, from 3 to 12 mm in diameter, tend to persist (100). A benign node commonly palpable in the femoral triangle serves as a reliable landmark for finding the femoral pulse adjacent to it.

The most frequent, abnormal congenital lymphatic masses are cystic hygroma or cystic lymphangiomas, which

P.341

are soft, compressible, and often poorly defined masses in almost any part of the body, but commonly in the head, neck, abdomen, and axilla. If markedly distended, the hygroma may transilluminate. Ultrasonography reveals their cystic anatomy. A discussion on the congenital abnormalities of the lymphatic system is available (101).

Chest and Abdomen

Size and Symmetry

In term neonates, the chest circumference is 1 to 2 cm less than the head circumference; it is relatively smaller with lower GA. The thorax is normally symmetric and wider than its anteroposterior dimension. The ribs are

compliant, and their shape is easily impacted by external and internal form. Compression from the infant's own arm or a twin's body part may lead to marked asymmetry in thoracic shape and pattern on inspiration. By encouraging the infant to assume the fetal position, the cause of a chest deformation may become apparent.

The abdomen is mildly protuberant compared with the chest. It should be softly rounded, with a diameter slightly greater above than below the umbilicus. The abdominothoracic relation is reversed in diaphragmatic defects, with herniation of abdominal contents into the thorax leaving a scaphoid abdomen. Diastasis recti, a separation between the rectus abdominus muscles, is a normal finding during the newborn exam. Supraumbilical fullness is increased in the presence of duodenal atresia with gastric distension or hepatomegaly, and infraumbilical fullness is increased with distension of the urinary bladder or in severe cases of IUGR with an abnormally small liver. Any significant abdominal visceral enlargement causes distension, as does forced depression of the diaphragm.

Retractions

Mild subcostal and intercostal retractions are common even in healthy neonates because of their compliant chest walls. Suprasternal retractions, indicating proximal airway resistance, are normally less pronounced; supraclavicular retractions are never normal. In conditions notable for loss of lung volume and poor compliance, respiratory movements may become paradoxical (i.e., seesaw) with a collapse of the chest wall on inspiration as the abdominal wall expands. With air trapping and increased thoracic volume, there is an increase in the anteroposterior dimension and abdominal distension as the diaphragm is pushed down.

Because the diaphragm is the primary muscle of breathing with little contribution by accessory muscles, quiet breathing is abdominal, with only mild but equal subcostal retractions. The umbilical stump moves caudally in the midline with each contraction of the diaphragm. In the absence of abdominal abnormalities, any lateral deviation of the umbilicus with inspiration suggests a diaphragmatic paresis with the deviation toward the nonfunctioning side (102). This belly dancer sign is lost during mechanical ventilation. Albeit rare, neonatal diaphragmatic paresis occurs most often with brachial plexus injuries, and it should be considered if an arm is weak.

Auscultation of Breath Sounds

Neonatal lung sounds are relatively more bronchial than vesicular because of better transmission of large airway sounds across a small chest. Changes in the pitch of bronchial sounds from one side to the other or between regions most likely represent main stem or conducting bronchial narrowing. The coarse crackle of a distal airway opening is particularly common in neonates in whom there is a natural tendency in many conditions for microatelectasis. If heard at the end of inspiration, adventitious sounds represent more distal disease compared with those in beginning inspiration, which usually represent conducting airway secretions. A characteristic sound of crushing styrofoam or walking on dry snow signals pulmonary interstitial emphysema.

Locating abnormal sounds requires listening carefully bilaterally. Breath sounds should be symmetric when auscultating right and left corresponding regions of the chest. If they are not, air leaks or fluid collections or consolidations may be present and the cause should be identified. If bowel sounds are heard, the examiner should differentiate direct transmission from herniated contents or referred abdominal sounds.

If there is stridor or wheezing, auscultation of the nose or throat may reveal a site of extrathoracic obstruction. Because there must be sufficient air flow to cause stridor or wheezing in the first place, stimulating the infant may accentuate an obstruction. If an endotracheal tube is in place and an air leak is present, a whistling sound corresponding to ventilator breaths may be evident in the periphery of the lung fields but is loudest over the upper trachea or outside the mouth.

Clavicles

Clavicular fracture is the most common form of birth trauma. If carefully sought by radiographs or repeated examinations, clavicular fractures are found in at least 1.7% to 2.9% of term deliveries and more frequently on the right side (103). These fractures most commonly occur in pregnancies complicated by macrosomia, shoulder dystocia, or operative vaginal delivery. Most clavicular fractures are asymptomatic and are incidental findings on a chest radiographs. When symptomatic, the most frequent findings are swelling from hematoma, crepitations, asymmetrical bone contour, and crying with passive movement. There may be an associated brachial plexus injury or pseudoparesis, with poor movement in the affected arm and an asymmetric Moro reflex. As well, an

infant may not be willing to breast-feed on one side because of discomfort with positioning. Standing at the foot of the infant, the examiner feels each clavicle, compares ease of outlining the distinct borders of the bones, and assesses tenderness,

swelling, or crepitation. Finally, the clavicles may be hypoplastic or absent as in cleidocraniodysostosis. If they are absent, the shoulders may be made almost to touch in the anterior midline.

Nipples

The breasts of term infants vary in diameter from 0.5 cm to several centimeters, with clinically insignificant differences between genders. The internipple distance varies with GA and body weight, but its relation to chest circumference is more constant. If the internipple distance divided by the chest circumference is greater than 0.28 cm, the space is more than 2 standard deviations above the mean regardless of body size (104). Larger breasts, influenced by maternal hormones, may secrete a thin, milky substance (i.e., "witches' milk") for a few days or weeks. Although the degree of enlargement may not be the same in both breasts, they should never be hot, red, or notably tender. Unless there are specific signs of inflammation, enlarged breasts should be left alone.

Supernumerary nipples occur in 1.2% to 1.6% of darkly pigmented infants but are more unusual in lightly pigmented infants. These supernumerary nipples, seen in the milk line below and lateral to the true breast, are rudimentary, occasionally only distinguishable because of the presence of a small pigmented mark or dimple. Speculation that infants with supernumerary nipples have a higher incidence of renal and urinary tract malformations has been refuted (105).

Umbilicus

The umbilicus normally is positioned approximately halfway between the xiphoid and pubis. A caudally placed insertion occurs in conditions of caudal regression or underdeveloped lower body segment. The neonatal appearance of the umbilicus does not indicate what the adult appearance will be because most are relatively protuberant with redundant skin.

The umbilical cord is assessed for appearance, length and diameter, number of vessels, and insertion site. The cord is a uniform ivory color ranging in length from 30 to 100 cm; a shorter cord suggests decreased fetal movement and a reason for fetal distress, failed descent, or avulsion. Deep green staining of the cord is a sign of prior fetal distress reflecting the passage of meconium at least several hours prior to delivery. Superficial staining reflects very recent passage of meconium. Longer cords are more likely to result in fetal entanglement or prolapse. At term, the cord diameter is an average of 1.5 cm and is relatively uniform throughout its length, without strictures. If the base of the umbilical cord itself is especially broad or remains fluctuant after vascular pulsations have stopped, there may be a herniation of abdominal contents into the cord.

At birth, the presence of two arteries and a single vein should be identified. Single umbilical arteries occur in approximately 1% of pregnancies with nearly 10% of identified cases having another congenital malformation. A thin cord with a paucity of Wharton's jelly is present in neonates with IUGR and may be compressed more easily by fetal parts. As the cord dries, it should remain odorless. The base should not appear red or indurated. After the cord falls off, the umbilicus should be examined for granuloma or continued leakage through a patent urachus.

Palpation of Abdomen

The infant tolerates palpation of the abdomen best when the organs are brought to the examining hand rather than the fingertips pushing into the abdomen and probing for the organs. Standing at the right side of the infant, with the left hand lifting the legs and raising the pelvis slightly off the mattress to relax the abdominal muscles, the examiner can keep the right hand flat and use the fingerpads rather than fingertips to palpate the abdominal organs. Palpation should start below the umbilicus on both sides and proceed toward the diaphragm. In some instances, it is helpful to palpate the abdomen with the infant in the decubitus or prone position, allowing the contents to fall toward the hand rather than being pushed away (106). Palpation of the abdomen in ill neonates increases centrally measured blood pressure by as much as 25% above baseline (107). The liver is normally palpable 3.0 ± 0.7 cm below the costal margin in the midclavicular line and across the midline as a left lobe that is distinguishable from the spleen, which is felt more laterally (108). Finding a left lobe larger than the right may reflect situs inversus. A liver edge that is palpable greater than 4.4 cm below the costal margin is

indicative of hepatomegaly although hyperinflated lungs may falsely give this impression (108). Assessing the liver span in this circumstance will provide a better assessment of liver size (109). By 34 weeks, the normal liver span, determined by percussing the upper and lower margins, is at least 6 cm in the midclavicular line (110). An exception to this is infants who are SGA in whom the span may be up to 1 cm less (110). An effective technique to outline the margins of the liver or any solid abdominal mass is to scratch lightly across the skin surface while auscultating with the diaphragm of the stethoscope held over the mass. The pitch elevates when the stroking overlies the solid mass or liver.

The normal edge of the liver is thin and soft, and the hepatic surface is smooth. A full or firm edge commonly represents a marked increase in total blood volume, increased extramedullary hematopoiesis, chronic infection, early cirrhosis, or an infiltrative process. Hepatomegaly is a late and inconsistent finding in cardiac failure. Cardiac pulsations in the liver occur in right-sided obstructive cardiac lesions, but these hepatic pulsations should be differentiated from a normally transmitted cardiac impulse or respiratory excursions. In the first 24 to 48 hours after birth, the liver often decreases markedly in size, probably reflecting redistribution of circulating blood volume.

Although the spleen is often not palpable in the newborn period, an attempt should be made to palpate it. Beginning in the right lower quadrant, one gently palpates with the

P.343

right hand in a direction cephalad and to the left side of the abdomen until the fingers come to rest under the left subcostal margin. Successful palpation may be achieved by placing the left hand under the left posterior subcostal margin and applying gentle anterior pressure to bring the spleen forward. If this maneuver is not fruitful, then positioning in the right lateral decubitus may displace the spleen in an anteriomedial direction, allowing for easier palpation.

