Chapter 54

Eye Disorders

Sherwin J. Isenberg

The eye is possibly the fastest developing organ in the body. As soon as 4 to 6 months after birth, some ocular functions are permanently set and if impaired, cannot be fully restored to normalcy. The neonate with a serious ophthalmic disorder may be compared to a time bomb. It is not adequate to simply reverse or cure the problem. The treatment must be conducted rapidly, effectively, and reconstruction (amblyopia) must be commenced. Thus, the neonatologist has some responsibility to recognize ocular abnormalities and quickly begin the process of healing.

GENERAL CONSIDERATIONS

Amblyopia

Amblyopia can be defined as a reduction in vision in the absence of, or beyond that explained by, an apparent organic cause. Amblyopia can be divided into a few etiologic classes. Strabismic amblyopia results from a child preferring one eye when the visual axes are misaligned. Reversal, generally with occlusion of the preferred eye, can only be achieved by age 7 to 9 years; the earlier treatment begins, the better. Refractive amblyopia generally results from significant inequality of the refractive errors in each eye. This form of amblyopia also should be reversed by 7 to 9 years of age, with treatment usually consisting of spectacles (or contact lenses) and occlusion of the sound eye. Either of these two forms of amblyopia can begin within the first few postnatal months.

The form of amblyopia that is most feared in infants is deprivation amblyopia. It usually arises before 3 months of age. The cause is blockage of clear images from reaching the retina. It may be unilateral or bilateral and may be caused by a cataract, corneal opacity, or severe eyelid ptosis. There is considerable urgency in reversing this form of amblyopia because good vision can only be attained within the first 3 to 6 months after birth. This timetable coincides with the "critical period" of ocular development in humans (1). Thus, for example, if a significant unilateral congenital cataract is discovered after 6 months of age, one would not expect excellent visual recovery, even after surgery and optical (usually contact lens or intraocular lens) therapy.

Growth and Development of the Eye

At birth, the sagittal (axial) diameter of the eye is 16 mm in full-term neonates (2). It is less in preterm infants at birth. In the first year, this dimension grows 3.8 mm, with half the expected lifetime increase achieved by 12 months of age. With this information, one can appreciate the early anatomic maturity of the eye.

The corneal diameter often is used as an indicator of the size of the entire eye. At term, the corneal diameter averages 10.0 mm. The diagnosis of microcornea (less than 9 mm) or megalocornea (greater than 11 mm) (Fig. 54-1) suggests a similar abnormality in size of the entire globe, which should lead to an appropriate workup (see following). Ultrasonography can be utilized to determine precisely the size of the entire eye. The tactile corneal reflex is absent in 90% of infants at birth, but develops in all by 3 months of age (3).

Three developmental markers exist in the preterm eye that can help the neonatologist define a neonate's postconceptional age. The tunica vasculosa lentis is a plexus of vessels, which is visible prior to 32 to 34 weeks postconception, crossing the pupil anterior to the lens. The lens surface is covered by these vessels at 27 to 28 weeks postconception, at which time they begin to disintegrate (4). Except for a few vessels at the lens periphery, they should be gone by 34 weeks (Fig. 54-2).

The status of the pupil follows a relatively predictable developmental pattern (Fig. 54-3) (5). At 26 to 31 weeks' postconception, the pupillary diameter in relative darkness is quite large (up to 5.0 mm), and the pupil does not respond to light. By 31 weeks, the pupil diameter has decreased to a stable size of 3.5 mm, and the pupil begins to react to light. The light reaction increases in magnitude until reaching stability at term.

The appearance of the macula in the retina is easily appreciated with the ophthalmoscope after the pupil is

dilated. The examiner can determine the infant's postconceptional age by observing the development of three landmarks

P.1470

in the macula: pigmentation, annular reflex, and foveola (Table 54-1) (6). With these three anatomic findings, a neonate's postconceptional age can be estimated from 27 weeks' postconception to term.

Figure 54-1 When the corneal diameter exceeds 11 mm in a neonate, a differential diagnosis must be considered. (See color plate)

EXAMINATION TECHNIQUES

Visual Acuity

In the neonatal period, there is seldom a reason to even attempt to determine the infant's visual acuity. In the first 2 months after birth, the visual acuity is no better than 20/400 because of immaturity of the retina. The retinal periphery, however, can be stimulated with horizontal optokinetic targets to produce nystagmus. This will prove that the infant is developing some vision. Vertical nystagmus responses develop later. Laboratory techniques can be utilized, if necessary, to more precisely determine the visual acuity. These techniques include preferential forced looking and pattern electroretinograms. A blink response to light confirms the presence of light perception.

Figure 54-2 Persistent pupillary membranes, remaining from tunica vasculosa lentis vessels, are the most common embryonic remnants found in adults.

Figure 54-3 Diameter of the pupil (mean \pm standard deviation) in term and preterm neonates in relative darkness (less than 10 ft-c) and after light stimulation (600 ft-c). (From Isenberg SJ. Examination methods. In: Isenberg SJ, ed. *The eye in infancy*, 2nd ed. St. Louis: Mosby-Year Book, 1994:47, with permission.)

Anterior Segment

The anterior segment can be examined using a strong penlight, with magnification as provided with loupes. Alternatively, a direct ophthalmoscope with a setting of about +5 can be utilized. The examiner should observe the eyelids, conjunctiva, cornea, iris, and lens. The corneal diameter can be measured. As described previously, the pupil diameter initially should be observed with a dim light, followed by evaluation of the reactivity to a bright light.

Posterior Segment

Prior to examining the vitreous and retina, it is usually necessary to dilate the pupil. The choice of dilating agents is important because retinal examinations often are indicated in low-weight preterm infants to rule out retinopathy of prematurity (ROP). Sympathomimetic eyedrops can raise a low-weight neonate's blood pressure (7), whereas anticholinergic eyedrops that are thought to be of low concentration can significantly increase gastric acid (8). A safe and effective combination mydriatic eyedrop is 1.0% phenylephrine/0.2% cyclopentolate. One drop should be applied to both eyes and then repeated 5 to 10 minutes later. A third set occasionally may be required if the iris is darkly pigmented.

Although the eyelids can be held open by an assistant if the examination will be brief, usually an eyelid speculum specifically designed for neonatal use is utilized after application of an anesthetic eyedrop. When the examiner is

P.1471

manipulating the eye, infants have been shown to display an oculocardiac reflex, defined as any dysrhythmia or a bradycardia of 10% or more, in as many as 31% of cases (9). Therefore, the assistant should monitor the baby, as well as the eye, as the retinal examination progresses. During the retinal examination, the cornea tends to become dry and opacify somewhat because of the heat of the light, exposure, evaporation, and the recent finding that neonates, especially preterm infants, produce both basal and reflex tears at a reduced rate (10). Thus, while ensuring the stability of the speculum, the assistant also will need to lubricate the cornea.

TABLE 54-1 DEVELOPMENT OF THE MACULA

Observations in the Macula	Postconceptional Age (weeks)
No pigmentation exists	31.5 ± 1.5
Dark red pigmentation appears	34.8 ± 1.0
Part of the annular reflex is evident	34.7 ± 2.4
Annular reflex is complete	36.3 ± 2.2
Foveolar pit is difficult to appreciate	37.6 ± 3.3
Foveolar light reflex is easily observed	41.7 ± 4.0

From Isenberg SJ. Macular development in the premature infant. *Am J Ophthalmol* 1986;101:74–80.

CONGENITAL ANOMALIES

Ocular Size and Shape

Enlarged Eyes

An enlarged eye is suspected when the corneal diameter exceeds 11.0 mm in a term newborn. For confirmation, an A-scan ultrasound can be obtained easily to measure the ocular axial length, which is normally 16 mm at birth (2). If the eye is enlarged, infantile glaucoma caused by an elevated intraocular pressure should be suspected immediately. Infantile glaucoma also often will present with tearing, squinting, photosensitivity, and a cloudy cornea (Fig. 54-4). The cornea often is found to have horizontal lines called Haab striae, which result from a disruption of Descemet membrane. The optic nerve is noted to have an enlarged cup on fundus examination. To differentiate the tearing of glaucoma from that of the much more common nasolacrimal duct obstruction, the examiner should look at, or into, the nostrils. If tears emanate from the nostrils, the nasolacrimal apparatus is patent and glaucoma is possible. If no tears are found in the nostril, a nasolacrimal duct obstruction is likely.

The treatment of glaucoma is fairly urgent because uncontrolled infantile glaucoma will cause opacification of the cornea, enlargement of the eye, creation of significant myopia, and damage to the optic nerve. If unilateral, the myopia engendered can cause amblyopia, even if the cornea is fairly clear. The corneal opacification can cause deprivation amblyopia.

The infant must be examined while under anesthesia to confirm the diagnosis. After confirmation, the treatment is surgical. The ophthalmologist must open the trabecular meshwork filtration system either internally (goniotomy) or externally (trabeculotomy). If those approaches fail, the ophthalmologist may create an external filtration area (trabeculectomy) or implant an artificial drainage device.

Infantile glaucoma has been associated with other ocular problems, such as aniridia; goniodysgeneses (or mesodermal dysgeneses), which include Axenfeld and Rieger syndromes; and persistent fetal vasculature (see following). It has been associated with a number of systemic disorders and syndromes, including Sturge-Weber, neurofibromatosis, Marfan, Pierre Robin, homocystinuria, Lowe, rubella, Rubenstein-Taybi, and chromosomal abnormalities.

The cornea also may be enlarged on a structural basis without glaucoma. However, in this case, the rest of the eye has a normal shape, as can be demonstrated by ultrasonographic examination. Megalocornea is uncommon and usually has an X-linked inheritance pattern.

Small Eyes

A small eye will present with a corneal diameter less than 9 mm in a term birth. Confirmation of an axial length less

than the normal 16 mm, as shown by ultrasound, is desirable. Microphthalmos can range from an eye that is slightly smaller than normal but otherwise intact to an eye that is so small that it cannot be found on routine examination (anophthalmos). In cases of anophthalmos, a small, often cystic, eye sometimes can be demonstrated by MRI, CT, or ultrasound. It may be associated with Klinefelter syndrome or trisomy 13.

Figure 54-4 This cornea is diffusely opacified and enlarged from infantile glaucoma.

There are two, not infrequent, ophthalmic disorders associated with microphthalmos. A coloboma is a developmental gap generally located inferiorly in the eye. It can be recognized externally as an inferior notch in the pupil caused by missing iris tissue, which by itself does not affect vision. More ominously, the defect also can include the optic nerve, macula, and other parts of the retina, which can result in legal blindness (Fig. 54-5). With experience, ophthalmologists now are recognizing the frequent combination of systemic findings called the CHARGE association. It consists of coloboma (C), heart defects (H), atresia choanae (A), retarded growth and development (R), genital hypoplasia (G), and ear anomalies and deafness (E). Facial palsy also is common. At least four of these findings must be present to make the diagnosis.

A second ophthalmic disorder commonly associated with microphthalmos is persistent hyperplastic primary vitreous. It has recently been renamed persistent fetal vasculature, a more encompassing name (11). This disorder often is associated with microphthalmos and hypoplasia of the fovea, as it represents an arrest of ocular development. Many of the sequelae result from abnormal vessels in the vitreous, anterior lens, and equator, causing persistent pupillary membranes, pigmented star-shaped structures on the anterior lens capsule, fibrovascular remnants on the optic nerve (Bergmeister papilla), and nonattachment of the retina. Serious secondary events can ensue, including cataract, glaucoma, lens subluxation, corneal opacities, intraocular hemorrhages, retinal detachments, and chronic inflammation. Because some of these manifestations are treatable, the neonatologist should seek an ophthalmic consultation for any infant with a small eye.

Figure 54-5 A. The inferior iris defect, which resembles a keyhole, does not by itself affect vision. **B:** In this coloboma of the posterior pole of the fundus, the optic nerve is seen at the *top*. A defect as large as this will compromise vision, especially if fibers to the macula are deficient.

Eyelid Abnormalities

Congenital eyelid ptosis is readily apparent to the parents and all who observe a baby. Therefore, its presence often generates an examination within a few weeks of birth. Although the ptosis can be surgically corrected at any time in the baby's life, two considerations will indicate the proper timing of surgery. If the ptosis threatens the infant's vision, it should be corrected early—even within the first few postnatal months. The vision can be threatened in two ways. If the ptosis is total or near total, the visual axis will be obstructed and the child may develop deprivation amblyopia. This is unusual because ptosis is seldom total, which allows the child, once head control is established, to elevate the chin to see under the ptotic eyelid. A more likely mechanism of potential visual loss is by an astigmatism induced by the ptotic eyelid applying subtle pressure to the cornea. This unilateral astigmatism can cause refractive amblyopia, even in a young infant. If vision is not threatened, the surgery can be deferred until 4 or 5 years of age.

A number of eyelid tumors can present at birth. Most frequent is the capillary hemangioma (Fig. 54-6), which generally continues to grow after birth. The skin overlying the mass can be dimpled and red, resembling a strawberry, or it can assume a diffuse purple color if the lesion is deeper. The lesion does not transilluminate and feels spongy. Left untreated, most of these tumors will spontaneously involute after 1 to 2 years of age. Treatment is indicated if vision is threatened by obstruction of the visual axis or induction of astigmatism, as noted previously. Treatment is by injection of a combination of corticosteroids directly into the tumor or by systemic corticosteroids. The direct route may be safer. Favorable results recently have been reported with subcutaneous injections of interferon alfa-2b (12). Lymphangiomas and dermoid cysts of the eyelid also can present at birth.

Figure 54-6 A hemangioma of the eyelid may not affect vision, even if it is large.

P.1473

Corneal Opacities

A number of congenital anomalies can cause corneal opacities at birth. Congenital glaucoma and persistent fetal vasculature have been discussed and must always be ruled out; however, other diagnoses also should be considered.

Birth trauma, usually induced by a forceps placed at or near the eye during delivery, can cause opacities of the cornea. These opacities usually clear within a few days but may leave corneal scars. The corneal damage can leave scarring in the visual axis or induce significant refractive error, which can result in poor vision.

Sclerocornea is a nonprogressive, usually bilateral, anomaly in which the cornea is replaced by opaque sclera-like tissue. Central or total sclerocornea usually is devastating to a child's vision.

Dermoid tumors of the cornea may affect vision similarly if located centrally. A peripheral corneal tumor can affect vision by inducing refractive error. The tumor may be isolated or part of Goldenhar syndrome.

Peters anomaly, characterized by a central corneal opacity and variable iris-corneal or lens-corneal adhesions, is uncommon but a frequent cause of corneal transplant in infants (Fig. 54-7). The periphery of the cornea usually is normal. It has been associated with fetal alcohol syndrome. Corneal surgery often is reserved for bilateral cases because the prognosis for good vision following even initially successful corneal transplantation is guarded. In unilateral cases, poor vision is almost inevitable because of amblyopia in the affected eye. The amblyopia may result from a number of causes, including a possible graft rejection, significant refractive errors, recurrent opacities, and secondary glaucoma.