The kidneys are palpable if the abdomen is soft, and they are moderately firm and rounded. It is often easier to palpate the right kidney as it is displaced more caudally than the left by the liver. An enlarged ureter simulates a filled segment of large bowel, although it is less mobile. A fullness in the lower abdomen may be a distended bladder in an infant with infrequent voiding.

An infant reveals abdominal tenderness by a grimace, cry, or drawing up of the legs on light palpation. True guarding is unusual. Rebound tenderness is difficult to detect, and infants with significant peritoneal disease are often too obtunded to show a reliable response. The presence of localized edema or discoloration of the abdominal wall is an important indicator of intraperitoneal disease. An unusual exception is ecchymosis caused by leaking of an umbilical vessel or urine edema from a patent urachus leaking into the subcutaneous space above the peritoneum. In either case, the dramatic findings are limited to the abdominal wall below the umbilicus. A thin abdominal wall allows transillumination of fluid- or gas-filled masses to outline their position and size. Meconium-filled bowel loops do not transilluminate, but stomach or bowel distended with air, hydronephrotic kidneys, or a distended bladder will. A transillumination pattern that shifts with patient rotation suggests free air.

Auscultation of the abdomen includes listening for pitch and activity of bowel sounds and for bruits. Infants normally have relatively inactive bowel sounds on their first day of life or if they are extremely premature and not fed for several days or weeks. Even in infants with clinical ileus, bowel sounds tend to persist to some extent; however, a true absence of bowel sounds is always significant. Detecting changes in the pattern of bowel sounds is more helpful than the findings of a single examination. Auscultation may reveal the presence of a bruit over the liver, indicating an arteriovenous fistula, or over the kidneys in the presence of renal artery stenosis.

Cardiovascular System

The changes that occur in the cardiovascular system during the neonatal period complicate the cardiac examination until the pulmonary and systemic pressures reverse their fetal associations, all communications have closed, and the left ventricle becomes predominant. The role for most clinicians in the newborn examination is not to determine precisely what the cardiac anatomy is but to rule out cardiac disease as part of a routine newborn examination, and in a symptomatic infant, to determine if the cause of the symptoms is cardiac.

The physician must determine the urgency of the condition by asking some basic questions. Is this a cardiac disease that could be fatal if not immediately diagnosed and treated (e.g., ductal-dependent lesions, cyanotic heart disease)? Is its presence aggravating or relieving other conditions (e.g., patent ductus arteriosus [PDA] in the presence of lung disease or pulmonary hypertension)? Is this something that requires following the patient

and potential future intervention but is not emergent and should not interfere with newborn and parental adjustment (e.g., mild pulmonic stenosis or a small septal defect)?

Palpation of the chest may be informative in several ways. The position of the point of maximal impulse (PMI) may be displaced downward and laterally from its common location in the fourth or fifth intercostal space in the midclavicular line. This finding suggests cardiac enlargement, which should be followed by palpation at the lower edge of the xiphoid. A strong impulse in this location is indicative of significant right ventricular enlargement, which could reflect right-sided or biventricular enlargement as the cause of PMI displacement. Additional information obtained from palpation may be parasternal heaves, another sign of ventricular enlargement, or thrills in the presence of significant murmurs.

Careful auscultation of the chest will reveal two heart sounds with an occasional splitting of the second heart sound due to changes in pulmonary blood flow with normal respiration. This split may be difficult to appreciate, however, in infants with heart rates in the upper range of normal or in those with frank tachycardia. In addition to examining the heart sounds, it is important to palpate the strength of the peripheral pulses, taking special note of the intensity of the femoral pulse relative to the brachial pulse. The femoral pulse is located just lateral to the femoral triangle beneath the inguinal ligament. The typical radial-femoral delay observed in older children with coarctation of the aorta is difficult, if not impossible, to appreciate in the setting of such rapid heart rates. It is critical, therefore, to establish the strength of the femoral pulses and if weak or not palpable, urgent echocardiographic examination is required. Bounding peripheral pulses are indicative of a *run-off* situation, such as a PDA with marked left to right shunt or less commonly an arterio-venous malformation.

Murmurs persisting after the first 12 hours are likely to reflect structural abnormalities even though they may not be hemodynamically significant. In one study of infants referred to the cardiology department for murmurs between 12 hours and 14 days, 84% had identifiable lesions, with ventricular septal defects (39%), pulmonic stenosis (15%), and PDA (15%) most common (111). The remaining 16% had normal hearts with innocent murmurs due to tricuspid regurgitation or peripheral pulmonic stenosis. Very commonly a systolic murmur from a closing PDA will be present in the first 24 to 48 hours of life. The key to diagnosing this murmur is serial examinations to confirm that in fact the murmur has disappeared. Whether or not echocardiatic evaluation is warranted requires clinical judgment if there is no option for reexamination in a timely manner. It is important

P.344

to remember that infants with the most serious forms of congenital heart disease may have no murmur but often will have other clues in the cardiac examination.

Evaluation of the cardiovascular system begins in the delivery room with assessment of the Apgar scores and includes evaluation of heart rate, color, and respiratory effort. Frequently, a line of demarcation is observed, with the head, right arm, and right side of the chest pink and the rest of the infant pale or cyanotic until there is functional closure of the ductus. With vigorous crying, its disappearance indicates an appropriate drop in pulmonary vascular resistance and transductal shunting. Another reassuring milestone in cardiac transition often noticed at the first bath by nursing staff is a brief but bright red flush over the entire body and extremities. This blush, reminiscent of cooked lobster, is distinguishable from the darker, ruddy, plethoric color of polycythemia, which is accentuated in the mucous membranes and less so on the palms and soles and is more persistent. The blush is not seen in infants with cyanotic cardiac disease. Specific points to be considered in the cardiac examination are outlined in Table 19-3.

Genitourinary System

In the delivery room, one of the first documented observations of the neonate is assignment of gender. Genital abnormalities are relatively uncommon but cause significant stress to new parents, and so it is important to distinguish the variations of normal from pathologic malformations. It is always urgent to start an appropriate evaluation of gender if it is in question.

The male infant should be examined by stretching the penis for an expected penile length at term of at least 2.5 cm. Although previously unrecognized, a recent study has indicated that there may be racial differences in the size of infant genitalia. As such, infants having measurements at the extremes of the standard length curves should be compared to others from their racial background if this information is available (112). The presence of chordee prevents complete stretching, but a twisted median raphe is of no significance. In obese infants, the shaft may be retracted and covered by suprapubic fat, appearing to be too small unless it is stretched. The observation of the presence of erectile tissue essentially eliminates true micropenis as a consideration. The meatal opening should be located although completely retracting the foreskin is unnecessary. Any significant

glandular hypospadias generally is accompanied by incomplete foreskin and therefore is readily apparent on simple inspection. Fortunately, the newborn frequently provides opportunities to observe the origin, direction, and force of his stream on urination.

The presence of both testes deep in the scrotal sac indicates term gestation. If a testicle is not felt within the sac or canal, use a lubricated finger to sweep from the anterior iliac crest along the canal while palpating the scrotum. The volume of the testes should be estimated. Table 19-4 summarizes the normal values. If the scrotum or a testis is distended but soft and nontender, transillumination may reveal a hydrocele. Deep discoloration suggests hematoma or torsion and a need for immediate surgical evaluation, but superficial scrotal cyanosis (see color plate) may represent benign ecchymosis after breech presentation. Only in rare instances will a salvageable testicle be found as most often it is a remote vascular insult and was resorbed before birth ("vanishing testicle"). Hydrocele of the cord, a harbinger of inguinal hernia, is not so likely to transilluminate but is easily felt.

The female genitalia should be inspected for size and location of the labia, clitoris, meatus, vaginal opening, and the relations of the posterior fourchette to the anus (Table 19-4). Virtually all female newborns have redundant hymenal tissue. Hymens tend to be annular with a smooth or fimbriated edge and a central or ventrally displaced opening. Tags of tissue may extend from 1 to 15 mm beyond the rim of the hymen and occur in at least 13% of female neonates. These tags disappear within a few weeks. A complete review of hymenal variations in newborns is available (113). An imperforate hymen can present with a hydrometrocolpos, a build-up of mucoid or bloody secretions causing a mass protruding from the vagina, which usually resolves with spontaneous rupture or regression but can enlarge significantly and cause urinary obstruction or apparent discomfort. Assessment for virilization in the female is difficult because there are varying degrees of clitoral hypertrophy and labioscrotal fusion. With clitoral size realized by 27 weeks of gestation but with little deposition of fat in the labia, there is particular confusion about clitoral hypertrophy in premature infants. As gestation progresses, the labia majora enlarge and by term should completely cover the labia minora. Masculinization causes posterior fusion of the labioscrotal folds independent of clitoral hypertrophy. The distance of the anus from the posterior fourchette varies by GA and body size, but its relation relative to other genital landmarks is more constant (Table 19-4). Measurements are made with the hips flexed and the infant relaxed so that the perineum does not bulge. It is important in both genders to identify a normally positioned anus. Anterior displacement of the anus, while not problematic in the early months of life, frequently causes significant constipation after the stools become more formed.

Musculoskeletal System

Examination of the spine includes observation for abnormal curving and cutaneous manifestations of underlying deformities such as sacral agenesis or spina bifida. A pilonidal sinus is suspected if the bottom of a sacral pit is not visible or there is moisture in an otherwise dry area. Long tufts of hair, an overlying hemangioma, or pigmented nevus potentially indicate a tethered cord unless well below the origin of the cauda equina. A palpable mass usually indicates a lipoma if covered by normal skin that moves with it. A sacrococcygeal teratoma tends to be a fixed mass just lateral to midline, and spinal dysraphism presents as a midline mass, most frequently without full skin coverage. One assesses the extremities for symmetry, size and length, range

P.345

P.346

of active and passive motion, and obvious deformity. The length of the upper extremities should allow the fingers to reach to the upper thighs on extension. The muscles are not well defined but should not feel atrophic or fibrotic.

TABLE 19-3 NEONATAL CARDIAC EXAMINATION

Finding	Key Location	Points to Consider
Color	Over entire surface except presenting part; inside oral mucous membranes	Peripheral cyanosis may include area around mouth but not inside mucous membranes Prominent venous-capillary plexus around mouth and eyes simulates cyanosis Acrocyanosis of extremities reverses with warming Mild cyanosis may appear as pallor or mottling Infant with PDA run-off looks washed out, particularly in the feet
Respiratory pattern	Lateral view of chest and abdomen Alae nasi	Most often have respiratory rate within normal range May be cyanotic but tachypneic without distress (e.g., retractions, labored breathing) unless there is pulmonary edema or severe acidosis
Heart rate rhythm	PMI	Resting rate 120-130 bpm (range 100-150); higher second to fourth weeks and in premature infants Most premature beats are transient and benign

Precordial bulge	Thorax compared side to side and to the abdomen	<p>Thoracic asymmetry indicates bulge with AVM, tricuspid regurgitation (i. e., Ebstein anomaly), tetralogy with absent PV, intrauterine arrhythmia, or myocardopathy</p> <p>Most commonly, asymmetry indicates pneumothorax, diaphragmatic hernia, atelectasis, or lobar emphysema</p>
PMI	Left parasternal area	<p>Visible until 4-6 h of life during transition; beyond 12 h, associated with volume overload lesions (e.g., AP shunt, transposition, or outflow obstruction)</p> <p>Normally more visible in premature infants but increases with PDA</p> <p>Abnormal to have PMI beyond 1-2 cm left of LSB at less than 1 wk of age</p> <p>Right sided indicates dextrocardia versus shift due to intrathoracic pressures</p> <p>Absence of increased impulse with cyanosis indicates pulmonary atresia, tetralogy, and or tricuspid atresia</p> <p>Increase with cyanosis indicates transposition</p>

BP

Right arm and leg

Thrill: gross insufficiency of AV valve, severe pulmonary stenosis, absent PV

Pressure in lower extremities is equal to or minimally higher than pressure in upper extremities in the first week

Pressures are preserved by ductal flow in the presence of severe left-sided obstructive disease

Norms vary by gestational and chronologic age and method

Pulses

Right and left brachial and simultaneous femoral and right brachial

Look for equality of intensity and timing, synchronicity, slope of impulse curve, no delay in peak between preductal and postductal pulses

Easily seen axillary pulses suggest run-off or wide pulse pressure

Pulse pressure	Systolic minus diastolic BP	25-30 cm of H ₂ O in term; 15-25 cm of H ₂ O in preterm Narrow indicates myocardial failure, vasoconstriction, and or vascular collapse Widened indicates AV malformation, truncus arteriosus, AP window, and or PDA; may not be widened until pulmonary vascular resistance has dropped
S ₁	Upper LSB	Usually single and relatively accentuated; audible split indicates Ebstein anomaly or slow heart rate; decreased with CHF, prolonged AV conduction
	Lower LSB	Increased accentuation with increased flow across AV valve indicates PDA, MI, VSD, TAPVR, AVM, and or tetralogy
S ₂	Upper LSB	Two components should be heard by 6-12 h of age Single sound indicates aortic atresia, pulmonary atresia, truncus arteriosus, and or transposition of great arteries Wide split indicates pulmonary stenosis,

S ₃ and S ₄	Base or apex	<p>Ebstein anomaly, TAPVR, tetralogy, and or occasionally left-to-right atrial shunts</p> <p>Loud sounds indicate systemic or pulmonary hypertension</p> <p>S₃ indicates increased atrioventricular valve flow, PDA, and or CHF</p> <p>S₄ indicates severe myocardial disease with diminished LV compliance</p>
Murmur	Precordium, back, under both axilla	<p>Many serious cardiac malformations do not have their classic murmurs in early neonatal period but will have some combination of signs suggesting pathology; absence of murmur does not preclude presence of serious malformation (e. g., transposition, TAPVR)</p> <p>At least 60% of infants have murmurs during the first 48 h of life; PDA, peripheral pulmonary stenosis, and or tricuspid regurgitation may be indicated</p> <p>Quiet is necessary to auscultate murmurs; may need to disconnect the infant from the ventilator</p>

		for a few beats Persistent murmurs first heard right after birth indicate ventricular outflow obstruction; most often pulmonic stenosis
Venous pulse	Jugular vein, liver	Jugular a and v waves in sleeping infant In presence of cyanosis, pulsating liver suggests RA or RV obstruction
Abdomen	Liver (left and right)	Span greater than 5.5 cm at term; late sign of CHF, presence of left-sided or central liver suggests likely cardiac anomaly
Edema	Presacrum, eyelids, legs and feet; Chest: hydrops	Causes are more often noncardiac except when associated with abnormalities of renal blood flow (e.g., left-sided obstruction of severe hydrops associated with myocardial pathology, such as severe anemia)

AP, aortopulmonary; AV, atrioventricular; AVM, arteriovenous malformation; BP, blood pressure; bpm, beats per minute; CHF, congestive heart failure; LA, left atrium; LSB, left sternal border; LV, left ventricle; MI, mitral insufficiency; PDA, patent ductus arteriosus; PMI, point of maximal impulse; PV, pulmonary valve; RA, right atrium; RV, right ventricle; S1, first heart sound; S2, second heart sound; S3, third heart sound; S4, fourth heart sound; TAPVR, total anomalous pulmonary venous return; VSD, ventricular septal defect.

From refs. 85 and 86.

Hand examination consists of observing its activity and appearance, including the nails, joints, and palmar creases. The creases of the fifth digit should be parallel. If there is shortening of the mid phalanx, the nonparallel creases mark a radial deviation, clinodactyly. Any curve less than 10 to 15 degrees is normal. The thumb should reach just beyond the base of the index finger. Extra digits that are postaxial or on the ulnar side are most often equivalent to skin tags and of no significance; they may be familial, most often in families of color. Extra digits on the preaxial or radial side are often enough associated with hematologic and cardiac abnormalities to warrant further evaluation, regardless of racial background.

The neonate's hips require assessment with each visit because dislocations may not be detectable on every examination. If the femur freely dislocates, it may appear to jerk spontaneously when the infant extends or flexes his or her hip. The legs should be symmetric in length on extension and with the knees flexed as the feet rest on the bed. If they are unequal, suggesting dislocation of the shorter leg (i.e., Galeazzi sign), the next maneuver is to attempt reduction on the shorter side while stabilizing the pelvis (i.e., Ortolani maneuver). With the hip and knee flexed, the thigh is grasped with the third finger over the greater trochanter and the thumb near the lesser trochanter. The other hand stabilizes the pelvis. As the thigh is abducted, gentle pressure applied to the greater trochanter reduces the dislocated femoral head into the acetabulum with a clunking sensation. The commonly felt, benign clicks are distinct from the pathologic clunks, which often are seen as much as they are felt when the femoral head jerks into place. If the legs are of equal length or if they rest in full abduction, the first maneuver is to attempt to dislocate the head (i.e., Barlow maneuver). With the hip and knee flexed, the thigh is grasped and adducted to 15 degrees beyond midline while applying downward pressure. If the hip dislocates on the maneuver, the Ortolani maneuver should then reduce it. If the hip rides to the edge but not out of the acetabulum during the Barlow maneuver, it is subluxable. Even if dislocation is undetectable, there may be telescoping with free movement of the femur up and down, indicating some degree of instability. The Ortolani maneuver may be negative if a teratologic hip dysplasia cannot be reduced. Unless both hips are involved, discrepancy

P.347

P.348

in leg length and inability to abduct fully to the affected side should be present.

TABLE 19-4 NEWBORN GENITALIA

	Parameter	Normal Range	Abnormal Range
Penis	Length	3.5 cm ± 1 cm	<2.5 cm
	Width	0.9-1.2 cm	
Testis	Volume	1-2 cm	
Anus			
Location, male	Anus to scrotum/	0.58 ± 0.06 cm	<0.46 cm
Location, female	coccyx to scrotum	0.44 ± 0.05 cm	<0.34 cm
Size	Anus to fourchette/	7 mm +(1.3 ×	
	coccyx to fourchette	weight in kg)	
	Diameter		
Masculinization (i.e., labioscrotal fusion)	Anus to fourchette/ anus to clitoris	<0.5 cm	>0.5 cm

^a From refs. 87 and 88.

TABLE 19-5 NEONATAL NEUROLOGIC EVALUATION

Test	Technique	Normal for Term	Deviant for Term
Resting posture	Observe unswaddled infant without contact in quiet awake, quiet active, or light sleep states	Moderate flexion of 4 limbs, held off bed Equal side-to-side and upper-to-lower if head is in midline Extension of neck in face presentation or legs in breech presentation	Constant tight flexion Full extension, flaccid or forced Knees abducted to bed (i.e., frog leg) Elbows flexed with dorsum of hands on bed Tight, persistent fisting ATNR persistent ≥ 30 seconds Strong lateral preference
State	Deep sleep Light sleep Awake, light peripheral movements Awake, large movements, not crying Awake, crying	Moves from one to the other with appropriate stimuli Self calms Modulated cry with expression	Is difficult to move from one to the other Stays too alert or cries without physical reason Does not come to fully awake state Weak or monotonous cry
Motor activity	Observe throughout physical examination	Appropriate for state of alertness Symmetric, fairly smooth Expressive face with yawn or cry	Bicycling, swatting without stimulus Asymmetric, weak Jittery while sucking Flat facial expression
Phasic (i.e., passive) tone: resistance to movement Tendon reflexes	Measure resistance to extension (limb recoil) Scarf, heel to ear Test patellar reflex with head midline	Response appropriate for gestational age Patellar reflex only one reliably present at birth	Resists too much or too little Asymmetry Sustained clonus

Postural (i.e., active) tone: resistance to gravity Traction response	Pull to sitting while grasping infant's hands	Infant pulls back with flexion at elbows, knees, and ankles Head comes with body with minimal lag and falls forward when sitting is obtained	Asymmetry in pulling back No resistance Full head lag Pull to stand instead Head does not fall forward as infant goes past upright
Upright suspension	Suspend infant facing examiner with both hands in axillae	Infant supports himself then yields slowly Holds head erect, flexes hips, knees, and ankles Eyes open	Infant falls through immediately Legs extend Eyes fail to open Infant fails to relax and fall through after 1 min
Ventral suspension	Hold infant under chest and suspend in prone position Galant: stroke adjacent to spine Landau: stroke caudocephalad along spine	Flexes arms, extends neck, holds back straight Curves toward side of stimulus Extends back, lifts head and pelvis, micturates	Hangs limply or excessively rigidly Asymmetric incurving Weak or absent response
Positive support	Hold infant to support trunk with feet touching firm, flat surface	Infant extends hips to bear his or her own weight and relaxes after 1 min	Infant fails to bear weight or extends too much or too long
Integrated reflexes Moro reflex	Hold infant in supine position; support head and neck with hand; allow head to drop while still supporting it	Spreading: arms abduct, extend; hands open Hugging: arms adduct and flex; hands close	Unequal laterality Absence of spread Asymmetry Exaggeration with disorganization in state
Tonic neck reflex	Infant in supine, neutral position; turn head to one side; repeat opposite side;	Mental extension, occipital flexion primarily of arms; does not remain in position for >30 seconds	Exaggerated response and stays in position >30 seconds

Withdrawal reflex	Painful stimulus to one foot	Withdrawal of stimulated foot; variable extension of opposite leg	Absence of flexion in stimulated leg
-------------------	------------------------------	---	--------------------------------------

ATNR, asymmetric tonic neck reflex.