Figure 54-7 In this unilateral case of Peters anomaly, the cornea is opaque centrally and clear peripherally.

Aniridia

Aniridia, in which much or even the entire iris visible to the examiner is missing, can be compatible with good vision (Fig. 54-8). However, vision can be quite compromised by other ocular associations, including cataracts, peripheral corneal opacities, foveal hypoplasia, glaucoma and nystagmus. If the vision is quite reduced in infancy, nystagmus usually is found.

These children must be followed closely because some of the problems, such as glaucoma and central corneal pannus, may arise later in childhood. The glaucoma is particularly difficult to treat because it often is refractory to medical management. Surgical treatment of the glaucoma can induce a cataract because there may be no iris to protect the lens during and after the operation.

Figure 54-8 Aniridia is evident by the largely missing iris.

Wilms tumor has been reported to occur in up to one third of all sporadic aniridia cases. Therefore, periodic abdominal ultrasonography of children with aniridia is justified. An 11p deletion has been associated with the complex of aniridia, ambiguous genitalia, and mental retardation. Wilms tumor also may occur with this deletion.

Cataracts

Lens opacities in infants may be isolated or associated with a systemic condition. The morphology of infantile cataracts often is distinctive, which differentiates the infantile from other forms of cataract (Fig. 54-9). The location of the opacity within the baby's lens permits a classification of polar, zonular (or lamellar), nuclear, sutural, or total cataract.

About 25% of infantile cataracts are hereditary, especially if bilateral. Therefore, in the workup of infantile cataracts, it is important to examine the parents and siblings. If an asymptomatic cataract that resembles an infantile cataract is found in a family member, the etiology is attributed to heredity and an extensive workup can be avoided. The most frequent mode of inheritance is autosomal dominant with variable expressivity but almost complete penetrance.

Metabolic problems have been noted to cause cataracts in infants. Among these are hypoglycemia, mannosidosis, hypoparathyroidism, maternal diabetes, and galactosemia. Galactosemia, inherited as an autosomal-recessive trait, should be diagnosed on neonatal screening of urinary-reducing substances. But a child with a galactosemia cataract may still present to the pediatrician if he or she was born abroad or has the galactokinase deficiency type, which usually presents after 5 months of age. The cataract resembles a typical oil droplet. Early intervention with a lactose-free diet may reduce the lens level of dulcitol and reverse some or all of the lens opacity. Medications, such as corticosteroids, may cause cataracts but seldom in neonates.

A number of systemic conditions are associated with cataracts. In rubella, cataracts are characteristically total or near total opacities in a smaller than normal lens. In addition, the eye in rubella often is small, has abnormalities of the retinal pigment epithelium (noted as "salt and pepper" changes), and may be glaucomatous. Live rubella virus can survive in the lens for years. Therefore, at surgery, care should be taken with the lens aspirates, especially if personnel in the operating room may be pregnant. Cataracts have been described in other congenital infections, including herpes simplex and varicella.

Figure 54-9 A: This zonular (or lamellar) lens opacity occupies a central area of the lens with small satellite opacities. B: The red retinal light reflex is disrupted by a cataract.

The presence of a cataract should initiate an appropriate workup with the many causes and associations in mind. The list of other conditions associated with infantile cataract is very long and have been discussed elsewhere (13). To rule out familial cataract, both a family history, including any consanguinity, and an examination of the lenses of the parents and siblings should be undertaken. The history should include questions regarding low-birth weight, ROP, hypoglycemia, serum calcium abnormalities, syndromes, or any systemic disorders. A maternal history of infections while pregnant, diabetes, drug ingestion, and toxin exposure should be sought. Laboratory evaluation should include serum for glucose, blood urea nitrogen, calcium, phosphorus, galactose, and "TORCH" titers (toxoplasmosis, rubella, cytomegalovirus, varicella, and herpes simplex). A newly described fetal teratogen, lymphocytic choriomeningitis virus, may also be responsible for some cataracts in families exposed to rodents (14). Urine should be sent for amino acid levels and hematuria. Other tests should be ordered as indicated by the nonocular findings.

An ophthalmologist should judge if the cataract(s) are vision threatening. If so and if the child is less than about 4 months old in unilateral cases or 4 to 6 months old in bilateral cases, surgery is urgent to avoid legal blindness from deprivation amblyopia. The surgeon will remove the cataract using an intraocular suction-cutting device

(lensectomy) and remove the anterior vitreous (vitrectomy) to avoid the postoperative development of posterior opacified membranes. It should be emphasized that many of the techniques used for cataract surgery in adults are not applicable to children. Compared with adults, a baby's sclera is more elastic, which can allow an eye to collapse during surgery; the lens itself is softer; the lens capsule is stiffer; and the vitreous is more

P.1475

solid. For these reasons, special training and experience is desirable prior to operating on the cataracts of babies.

The end of the surgery is far from the end of the infant's visual rehabilitation. An optical device must be used to provide focus after loss of the lens. Spectacles could work, but few infants will keep spectacles in place while in the crib or toddling later. Intraocular lenses, as commonly utilized in adults, generally are not used in infants in developed countries. Current intraocular lenses have one fixed power (focal length), which the surgeon must choose at the time of surgery. The refractive power of the baby's eye will decrease up to eight diopters by 12 months of age and decrease even more later (15). Thus, a lens properly powered for a 1-month-old infant will make the baby highly myopic by 1 year of age. Conversely, a lens placed in an infant's eye with a power appropriate for later in life will leave him quite hyperopic in infancy, when good focus is crucial to developing vision and avoiding amblyopia. For these reasons and because of the concern of leaving a "plastic" lens in an eye for perhaps more than 80 years, intraocular lenses generally are not used by ophthalmologists in infants, unless under a special protocol. New studies are underway to investigate the use of different types of intraocular lenses in infants (16). In underdeveloped countries where no alternative exists, intraocular lenses are being implanted in infants.

The current method of choice to rehabilitate infant's eyes after cataract surgery is contact lenses. The parents are taught to insert the lens in the morning and remove it in the evening. Certain types of contact lenses may be left in overnight, but some ophthalmologists avoid them because of the increased risk of ocular infection. With contact lenses, the eye doctor can easily change the power as the eye grows and the hyperopic prescription decreases.

In all unilateral cases and some bilateral cases, the optical rehabilitation must be accompanied by occlusion of the better seeing eye to reverse amblyopia. Whether to occlude many hours a day to best improve visual acuity or fewer hours to maximize binocularity is a controversial subject (17).

Optic Nerve Hypoplasia

Optic nerve hypoplasia is a frequent cause of unsuspected visual loss. It results in a diminished number of axons in the optic nerve. The number can be low enough to cause legal or complete blindness, or sufficiently reduced vision to cause peripheral field loss with normal visual acuity. The appearance of the nerve can vary from a subtle reduction in size in one segment to a grossly small nerve surrounded by a pigment ring and yellow halo known as the "double ring sign" (Fig. 54-10). If bilateral and vision reducing, this entity often will cause nystagmus in infancy. If unilateral and vision reducing, it may present as a unilateral strabismus in the first 5 years of life. The diagnosis can be made with the direct ophthalmoscope by comparing features of the two optic nerves or with other instruments.

Although this disorder is associated with a number of other entities, two deserve the special interest of neonatologists. Fetal alcohol syndrome appears to be a major cause of optic nerve hypoplasia. In Scandinavia, optic nerve hypoplasia was found to occur in almost half the cases of fetal alcohol syndrome (18). It may be the most frequently encountered ocular teratogenic event.

Another association with optic nerve hypoplasia is septooptic dysplasia (de Morsier syndrome), in which the child has a number of midline central nervous disorders, such as absence of the septum pellucidum, agenesis of the corpus callosum, and dysplasia of the third ventricle. Hypopituitarism, most commonly evident by dwarfism, occurs frequently. Hypothyroidism, neonatal hypoglycemia, sexual infantilism or precocity, hypoadrenalism, hyperprolactinemia, and diabetes insipidus also have been reported. This diagnosis, suggested by the presence of optic nerve hypoplasia, can lead to early treatment to modify these endocrino-pathies. Therefore, all infants with bilateral optic nerve hypoplasia should have imaging to look for abnormalities of the septum pellucidum, corpus callosum, and third ventricle. Endocrine abnormalities are especially likely if the posterior pituitary is ectopic or bright on MRI or the infundibulum is absent (19). The same workup may also be warranted for unilateral hypoplasia of the optic nerve.

Strabismus

In the first few months after birth, infants usually display a variable intermittent exotropia. This divergence decreases with time, as visual acuity and binocularity develop, until the eyes are generally straight by 3 to 6 months of age. Even infants who develop infantile esotropia are initially exotropic after birth (20). Unless the eye position is constantly abnormal in the first 3 postnatal months, observation is appropriate until the baby is 4 months old. Babies with small or variable angles of esotropia may spontaneously improve (21). A constant unilateral strabismus may suggest an examination for the strabismus and the presence of amblyopia, possibly caused by an organic lesion such as retinoblastoma. Neonatologists and pediatricians should

P.1476

examine the posterior fundus of any child with unilateral constant strabismus to rule out a retinoblastoma because an early diagnosis can be life saving.

Figure 54-10 The diagnosis of optic nerve hypoplasia, although not extremely small, is revealed by the rings of white representing sclera and pigmentation representing retinal pigment epithelium.

ACQUIRED DISORDERS

Infections

Ophthalmia Neonatorum

This infection arises in the first postnatal month by microorganisms entering the eye during the birth process. The most feared infection is caused by *Neisseria gonorrhoeae*. In the nineteenth century, neonatal gonococcal conjunctivitis was the major cause of blindness in European children. An extremely marked inflammation characterized by eyelid swelling, conjunctival edema, and copious amounts of purulent discharge usually arises at postnatal day 4 to 6 (Fig. 54-11). The cornea can be perforated within days, which can lead to loss of the eye or corneal scarring and possible blindness in milder cases. The majority of cases are bilateral. As the incidence of adult gonococcal infections has increased in recent decades, so has the incidence of neonatal gonococcal conjunctivitis. Treatment is with ceftriaxone 50 mg/kg intravenously or intramuscularly with proper toilet for the eye to prevent conjunctival membranes.

Chlamydia trachomatis infection is the most common form of ophthalmia neonatorum today, occurring in up to 1% of births in developed countries. The infection produces a mild and chronic conjunctivitis, with pseudomembrane formation and corneal scarring. The signs first appear between 4 and 12 days of age. After a few months, follicles appear in the conjunctiva. Because these infants also can develop pneumonitis, systemic treatment is necessary with erythromycin (usually as an oral syrup), as well as ocular treatment with erythromycin or sulfacetamide ointment.

Figure 54-11 Gonococcal ophthalmia neonatorum.

Other organisms, such as *Staphylococcus* and *Streptococcus*, also can cause ophthalmia neonatorum. The onset of infection usually is later—often after 1 week of age. Some of these organisms may be acquired postnatally. Treatment is with a broad-spectrum ocular antibiotic ointment, such as sulfacetamide or polymyxin B-bacitracin combination.

Chemical conjunctivitis must always be ruled out. This is a noninfectious inflammation caused by the toxic effects of some prophylactic eye medications on the sensitive conjunctiva of newborns. The inflammation almost always is gone by 24 to 48 hours after birth. It is especially frequent after application of silver nitrate to the eyes.

Prophylaxis against ophthalmia neonatorum began in 1881 by Credé in Leipzig, Germany. Using 2% silver nitrate solution placed in the eyes at birth, he reduced the incidence of ophthalmia neonatorum in his hospital from 10% to 0.3%. Today prophylaxis is required in the United States and most developed countries. Silver nitrate is no longer manufactured in the United States and many other countries. Tetracycline ointment can be useful, but has lost popularity because of the frequency of tetracycline-resistant gonococci. Erythromycin ointment may be used (22), but it is better at reducing than eliminating organisms (23). A new prophylactic agent, povidone-iodine 2.5% ophthalmic solution, has proven to be very effective and inexpensive in a large clinical trial in Kenya when compared with silver nitrate and erythromycin (24). It now is being used in underdeveloped countries and may become the medication of choice for ophthalmia neonatorum prophylaxis.

Workup for a neonate with an inflamed eye includes a history obtained from each parent about genital discharge, genital vesicles, and a history of any sexually transmitted diseases. Laboratory analysis includes conjunctival scrapings for Gram and Giemsa stains. *Chlamydia* is assessed by culture or direct fluorescent antibody assay. Cultures should be sent using Thayer-Martin and blood agar media. More specific tests can be ordered if herpes or other organisms are considered.

Nasolacrimal Obstructions

The distal end of the nasolacrimal duct frequently is imperforate at birth. Subsequent infection of the nasolacrimal sac is evidenced by a purulent discharge from the puncta and tearing in the presence of a relatively white eye. In most cases, the infection is alleviated by opening of the occluded duct by 7 months of age (25). The opening may occur spontaneously or be induced by conservative treatment, which consists of digital massage over the duct followed by application of an antibiotic eyedrop, if a discharge is observed. Ointments may only further occlude the duct.

When the symptoms persist beyond 6 to 7 months of age, a probing of the duct usually is indicated. The success rate of a probing procedure is greater than 90%. For persistent obstruction, the probing can be repeated, the turbinate bone can be infrafractured, or the entire nasolacrimal system

can be intubated with silicone tubing. The tubes are removed in 3 to 6 months. A new and quite successful method of treating cases that fail an initial simple probing is to dilate the nasolacrimal duct with a balloon catheter (26).

Systemic Infections

Acquired Immunodeficiency Syndrome

Most infants with human immunodeficiency virus (HIV) infection are asymptomatic. Young HIV-positive children have been reported to have retinal vascular sheathing, optic atrophy, and dry eye syndrome, but these are unusual. They may have a mildly increased risk to develop strabismus and amblyopia. Opportunistic infections of the eye, such as ocular toxoplasmosis and cytomegalovirus retinitis, are less common than in adults and often develop later in childhood. Bacterial infections of the ocular adnexa may be more common than in adults (27).

Rubella

Ocular manifestations of congenital rubella syndrome include pigmentary retinopathy, cataracts, glaucoma, shallowing of the anterior chamber, anterior uveitis, microphthalmos, and corneal clouding with or without glaucoma. About half of all children with rubella will have ocular symptoms, which are bilateral in 70% of cases.

Rubella retinopathy, characterized by pigmentary changes secondary to damage to the retinal pigment epithelium, may be the most common ocular manifestation. The appearance has led to the term "salt and pepper" retinopathy. It usually is concentrated in the posterior pole and can be seen with the direct ophthalmoscope if the media are clear. Despite the appearance, visual acuity is seldom affected by the retinal involvement alone.