TABLE 19-6 ASSESSMENT OF CRANIAL NERVES

Cranial Nerve	Assessment	Pitfalls
I	Withdrawal or grimace to strong odor (e.g., peppermint, oil of cloves)	Rarely tested clinically; rapid habituation
II	Behavioral response to light (i.e., blinking fixing, following, turning to light source); searching nystagmus	Room too bright; infant too deeply asleep; overstimulation of other senses
III, IV, VI	Ocular movement, doll's eyes, oculovestibular response, pupil size, gemini red reflex	Should not force eyes to open; ocular alignment usually poor in neonates; light for pupil response causes eye closing
VII	Facial muscle tone at rest and during crying	Poor mouth opening due to absence of depressor anguli oris muscle
V, VII, XII	Sucking strength, rooting reflex	Gestational age dependent; infant should be hungry
VIII auditory a portion	Behavioral response to horn (i.e., blinking widened eyes); quieting to voice	Room too loud; difficult to distinguish unilateral loss; rapid habituation
IX, X	Swallowing with normal gag	Irritated throat after suctioning
VII, IX	Facial expression to strong flavor	Rapid habituation
XII	Tongue fasciculation, thrust, ability to shape around nipple	Macroglossia

Nervous System

Neurologic evaluation begins with the initial observations made on approaching the infant and continues as the infant is positioned and stimulated for the remainder of the routine physical examination. As discussed earlier, assessing GA includes many of the steps also used to evaluate motor tone and symmetry. Much can be learned about the neurologic state just by observing what the infant does on his or her own; little more is needed unless the observations indicate abnormality or there are particular risk factors. Subtle differences in tone or use require more specific evaluation.

A neonate with facial asymmetry while crying and who has a flattened or absent nasolabial fold has a facial palsy. These are most often acquired during forceps delivery and have an incidence of 1.8 per 1,000 deliveries. More than 90% are expected to recover in the first few years of life (114).

Infants display patterns of spontaneous muscular activity referred to as general movements. In the first three months they are typically writhing of slow to moderate speed and small amplitude (115). There appears to be a correlation between abnormal general movements and later development of cerebral palsy (116,117).

These abnormalities are characterized as those confined to one or few body parts (poor repertoire), involving simultaneous contraction of all limb and trunk muscles (cramped-synchronized), or are chaotic with large amplitude. The most worrisome are the "cramped-synchronized" as they have been most closely linked to the later development of cerebral palsy (117).

The most common peripheral nerve injury associated with vaginal delivery is a brachial plexus injury. Injuries may be incurred secondary to traction on an arm during birth. The upper roots, C-5 and C-6, are most commonly damaged, leaving the infant with a prone adducted arm at his or her side. It is generally advised that infants undergo operative repair if function is not recovered by 3 months of age (114).

Fortunately quite rare, spinal cord injury initially may be confused with bilateral brachial plexus injury if it occurs below C-5. Careful exam, however, will disclose paresis or paralysis in the lower extremities as well. Lesions above this level are likely to incapacitate the diaphragm and present with apnea or severe respiratory distress and may also be complicated by cardiovascular instability (114).

Jitteriness, characterized by rhythmic tremors of equal amplitude around a fixed axis in an extremity or the jaw, may occur in 41% to 44% of healthy newborns in the first hours of life and thus deserves special comment (118). It occurs more often if the infant is awake, after a startle, or after crying. Accompanying symptoms of CNS irritation, hypertonicity, and low-threshold startle may also be present. Jitteriness is distinguishable from clonic seizure activity because of its more rapid rate and its cessation either by pressure or by stimulating sucking; it is most often a physiologic activity. If it fails to cease during sucking, it may be a sign of hypoglycemia, hypocalcemia, or drug withdrawal (118). Jitteriness may persist in some infants for many months with the infants having more severe accompanying CNS symptoms having longer persistence (119).

The basics of the neonatal neurologic examination include assessment of state; spontaneous muscle activity for assessing amount, quality, and strength; passive and active muscle tone; and functioning of the cranial nerves. The steps are described in Tables 19-5 and 19-6.

Chapter 20

General Care

Ian Laing

This chapter describes the general care of the well infant and discusses how a pediatrician may meet the needs of the majority of families whose infants do not require admission to a neonatal unit.

No pediatrician should act independently of midwives, neonatal nurses, obstetricians, fetal medicine specialists, radiologists, geneticists, and practitioners of many other disciplines. The pediatrician should be a member of a multidisciplinary group that meets weekly to discuss the anticipated antenatal problems and to provide an audit of outcomes from the previous months.

There are four phases of care:

- Antenatal
- Intrapartum

ANTENATAL

The past 20 years have seen a revolution in the general public's expectations regarding the standard of care received and the quality and extent of information provided. Midwives and obstetricians are not the only professionals responsible for providing this care and information. The pediatrician must work with these other professionals to ensure the clarity and accuracy of information provided antenatally to mothers and their partners. The team must also grapple with the legal and ethical aspects of "informed consent." Wherever possible, all professionals should strive toward evidence-based medicine. The concept of risk is not yet well understood by the general population.

Information

The developed world has now emerged from the days when underinformed patients conveyed their decisions to professionals. The patient-professional partnership is now crucial. Information should be given to mother and partner as fully as possible, in verbal and written form. Such information should maintain perspective, while being spoken or written in language that the patient can understand.

Risk

Today our communities strive toward “natural” childbirth, emphasizing that birth should ideally be a normal physiologic phenomenon for a healthy woman and fetus. Nevertheless, even the healthiest pregnancy carries a small risk of maternal mortality and a significant risk of morbidity. For the fetus and neonate the risks are much higher: The perinatal mortality is usually between 6 and 10 deaths per 1,000 total deliveries in the developed world. The anticipated risk may change. New possibilities may emerge unexpectedly. Unforeseen emergencies occur without time to discuss them completely. Further-more, some pregnancies may appear to cause initial concern, and such worries may resolve as the pregnancy progresses. The clinician must address the question of whether the mother should be told of all possibilities, even those that may occur once in 500 events. In striving to do so, there is a chance that all perspective may be lost for the patient. A value judgment must be taken in each individual case. This risk, however great or small, is communicated to mother and a plan is chosen accordingly. Written information should capture the idea that the plan may have to change in light of forthcoming events.

Because labor is usually a tiring process for the mother, it is not an ideal time to discuss options that could be better addressed beforehand. Mode of feeding, vitamin K prophylaxis, and immunization schedules are examples of subjects that should be explored in depth before the mother enters labor.

Informed Consent

In theory, there should be “fully informed consent at all times.” This is an important goal, but it is not entirely achievable. Pregnancy, labor, delivery, and the neonatal period are all times when unexpected events may arise. Anticipating them all is impossible and would be detrimental to the perspective that a woman and her partner require. Fully informed consent can be aimed at exploring all likely events and their outcomes, test findings, including the implications of false-positive and false-negative results, and

P.352

the concept of changing risk. These goals are commendable, very time-consuming, and potentially bewildering, even for educated parents. Compromises

therefore must be embraced. Professionals should obtain written informed consent where possible, and those who administer, manage, and finance the health program must recognize that the informed consent procedure is time-consuming and requires increased staff resources.

Infant Feeding Information

There is great variation throughout the world in rates of breast-feeding. This variation is largely cultural in origin. Some parts of the developed world, including Europe, the United States, and Canada, have low rates of breast-feeding and physicians are required to provide mothers with clear information about the proven advantages of breast-feeding. Advantages include lower prevalence of maternal breast cancer, lower incidence of infant infections (1) (including necrotizing enterocolitis), lower prevalence of obesity in childhood (2), and lower incidence of sudden infant death syndrome (SIDS) (3,4). Breast-feeding may also provide some protection against allergic disease in childhood.

Vitamin K Information

Hemorrhagic disease of the newborn (HDN) can cause significant neonatal morbidity and mortality. It may present in the early days of neonatal life as bleeding from the umbilicus, skin, or as intestinal hemorrhage. Late-onset HDN may cause intracranial bleeding, with consequent death or brain damage. Infants who are breast-feeding or born of mothers taking anticonvulsants are at particular risk (5). Because of these hazards, all parents should be advised to choose vitamin K prophylaxis for their newborn infants. One intramuscular dose of vitamin K can prevent almost all episodes of HDN. This is a simple and reliable method of prophylaxis. Some reports suggest that there is an increased incidence of childhood malignancy after intramuscular vitamin K prophylaxis, whereas other studies fail to confirm this.

Oral prophylaxis may be given on days 1, 8, and 28, and is effective at dramatically reducing the incidence of HDN (6). Oral prophylaxis requires a motivated parent to remember to administer the second and third dose, or else an efficient community support program must be in place to ensure that the infant is similarly protected.