Cataracts occur in 30% to 75% of cases (Fig. 54-12). The morphology of the cataract is fairly typical, being either a total opacification or dense nuclear opacities. About half of the cataracts develop and worsen after birth. Because live virus can still be cultured from the lens up to 3 years after birth, it is wise to exclude from the surgical suite during lensectomy any surgical personnel who could potentially be pregnant, even if rubella is only suspected. The surgeon must obsessively remove all the lens protein and much of the capsule. Residual lens particles in rubella can cause a severe inflammation that itself can lead to blindness.

Figure 54-12 Rubella cataracts in a 7-week-old infant.

Cytomegalovirus

The cytomegalovirus reaches the eye hematogenously. It essentially affects only the retina and choroid. The retinopathy presents as patches of retinal whitening, generally in the periphery. The borders of the lesions are indistinct, and retinal hemorrhages with vascular sheathing may be found. The retinopathy occurs in about 5% of infected infants either at birth or later.

Toxoplasmosis

Seventy-five percent of all patients with congenital toxoplasmosis will have ocular involvement. In 10%, the ocular lesions will be present with no evidence of infection in other organs. *Toxoplasma gondii* causes a focally destructive retinal lesion, with severe inflammation that also affects the choroid. The overlying vitreous becomes hazy with inflammatory cells and exudate. The infection often is unappreciated when it is acute, but is

recognized later as a discrete yellow-white atrophic scar with hyperpigmented borders and smaller satellite scars (Fig. 54-13). The macula, which is involved in approximately 46% of cases, will reduce vision and may cause a secondary strabismus (28). This is the single major cause of pediatric blindness in South America and other regions of the world. Peripheral retinal lesions are generally asymptomatic. Although lesions may look quiescent, live organisms may survive within them for years. This is probably the cause of recurrent inflammation in children and adults.

Figure 54-13 A large chorioretinal scar has destroyed the fovea in this child with toxoplasmosis.

P.1478

Local treatment with subconjunctival corticosteroid injections usually is reserved for severely inflamed eyes in conjunction with systemic therapy, as with pyrimethamine and sulfonamides (29). Treatment may not prevent late recurrence.

TRAUMA

Birth Trauma

Any portion of the eye or adnexa can be injured in the birth process in up to 50% of difficult deliveries. The eyelids may be swollen and ecchymotic. Rarely, the eyelids may be everted totally, with the conjunctiva exposed to the environment. If everted, the exposed surfaces should be kept moist with lubricants until reversion is achieved spontaneously or with manual or surgical measures.

The eyeball may be subluxated, usually by delivery forceps. Orbital fractures and hemorrhages may be reported. The conjunctiva may have hemorrhages in at least 13% of births.

A cloudy cornea may result from forceps injury. It almost always is unilateral. Glaucoma, which also presents with a cloudy cornea, must be ruled out (see glaucoma section). Following birth, the cornea trauma often is accompanied by eyelid edema and ecchymosis, as well as conjunctival hemorrhage. Corneal examination may reveal linear opacities, usually oriented vertically, caused by Descemet membrane rupture. Although the overall corneal opacity clears within 2 weeks, healing of the Descemet membrane rupture can create a severe astigmatism or myopia, which can lead to amblyopia and strabismus.

A hyphema (hemorrhage within the anterior chamber) may result from forceps delivery, especially if residual fetal vessels are present. These hyphemas clear in a few weeks with no specific treatment. Vitreous hemorrhages, however, can cause amblyopia and severe myopia, especially if they persist for more than 3 weeks (30). They have been associated with protein C deficiency. Vitrectomy ultimately may be necessary if the hemorrhage does not spontaneously clear. Compression of the head in the course of a vaginal delivery often results in retinal hemorrhages (Fig. 54-14). The incidence has been reported to be 40% within 1 hour of birth, which decreases to 11% by 72 hours (31). They can occur in any area or layer of the retina. Retinal hemorrhages appear flame shaped in the nerve fiber layer, dot shaped in the inner plexiform layer, and dome shaped beneath the internal limiting membrane. The domes may look like Roth spots, with a white center surrounded by an elevated red hemorrhage. Even extensive hemorrhage will resorb within 6 weeks after birth. Rarely, hemorrhages in the fovea resorb slower, resulting in amblyopia in a normal-appearing eye.

Nonaccidental Trauma

Amniocentesis has been reported to damage eyes, usually in the midtrimester of pregnancy. Although most cases have resulted in blindness with frequent loss of the eye, early repair may salvage vision (32). The presence of segmental edema of the conjunctiva or corneal edema in a neonate should raise the possibility of an amniocentesis injury.

Figure 54-14 Retinal hemorrhages in an infant 1 day after birth.

Child abuse often will affect the eye. There are many possible ocular effects of abuse, but intraocular hemorrhage is the most specific sign. Buys and colleagues (33) reported no retinal hemorrhages in a series of 75 children with documented accidental head trauma; however, their nonaccidental trauma cases all had retinal hemorrhages. Thus, any case of suspected child abuse should have an ophthalmology consultation (34).

A different sort of "child abuse" also should be considered. The self-abusing mother may affect ocular development. The most frequent teratogenic effect is probably optic nerve hypoplasia in fetal alcohol syndrome, as described previously. Cocaine abuse has been noted to affect the eye by inducing hypervascularization of the iris (Fig. 54-15) (35). The dilated and tortuous vessels, which run from the pupil to the periphery, usually are gone 1 week after birth. If these vessels are noted shortly after birth, a toxicity screen, which includes cocaine, is indicated.

PHOTOTHERAPY FOR HYPERBILIRUBINEMIA

Light has the ability to photooxidize bilirubin from the skin and subcutaneous tissue. Although useful to reduce hyperbilirubinemia, animal studies have shown that very intense light damages the outer retinal layers irreversibly. In human

P.1479

infants, however, there has been little evidence of long-term damage from these lights (36). Nonetheless, it is prudent to occlude both eyes with an opaque mask or eye patches during this therapy. To prevent the possibility of amblyopia, both eyes should be occluded equally and securely.

Figure 54-15 Tortuous and dilated iris vessels run peripherally to and from the pupil in this cocaine-intoxicated newborn.

RETINOPATHY OF PREMATURITY

In developed countries, ROP is one of the major causes of blindness in infants. This disorder of abnormal vascularization of the retina, formerly called retrolental fibroplasia, tends to occur in low-weight neonates often exposed to large amounts of oxygen. The more premature the child, the more likely is the disease. Of infants with a birth weight under 1 kg, 82% will develop ROP, with 9.3% progressing to vision-threatening sequelae (37). Of infants with a birth weight between 1 and 1.5 kg, 47% will develop ROP, and 2% will be in danger of losing vision.

Prevention

Infants who develop ROP often have other morbidities of the very preterm infant, as well as a complicated hospital course. This makes clinical correlations between ROP and other clinical entities difficult to interpret. Nonetheless, measures have been taken to prevent ROP. Oxygen use is often minimized because hyperoxemia has been shown to be associated or causative in many but not all studies (38). Although it has been recommended to keep arterial oxygen levels between 50 and 80 mm Hg, studies have not definitively determined that this range is safe. Pulse oximetry can be useful, but when the saturation reaches 98% or 99%, the arterial oxygen tension can be very elevated, which may be conducive to the development of ROP. Monitoring the oxygen tension from the conjunctiva may prove to better control hyperoxemia (39).

A number of studies have investigated the use of vitamin E to prevent ROP. Despite early enthusiasm, especially in infants born beyond 27 postconceptional weeks (40), more recent studies have been less supportive. Any benefit from high doses of vitamin E has been overshadowed by the morbidity it has produced in clinical trials, including sepsis, necrotizing enterocolitis, intraventricular hemorrhage, and increased mortality (41,42,43).

The bright lights often found in nurseries have been considered as possibly contributing to ROP. Glass and associates (44) found less ROP in two nurseries utilizing lower ambient light levels. However, problems with controls, randomization, and masking in this study have left the topic of bright lights still in doubt. Studies in humans and animals have yielded conflicting results regarding the effects of bright lights on ROP (45). A subsequent prospective study of 409 neonates found that reducing ambient light exposure in the nursery did not affect the incidence of ROP (46).

Pathogenesis

The pathogenesis of ROP is thought to begin from a combination of prematurity, supplemental oxygen, and

other possible factors causing vasoconstriction of immature retinal vessels. This vasoconstriction interrupts the normal developmental migration of the blood vessels from the optic nerve peripherally to the ora serrata. Vascular closure may cause localized ischemia. Endothelial proliferation adjacent to the vessels extends within the retina and into the vitreous. Fibrous and glial tissue grows, producing hemorrhage, traction, and retinal detachment.

Others feel that the neovascularization is induced by oxidative insult to spindle cells, resulting in gap junctions. If correct, antioxidants would help prevent the disease. The lack of strong evidence for the role of antioxidants, as tocopherol (vitamin E), has limited the acceptance of this theory.

Examination

The decision of which babies to screen is somewhat controversial. Most nurseries desire an examination of any infant with a birth weight below 1,250 g, whereas others use a weight as high as 1,600 g. A University of Pittsburgh study found that above a birth weight of 1,500 g, ROP developed only in infants exposed to at least 6 weeks of continuous oxygen (47).

The examination should be performed as soon as the media is clear enough to permit ophthalmoscopy and the neonate can tolerate the "trauma" of a retinal examination. The use of proper dilating eyedrops was discussed previously.

P.1480

A number of centers advise the first examination be performed 6 weeks after birth. Because vision-threatening ROP has been shown to arise at 33 to 41 weeks postconception, it would be wise to time the first examination at approximately 32 weeks, if possible. Larger preterm newborns may need their first examination sooner after birth than smaller ones.

The subsequent examinations should be conducted as indicated by the findings of the first examination. If no ROP is found but the retina is still being vascularized, the examination should be repeated every 1 to 2 weeks. If ROP is found, the examinations should be repeated weekly. If "plus disease" (tortuosity and dilation of the blood vessels in the posterior pole of the fundus) is noted, the disease may be progressing faster, justifying a repeat evaluation in 3 to 4 days. The examinations are continued until the retinal vascularization has reached zone III (see following), the threshold for treatment (see following) is achieved, or the disease has definitely regressed. There are some rare cases in which regression was followed by reactivation.

Classification

The internationally established classification of acute ROP is meant to characterize accurately the extent of the disorder in a particular eye. Three dimensions or criteria are used—stage, location (anterior to posterior), and extent.

The staging scheme is presented in Table 54-2. In stage 1, the normal progression of vascularization of the retina toward the periphery is halted at a thin demarcation line found by an abrupt change in color of the retina. The line divides the vascularized from the nonvascularized retina. Importantly, the vessels multibranch or arcade at the line. The latter appearance differentiates early ROP from normal vascularization because in the normal state, the advancing vessels usually bifurcate and do not break into an arcade. In stage 2, the demarcation line extends up out of the retinal plane toward the vitreous. This ridge may change color from white or tan to red. In stage 3, extraretinal fibrovascular tissue grows either on the top of the ridge, yielding a ragged appearance, or just posterior. As it grows, it reaches into the vitreous (Fig. 54-16). Stage 4 is reached when the retina begins to detach from traction exerted by the extra-retinal fibrovascular tissue condensing (analogous to a purse string) or, less commonly, from serous fluid elevating the retina. The macula still is spared from detachment in stage 4A, and the visual prognosis is still hopeful. The visual prognosis decreases markedly in stage 4B as the macula detaches. In stage 5, the retinal detachment is total and shaped like a funnel or tulip. In describing the stage, one also should indicate if "plus disease" is present. "Plus disease" is the presence of tortuosity and dilation of the blood vessels in the posterior pole of the fundus. These posterior vascular changes usually indicate that an arteriovenous shunt is occurring in the extraretinal fibrovascular tissue on top of the ridge. "Plus disease" is a worse prognostic sign and may indicate that the disease is progressing faster.

TABLE 54-2 STAGES OF RETINOPATHY OF PREMATURITY

Stage	Character
1	Demarcation line
2	Ridge
3	Extraretinal fibrovascular proliferation
4A	Partial retinal detachment, macula still attached
4B	Partial retinal detachment, macula detached
5	Total retinal detachment
Plus	Dilation and tortuosity of posterior retinal vessels

Figure 54-16 In stage 3 retinopathy of prematurity, laser or cryotherapy is applied when all criteria are met. Note the dilation and tortuosity of the retinal vessels in “plus disease.”

The location is described in zones (Fig. 54-17). Zone I, the most posterior, is a circle centered on the optic nerve, with a radius twice the distance from the optic nerve to the fovea. Zone II extends from the edge of zone I all the way to the ora serrata on the nasal side and, on the temporal side, to the anatomic equator. This leaves zone III, which is a peripheral crescent on the temporal side. ROP in zone I is potentially the most dangerous, whereas disease in zone III is seldom of any concern. The circumferential extent of the disease is noted in clock hours, with an entire eye composed of 12 clock hours. One clock hour equals 30 degrees.

This classification pertains to the acute changes of ROP. There also are cicatricial changes that should be considered. Classification of the cicatricial changes is not yet universally accepted. Usually these changes arise in eyes that have reached acute stage 3 but did not progress to a significant retinal detachment. In these eyes, the vessels are drawn to the lateral side by cicatrization distorting the optic nerve and dragging the fovea laterally (Fig. 54-18). A retinal fold may form. These developments often reduce vision significantly.

Treatment

Many eyes that develop ROP will improve without treatment to the point that few or no remnants of the disorder are evident later. The point at which the prognosis for

P.1481

regression is below 50% is considered the threshold level for treatment. The multicenter trial of cryotherapy defined the threshold level as stage 3 in five adjacent or eight cumulative clock hours in combination with “plus disease” (48). This definition has proven appropriate for disease in zone II. But the results of treatment using this threshold have not been as favorable for disease in zone I. It is very likely that a lower threshold for treatment will be established for zone I disease in the next few years.

Figure 54-17 The scheme of zones and clock hours in the classification of acute retinopathy of prematurity.

The rationale behind this treatment is to ablate the peripheral avascular retina for 360 degrees in the affected eye(s). This approach has been shown in numerous studies to improve diabetic retinopathy, presumably by reducing or eliminating the signal from the ischemic or avascular tissue to the retina to produce neovascular vessels. Initially, cryotherapy was used to destroy areas of the peripheral retina by freezing. Cryotherapy had a number of both trivial and important complications, including subconjunctival hematoma, vitreous hemorrhage, bradycardia or dysrhythmia, and conjunctival laceration.

Figure 54-18 The macula is dragged laterally amidst the retinal folds in cicatricial retinopathy of prematurity.

Currently, cryotherapy has been replaced for most applications by the use of lasers, which usually are mounted on an indirect ophthalmoscope worn on the head of the surgeon (49). There are some specific instances in which cryotherapy is still the method of choice. However, laser therapy has a number of advantages over cryotreatment. Laser surgery can be performed in the nursery with mild sedation and only topical anesthesia because it probably causes less pain than cryotherapy. The treatment session is faster with laser. The eyelids, conjunctiva, and cornea look normal after laser, whereas, after cryotherapy, they easily become edematous and inflamed. The latter consideration often is important to parents concerned about the fate of their premature child. In some studies, laser therapy was reported to produce better visual and structural results than cryotherapy (50). With laser, the incidence of subconjunctival hematoma, conjunctival laceration, and other complications seen with cryotherapy has been reduced to almost zero. However, cataracts have been reported to occur after laser treatment in less than 1% of cases.

The long-term beneficial effects demonstrated by cryo-therapy were evaluated in a large multicenter trial. The

frequency of the potentially blinding ROP sequelae of retinal detachment and retinal fold was reduced by half after cryotherapy (51). At about 6 years of age, poor visual acuity (20/200 or worse) was found in 62% of untreated eyes compared with 47% of treated eyes (52). Despite the destruction of parts of the peripheral retina by cryotherapy, long-term follow-up has found only a six-degree loss of peripheral visual field (53). Whether their infant is treated with laser or cryotherapy, the parents must be

P.1482

informed that although the treatment will reduce the possibility of blindness, blindness may still result despite treatment. Too often, parents assume that, with treatment, blindness definitely will be avoided.

If retinal detachment occurs, all is not lost. Modern vitreoretinal surgery can reattach a detached retina with ROP more than 30% of the time. Once the macula detaches, however, the visual prognosis decreases markedly, even if the retina is reattached successfully. For stage 4A, visual acuity results as good as 20/20 have been reported with the macula still attached. Stage 4B results have been in the 20/80 to 20/200 range. With a total detachment (stage 5), the results decrease considerably to the 20/600 to 20/1600 range or even lower (54). This low level of vision may allow the child to ambulate independently and certainly is better than the blindness that would occur without surgery.

Long-Term Problems

Aside from the problems of poor vision from a detached retina or retinal folds, there are other sequelae that can arise in the eyes of infants with regressed ROP. Even with an attached retina and intact macula, children with regressed ROP have been shown to be more susceptible to a number of visual disorders, including myopia, amblyopia, strabismus, and nystagmus. Children who develop cicatricial retinal changes, even with good vision, are at risk for future retinal problems, including detachment. Therefore, these children should be examined at least annually throughout their life, or at least until they are mature and literate enough to rule out amblyopia and strabismus.

COMMON DIFFERENTIALDIAGNOSTIC PROBLEMS

Leukocoria

When faced with an infant with a white pupil or unusual retinal light reflex, the neonatologist or pediatrician should consider the differential diagnosis and begin a workup (Fig. 54-19). The first obligation is to rule out the potentially fatal retinoblastoma, even in a neonate (Fig. 54-20). The most common lesions that may, to some extent, simulate a retinoblastoma by presenting with leukocoria in infancy include cataract, persistent fetal vasculature, Coats disease, large retinal coloboma, and retinal detachment resulting from ROP. Toxocariasis is not a disease of infants. Coats disease is caused by anomalous telangiectatic retinal vessels that cause massive exudation and retinal detachment. It is important to realize that behind an opaque cataract can lie other problems, such as retinal detachment or a mass.

The history should reveal the presence of prematurity, oxygen use, illnesses during pregnancy (such as rubella, toxoplasmosis, and cytomegalovirus), possible child abuse, or traumatic birth. The nonocular history may help. Deafness suggests the possibility of rubella or Norrie disease (cataract with retinal detachment). Toxoplasmosis or tuberous sclerosis may present with seizures. Incontinentia pigmenti or tuberous sclerosis may have skin lesions. Bilateral leukocoria would favor the diagnoses of ROP, Norrie disease, child abuse, and retinal dysplasias. Unilateral leukocoria is more consistent with Coats disease, persistent fetal vasculature, and intraocular foreign body. Although Norrie and Coats diseases are more common in males, incontinentia pigmenti is more frequent in females.

Figure 54-19 Bilateral leukocoria was found in this neonate. A family history of Norrie disease simplified the diagnosis.

The examination may actually begin with the eyes of the parents. Parents have been found to have an asymptomatic congenital cataract, regressed retinoblastoma, unappreciated coloboma, and findings of familial exudative retinopathy, which closely resembles ROP. Any of these findings in a parent, who usually cooperates better in the examination, generally establishes the diagnosis for the baby. Examination of the child may reveal microphthalmos, which is consistent with coloboma or persistent fetal vasculature. The level of the opacity may be evident with a light or portable slit lamp. If there is a defect in the inferior iris, coloboma should be considered. Lens opacity, of course, constitutes a cataract, but

P.1483

additional examinations, perhaps with ultrasound or radiologic tests, may reveal pathology in the vitreous or retina. A detailed retinal examination is crucial, if the media are sufficiently clear, to diagnose many entities that present with leukocoria.

Figure 54-20 A calcified intraocular mass in an infant with retinoblastoma.

Cloudy Cornea

Profound amblyopia will result from an opacified cornea, especially if it is unilateral. Although some opacities clear with time, others remain. The history, associated findings, and examination will clarify the prognosis.

The history should include illnesses during pregnancy to rule out rubella, syphilis, and herpes, which can cause keratitis. Delivery by forceps of a large neonate suggests birth trauma (Fig. 54-21). Conjunctival hemorrhages suggest a traumatic etiology. The presence of conjunctival inflammation implies infection or pupillary block glaucoma as an etiology.

Systemic physical abnormalities may imply an etiology as an umbilic hernia suggests glaucoma associated with Rieger syndrome. Glaucoma also is suggested by a history of photosensitivity and tearing. Family history is important. On examination, the eyelids may reveal evidence of phakomatoses as the angiomas of Sturge-

Weber syndrome or a neurofibroma.

Most important is the corneal examination. The corneal diameter should be measured as accurately as possible. An enlarged cornea strongly indicates glaucoma, whereas a small opacified cornea may result from sclerocornea, microphthalmos, trisomy 13, or rubella. Striae in the cornea are often helpful. Horizontally oriented striae are compatible with glaucoma, whereas vertical or oblique ones often result from birth trauma. A mass overlying the cornea may be a dermoid tumor.

Measurement of the intraocular pressure in these cases often is imperative to rule in glaucoma. Examination of the iris may reveal adhesions to the cornea. This can result from trauma or may indicate a mesodermal dysgenesis syndrome. This syndrome encompasses a number of developmental disorders, such as Peters anomaly—the most frequent reason to perform corneal transplants in infants. A cataractous lens behind an opacified cornea may be caused by rubella, birth trauma, Lowe syndrome, or mesodermal dysgenesis. If the eye and intraocular pressure are otherwise normal, the opacified cornea may result from a hereditary corneal dystrophy.

Figure 54-21 One week after birth, the corneal opacity caused by a forceps injury is fading.

Chapter 55

Dermatologic Conditions

James G. H. Dinulos

Gary L. Darmstadt

INTRODUCTION

As an organ, the skin provides essential functions for survival and can be an indicator of overall health. At no other time in life are these roles more evident than in a newborn infant who is adjusting to life outside the uterus. Abnormalities in the skin may be extremely distressing to parents and it is important for medical providers to be able to distinguish a worrisome from a banal newborn skin disorder. To assist in this process, this chapter reviews basics of skin structure and development, techniques of skin examination and recognition and management of important newborn skin disorders.

SKIN DEVELOPMENT, STRUCTURE, AND FUNCTION

The skin is composed of three anatomic layers, epidermis, dermis, and fat; and three adnexal structures, hair, nails, and glands. The formation of these skin layers and structures from primitive embryonic tissues occurs in a predictable and sequential manner. Most structural development is complete by 24 weeks of gestation, however, complete functional activity of the skin, such as epidermal barrier development, is not achieved until after birth (1).

The epidermis plays critical functions in fluid homeostasis and in protection from infections, toxins, and adverse effects of ultraviolet radiation (2). The outermost layer, the stratum corneum, provides most of this protection. Lamellar bilayers composed of hydrophobic lipids, principally fatty acids, cholesterol and ceramides, are "cemented" between multiple layers of tightly knit protein- and keratin-rich cornified cells (2,3). These lipids and proteins protect by creating an impermeable barrier and by providing an acidic and xeric environment that impedes microbial invasion. The epidermis is not merely a static barrier, however, as keratinocytes actively produce antibacterial products, including cytokines, lipid breakdown products and cationic antimicrobial peptides that provide an important link between the innate and adaptive immune systems (4,5).

Prematurity and a number of skin disorders disrupt epidermal permeability barrier function and may allow for massive transepidermal water loss (TEWL) (6). Premature infants can lose up to 30% of their total body weight in 24 hours, as their rate of TEWL may be 10 to 15 times greater than in a full-term infant (7). Such significant fluid losses can cause hypotension, electrolyte imbalance, increased caloric demands, and may contribute to intraventricular hemorrhage (IVH) and necrotizing enterocolitis. Epidermal barrier development is accelerated by exposure to the dry, extra-uterine environment (7,8). This barrier maturation typically takes 2 to 4 weeks and may be delayed for 8 weeks in extremely premature infants. Thus, premature infants are particularly vulnerable to infections and toxins, particularly during the first week of life when approximately two thirds of all neonatal deaths worldwide occur.

During development, skin and its structures are thought to migrate along the "lines of Blaschko" (9). Most authorities believe that Blaschko lines are an expression of epidermal and not dermal migration. Conditions that follow these lines are thought to result from a single postzygotic mutation of a single clone of cells or from a mutation on the X chromosome that is brought about by X-inactivation (10). Incontinentia pigmenti and linear epidermal nevi are two

examples of conditions that occur along lines of Blaschko.

Newborn skin may look and feel different depending on the newborn's gestational age. Premature infants less than 32 weeks estimated gestational age (EGA), have skin that appears thin and transparent. Infants born after 40 weeks EGA have thicker skin with wrinkles and peeling. Most term infants have a pasty substance on their skin, referred to as vernix caseosa. Vernix caseosa is a substance composed of sloughed corneocytes, shed lanugo hair and lipids (11). The role of this substance is not fully understood, although it is thought to assist in passage through the birth canal and have an important role in skin hydration and innate immune defense (12). Most premature and postmature infants have little vernix.

Skin adnexal structures (hair, nails, and glands) can provide valuable clues to the overall well-being of the newborn.

P.1486

Most infants are born with hair on the scalp and some have hair on the body. Typically, hair in the newborn undergoes "physiologic" shedding at approximately 3 months of age.

TABLE 55-1 STEPS IN A NEWBORN SKIN EXAMINATION

1. Assess skin integrity.
 - a. Skin breakdown
 - b. Texture
 - c. Hydration
 - d. Swelling
2. Determine primary and secondary skin lesions (See Table 2).
3. Determine the location, configuration and distribution of the skin lesions.
4. Evaluate mucous membranes, palms, soles, hair and nails.
5. If there is a rash, determine whether it is fixed or evolving.
6. Develop a differential diagnosis.
7. Perform appropriate diagnostic tests.
8. Consider referral to a specialist.

EXAMINATION OF NEWBORN SKIN

Newborns should be examined with an adequate light source, preferably natural sunlight. Side-lighting and magnification are helpful to accentuate surface topography. Handheld devices applied directly to the skin such as a dermatoscope can be helpful, especially to examine pigmented lesions. The environment should be kept warm to minimize reactive vascular changes as a result of temperature. Table 55-1 summarizes the steps of a newborn skin examination and an approach to dermatological diagnosis. Table 55-2 lists primary lesions, secondary lesions, special configurations and distributions of skin lesions.

SCALY RASHES

Rashes are common in the first month of life, affecting 80% of newborns (13). During the first week of life, the vast majority of term and postterm infants will have superficial peeling or desquamation of skin; it rarely occurs in those under 35 weeks of gestation. Deeper skin peeling that results in denuded skin or continuous peeling for longer than 1 week are potential warning signs of an underlying systemic process. Scales should be examined for quality (firm, adherent), color (white, yellow), and associated inflammation (redness), features which help in identification of a variety of skin diseases.

Inflammatory Rashes

Diaper Dermatitis

Diaper dermatitis is common in newborns. It is characterized by a pink to red scaly rash localized to the diaper area and is caused by prolonged exposure to urine and stool combined with the frictional forces of the diaper. This irritant contact dermatitis should be distinguished from numerous other dermatological conditions affecting the diaper area. Irritant contact dermatitis affects skin contacting the diaper, such as the pubis, penis, labia majora, scrotum, upper thighs, and buttocks. Generally, the creases are spared. Continued irritant exposure may produce painful fissures and ulcerations (Jacquet's erosive dermatitis), especially in premature infants (Fig. 55-1). Involved skin is susceptible to secondary infection, primarily with *Candida albicans*, *Staphylococcus aureus* and *Streptococcus pyogenes*. *Candida albicans* causes pustules on a red base ("beefy-red") that, after rupture, form erosions surrounded by fine superficial white scale. Frequently, the inguinal and gluteal folds are involved. *Staphylococcus aureus* and *S. pyogenes* cause a superficial skin infection called impetigo, which is characterized by pustules on a red base that form yellow crusts when ruptured. Certain types of *S. aureus* produce an epidermolytic toxin, causing superficial bullae. However, secondary bacterial infection with *S. aureus* and *S. pyogenes* may be characterized primarily by superficial erosions and crusting.

TABLE 55-2 PRIMARY AND SECONDARY SKIN LESIONS, CONFIGURATIONS, AND LOCATIONS

1. Primary lesions
 - a. Macule (<0.5 cm) and Patch (>0.5 cm) - well-circumscribed flat lesion
 - b. Papule (<0.5 cm) and Plaque (>0.5 cm) - well-circumscribed raised lesion
 - c. Vesicle (<0.5 cm) and Bullae (>0.5 cm) - fluid-filled raised lesion
 - d. Pustule - well-circumscribed raised fluid-filled lesion containing leukocytes
 - e. Nodule (>0.5 cm) - deep-seated raised lesion
 - f. Tumor - a large nodule
 - g. Wheal (hive) - raised transient (<24 hours) lesion
 - h. Cyst - fluid-filled nodule
 - i. Telangiectasia - dilated dermal blood vessel
 - j. Petechiae - areas of extravasated red blood cells resulting from broken capillaries
2. Secondary lesions
 - a. Atrophy - depressed lesion
 - b. Erosion - superficial break in the skin
 - c. Ulceration - full-thickness (i.e., break in the skin through the dermis)
 - d. Scale - flakes of skin
 - e. Crust - scale with serum
 - f. Fissure - linear erosion
 - g. Scar - fibrosis of the dermis
3. Configuration
 - a. Blaschko - embryologic lines of skin cell migration (i.e. whorled)
 - b. Linear - straight
 - c. Annular - round with normal skin in central "ring"
 - d. Iris - round with a dark center
 - e. Nummular - round, 'coin-shaped'
4. Location
 - a. Symmetric - both sides of the body
 - b. Localized - one area

Figure 55-1 Erosive dermatitis. (See color plate)

Factors involved in the genesis of diaper dermatitis include increased skin wetness (e.g., sweat, urine and stool) of the stratum corneum (14), which makes the skin more susceptible to friction from the diaper material; and irritation from elevated pH caused by urinary ammonia and from activation of fecal proteases and lipases in the alkaline milieu (15,16). When alkaline urine combines with feces, the potential for irritation is compounded. Breast-fed infants have been noted to have stools with lower pH, which may account for their decreased incidence of diaper dermatitis.