TABLE 20-1 IMMUNIZATION SCHEDULE

TABLE 20-1 IMMUNIZATION SCHEDULE

Age (Months After Delivery)	Immunization
At birth	BCG (high risk) Hep B (mother carrier)
2	Dip Tet Pertuss Polio HIB MenC
3	Dip Tet Pertuss Polio HIB MenC
4	Dip Tet Pertuss Polio HIB MenC

BCG, Bacille Calmette-Guérin (tuberculosis); Dip, diphtheria; HIB, *Haemophilus influenzae* B; MenC, meningococcal C; Pertuss, pertussis; Tet, tetanus.

Written information should be available for all parents to examine the evidence, and professionals should be available to discuss the issues and provide parents with a recommendation. Anxieties expressed in the literature, whether justified or not, should not lead parents to reject vitamin K prophylaxis altogether. HDN is a potentially lethal condition.

Immunization Information

Throughout the world there are differences in immunization programs. These depend on varying risks of disease in different parts of the planet, availability of vaccines and ability to refrigerate them, and community education programs. Preterm infants should be immunized at the same postnatal age as their term counterparts. Provided the infant is clinically well, the timing of immunization should be unaffected by gestation. Table 20-1 shows an example of recommended immunization schedules in the developed world. Because each country has its own schedule, the pediatrician should check both the local and current recommendations.

INTRAPARTUM

Ideally the pediatrician attending the delivery of a newborn infant has full information available. The reality is often different. An urgent call to a labor suite is followed gradually by an unfolding history. The pediatrician relies on close observation of the neonate to guide emergency care while the history is gathered.

Information from case records should include the following:

- *Maternal health:* Diseases prior to and during the pregnancy are documented; these include diabetes mellitus and positive human

immunodeficiency virus (HIV) status. In addition, there should be an account of diseases associated with the pregnancy, such as pregnancy-induced hypertension and gestational diabetes.

- *Prescribed drugs during pregnancy:* Some therapeutic drugs may have significant effects on the fetus and neonate (see Chapter 15).

P.353

- *Drug abuse:* A mother may be a chronic drug abuser. Frequently this involves a cocktail of drugs, only some of which are known by professionals. The chronic drug abuser may be a caring mother with feelings of guilt and sincere intentions of creating a healthy environment for the new baby. The mother however, may have a chaotic lifestyle, and there might also be coincident malnutrition, heavy smoking, alcoholism, and positive HIV status.
- *Fetal growth and apparent well-being, including all tests of fetal assessment:* These may involve fetal ultrasonography scans for structural anomalies and nuchal translucency. Data from amniocentesis or chorionic villus sampling may be available. Doppler studies of uterine arteries may have been used to predict preeclampsia and fetal growth retardation. Umbilical arterial Doppler studies may have predicted placental damage and vascular occlusion. Doppler studies of fetal arteries and veins can also be used to assess fetal hypoxemia. Biophysical profile scoring involves cardiotocography, amniotic fluid volume, and three dynamic ultrasonography variables (fetal movement, fetal breathing, and fetal tone). Chapter 12 includes a detailed discussion of these techniques.
- *Gestation:* It is important to know the best estimate of gestation and how this was calculated. An ultrasonography examination in the first trimester is accurate to within ± 2 to 3.5 days. The mother's history of the first day of the last menstrual period may be helpful but is not always available. Remember too that a mother may experience a menstrual period even after conception has taken place, and in these circumstances an early ultrasonography scan may correctly declare that the pregnancy is 4 weeks further advanced than the mother's history would suggest.
- *Date and time of rupture of membranes:* The definition of prolonged rupture of the amniotic membranes is not consistent and is variously described as 12, 18, 24, 48, and 72 hours. It is associated with chorioamnionitis and an increased risk of fetal and neonatal infection.

Events during labor: Assessment of fetal well-being including cardiotocography, passage of meconium, maternal pyrexia, and the results of any fetal scalp pH measurements may guide the resuscitation. The combination of profound fetal acidosis and neonatal apnea requires the presence of an experienced pediatric team that can begin immediate assisted ventilation.

- *Mode of delivery:* Resuscitation of the infant in the room where mother has labored allows the pediatrician to learn firsthand about the ease or difficulty of delivery. Forceps or ventouse (vacuum) deliveries may account for local trauma observed.

NEONATAL

Chapter 18 describes resuscitation of the neonate in detail.

The transformation from fetus to neonate is a remarkable one. The placenta, which until this point has been the provider of food and oxygen and the remover of fetal waste products, is clamped off and the neonate must immediately adapt to take responsibility for these functions. Collapsed, liquid-filled lungs become inflated within seconds, and the capillaries and lymphatics drain most of the pulmonary fluid in a few hours. The fetal partial pressure of arterial oxygen (PaO₂) changes from 32 mm Hg to 80 mm Hg in minutes and achieves 100 mm Hg in a few days. Approximately 95% of infants establish spontaneous respiration by 1 minute after delivery and thereafter become pink and vigorous spontaneously. The purpose of resuscitation is to intervene when these natural processes are disturbed pathologically. Dr. Virginia Apgar's scoring system for assessment of the neonate at 1 and 5 minutes is still used widely today, but the pediatrician should concentrate on assisting the infant to achieve a heart rate greater than 100 per minute and active, crying respirations. In the absence of congenital abnormalities, central pinkness is soon achieved thereafter.

General Principles of Resuscitation

The following principles are guides to the general care of the newborn in the early minutes of life:

- Resuscitation in the delivery room can be readily described to parents while it is happening. Parents fear silences.
- Identification anklets or wristbands are important, but not at the expense of

causing a tiny infant to become cold.

- The loudly crying baby never needs to be intubated or to be given bag-and-mask insufflation. Enrichment of the inspired gas may be required but never under positive pressure. The infant is more efficient than the clinician.
- Do not ever sound frustrated or critical of colleagues during resuscitations. Such sentiments result in a breakdown of essential teamwork and sap the confidence of parents.

Meconium

The contents of the fetal bowel may have been passed prematurely and may have been inhaled during asphyxial gasping prior to delivery. Meconium is a chemical irritant to the lungs as well as a marker of fetal distress. In 9% to 11% of deliveries, meconium is present. The caregiver should thoroughly suction any meconium from the mouth and nares with the head on the perineum. Whether or not meconium should be aspirated from the newborn's oropharynx is controversial (7); the current author is in favor of this practice, but recognizes that more data are required to support or refute this maneuver. It is clear that those infants who are vigorous do not require invasive care. Those who are in poor condition should be intubated and any inhaled meconium aspirated from the trachea.

Cord Clamping

Data are currently being gathered about the ideal time of cord clamping and whether the infant should be held for a

P.354

few seconds below the placenta in order to receive a gravitational transfusion (8). Consequences of receiving too much blood volume are fluid overload, polycythemia, and (later) hyperbilirubinemia. Until the data from research studies are complete, it may be reasonable to allow a 15-second delay to achieve a modest blood transfusion. Because delayed clamping of the cord increases the infant's blood volume, it may be advantageous in extreme preterm infants to ensure an adequate intravascular volume, and perhaps to decrease the necessity for subsequent blood transfusion. There is no place for "stripping" of the cord by "milking" the blood from placenta to baby. The cord should initially be clamped several centimeters from the umbilicus and then be cut (9). Then the cord should be clamped 1 or 2 cm from the umbilicus using a disposable clamp, and cut with sterile scissors distal to the clamp. The cord clamp can be safely removed during the second day of life, at which time the cord should be inspected to insure that

there is no residual hemorrhage.

Drying

The neonate is delivered covered in amniotic fluid that immediately extracts latent heat by evaporation from the infant's body. Consequently, most infants should be thoroughly dried with warm towels.

Temperature Control

Newborn infants lose heat by four physical mechanisms: evaporation, conduction, convection, and radiation. Evaporation is at its most important in the early seconds of life when the newborn is covered in amniotic fluid. Conduction in general contributes little to heat loss because the infant is in contact with warm garments of low conductivity. Convection losses become important when a child is exposed to drafts, and most especially when a child is being nursed naked on an open radiant warmer. Radiant heat loss occurs to cold surrounding objects, that is, the incubator wall in a cool room. Recognition of these physical principles allows heat loss to be minimized by early drying, warm clothing, freedom from drafts, and ensuring that incubators are double-walled with warm gas between the walls. Physical examination, weighing, and bathing of the infant should always be carried out in a warm environment. The neonatal unit and postnatal wards should audit the incidence of neonatal hypothermia and identify the sources of baby cooling. The areas or procedures at fault should be corrected and the quality of care surveyed prospectively.

Identification

Before leaving the delivery room, every infant should be identified by the fixing of a wristband and anklet; the parent(s) should witness the bands being attached. In addition, many institutions now routinely do footprinting, handprinting, and fingerprinting, although it is not yet clear that this is reliable and worthwhile (10).

Security

Because of sporadic baby abductions in maternity units, each unit should have a written policy to protect the infants. Both antenatally and postnatally, parents should be given instructions to maximize the safety of the infant. Parents and staff must verify the identity of anyone requesting to remove the baby from the room. Parents should be encouraged, when in any doubt, to summon another member of the staff to check the identification of the person asking to take the child.

Bonding

The early minutes and hours of a child's life are important times for establishing a close bond between mother and infant. After the majority of deliveries it should be possible to put the infant immediately to the maternal breast for close physical contact even if the mother does not intend to breast-feed.

Control of Infection

Even today infection is one of the major causes of mortality and morbidity in newborn infants. Gowning does not decrease bacterial colonization of the baby nor the incidence of neonatal sepsis (11). The maternity service, in all its departments, must have high-quality handwashing facilities. The troughs should be large with elbow-operated, knee-operated, or automatic taps that produce warm water. Soap must be plentiful. Alcohol rubs should be readily available wherever infants are cared for. Staff should be free of all clothes and jewelry from elbows to fingertips. Each institution should have regular (at least annual) education sessions for staff, and a culture of nonthreatening criticism by peers should be ever-present. All staff on entering a nursery must wash their hands and forearms with an antiseptic (e.g., chlorhexidine or hexachlorophene). Before and after touching each baby, staff should douse hands and forearms in at least 5 mL of alcohol rub or thoroughly wash their hands (12).