The differential diagnosis of irritant diaper dermatitis includes psoriasis, seborrheic dermatitis, secondary syphilis, histiocytosis, acrodermatitis enteropathica, and cystic fibrosis. In those conditions, however, unlike diaper dermatitis, skin outside the diaper area is usually involved.

Treatment of diaper dermatitis should be targeted toward reducing skin wetness, minimizing contact of the skin with urine and feces, and eradicating infectious organisms. Skin wetness and irritation can be minimized in several ways. Ultra-absorbent diapers have been shown to be superior to cloth diapers in decreasing skin wetness and maintaining an acidic skin pH (17,18). Frequent diaper changes also help to minimize wetness. Barrier ointments (e.g., containing petrolatum) help keep urine and feces from contacting the skin. Other commercial products containing zinc, vitamin A and D also may be effective. The skin should be gently cleansed with water, or if necessary, a mild nonalkaline soap before barrier ointment re-application. Complete removal of barrier ointment with diaper changes is not necessary, however if attempted, may

further exacerbate skin injury. When diaper dermatitis is unusually severe, recalcitrant, or when risk factors are likely to be ongoing (e.g., malabsorption syndromes), a thick layer of pectin-based paste without alcohol, followed by a barrier ointment or zinc oxide ointment, may prove efficacious. Commercially available diaper wipes can exacerbate irritation, and should be reserved for healthy appearing skin or for circumstances in which soap and water is not available.

Mild, low-potency topical corticosteroids such as 1% hydrocortisone ointment can be applied if inflammation is significant; however, higher potency topical steroids should be avoided because of the risk of cutaneous atrophy, striae, adrenal suppression, and Cushing syndrome. Combination antifungal-steroid compounds such as Lotrisone® and Mycolog II® have no use in treating neonatal skin conditions involving the diaper area. Each contains a potent topical corticosteroid (betamethasone dipropionate, and triamcinolone 0.1%, respectively) that when placed under diaper occlusion can cause cutaneous and systemic side effects. Use of powders also should be avoided. Fungal or bacterial superinfection can be managed with appropriate topical antimicrobial agents (19). Topical antifungal agents such as nystatin, clotrimazole, miconazole or ketoconazole can be safely applied to newborn skin. Bacterial infection generally responds to mupirocin or bacitracin. Neomycin carries a higher risk of allergic contact sensitization and should be avoided.

Intertrigo

Intertrigo is a symmetric, red, moist, macerated eruption that occurs in the skin folds. It is thought to be as a result of excessive sweating and close approximation of the skin surfaces. Yeast and bacterial super-infection is common (see diaper dermatitis). The most effective treatment is exposure of skin to air. Barrier creams and occlusive ointments can exacerbate intertrigo. A light application of 0.5% to 1% hydrocortisone cream two to three times a day, pimecrolimus or tacrolimus can help. Concurrent bacterial and/or yeast infections must be treated in a manner similar to irritant contact diaper dermatitis.

Seborrheic Dermatitis

Seborrheic dermatitis is characterized by red skin with white-yellow waxy scale, occurring on the scalp, eyebrows and in the intertriginous areas, especially in the posterior auricular, neck, axillary and inguinal folds (Fig. 55-2). Typical scale is absent in the intertriginous areas. The eruption begins at 2 to 3 weeks of age and in some infants becomes widespread over the ensuing months. The vast majority of patients with seborrheic dermatitis improve significantly during the first year of life. Persistent and severe seborrheic dermatitis may be associated with human immunodeficiency virus (HIV) infection and other underlying systemic diseases.

Alterations in fatty acid metabolism, nutrition, and/or immunity, and infection with *Pityrosporum ovalae* have been thought to contribute to seborrheic dermatitis, but no firm cause has been established.

Atopic dermatitis, psoriasis, Langerhans cell histiocytosis, scabies, and dermatophyte infections are the principle conditions that must be excluded. In general, atopic dermatitis produces itching and psoriasis is more difficult to control than seborrheic dermatitis. Sometimes, several visits with careful observation and assessment of the therapeutic response are required to establish the proper diagnosis; skin biopsy sometimes becomes necessary for diagnosis.

When infants have limited involvement, no specific therapy is required other than mild shampoo and/or mineral oil to gently remove the scale. For more adherent, thick scalp scale, selenium sulfide shampoo or 2% ketoconazole shampoo may be helpful. Ketoconazole 2% cream, hydrocortisone 0.5% to 1% (lotion, cream, ointment), pimecrolimus cream and tacrolimus ointment applied once to twice daily are alternative therapies.

Psoriasis

Psoriasis can produce various cutaneous patterns such as guttate (tear drop), papules, pustules, and plaques. Most infants with psoriasis develop thick, pink plaques with firmly adherent thick white (micaceous) scale in a distribution similar to seborrheic dermatitis. Psoriasis in the newborn period is uncommon and congenital psoriasis is rare. When newborns are affected, they tend to have localized plaques, either on the scalp, diaper area, or hands. One can also see isolated nail and nail-fold involvement. Rarely, newborns develop generalized pustular erythroderma with fever.

The cause of psoriasis is unknown, but genetic influences play an important role because children with two psoriatic parents have an approximately 50% lifetime risk (20). Infection (*S. pyogenes*), cold weather, emotional stress, medications (antimalarials), and withdrawal from systemic corticosteroids have all been shown to provoke psoriatic flares. Psoriasis improves with therapies targeting T-lymphocytes (cyclosporine), suggesting that psoriasis is a T-lymphocyte mediated disease (21). T-lymphocytes comprise most of the psoriatic inflammatory cell infiltrate, further supporting the central role of T-lymphocytes (22).

A family history of psoriasis and "soft signs" of psoriasis (e.g., pink skin in the gluteal cleft, nail pitting, geographic tongue) are useful aids to diagnoses.

Medium-strength topical corticosteroids, tacrolimus, and pimecrolimus are the mainstay of therapy for infantile psoriasis. Short contact therapy (application for less than 30 minutes, followed by washing) with anthralin is a safe therapy, but may be limiting because of skin irritation. Calcipotriol may be applied, but to limited areas because of risk of vitamin D toxicity. Tar ointments are effective, but have an unpleasant odor, and stain the skin, and may not be well accepted by caregivers. Treatments targeting T-lymphocytes and associated cytokines are showing promising results in adults, but have not been studied in infants.

Atopic Dermatitis

Newborns with atopic dermatitis develop red, itchy, papules and plaques involving the forehead, cheeks and flexural surfaces, with relative sparing of the diaper area; there may be widespread

generalized redness and scaling. Well-defined criteria exist to diagnose atopic dermatitis (23). In the newborn, atopic dermatitis is recognized when an infant has the typical rash and a family history of atopy, asthma or atopic dermatitis. In the young infant, pruritus may not be evident because of lack of scratching. Many infants are colonized with *S. aureus* and all are susceptible to viral infections (e.g., herpes simplex virus, small pox virus, molluscum contagiosum virus, and human papilloma virus).

Although up to 30% of infants have concurrent food hypersensitivity, atopic dermatitis is not thought to be caused simply by allergies. Rather, atopic dermatitis is a complex disorder subject to genetic, immunological, and environmental influences (24). Atopic dermatitis must be differentiated from seborrhea, psoriasis, fungal infection and scabies, and the treatment is similar to other noninfectious inflammatory conditions. Moisturizers, low-potency topical steroids, tacrolimus, pimecrolimus, avoidance of cutaneous irritation, and treatment of secondary infections are the fundamental elements of therapy.

Erythroderma

Erythroderma is a generalized red eruption as a result of a number of inherited and acquired conditions. Inflammatory conditions (atopic dermatitis, seborrheic dermatitis, mastocytosis), infectious conditions (syphilis, herpes, *S. aureus*), metabolic conditions (methylmalonic aciduria, maple syrup urine disease, cobalamin deficiency), genetic skin diseases (ichthyosis, Netherton syndrome, nonbullous ichthyosiform erythroderma) immunodeficiency (severe combined immunodeficiency, common variable

P.1489

hypogammaglobulinemia) are examples of conditions that can result in erythroderma. These infants have a compromised epidermal permeability barrier and are at risk for hypothermia, dehydration and sepsis. Diagnostic evaluation should be directed by history and physical examination. Typically, a skin biopsy is not helpful during acute erythroderma. Management focuses on fluid and temperature homeostasis, utilizing intravenous fluids, emollients and placing infants in isolettes with warm humidified air. The caloric requirements of the infant are dramatically increased and parenteral nutrition is sometimes required. Emollients applied two to three times daily assist in healing the skin barrier. Fissures should be treated with topical antibiotics such as mupirocin or bacitracin. Infants with signs of skin infection (e.g., crusting, oozing, malodorous areas) and sepsis should be cultured and treated with appropriate systemic antibiotics.

Neoplastic

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is a malignant condition as a result of abnormal clones of Langerhans cells. Langerhans cells are skin antigen presenting cells, derived from the bone marrow. Infants with LCH can develop a range of cutaneous findings, including crusted papules, pustules, vesicles, bullae, petechiae, purpura and nodules. Lesions can occur in the "seborrhea areas" (scalp, face, and flexural areas), and extremities, including the palms and soles. Many infants with LCH develop lesions limited to the skin. Cutaneous features of LCH often precede systemic signs (e.g., fever, hepatosplenomegaly, lymphadenopathy, anemia), however, making early diagnosis in more aggressive forms of LCH more difficult.

Acral vesicles and bullae must be differentiated from bullous impetigo, scabies and syphilis. LCH in the seborrheic areas can mimic benign inflammatory conditions such as intertrigo, seborrhea,

psoriasis and atopic dermatitis.

All infants with LCH should have an evaluation for systemic involvement (hematologic, pulmonary, hepatic, renal, and skeletal) and they should be followed closely, because extracutaneous relapses may occur months to years after diagnosis. Topical corticosteroids and moisturizers can be used for cutaneous lesions, however, the rash typically responds poorly. Patients with systemic signs of disease should also be followed by pediatric hematology and/or oncology specialists.

Genetic Skin Diseases

Collodion Baby

Infants born with a thick "saran-wrap" covering of skin (collodion membrane) are referred to as collodion babies (Fig. 55-3). In the early newborn period, this covering can produce respiratory distress, painful cracks and fissures, temperature and fluid instability. Newborns frequently require oxygen, a humidified air isolette, and liberal applications of emollients. The eyes should be meticulously cared for because desiccation may cause corneal scarring. The collodion membrane sloughs over a period of 2 to 4 weeks. The vast majority of infants who present with a collodion membrane have lamellar ichthyosis. Other causes of collodion membrane include trichothiodystrophy, Sjogren-Larsson syndrome, Conradi-Hunermann syndrome, Gaucher's disease (Type IIB), and Refsum disease. Ten percent to 15% of infants have no underlying disorder and have normal skin when the collodion membrane resolves.

Harlequin Ichthyosis

Infants with harlequin ichthyosis are born with an extremely thick and cracked, armor-like covering with pronounced eclabium and ectropion. Harlequin infants are exceedingly rare and usually die during infancy; however, there are some long term survivors. This condition is inherited in an autosomal recessive manner and the underlying genetic defect remains unknown. Treatment with a systemic retinoid may increase survival of these infants.

Ichthyosis

Ichthyosis is a term utilized to describe inherited and acquired conditions that produce "fish-like"

scales. There are different clinical forms, including ichthyosis vulgaris, X-linked ichthyosis, and lamellar ichthyosis. Ichthyosis vulgaris, the most common form is inherited in an autosomal dominant manner and usually manifests after 3 months of age. Ichthyosis vulgaris can be associated with atopic dermatitis. Infants with ichthyosis vulgaris often have fine light-colored scale that becomes thicker on the lower extremities. X-linked ichthyosis occurs with an incidence of 1:6,000 males. Most infants show signs of this form of ichthyosis by 3 months of age. The skin develops thick brown firmly adherent scale with relative sparing of the flexural regions. X-linked ichthyosis is caused by a mutation in the steroid sulfatase gene, resulting in decreased

P.1490

shedding of keratinocytes. Infants with X-linked ichthyosis are frequently born after prolonged labor, because absence of steroid sulfatase can lead to increased fetal productions of DHEAS and decreased placental estrogen. Undescended testes, testicular cancer, and cataracts are associated with X-linked ichthyosis. Lamellar ichthyosis is rare and inherited in an autosomal recessive manner, although autosomal dominant forms have been described. Most infants with lamellar ichthyosis have mutations in the transglutaminase 1 gene. Transglutaminase is important in keratinocyte differentiation. Alterations in this protein produce the thick plate-like scale seen in infants with lamellar ichthyosis. Sometimes, infants with lamellar ichthyosis are born with a saran-wrap covering of skin referred to as a collodion membrane (see section on collodion membrane). New-borns with ichthyosis are primarily managed with emollients, such as vaseline and aquaphor. A thinner lotion may be preferable, if a thicker emollient is difficult to apply. Keratolytic emollients containing lactic and salicylic acid should be avoided, because they can be systemically absorbed. Infants with severe forms of ichthyosis can benefit from topical and/or systemic retinoids, but these medications should be used in consultation with a dermatologist. Genetic counseling is essential for families of infants with ichthyosis.

Ectodermal Dysplasia

Ectodermal dysplasia is a term that refers to conditions resulting in abnormalities of the skin and adnexal structures (teeth, hair, and nails). There are many different forms of ectodermal dysplasia. Hypohidrotic ectodermal dysplasia, hidrotic ectodermal dysplasia, keratosis ichthyosis and deafness (KID) are examples. Infants with ectodermal dysplasia are difficult to diagnose in the newborn period, because teeth are rarely present at birth, and most infants have sparse hair and thin nails. Unexplained fevers may be the first clue to hypohidrotic ectodermal dysplasia. There is no specific therapy for ectodermal dysplasia. Skin health should be maintained with mild soaps and meticulous applications of bland emollients. Families should be referred to a dermatologist and geneticist to assist in diagnosis and genetic counseling.

Netherton Syndrome

Netherton syndrome is a condition that causes progressive and diffuse cutaneous findings (Fig. 55-4). Newborns are frequently born prematurely and fail to thrive. Typically, there is erythroderma in the newborn period. Newborns with extensive skin barrier compromise are at risk for dehydration and sepsis. The rash can appear very similar to atopic dermatitis with significant involvement of the face and scalp. Infants develop sparse scalp hair as a result of hair fragility. Netherton syndrome is diagnosed after finding a characteristic hair shaft abnormality referred to as trichorrhexis invaginata ("bamboo hair" or "ball-and-socket hair"). Only 30% of hairs may be involved and typically trichorrhexis invaginata occurs after 3 months of age, making early diagnosis of Netherton syndrome difficult. There are no specific laboratory abnormalities, except most infants have elevated levels of immunoglobulin E (IgE). A mutation in SPINK5, encoding a serine protease inhibitor, (LEKTI) has been shown to cause Netherton syndrome in some patients (25). Patients are managed with topical corticosteroids, emollients and antihistamines. Tacrolimus

and pimecrolimus should be used with caution in infants with Netherton syndrome, because high serum levels of tacrolimus have been detected in some infants. Serum levels of tacrolimus should be checked in infants treated with this medication. Special attention should be given to nutrition, because these patients tend to have problems with growth.

Figure 55-4 Netherton syndrome.

Metabolic and Nutritional Disorders

There are a number of metabolic diseases and nutritional deficiencies that can cause diffuse red dry flaky skin in the newborn period (26). Examples include maple syrup urine disease, carbamoyl phosphate synthetase deficiency, argininosuccinic aciduria, propionic acidemia, methylmalonic aciduria, cystic fibrosis, biotinidase deficiency (multiple carboxylase deficiency), and essential fatty acid deficiency. Acrodermatitis enteropathica (zinc deficiency) produces a unique rash and will be discussed in more detail.

Acrodermatitis Enteropathica

Acrodermatitis enteropathica (AE) is caused by zinc deficiency. This condition results from decreased zinc intake, poor gastrointestinal absorption and/or increase metabolic needs. Infants develop a tetrad of diarrhea, periorificial and acral vesiculobullous dermatitis, alopecia, and apathy (Fig. 55-5). Autosomal recessive AE is as a result of an altered gastrointestinal zinc transport mechanism and develops within the first several months of life. Usually, the dermatitis is the first sign. Acquired forms of AE are more common and result from low or absent levels of zinc in the breast milk, decreased gastrointestinal absorption (as a result of diarrhea), or increased metabolic requirements.

P.1491

Absent or low zinc in the breast milk occurs because of altered transfer of zinc from maternal serum. Mothers usually have normal serum zinc levels. Breast-fed premature infants can develop symptoms when their nutritional requirements rise. Premature infants and those with HIV infection develop more severe disease. A low plasma zinc level (<65 mg/dL) is diagnostic, although AE can occur in the setting of normal zinc levels. Administration of zinc gluconate or sulfate at a dose of 5 mg/kg per day divided into two doses results in rapid improvement of symptoms in 2 to 4 days and may prevent death. Metabolic disorders such as cystic fibrosis may also produce a similar rash (27,28).

Figure 55-5 Acrodermatitis enteropathica. (See color plate)

Connective Tissue Disorders

Neonatal Lupus Erythematosus

Neonatal lupus erythematosus (NLE) is a connective tissue disorder resulting in an annular, red, scaly rash and/or congenital heart block in newborns. Except for the rash, most infants thrive and appear well. Affected newborns develop sharply demarcated plaques with central atrophy and peripheral white scale. The rash can be purpuric and appear lacy. Typically the head, neck, and periorbital areas (raccoon eyes) are involved. Skin biopsy shows vacuolar interface dermatitis with perivascular and perifollicular lymphocytes. Increased mucin is found within the superficial and deep dermis. Less than 5% of newborns develop involvement of other organ systems. Mothers with systemic lupus erythematosus (SLE) have a 30% chance of delivering a newborn with NLE. Infants born to mothers with SLE should be followed closely for congenital heart block, because not all infants develop cutaneous findings. Anti- Ro antibody is found in 98% of infants with NLE. Newborns with NLE should receive special protection from ultraviolet radiation. Topical corticosteroids are effective for skin lesions. Infants with NLE have an excellent prognosis with most symptoms resolving by 1 year of age.

Infections

Staphylococcal Scalded Skin Syndrome

Newborns can acutely develop widespread red skin referred to as erythroderma (see erythroderma section). Bacterial exotoxins are an important cause of diffuse erythroderma in the newborn period (29). These extracellular toxin(s) can be produced at a focus of infection or colonization, and oftentimes the site of bacterial replication is inconspicuous. Toxins can act locally, as in bullous impetigo; or can cause widespread clinical signs as a result of hematogenous spread, as in scalded skin syndrome.

Staphylococcal scalded skin syndrome (SSSS) is a staphylococcal epidermolytic toxin-mediated disease characterized by painful, diffuse redness of the skin with accentuation in flexural and periorificial areas (Fig. 55-6). In 2 to 5 days, the skin develops fine flaky desquamation, especially

in the flexural surfaces. Severely affected newborns can develop widespread sterile, flaccid blisters that easily rupture with gentle shear forces (Nikolsky sign), leaving large areas of open, weeping skin. Many newborns develop a distinctive radial crusting and fissuring around the eyes, mouth, and nose. Widespread skin break-down compromises the epidermal permeability barrier, putting newborns at risk for sepsis, fluid and electrolyte imbalance, and temperature instability.

SSSS is caused predominantly by phage group II staphylococci, particularly strains 71 and 55; occasionally, a group I or III isolate is involved. Foci of infection include the nasopharynx, umbilicus, urinary tract, a cutaneous wound, and the conjunctivae. Bacteria produce epidermolytic (i.e., exfoliative or exfoliatin) toxins A or B, which enter the bloodstream. Rarely, disease has also been transmitted through breast feeding. The disease severity is related to the toxin load in the blood, rather than the site of infection or colonization. Reduced renal clearance of the toxin is thought to put newborns at risk for SSSS. The epidermolytic toxins produce superficial blisters by binding to an epidermal cadherin called desmoglein I. SSSS may be mistaken for a number of other disorders, including scarlet

P.1492

fever, bullous impetigo, epidermolysis bullosa, diffuse cutaneous mastocytosis, familial peeling skin syndrome with eosinophilia, epidermolytic hyperkeratosis, drug eruption, erythema multiforme, and drug-induced toxic epidermal necrolysis (TEN; Lyell's Disease). TEN often can be distinguished by a history of drug ingestion, presence of the Nikolsky sign only at sites of erythema, and absence of perioral crusting. The differentiation of TEN from SSSS may occasionally require a skin biopsy: TEN results in full-thickness epidermal necrosis, with a blister cleavage plane in the lowermost epidermis. Distinguishing between these conditions is particularly important because mortality rates are relatively higher with TEN and avoidance of the offending drug is crucial to preventing a recurrence.

Figure 55-6 Staphylococcal scalded skin syndrome. (See color plate)

Recovery usually is rapid once appropriate antibiotic therapy is begun. Parenteral therapy with nafcillin or methicillin should be given promptly. General principles include minimizing handling of the infant and use of emollients (e.g., petrolatum and vaseline gauze) and semi-occlusive dressings to provide lubrication and minimize pain. Healing occurs without scarring in 10 to 14 days.

VESICLES AND PUSTULES

Commonly, newborns develop transient noninfectious vesicles and pustules. Infectious causes

must be investigated by history, physical examination and laboratory tests.

Idiopathic

Erythema Toxicum Neonatorum

Erythema toxicum neonatorum is a common benign transient eruption characterized by evanescent macules that become pink papules and pustules on an erythematous base. Occasionally, only small pink macules develop. Erythema toxicum is most prominent on the face, torso, and extremities, with sparing of the palms and soles. Typically, lesions are not present at birth, but develop within 2 days of life and continue to appear for the first 3 to 4 weeks of life. The appearance can be striking, especially when the pustules coalesce to form large pustular plaques (Fig. 55-7). When the diagnosis is in question, a smear of a pustule shows abundant eosinophils, a few neutrophils and no bacteria and yeast. Cultures should be done for bacteria and yeast to rule out infections. The cause of erythema toxicum is unknown and treatment is not necessary.

Acropustulosis of Infancy

Acropustulosis of infancy is a benign recurrent pustular eruption, occurring from birth to 1 or sometimes 2 years of age. Infants develop pruritic pink papules that quickly evolve into vesicles and pustules. Most infants are irritable and have pruritus. Pustules resolve in 7 to 14 days, leaving white scale, but tend to recur in crops in 2- to 4-week cycles. The lesions occur on acral sites such as the palms and soles; however, this condition can involve other areas of the body. The cause of acropustulosis is unknown. Many infants with suspected acrodermatitis of infancy have scabies. Diagnostic evaluation should include a scabies preparation, bacterial and fungal cultures. Topical corticosteroids and oral antihistamines are effective to control symptoms.

Figure 55-7 Erythema toxicum neonatorum.

Eosinophilic Pustular Folliculitis

Infants with eosinophilic pustular folliculitis develop recurrent crops of very pruritic papules and pustules on the head and neck, especially the scalp (30). The scalp can have yellow scale, similar to seborrheic dermatitis. Usually, the rash is not present at birth, and occurs during the first year of life. Diagnosis is established with a Giemsa or Wright stain of the contents of a pustule and a

skin biopsy. A smear of the pustule contents shows abundant eosinophils and lacks bacterial and fungal organisms. Skin biopsy shows a dense infiltrate of eosinophils (primarily), lymphocytes, and histiocytes, involving the dermis and hair follicle outer root sheath. Like acropustulosis of infancy the cause of eosinophilic pustular folliculitis is unknown; however, both conditions have a similar clinical course, suggesting these two conditions lie on the same disease spectrum. Infants should be treated with low potency topical corticosteroids and selenium sulfide or zinc pyrethrin shampoo. Unlike adults, eosinophilic pustular folliculitis of infancy is not associated with HIV infection. The eruption typically resolves within the first year of life.

Miliaria

Miliaria is a rash that occurs as a result of blocked eccrine ducts and retention of sweat. There are four types: (a) miliaria crystallina is composed of small superficial clear vesicles as a result of blockage in the stratum corneum (i.e., sudamina), (b) miliaria rubrum has small pink papules and vesicles as a result of blockage at the dermal-epidermal junction (i.e., prickly heat), (c) miliaria pustulosa includes pustules on an erythematous base as a result of blockage at the mid-dermal level, and (d) miliaria profunda is

P.1493

characterized by pink nodules as a result of blockage at the deep dermal level. Miliaria is more common in intertriginous areas, but can occur on any body surface. This disorder tends to occur in the setting of increased temperature and humidity (e.g., heat lamps, bundling) and resolves in a cool dry environment. Miliaria crystallina and rubrum resolve quickly with environmental cooling. Lesions of miliaria pustulosa and profunda are not quick to resolve as they involve blockage of eccrine ducts at deeper levels, creating a more intense inflammatory response within the skin. Affected infants may benefit from low potency topical corticosteroids.

Transient Neonatal Pustular Melanosis

Transient neonatal pustular melanosis is a benign eruption occurring at birth in healthy newborns. Approximately 5% of African American and 0.6% of Caucasian newborns are affected. The rash is characterized by superficial pustules that easily rupture, forming fine collarettes of scale and hyperpigmented macules. The pustules may rupture before birth and may not be seen. The most common sites are the head and neck folds. Pustules and scales resolve over 1 to 3 weeks, however, hyperpigmented macules can persist for several years. Fluid from a pustule shows neutrophils and is sterile. No treatment is necessary.

Acne Neonatorum

Acne neonatorum develops within the first 2 months of life and is more common in boys and breast-fed infants. Like acne seen in adolescents, the rash is characterized by comedones (open and closed), and erythematous papules and pustules on the cheeks, chin and forehead. Rarely, cysts and scars develop (Fig. 55-8). Most cases resolve within 2 years. Neonatal acne is thought to be caused by blocked sebaceous ducts, increased sebum production, inflammation and *Propionibacterium acnes* infection. Most infants respond to low-strength salicylic acid, sodium sulfacetamide and/or low strength benzoyl peroxide washes. For moderate neonatal acne, topical antibiotics such as erythromycin or clindamycin in combination with topical retinoids can be effective. Severe nodulocystic and scarring acne should be treated aggressively with oral erythromycin or amoxicillin and, rarely, isotretinoin. Tetracycline antibiotics should be avoided because of the risk of staining permanent teeth. Petrolatum, baby oils, and lotions can block sebaceous pores, making neonatal acne worse, and should be avoided. Neonates with severe acne should be referred to a dermatologist for management.

Neonatal cephalic pustulosis is a variant of neonatal acne that is thought to be as a result of *Malassezia* spp. This condition manifests as monomorphic appearing pustules without comedones. Infants with pustules should be cultured for bacteria and fungus to evaluate for resistant organisms. Topical antifungal creams can be helpful for more severely affected newborns. Generally, neonatal cephalic pustulosis spontaneously remits.

Figure 55-8 Acne neonatorum.

Genetic Skin Disease

Genetic skin conditions are rare, but important causes of blisters and bullae in the newborn period. Bullous congenital *ichthyosiform erythroderma*, *epidermolysis bullosa*, and *incontinentia pigmenti* are examples.

Bullous Congenital Ichthyosiform Erythroderma (Epidermolytic Hyperkeratosis)

Bullous congenital ichthyosiform erythroderma (BCIE) is an autosomal dominant condition as a result of mutations in keratin 1 and 10 genes. Keratin 1 and 10 are intermediate filament proteins found in the superficial layers of the epidermis (granular cell and upper spinous layers). Alterations in these proteins weaken the epidermis and affected newborns develop widespread areas of denuded skin with superficial blisters. These infants are at risk for secondary cutaneous infection with *Staphylococcus aureus* and sepsis. Later in infancy and early childhood, blistering becomes less evident and the skin develops verrucous appearing scale that is prominent in the flexures. Typically, involved areas are heavily colonized with bacteria, producing an odor. Newborns should have topical emollients such as vaseline and aquaphor applied to assist with skin barrier function and be monitored closely for sepsis.