Eye Prophylaxis

Throughout the developed world there is great variation in the use of eye prophylaxis. Each individual community should make a risk assessment depending on the incidence of identified *Chlamydia* and gonococcal infections. Erythromycin 0.5% and tetracycline 1% are effective antibiotics against sensitive gonococci, but penicillinase-producing gonococci are increasing in numbers and are best prevented with silver nitrate 1% (13).

If prophylaxis is to be given, the ointments should be instilled within the first hour of life into the lower conjunctival sac. The lids are then gently massaged. It is difficult to produce effective prophylaxis against *Chlamydia*. If conjunctivitis is identified, scrapings of the tarsal conjunctiva should be sent to the laboratory to identify typical cytoplasmic inclusion bodies. Treatment with combined

P.355

oral and topical erythromycin has the advantage of eradication of nasopharyngeal carriage of *Chlamydia*. Equally, if the mother is known to have gonococcal disease, prophylaxis with ointments is insufficient for the infant, who should be fully treated with parenteral antibiotics (13).

General Concepts of Clinical Examination

Chapter 19 describes the details of clinical examination. The purpose of newborn

clinical examination is to identify the child who is unwell and the child who has an evident congenital abnormality. Reassurance is given, along with an opportunity for parents to ask questions of the examining doctor. There is no universally accepted ideal time for carrying out the examination. The pediatrician cannot exclude all congenital abnormalities but rather is highlighting those that can be identified at that time. On day 1 the systolic murmur of ventricular septal defect is not yet manifest. On day 4 the infant may seem well yet may perish on day 5 from aortic atresia as the ductus arteriosus closes. Congenital metabolic diseases may occasionally take weeks, months, or even years to be symptomatic. It should be made clear in writing to parents that the examination is a description of the child's condition on a particular day and time, and that a normal examination does not guarantee that the neonate is perfect in every respect.

Birth weight and head circumference should be accurately measured. This is documented as a baseline for any further consultations, which may arise, and also to contribute to epidemiological data for the population.

Screening Tests

The developed world has the opportunity to use bloodspot screening for conditions not readily identifiable by other means. These diseases screened for vary from country to country and even from region to region. In the United Kingdom, the national universal newborn screening program for phenylketonuria was introduced in 1969, and the program for congenital hypothyroidism was introduced in 1981. Galactosemia, tyrosinemia, and maple syrup urine disease have been screened for in the past but have been discontinued. Cystic fibrosis and anonymous testing for HIV-positive blood are screened for in some regions, and there are plans to screen for sickle cell disorders in the future.

The screening may be done in the hospital, or the midwife or public health nurse may do it during a home visit. The baby's heel is pricked, and four "bloodspots" are collected on a filter paper (the "Guthrie" card). Each country must decide whether they have the time to obtain fully informed written consent from a parent in every case. Some authorities recognize that making written consent compulsory may have the undesirable side effect of reducing uptake of the screening program, with consequent detriment to the individual children with undetected disease. Written information should be provided to parents both antenatally and postnatally. There should also be high-quality verbal communication with all mothers on the subject of newborn bloodspot screening. Pediatricians caring for newborns must be acquainted with their local newborn screening program, not only for the diseases being screened but also for the timing and implementation of the screening and the procedure to be followed for questionable and abnormal results.

Fluids and Growth

Of all infants, 95% are observed to pass urine in the first 24 hours of life (14). The 5% who have dry diapers have probably voided during labor or in the labor suite. Failure to pass urine in 48 hours should trigger careful examination and investigation.

Meconium is usually passed in the first day of life. Failure to do so should prompt the clinician to ask whether meconium was passed prior to or during labor. If failure to pass meconium is confirmed, careful examination should exclude anorectal atresia. Abdominal examination should ensure that there is no evidence of distention. Hirschsprung's disease and meconium ileus may both present with delayed passage of meconium, and the child should be evaluated for these conditions. The infant should be observed until there is reliable documentation of the passage of meconium (14).

Meconium is a dark green viscous substance consisting of bile-stained intestinal secretions, intestinal debris, and cells. It is usually observed more than once per day for the first 3 days of life. After approximately 3 days of milk feedings, the meconium appears mixed with milk stool ("changing stool") and in 2 more days there are well-established yellow milk stools. Delay in appearance of milk stools should trigger the clinician to question the adequacy of oral feedings. Passage of stool in the neonatal period varies in frequency and consistency. Breast-fed infants typically pass stool several times daily, and the laxity is occasionally confused with diarrhea. The stool frequency of formula-fed infants is usually less, and the stool is of a firmer consistency, occasionally confused with constipation (Table 20-2).

Breast-feeding

Breast-feeding should be actively promoted in all societies. Whenever possible the infant is put directly to the breast at delivery. This maintains baby's temperature, promotes bonding, and allows early suckling, which in turn stimulates prolactin production by the anterior pituitary, resulting in milk production in the maternal breast. Nipple stimulation also promotes oxytocin release by the posterior pituitary gland. Oxytocin leads to contraction of the myoepithelial cells in the breast, and this causes the lactiferous sinuses to release milk ("the let-down reflex"). For the first 3 days mother produces colostrum, which is high in protein, immunoglobulins, hormones, and white cells. These probably have a role in protecting the infant against infection. Initially the volumes of fluid produced are low,

P.356

and the infant must break down stored glycogen to maintain blood glucose concentrations.

TABLE 20-2 FREQUENCY OF VOIDING AND STOOLING IN THE EARLY DAYS OF LIFE

	Days 1-2	Days 3-4	Day 5 Onward
Passage of urine	2 or more	3 or more	5 or more heavy diapers
Passage of stool	1 or more meconium	2 or more changing stool, brownish green	2 or more yellow

After the first 3 days, mother reports that her "milk has come in". The clear colostrum is now replaced by creamy-colored breast milk, rich in fat. The exact composition of breast milk varies from mother to mother, and the hind-milk, that which is produced later in the feed, is richer in fat and calories. Once the mother and infant have established satisfactory breast-feeding, almost all of the milk taken is in the first 10 minutes; any suckling thereafter is for social purposes. Suckling for too long, such as greater than 20 minutes, might exhaust both mother and baby and can result in trauma to the nipple with consequent interference with pleasurable breast-feeding.

Pediatricians tend to delegate the instruction and encouragement of breast-feeding to midwives and nurses. Although it is highly probable that these professionals give the best advice to mothers, pediatricians should possess a working knowledge of the mechanics of breast-feeding and the most common associated problems. Infants who fail to breast-feed may develop hypernatremic dehydration, a condition that can be fatal or cause major morbidity. For a detailed review of this lethal and underrecognized condition, see reference 15.

All staff should be familiar with the following principles of breast-feeding:

- Mother and baby should be relaxed and comfortable.
- No artificial teats (soothers, dummies) should be used.
- No artificial milks should be given unless medically indicated.
-

Babies are commonly “sleepy” in the first 24 hours but may demand feeds every 2 to 3 hours thereafter.

- After the full fatty milk has been established on day 3 or 4, infants settle with demand feeds every 3 to 4 hours.
- Babies should suckle often, especially in the early days of life.
- Successful breast-feeding involves a wide-mouthed approach of the baby, the tongue underneath the nipple, the chin pressed into the breast tissue, and the nose high.
- Sucking should be powerful and rhythmic with pause periods for breath while the child remains latched on.
- If mothers are separated from their infants out of necessity, they should be shown how to manually express breast milk manually.
- Possetting and small vomits are common, but all bile-stained vomiting should be considered pathologic until proven otherwise.
- Term babies lose up to 10% of their birth weight and then should show a growth velocity thereafter of approximately 150 to 200 g per week. If there is any doubt about the adequacy of breast-feeding, accurate weighing can be a simple and helpful intervention.
- There is no place for “test weighing,” a procedure whereby a baby is weighed before and after a feed.

Despite these important written recommendations, there is no substitute for an experienced breast-feeding counselor sitting with mother during the early feeds, optimizing mother's position, baby's position, observing latching onto the breast, ensuring that the tongue is able to milk the ducts, and noting that milk supply is adequate and that the infant successfully receives the nutrition required. Every neonatal unit and postnatal ward should possess a copy of the WHO/UNICEF recommendations on “The 10 Steps to Successful Breast-feeding” (16).

Bottle-feeding

If a mother has made an informed decision to bottle-feed her infant, there is no reason why a small formula feed should not be offered in the early minutes or hours of life. Some professionals prefer to offer a water feed first (17), but in healthy newborn infants with no history of polyhydramnios, it is not clear that this is required. Glucose feeds should not be offered, on the grounds that inhalation of glucose can cause a severe chemical pneumonitis. Newborns may take 15 to 30 mL of formula every 3 to 4 hours in the first day, rising to 90 mL feeds 4 to 5 times a day by day 5 (18). A healthy infant can establish demand feeds in the early days of life.

Poor Feeding

Poor breast-feeding is common. Poor bottle-feeding is not. The infant who is thought to be feeding poorly at the breast should be seen by an experienced professional to ensure that there is no underlying serious structural or systemic problem. Never forget infection. If the child is thought to be well, then the most important therapeutic measure is the prolonged patient attentions of a member of staff who is an expert on teaching breast-feeding.

P.357

Primigravid mothers often experience difficulties in achieving good breast-feeding, but even mothers who have breast-fed before may require further encouragement and assistance. They might say, "I have breast-fed other babies before, but I have never breast-fed that baby."

Poor bottle-feeding is much simpler to approach. The milk is available and the intake is readily measured. Again, however, structural and systemic problems should be considered, because the baby with meningitis may feed neither at the breast nor at the bottle. If there is thought to be no underlying pathology, the technique of feeding should be observed. Is the teat (nipple) adequate to allow milk flow? How is the mother holding the infant and bottle? Is the child lethargic, indicating some disease process? Is the child irritable and frustrated, indicating some mechanical difficulty in obtaining the milk desired?

Possetting

Possetting refers to the recurrent production of mouthfuls of milk from a recently fed, satisfied child. This is normal and perhaps universal. The experienced clinician must provide reassurance to the parent on the basis of a careful history and observation of the phenomenon. Adequate weight gain strongly implies that the infant is thriving. In the first few days, when weight loss is the norm, a healthy eager child who produces mouthfuls of milk is unlikely to be concealing a serious disease.