Epidermolysis Bullosa

Epidermolysis bullosa (EB) as its name suggests represents a large group of inherited skin disorders characterized by blisters and breakdown of the epidermis. This condition is caused by mutations in genes responsible for structural proteins important in maintaining the skin integrity, especially the epidermis. Minimal skin friction can produce extensive erosions in the skin. Although classifications schemes may change as new genes are identified, traditionally,

epidermolysis bullosa has been classified as EB simplex, junctional EB, and dystrophic EB. EB simplex is due alterations in proteins found in the epidermis (Weber-Cockayne: keratin 5/14), junctional EB is as a result of

P.1494

altered proteins at the dermo-epidermal junction (Herlitz: laminin 5), and dystrophic EB is as a result of altered proteins below the dermoepidermal junction (dominant dystrophic EB: collagen type VII). It is thought that the severity of EB is determined by the location of the mutation within the gene; mutations in highly conserved regions produce more severe disease. These phenotypic-genotypic correlations will become more apparent in the future. Some of the proteins involved in EB are important for the proper function of other organ systems. For instance, autosomal recessive junctional EB associated with pyloric atresia is as a result of abnormal plectin. These patients also have muscle disease, indicating that this protein is also important in muscle as well. In the newborn period, distinguishing between subtypes on clinical appearance alone can be extremely difficult, because all forms of EB can present with widespread blisters. Skin biopsies taken for routine histology, transmission electron microscopy, immunofluorescence mapping, and deoxyribonucleic acid (DNA) mutational analysis assist in properly classifying newborns with EB.

A newborn who presents with blisters and erosions as a result of friction should be suspected as having EB. The blisters of EB simplex are more superficial than those of junctional and dystrophic EB. Groups of blisters can be seen in EB simplex Dowling Meara variant. This form of EB can be severe in the newborn period (Fig. 55-9). Significant mucosal erosions suggest junctional or dystrophic EB, although newborns with EB simplex can develop mild mucosal blisters. Laryngeal, urological and gastrointestinal involvement is seen in the more severely affected infants. This extracutaneous involvement is more commonly seen in the junctional and dystrophic variants.

Managing newborns with severe EB is difficult. Friction should be minimized as much as possible and wounds should be carefully dressed with a nonadherent dressing (vaseline gauze, Mepitel, exu-dry). Gauze wrap is then placed, followed by tube wrap. Tape should not be applied directly to the skin. Extra petrolatum added to the vaseline gauze can keep the vaseline gauze from adhering to the skin. Topical antibiotics such as bacitracin can be helpful to prevent wound infection. Bacterial resistance (*S. aureus*) to bactroban has occurred and this topical antibiotic should only be used for cutaneous infection in EB patients. The skin is the portal of entry for bacteria that result in sepsis, thus the skin should be assessed daily. Prophylactic oral or intravenous antibiotics should be avoided. Like burn patients, dressings should be gently removed; removal can be facilitated by soaking off the dressing in a tub with warm water. Blisters should be opened in a sterile manner and the roof left in place. Tense blisters easily spread in EB patients because of the inherent skin fragility. Newborns with EB have increased nutritional and fluid requirements. If intravenous catheters are required, they can be sutured in place. Nasogastric tube feedings can be used sparingly to assist in the early newborn period. Percutaneous gastrostomy tubes should be placed early, if feeding and nutrition are problematic. The Haberman feeder (<http://www.melela.com>) is a nipple with a valve that allows for delivery of breast milk or formula without having to exert too much negative pressure.

Figure 55-9 Epidermolysis bullosa.

The diagnosis of EB is psychologically distressing for parents and families. Addressing these issues is an essential part of EB management. Advocacy groups such as Dystrophic Epidermolysis Bullosa Research and Advocacy (DebRA of America, Inc. 5 West 36th Street, Suite 404; New York, NY 10018) are invaluable resources for families.

Incontinentia Pigmenti(Bloch-Sulzberger Syndrome)

Incontinentia pigmenti (IP) is an autosomal dominant skin disease characterized by linear streaks and whorls of blisters. The blisters pass through stages and become verrucous or warty, then flatten forming hyperpigmented patches and finally hypopigmented patches. Typically, these four stages occur in sequence, although patients can "skip" stages and different stages can be seen together. (Fig. 55-10) The vesicles that are seen in stage one can be confused in the newborn period for infection such as herpes simplex, varicella, or impetigo. Females with IP

P.1495

develop characteristic skin lesions within the first 2 to 3 weeks of life. This condition is lethal in males and is as a result of mutations in the NEMO gene on Xq28.

Figure 55-10 Incontinentia pigmenti. (See color plate)

Early on in the condition, peripheral eosinophilia can be seen. Other extracutaneous findings seen

in association with IP include: central nervous system (CNS) abnormalities (seizures), ocular defects (retinal changes), immunological abnormalities (elevated IgE) skeletal anomalies (spina bifida). Newborns suspected of having IP should have a skin biopsy and appropriate bacterial and viral cultures performed. Parents should be referred to a geneticist for genetic counseling.

Immunologic

Mastocytosis

Mast cell disease is rare in the newborn period. Like older affected infants and children, newborns can develop solitary mastocytomas, urticaria pigmentosa, systemic mastocytosis and mast cell leukemia. Cutaneous signs of mast cell disease include hyperpigmented macules, papules and nodules which form wheals with rubbing (Darier's sign) (Fig. 55-11). In some instances, frank bullae develop, especially on the palms and soles. More commonly, infants develop single to multiple hyperpigmented macules on the torso, extremities and scalp that show Darier's sign. Although this sign is characteristic of mast cell disease, other conditions such as leukemia cutis can form wheals when rubbed. Thus, skin biopsy should be done if the diagnosis is in doubt. In the vast majority of cases, cutaneous involvement resolves within several years. Systemic mastocytosis occurs in less than 2% of patients with cutaneous mastocytosis and most infants present with diffuse cutaneous involvement with blisters. However, systemic mastocytosis can occur with minimal cutaneous involvement. When affected infants show signs of systemic disease such as flushing, diarrhea, respiratory distress, tachycardia, hypotension and/or hepatosplenomegaly, they should be evaluated for systemic mastocytosis. Serum tryptase levels (to assess overall mast cell burden), abdominal ultrasound, and bone marrow biopsy should be considered.

Figure 55-11 Mastocytosis.

Parents of infants with mast cell disease should carry an Epi-pen and should be aware of medicines that cause spontaneous degranulation of mast cells such as opiates, radiocontrast dyes, and bee stings. Antihistamines such as hydroxyzine (Atarax) and diphenhydramine

(Benadryl) can help control symptoms as a result of histamine release.

Traumatic

Sucking Blisters

Blisters and erosions can occur at sites of *in utero* sucking, especially the thumb, index finger, wrist, or lip. Sucking blisters should be differentiated from mechanobullous eruptions such as epidermolysis bullosa, bacterial and viral infections.

Infectious

Herpes Simplex Infection

Herpes simplex virus 1 and 2 (HSV-1 and HSV-2) infections can be seen in the neonatal period and have different patterns of disease. Congenitally acquired HSV presents differently depending on when the infection was acquired. Infection acquired within the first two trimesters can result in intrauterine growth retardation and microcephaly. HSV acquired just before or at the time of delivery presents within the first month of life, most commonly within the first week. Up to 30% of infants can have symptoms on the first day of life. Symptoms can be varied and include cutaneous signs involving skin and mucous membranes and systemic signs involving multiple organ systems, but especially the CNS.

The primary cutaneous lesion of HSV is a vesicle with a central dell. The vesicles are grouped. Within 1 to 2 days the vesicles develop into pustules and form crusts (Fig. 55-12). The edge of a group of herpes vesicles appears as a scalloped border. The mucous membranes are typically involved and can appear as blepharitis, conjunctivitis, stomatitis, and urethritis. Infants with eczema are at risk for disseminated herpes infection referred to as eczema herpeticum (Figure 55-13). Children with neonatally acquired HSV can have reactivation of their herpes later in life, often as recurrent localized eruptions of crops of vesicles.

HSV infections can be diagnosed with direct immunofluorescence and viral culture of the lesions. Direct immunofluorescence is performed by unroofing a vesicle and scraping the base of the vesicle. Skin biopsy can show signs of viral cytopathic effect in the epidermis. Neonatal HSV should be treated with acyclovir (see Chapter 48).

Figure 55-12 Herpes simplex.

P.1496

DISORDERS OF PIGMENTATION (BROWN SPOTS/WHITE SPOTS)

Most irregularities in pigmentation are normal; however, pigment alterations can be the first indicator of an underlying inherited genetic skin condition. Hyperpigmentation or hypopigmentation occurring in whorls or in straight lines is thought to be as a result of genetic mosaicism. Newborns with alterations in skin pigment following the lines of Blaschko should be evaluated closely for associated extracutaneous defects. Examples of genetic conditions with hyperpigmentation following the lines of Blaschko include: incontinentia pigmenti, Conradi-Hunermann disease, and segmental neurofibromatosis. Examples of genetic conditions with hypopigmentation following the lines of Blaschko include: piebaldism, and hypomelanosis of Ito.

BROWN SPOTS

Cafe' Au Lait Macules

Cafe'-au-lait macules (CALMS) are small, oval, and tan to brown macules. They can be quite large and involve a large surface area of the body (giant CALMS). They are more common in heavily pigmented children and are as a result of increased melanin content of the basal melanocytes and keratinocytes. The number and size of CALMS increase during infancy and early childhood. Although 19% of normal children have CALMS, they are seen in increased numbers in several inherited conditions such as neurofibromatosis, proteus syndrome, and McCune-Albright syndrome. Six or more CALMS larger than 0.5 cm (they may be smaller in infancy) is one of the diagnostic criteria for neurofibromatosis type I. Crowe's sign (axillary and inguinal freckling) is another clinical feature of neurofibromatosis type I.

Figure 55-13 Eczema herpeticum. (See color plate)

Congenital Melanocytic Nevi

Congenital melanocytic nevi (CMN) are tan to brown hyperpigmented macules, papules and plaques, consisting of increased numbers of melanocytes. Typically, they contain increased numbers of hairs (vellus and terminal) and have been termed "hairy nevi." Congenital melanocytic nevi are classified with respect to the largest diameter that they would achieve in adulthood (small: <1 to 1.5 cm; intermediate: 1 to 1.5-20 cm; large: >20 cm) (Fig. 55-14). The size of the CMN is relevant for future melanoma risk. Patients with large CMN have a 5% to 8% lifetime risk of developing a malignant melanoma. This risk is highest in prepubertal children; approximately 50% of the melanomas occur by age 5. The prognosis of melanoma, occurring within large CMN is poor with many infants developing early metastasis. Large CMN involving the scalp and midline back are associated with neurocutaneous melanosis or involvement of the leptomeninges. Magnetic resonance imaging can be helpful to evaluate for leptomeningeal involvement. Other malignant tumors arising within large CMN include neuroblastoma, rhabdomyosarcoma,

P.1497

primitive neuroectodermal tumors, liposarcoma and mixed neoplasms. The risk of malignant melanoma in association with small and intermediate CMN is unknown, but probably increased in the postpubertal child. Other factors such as family history of melanoma and ultraviolet radiation exposure are important to determine melanoma risk for these lesions. High risk CMN are prophylactically excised. When considering surgical excision, lesions should be evaluated for size, location, color, border, family history and evolution of the lesion. Infants with CMN should be referred to a dermatologist for management.

Figure 55-14 Large congenital nevus.

Other Types of Melanocytic Nevi

A blue nevus is a blue to black macule or papule, consisting of spindle-shaped dermal melanocytes. A Spitz nevus is a pink to brown papule, consisting of spindle-shaped melanocytes at the dermal-epidermal junction and in the dermis. A nevus spilus is a hyperpigmented macule studded with darker brown macules. All three nevi are considered benign, although malignant variants have been described.

Dermal Melanocytosis

Dermal melanocytosis (Mongolian spot) arises as a result of increased numbers of melanocytes within the dermis (Fig. 55-15). They are very common in newborns of color, and should not be confused with child abuse. Mongolian spots have a tendency to fade over a number of years. Extensive dermal melanocytosis has been described as an early sign of GM1 gangliosidosis.

Epidermal Nevi

Epidermal nevi are papules and plaques that develop as a result of hyperplasia of keratinocytes. Typically the lesions are solitary, however, they can be linear (linear epidermal nevus), inflamed (inflammatory epidermal nevus), widespread (systematized epidermal nevus), and associated with underlying neurological deficits, blindness, and skeletal abnormalities (epidermal nevus syndrome) (Fig. 55-16). Epidermal nevi are thought to occur as a result of somatic mutations in keratinocytes. Some epidermal nevi show a characteristic microscopic finding called epidermolytic hyperkeratosis. These nevi arise as a result of mutations in keratins 1 and/or 10, and females with gonadal tissue involvement can give birth to infants with bullous congenital ichthyosiform erythroderma, a rare congenital form of ichthyosis.

Figure 55-15 Dermal melanocytosis (Mongolian spot).

Figure 55-16 Epidermal nevus syndrome.

Disorders of Pigmentation—White Spots

White spots occur when there is either a decreased number or function of melanocytes. The exception is nevus anemicus, which is caused by blood vessel constriction. Hypopigmentation or decreased pigment should be distinguished from depigmentation or absence of pigment. With natural lighting, this distinction may be difficult. Fluorescent light (Wood's light) shows pure white in depigmentation and off-white in hypopigmentation. Nevus anemicus loses its border with diascopy (pressure) and does not show a color change with Wood's light examination.

Ash Leaf Macules

Ash leaf macules are small oval areas of decreased pigmentation. They are seen in 3% to 5% of the normal population, but can be an indicator of tuberous sclerosis. Other cutaneous signs of tuberous sclerosis include connective tissue nevus (shagreen patch), periungual fibromas, confetti hypopigmentation, gingival fibromas and facial angiofibromas (adenoma sebaceum).

Hypomelanosis of Ito

Hypomelanosis of Ito consists of whirls of hypopigmentation following Blaschko lines that can be seen in association with seizures, developmental delay, and ocular and/or skeletal anomalies.

P.1498

Nevus Achromicus

Nevus achromicus or depigmentosus is a hypopigmented patch occurring as long linear streaks or as well circumscribed isolated patches. Affected areas are usually unilateral and may be small or they may be very broad affecting a large part of the body. Nevus achromicus is not associated with extra-cutaneous organ involvement.

Diffuse Hypopigmentation/Depigmentation

Generalized hypopigmentation or pigment dilution is seen in newborns with Chediak-Higashi syndrome and phenylketonuria. Generalized depigmentation is seen in the different forms of oculocutaneous albinism.

ATROPHIC LESIONS

Atrophic skin or thinned skin results from an underdevelopment of one of the components of the skin. Atrophic lesions can occur in isolation or they can be seen as part of syndromes with multiple malformations.

Aplasia Cutis Congenita

Aplasia cutis congenita (ACC) is absence of the skin. (Fig. 55-17) There are nine different groups of the condition: (a) ACC of the scalp without multiple systemic anomalies, (b) ACC with associated limb abnormalities, (c) ACC with organoid and epidermal nevi, (d) ACC with overlying embryologic abnormalities, (e) ACC with associated fetus papyraceus or placental infarcts, (f) ACC associated with epidermolysis bullosa, (g) ACC localized to the extremities without blistering, (h) ACC caused by teratogens, and (i) ACC associated with malformation syndromes (31). Most infants have isolated scalp ACC (Group 1). Eighty percent of the lesions are near the parietal scalp whorl and 76% are single lesions. Up to one-third of cases of ACC have underlying defects in the bone. Sometimes ACC is partially healed at birth, giving variable morphologies from a small patch of alopecia to full thickness ulceration with an underlying bony defect.