Vomiting

Vomiting is the production of larger amounts of emesis than mere mouthfuls. The occasional episode is common, even in the healthy infant, but this symptom should always be taken seriously. The vomiting infant who is otherwise clinically well and gaining weight at a normal rate is being overfed: there is no other logical explanation. This simple principle can be very reassuring to parents. The infant who is vomiting and failing to gain weight adequately has a problem that must be taken very seriously. The differential diagnosis is large (see Chapter 40). The following general principles may be helpful to the pediatrician.

- Establish the timing and quality of the vomiting. Huge projectile vomits may indicate pyloric stenosis (note that this is more common in 4 to 8 weeks of life and in boys, but it has been described in newborns and in females). Meningitis may also present as projectile vomiting. *Warning:* Both pyloric stenosis and meningitis may present in more subtle ways.
- Always observe a feed and try to establish whether it is accomplished satisfactorily. Mechanical problems, such as cleft palate, may present as vomiting during the feed itself.
- Any child who looks unwell and is vomiting may be septic. Other possibilities include metabolic disease.
- A full clinical examination is required for any newborn presenting with vomiting. Abdominal palpation may reveal the tenderness and guarding associated with necrotizing enterocolitis. Tachypnea may point to infection or metabolic disease, triggering a full infection screen, often including lumbar puncture, and preliminary investigations for underlying metabolic conditions.

Common Neonatal Problems

Potential neonatal problems include cold and hypoglycemia.

Cold

Delivery suites that are designed for maternal comfort may be at inadequate temperatures for the infant. The neonate is limited in compensatory mechanisms, including shivering and vasoconstriction. An acute cold insult may cause the infant

to become hypoglycemic and apneic. Chronic cold injury may result in failure to thrive (19).

Hypoglycemia

Over the years neonatal hypoglycemia has been defined in a multitude of ways. An infant may be said to be hypoglycemic when the blood glucose concentration is less than 2.6 mmol/L (20). Indications for testing blood glucose concentration include growth retardation, jitteriness, lethargy, cold injury, suspected infection, asphyxia, and if the infant is born of a mother with diabetes mellitus. When present, the predisposing condition should be treated. Meanwhile, a strategy must be adopted that will return the plasma glucose to normal levels promptly. This may require the establishment of an intravenous infusion of glucose. There is no "evidence-based" level for such treatment, but if the blood glucose is less than 1.7 mmol/L consideration should be given to the use of intravenous therapy. If the baby is systemically well, it is usually possible to avoid admission to a neonatal unit. Increasing the frequency of oral feeds, hand expression of breast milk, and supplementation with proprietary milk may keep the infant by mother's side. Asymptomatic hypoglycemia warrants careful observation, and the need for intervention is carefully assessed.

Skin Appearance

Chapter 55 addresses this topic in detail. The most common skin appearances that cause parental anxiety are capillary hemangioma; dry, cracked skin; an inflamed perineum; and a maculopapular rash.

Capillary hemangioma ("stork's beak mark"), is seen most frequently at the bregma and the nape of the neck. This red or pink capillary nevus blanches on pressure and fades over the early months of life, being most prominent during crying.

Dry, cracked skin is common particularly in postmature infants. Weeping and erythema should lead the clinician to further pursuit of a diagnosis.

Inflamed perineum, is usually caused by one of two events: ammoniacal dermatitis and candida. Ammoni-acal

P.358

dermatitis tends to show itself as acute erythema on areas of skin exposed to the diaper. Candida is similar except that the abnormality also invades the perineal crease including the groins and often produces satellite lesions over the suprapubic area. This finding should trigger the search for thrush in the mouth; especially on the buccal mucosa.

In the early days of life a maculopapular rash is commonly seen. The papules are

typically pale in the center and surrounded by a halo of erythema. In the well child, this is almost certainly erythema toxicum, which is an entirely benign self-resolving appearance requiring only reassurance. In its most flamboyant form, even experienced neonatologists may wish to culture any weeping area to ensure that the infant does not have staphylococcal dermatitis.

The Clicky Hip

In the absence of a screening program, the incidence of developmental dysplasia of the hip (DDH) would be approximately 1 in 1,000 infants delivered (21).

Chapter 19 describes how to examine an infant for DDH. Only after examining many hundreds of neonatal hips can the clinician be confident of differentiating between a lax dislocatable hip and one that is stable. The dislocatable hip provides a "clunk" in the examiner's hands. A "click" is frequently felt and can be differentiated because it is not associated with a movement of the femoral head at the acetabular lip. Indeed the source of the click is often tendon movement at the knees. Where there is doubt, the clinician should not hesitate to refer the child for an orthopedic opinion. It is much better to have a click confirmed than to miss DDH. The American Academy of Pediatrics has produced an extensive review of this subject as well as clinical practice guidelines (22,23). Primary screening of all newborn infants with ultrasonography examination of the hips is unlikely to be helpful (24). Ultrasonography may, however, be a useful adjunct in studying the hips of infants suspected to have DDH on clinical examination.

The Systolic Murmur

The population of babies with systolic murmurs changes according to the discharge policy of the hospital. If infants are discharged home in the early hours of life, there has frequently not been time for the common systolic murmurs to be heard, because the pulmonary arterial pressures are still similar to aortic pressures, and therefore shunts are small in volume. Thus the ductus arteriosus and ventricular septal defect (VSD) are probably inaudible on day 1. The VSD may first present at the community pediatrician's office when the second examination takes place.

Murmurs have been found in 1% to 2% of babies undergoing routine newborn examination (25), but less than half of these are caused by congenital malformations (26). Furthermore, of babies found to have congenital cardiac malformations, fewer than half have a murmur heard in the newborn period (27). What should the clinician do in the hospital when a systolic murmur is heard? It is a council of perfection that all parents should be told the diagnosis before discharge home. Currently this ideal may not be achievable because of lack of local expertise in echocardiography. In practice, the pediatrician must be satisfied that the child is well, in no distress, with a normal oxygen saturation in room air

and with no cardiac failure. Careful auscultation may lead to a probable diagnosis based on the character, position, and transmissibility of the murmur. Even the most experienced pediatrician should avoid being dogmatic about the complete diagnosis: the typical murmur of VSD may be the only evidence of tetralogy of Fallot, and parents will rightly feel aggrieved by being told that this is a small hole in the inner heart wall that should close off by itself. An electrocardiogram is carried out, and, provided this is normal, the family is provisionally reassured and an appointment is made for early review when the ductus arteriosus might be expected to have closed. On review, persistence of a murmur requires early referral to a pediatric cardiologist for a definitive opinion including echocardiography.

Jaundice

Jaundice is a yellow pigmentation of the skin and sclera, and is manifest to some degree in two thirds of babies in the first week of life (28). Most jaundiced babies are normal (29). The differential diagnosis and treatment of neonatal jaundice are described in Chapter 35. Each jaundiced infant should be carefully examined to exclude infection. The pediatrician should also inquire about mother and infant blood groups and the result of the Coombs (direct antiglobulin) test. In a child established on milk feeds, test a sample of urine for reducing substances: the finding of a nonglucose sugar may indicate a diagnosis of galactosemia. If the child is well, however, the majority of infants manifest jaundice as a transient phenomenon that is more common in breast-feeding babies (30). This is often a result of lower volumes of milk swallowed in early breast-feeding, and the difference is largely eliminated by encouraging the mother to feed her infant every 2 to 3 hours (31). Jaundice should never be a reason for changing a baby from breast-feeding to bottle-feeding. Transcutaneous bilirubin monitoring is a useful, noninvasive technique that can help identify a population of babies who require to be tested by plasma bilirubin levels. Each perinatal unit should have clear protocols for initiation of phototherapy, a therapy whose main purpose is to avoid exchange transfusion, which, in turn, is intended to avoid bilirubin encephalopathy.

Cryptorchidism

At birth approximately 2% of males exhibit failure of descent of one or both testes. Most of these will descend in the next four months of life, perhaps because of a postnatal surge of testosterone. It is true that cryptorchidism is associated with decreased fertility and increased malignancy, but it is not yet

clear that orchidopexy is preventive. Nevertheless, pediatric surgeons may wish to operate when the child is around 1 year of age.

SPECIFIC CONGENITAL INFECTIONS

Syphilis

Syphilis is again beginning to show itself as a significant pathogen worldwide, and consequently congenital syphilis is a resurgent problem. Adequate treatment of the mother prior to 18 weeks gestation almost always protects the fetus. If the mother is untreated, there is up to a 70% chance that the newborn will be infected. There may be fetal loss or hydrops. A surviving newborn infant may present with anemia, hepatosplenomegaly, and pneumonia.

The subject of screening is a vexed one, and each community may reasonably develop a program based on the incidence of congenital syphilis and its anticipated occurrence in years to come.

The Centers for Disease Control and Prevention (CDC) (32) recommends that

Pregnant women should be screened early in pregnancy.
... In areas of high syphilis prevalence, or in patients at high risk, screening should be repeated in the third trimester and again at delivery.... An infant should not be released from the hospital until the serologic status of its mother is known.

Diagnosis in the mother is based on the visualization of *Treponema pallidum* by dark ground microscopy or complement fixation (Wasserman) or flocculation tests (Kahn, Venereal Disease Research Laboratory [VDRL]). The *T. pallidum* immobilization test (TPI) and the direct fluorescent treponema antibody absorption (FTA-Abs) immunoglobulin (Ig) M test are more specific. The obstetrician and pediatrician should work closely with the microbiology laboratory to ensure that the results are correctly interpreted. Such interpretation may vary based on the mother's treatment or partial treatment during pregnancy.

Evaluation of the infant includes the following measures (32):

- Complete physical examination
- Serologic test for syphilis (the same test performed on the mother so that titers can be compared)
- Lumbar puncture for analysis of cells, protein, and VDRL

- Long-bone radiographs

The evaluation and treatment of maternal and congenital syphilis are complicated and should always be managed by a multidisciplinary team.

Hepatitis B

The mother who tests positive for hepatitis B surface antigen (HBsAg-positive) can transmit hepatitis B virus (HBV) perinatally to her newborn. In up to 90% of newborns, the immune response to infection is incomplete and a chronic infective carrier state occurs. The disease in the newborn may present as a very wide spectrum from apparent normality to severe, fatal hepatitis. Perinatally infected infants are at particular risk of becoming chronic carriers, and, even if free of chronic hepatitis, they are at increased risk of developing later cirrhosis or hepatocellular carcinoma. Because immunoprophylaxis against HBV initiated at birth is 98% to 99% effective in preventing virus acquisition by the infant, identification of HBsAg-positive pregnant women is essential (33). In the developed world each country must make decisions about a screening program based on prevalence of hepatitis B, incidence of congenital disease, and the resources available to tackle this major problem. In the United States and Canada, confining testing to high-risk women (e.g., Asian or African race, intravenous drug abuse, multiple sexual partners) may miss 50% of those who are HBsAg-positive; therefore, "prenatal HBsAg testing of all pregnant women is recommended..." (33).

Treatment of the infant whose mother is HBsAg-positive or hepatitis B e antigen (HBeAg)-positive or who has had acute hepatitis during pregnancy consists of immediate, thorough bathing; administration of 0.5 mL of hepatitis B immunoglobulin (HBIG) intramuscularly within 12 hours of birth; and the first dose of hepatitis B vaccine (0.5 mL) intramuscularly, concurrently with HBIG but at a different site.

Additional doses of vaccine are given at 1 and 6 months of age (33).

Babies born to mothers who are HBsAg-positive and anti-HBeAg-positive should have hepatitis B vaccine but not HBIG. When in doubt, the pediatrician must always consult with a virologist expert in perinatal disease.

Note that no special isolation is necessary. Although HBV is found in breast milk, breast-fed infants, even if they are not receiving immunoprophylaxis, are not at increased risk of acquiring HBV infection, and breast-feeding therefore is allowed. In the United States, infants born to known HBsAg-positive women should receive HBIG and the recommended 3 doses of vaccine, but there is no need to delay the initiation of breast-feeding until after the infant is immunized (33).

In some countries a hepatitis B immunization series is recommended for all

infants, including those of HBsAg-negative mothers. National guidelines must be consulted and local programs adapted to the community need. This requires the input of an expert multidisciplinary team.

Recently, because of concerns about thiomersal, which is an organic compound containing mercury, thimerosal-free hepatitis B vaccines have been developed.

Human Immunodeficiency Virus (HIV)

Human immunodeficiency virus (HIV) is a retrovirus that can cause meningitis and encephalopathy. Vertical transmission may occur transplacentally, and also acutely during labor. Such transmission occurs in 13% to 45% of cases, but this risk

P.360

can be reduced by zidovudine and perhaps by cesarean section delivery. Approximately one-third of infected children will become symptomatic in the first year of life.

Maternal antibodies are transferred passively to the infant and are detectable for 15 to 18 months; therefore, HIV culture and identification of HIV proviral deoxyribonucleic acid (DNA) by means of the polymerase chain reaction (PCR) are the preferred diagnostic tests for the newborn. Because false-negative results are common within the first month of life, retesting at 4 to 6 months is recommended. All exposed infants need comprehensive follow up, preferably by a pediatrician with a particular expertise in HIV infection and its profound effects on families.

There are documented cases of infants acquiring HIV infection through breast-feeding. The American Academy of Pediatrics (AAP) recommendation states, "In the United States, where safe alternative sources of feeding are readily available and affordable, HIV-infected women should be counseled not to breastfeed their infants..." (34). This recommendation is now widely adopted throughout the developed world. No special isolation for mother or infant is necessary as long as universal precautions are followed.

POST-DISCHARGE

Car Safety

Car safety ideally should be planned before delivery of the infant. Staff should be aware of the regulations of the national car safety authorities to ensure that the guidelines available in the perinatal service are compatible with the law and are up to date.

The following principles are important:

- The child car seat should be suitable for the weight and size of the child.
- The seat should have a United Nations "E" mark, a British standards "kitemark," or a European "e" mark.
- The parent fitting the car seat should ensure that the adult seat belt passes through all the correct guides.
- If the adult seat has an airbag in front of it, do not fit a rear-facing child restraint.
- It should be possible to fit an adult hand between the child's chest and the restraining harness.

Timing and Planning

Throughout the developed world there is great variation in the timing of discharge home. It should be dictated primarily by the well-being of the infant and of the mother. Mothers with other children at home may be anxious to achieve early discharge, perhaps within hours of delivery. In the United Kingdom this is exemplified by the DoMInO (Domiciliary Midwife In and Out) scheme, where a mother is cared for antenatally, intrapartum and postpartum by the same midwife or team of midwives. No matter what the program available, the professionals should ensure that mother and baby are healthy and that they have been adequately prepared for life in the community.

A checklist should be completed and signed by parents and professionals prior to discharge. The checklist should include at least the following items:

- Parents are able to care for their infant independently.
- Feeding is satisfactory and will be further supported in the community.
- If the child is bottle-feeding, parents demonstrate ability to sterilize bottles and teats.
- Parents have been given information on choking, crying, frequency and

consistency of passage of stool.

- Parents given advice on baby's day and night clothing, outdoor clothing, and how to assess baby's temperature.
- Parents given verbal and written information about prevention of sudden infant death syndrome.
- Audiologic screening has been performed (where this is available).
- Arrangements for follow up are clear, whether this is domiciliary visiting, at the practitioner's office in the community, or by return to a hospital clinic.
- Parents have discussed car seat safety and have a car seat that meets the national safety requirements.
- Parents have demonstrated satisfactory knowledge of elementary cardiopulmonary resuscitation.
- Parents possess any drug prescriptions and have demonstrated ability to administer drugs to the baby.
- Parents possess a written record of any immunizations given and have clear written plans for future immunizations.

It is also important that the discharge plan for mother and infant be individualized. Factors that may alter the plan include baby's birth weight, any illnesses or congenital abnormalities present, parents' wishes and confidence, educational attainment of the parents, staff knowledge of parents' lifestyle and support available, whether the home is urban or rural, and whether transportation is readily available. Special planning is required to support an adolescent mother and her infant: the responsibility of care must be clear, and robust systems should be put into place to allow the teenage mother to return to school whenever this is practical.

The hospital should communicate clearly with the team responsible for care of the family in the community to ensure that continuity of care is seamless.

Chapter 21

Fluid and Electrolyte Management

Edward F. Bell

William Oh

Infants who are born prematurely or who are critically ill cannot regulate their own intake of fluids and nutrients. Moreover, enteral feeding is often limited by feeding intolerance or medical problems that preclude or limit use of the gastrointestinal tract for feeding. In other cases, the infant presents with disordered fluid and electrolyte balance as a primary result of an underlying illness. In all of these situations, water and electrolytes must be provided by prescription of the health provider. Prescribing the correct amounts of water and electrolytes helps to assure the infant's healthy recovery.

The goal of fluid and electrolyte management is to replace losses of water and electrolytes so as to maintain normal balance of these essential substances during growth and recovery from disease. A subsidiary aim in the first days of life is to allow successful transition from the aquatic environment of the uterus into the arid extrauterine milieu. The principles of fluid and electrolyte management in the neonatal period are similar to those established for older children, except for some variations and specific features of body composition, insensible water loss (IWL), renal function, and neuroendocrine control of fluid and electrolyte balance.

To manage fluid therapy of newborns appropriately, the clinician should understand the normal physiologic mechanisms that govern water and electrolyte balance and the variations in these mechanisms that can occur in sick or premature infants. The clinician should develop a systematic approach to the estimation of fluid and electrolyte requirements for correction of deficits and replacement of ongoing losses, both normal and abnormal. Finally, the results of fluid and electrolyte management must be carefully monitored so that the intakes of water and electrolytes can be adjusted as needed.

BODY COMPOSITION OF THE FETUS AND NEWBORN INFANT

Changes in Body Water During Growth

The total body water (TBW) is divided into two major compartments, intracellular (ICW) and extracellular (ECW). The ECW is further divided into the interstitial water and the plasma volume, which is the intravascular component of the ECW

(Fig. 21-1).

In the early stages of fetal development, a large part of the body consists of water (1). It has been estimated that TBW is 94% of the body weight during the third month of fetal life. As gestation progresses, the TBW per kilogram declines. By 24 weeks the TBW is approximately 86%, and by term it is about 78% of body weight (Fig. 21-2). There also are characteristic changes in the partition of body water between ECW and ICW during development. ECW decreases from 59% of body weight at 24 weeks of gestation to about 44% at term, and ICW increases from 27% to 34% of body weight during the same period (Table 21-1) (1,2,3,4,5,6). Infants born prematurely thus have higher TBW and ECW per kilogram than their term counterparts (7,8,9), and small-for-gestational-age infants have higher TBW per kilogram than do appropriate-for-gestational-age infants (9).

After birth, TBW per kilogram of body weight continues to fall, due primarily to contraction of the ECW (2,7,8,10,11,12,13). This mobilization of extracellular fluid occurs in conjunction with the improvement in renal function that takes place following birth (14,15), which is thought to occur as a result of increasing glomerular filtration rate and perhaps, too, as a result of increasing levels of the epithelial transport proteins involved in renal tubular function (16). It has also been suggested that atrial natriuretic peptide

P.363

plays a role in the postnatal contraction of the ECW (13). Various studies have shown an increase, decrease, or no change in the ICW after birth. ICW probably increases roughly in proportion to body weight in the first weeks of postnatal life (2,7,8,17). Thereafter, ICW increases faster than body weight and exceeds ECW by 3 months of age (Fig. 21-2) (1,2). These postnatal changes in body water and its partition between ECW and ICW are influenced by the intake of water and electrolytes (11,18). Failure to allow the normal postnatal contraction of ECW in premature infants may increase the risk of significant patent ductus arteriosus (PDA) (19), necrotizing enterocolitis (NEC) (20,21,22), and bronchopulmonary dysplasia (BPD) (23,24).

Figure 21-1 Distribution of body water in a term newborn infant.

Solute Distribution in Body Fluids