Figure 55-17 Aplasia cutis congenita.

Figure 55-18 Subcutaneous fat necrosis.

Subcutaneous Fat Necrosis

Subcutaneous fat necrosis presents as red-purple, indurated subcutaneous nodules or plaques on the extremities, trunk, or buttocks during the first weeks of life (Fig. 55-18) (32). It has been attributed to trauma, shock, cold, and asphyxia. Infants appear healthy, although subcutaneous fat necrosis has been associated with hypercalcemia. Lesions spontaneously resolve over a period of weeks to months. Rarely, sterile abscesses form with attendant atrophy and scarring. The sterile abscesses should not be drained.

Sclerema Neonatorum

Extensive subcutaneous fat necrosis occurring in preterm or severely ill term infants is referred to as sclerema neonatorum. The extremities may be involved at first, but generalized involvement occurs quickly within 3 to 4 days. If the infant survives, sclerematoses skin changes resolve within

about 3 weeks. The cause is unknown, but because the microscopic appearance is identical to subcutaneous fat necrosis, similar etiological factors are likely involved. Other than treating the associated illness, no specific therapy is indicated.

Focal Dermal Hypoplasia of Goltz

Focal dermal hypoplasia (Goltz syndrome) is an X-linked dominant condition characterized by thinned or absent dermis with fat herniation, following the lines of Blaschko. Other cutaneous signs include alopecia, nail dystrophy, atrophic scars, ACC, telangiectasias, dermatographism, and red papillomas (perioral, intraoral, perianal, vulvar). Infants with Goltz syndrome can have skeletal, ocular, dental, and neurological defects. Patients suspected of having focal dermal hypoplasia should be referred to a dermatologist and geneticist.

Figure 55-19 Cutis marmorata telangiectatica congenita. (See color plate)

P.1499

TRANSIENT VASCULAR LESIONS

Cutis Marmorata

Cutis marmorata is a transient net-like erythema, occurring in newborns exposed to cooler temperatures. This reaction pattern is caused by constriction of the capillaries and venules and usually disappears quickly with rewarming. Persistent and extensive cutis marmorata can be seen in association with trisomy 18 and 21 and Cornelia De Lange syndrome. Cutis marmorata should not be confused with a vascular malformation referred to as cutis marmorata telangiectatica congenita (CMTC) (Fig. 55-19). Infants with CMTC are born with atrophic net-like red-blue patches in a dermatomal pattern. Lesions have a tendency to become less noticeable by adulthood (33). Rarely, CMTC is associated with underlying ocular, skeletal and cardiac malformations.

Halequin Color Change

Harlequin color change describes a sharply demarcated erythema that develops on the dependent

half of an infant who is in the lateral decubitus position. This interesting phenomenon occurs in both healthy and ill newborns (especially low birth weight infants), lasts 1 to 30 minutes, and reverses if the infant is placed on the opposite side. The underlying mechanism for harlequin color change is unknown. This reaction may last up to 3 weeks and is not associated with long term sequelae.

VASCULAR GROWTHS

Hemangioma of Infancy

Hemangiomas of infancy (HOI) are benign growths of endothelial cells (34). They represent the most common vascular tumor of childhood, affecting 1% of all newborns and 10% of 1-year-olds. Only 30% are noticeable at birth; most are noted within the first month of life. Deeper lesions may not be detected until later in infancy. Characteristically, HOI have a growth phase lasting up to a year; then a stabilization phase, followed by an involution phase. Approximately 50% of HOI are completely involuted by age 5 years, 60% by age 6 and involution is usually complete by age 10. HOI are more common in female and premature infants and have a predilection for the head and neck. Most infants have solitary HOI; however, 10% to 15% have multiple HOI. Nascent or early HOI may appear as pale macules or patches, and contain a few dilated blood vessels. The color of HOI is determined by the depth and phase of growth. Growing HOIs are firm, rubbery, and their color can range from red (superficial) to blue (deep) (Fig. 55-20). When a HOI begins to involute, it softens and develops centrally located fibrotic grey bands (Fig. 55-21).

Figure 55-20 Deep hemangioma.

The vast majority of HOI follow a benign course. Local complications include infection, ulceration, and scarring. HOIs can be life threatening by obstructing the airway or by interrupting feeding. They can also compromise vision.

P.1500

HOIs located near or on the mandible ("beard distribution") can be associated with glottic involvement. Multiple HOIs or visceral hemangiomas can cause a consumptive coagulopathy (Kasabach-Merritt syndrome); however, this complication occurs more frequently with other vascular tumors such as tufted angioma and hemangioendothelioma. Midline HOI can be associated with underlying occult cranial and vertebral anomalies; midline sacral hemangiomas

have been associated with a tethered spinal cord (Cobb syndrome). Large plaque-like hemangiomas involving the face can be associated with multiple anomalies (PHACES syndrome—posterior fossa malformations, hemangioma, arterial anomalies, coarctation of the aorta and cardiac defects, eye anomalies, and sternal defects)³⁵. Multiple cutaneous HOI can be an indicator of internal involvement, however, visceral hemangiomas can occur without cutaneous HOIs, and the vast majority of infants with multiple cutaneous HOIs do not have involvement of the viscera.

Figure 55-21 Involuting hemangioma.

Pyogenic Granuloma

Pyogenic granulomas or lobular capillary hemangiomas are small pink to red papules occurring on the head, neck, torso and mucous membranes. They are collections of endothelial cells that are thought to arise from trauma. They are rare in the newborn period.

Vascular Malformations

Vascular malformations are anomalies in blood and lymphatic vessels as a result of altered morphogenesis. As such, they are all congenital; however, they may not be noticed until sometime after birth. Unlike HOI, they exhibit normal endothelial cell growth and grow with the somatic growth of the patient. Vascular malformations can undergo apparent rapid increase in size as they fill up with blood or lymph fluid. They are classified by the vessel type (capillary, venous, arterial, lymphatic, mixed and arteriovenous) and the flow characteristics (high and low flow). Almost all vascular malformations are sporadic, although new genes are being discovered in some familial cases. Blue rubber bleb nevus syndrome and multiple glomovenous malformations have autosomal dominant inheritance.

Capillary Malformations

Capillary malformations can appear as “macular stains” of the nape (“stork bite”), eyelids (“angel kisses”), and glabella. They are found in at least 50% of newborns, and fade with time. Many nuchal patches and some glabellar patches persist into adulthood and are more noticeable with crying or anger. Capillary malformations can be more substantial and involve diffuse segments of skin, particularly segments of skin innervated by the trigeminal nerve (Fig. 55-22). Approximately 10% of newborns with V1 involvement will also have ocular and CNS involvement. This triad is

referred to as Sturge-Weber syndrome (SWS). Patients with SWS can develop glaucoma, seizures, and facial asymmetry as a result of overgrowth of facial bones. Imaging of the CNS should be delayed until after infancy in an asymptomatic infant, because radiographic changes sometimes occur later. Almost all capillary malformations occur as isolated defects. They have been described, however, in association with trisomy 13, Rubenstein-Taybi, Beckwith-Weidemann, and Klippel-Trenaunay-Weber syndromes. Some lesions lighten with age, and some darken. Vascular laser therapy is an excellent modality and may be more effective if used in infancy. Green tinted cosmetics (e.g., Covermark, Retouch) effectively conceal most capillary malformations.

Figure 55-22 Capillary malformations.

Venous Malformations

Malformations of the veins are slow-flow vascular malformations, taking on a variety of clinical appearances: varicosities, isolated local spongy nodules, or large complex infiltrating channels. The vast majority of venous malformations are sporadic, although they can be inherited in autosomal dominant and recessive manners. Multiple lesions are more likely to be inherited. Patients with venous malformations often complain of pain and swelling, especially in the morning with ambulation. Venous stasis, intravascular thrombosis and calcifications (phleboliths) are thought to be responsible for the pain. Extensive venous thrombosis can result in widespread coagulopathy.

Lymphatic

Lymphatic malformations (lymphangiomas) are uncommon lesions resulting from dilated lymphatic channels and abnormal flow of lymph fluid. They can be classified broadly as microcystic (small channels), macrocystic (large channels) or mixed.

Microcystic lymphatic malformations have been referred to as lymphangioma circumscriptum. Lymphangioma circumscriptum appear as small translucent pseudovesicles

P.1501

that resemble "frogs spawn" (Fig. 55-23). Commonly, some of the vesicles are hemorrhagic and there may be an underlying deep component giving a blue hue. Microcystic lymphatic malformations can occur on any site, however, axillary folds, neck, shoulders, proximal limbs, perineum, tongue, and buccal mucous membranes are more commonly involved. These

malformations have been mistaken for warts and can be confused with sexual abuse (36). They may be small (<1 cm) or very large, covering an extensive surface area. Patients can develop cellulitis in the involved areas and lymphatic malformations commonly recur around previously excised sites.

Figure 55-23 Lymphangioma circumscriptum.

Macrocystic lymphatic malformations (cystic hygroma) are large single or multiple masses occurring on the neck, axillae, groin and/or chest. Most commonly, these malformations are detected within the first 2 years of life and can cause significant morbidity and even death as a result of airway compromise and infection. They may be detected en utero by ultrasound and increased α -fetoprotein levels and may be associated with Down syndrome or Turner syndrome. The lesions are persistent and can expand, although spontaneous remission has been described, usually after infection. Treatment measures have included sclerotherapy and surgical excision.

Arteriovenous Malformations

Arteriovenous malformations (AVM) are most common in the head and neck region, but also occur on the extremities. These fast-flow malformations are dangerous and can produce cardiovascular instability. Increased warmth, swelling, bruits and thrills are signs of an AVM. A warm swollen extremity with an associated capillary malformation can be a sign of an underlying AVM. Doppler ultrasound and MRI with angiography are helpful to assess the extent of an AVM. These malformations are difficult to manage and may require surgery and/or endovascular embolization.

Figure 55-24 Dermoid.

CYSTS AND NODULES

Dermoid Cysts

Dermoid cysts are common cysts composed of tissue of all three embryonic tissues along lines of fusion. They can occur in any cutaneous site, but are more common on the scalp, especially on the lateral eyebrow. Dermoid cysts can be superficial or they can have a deeper component that involves muscle and bone (Fig. 55-24). Midline cysts should raise concern for a possible underlying connection with the CNS. An imaging study such as an MRI should be performed before operating on a midline lesion. Newer techniques utilizing endoscopy can be performed, minimizing scar formation.

Developmental Anomalies

Skin abnormalities in the form of cysts and nodules can occur as a result of abnormalities in embryonic development. Branchial cleft abnormalities can produce pits, nodules, and cysts along closure lines on the corresponding branchial arch of the face and neck. Common abnormalities include accessory tragus (1st branchial arch) in the pre-auricular region (Fig. 55-25), midline clefts (1st branchial arch), preauricular cysts (1st branchial arch), lateral cervical cysts, sinuses, and fistulae (2nd branchial arch) (Fig.55-26). Thyroglossal duct cysts occur in the midline neck and are as a result of failure of fusion of the thyroglossal duct. Bronchogenic cysts occur on the chest, and develop as a result of abnormal development of the primitive foregut. They can drain mucous fluid. Median raphe cysts occur along the ventral surface of the penis and scrotum (Fig. 55-27). They are thought to occur because of entrapped epidermal or urethral cells. If median raphe cysts enlarge or become infected, they can be surgically removed.

Figure 55-25 Accessory tragus.

P.1502

Multiple Red-Blue Nodules (“Blueberry Muffin Baby”)

A number of conditions produce cutaneous infiltrates in the skin. When infants develop multiple nodules, they have been described as having the “blueberry muffin” phenotype. Leukemia cutis, extramedullary hematopiesis, Langerhans cell histiocytosis, neuroblastoma, congenital syphilis, congenital toxoplasmosis, and erythroblastosis fetalis are several of the conditions capable of causing multiple red-blue nodules in the newborn period.

EDEMA

Congenital lymphedema can be primary or secondary. Milroy disease describes primary congenital lymphedema that is primarily located distally on the lower legs and feet. Initially the edema is pitting, but later becomes firm and nonpitting. Turner syndrome and Noonan syndrome are two important conditions associated with congenital lymphedema.

Figure 55-26 Lateral cervical cyst.

Figure 55-27 Median raphe cyst.

Caput Succedaneum

Caput succedaneum develops during delivery as marked swelling of the presenting part of the scalp and can be especially pronounced with a prolonged second stage of labor (37). Pressures from the uterus and vacuum extraction have been shown to cause caput succedaneum. Swelling crosses bony sutures and can be noted at birth or within the first hours of life. Scalp molding is usually noted after the swelling subsides. Rarely, caput succedaneum is associated with skin necrosis and alopecia. No treatment is necessary.

Cephalohematoma

Cephalohematoma is as a result of bleeding, which occurs at the subperiosteal level. Typically, the swelling is unilateral and does not extend beyond the respective suture lines. Cephalohematomas are thought to be as a result of rupture of diploic veins. Bleeding is slow and can take several days to become apparent. Like caput succedaneum, prolonged labor and vacuum extraction are risk factors. Cephalohematomas can be complicated by skull fracture and bacterial infection. They resolve over a period of months and can be associated with cutaneous calcifications.

PURPURA

Purpuric Light Eruption

Purpuric light eruption is a transient purpuric generalized eruption occurring in newborns who received blood transfusions and phototherapy for hyperbilirubinemia. The purpura appears within 4 days of the light therapy and clears within one week of stopping phototherapy. The underlying cause of this eruption is unknown, but in some infants it may be related to a transient increase in porphyrins.

Purpura Fulminans

In the newborn period, purpura fulminans appears as widespread purpura as a result of congenital deficiencies of

proteins C and S38. It can also occur in the setting of overwhelming sepsis.

Figure 55-28 Nevus sebaceus.

YELLOW-ORANGE LESIONS

Nevus Sebaceus

Nevus sebaceous is a common congenital hamartoma consisting of increased numbers of sebaceous glands. Most lesions occur on the head and neck and are isolated, although larger facial, especially midline lesions can be associated with underlying bony, brain, ocular, and palatal abnormalities. In some instances, benign (trichoblastoma, syringocystadenoma papilliferum) and malignant (basal cell carcinoma, squamous cell carcinoma) tumors arise within sebaceous nevi, prompting prophylactic surgical excision of these lesions before puberty (Fig. 55-28). The incidence of tumors arising within sebaceous nevi is subject to some controversy and not all sebaceous nevi need to be prophylactically removed. Lesion size and location should be considered when determining timing of surgical excision. Large scalp lesions should be removed in infancy because the skin of the scalp is more elastic and the scalp is easier to close at a younger age. Other treatment methods include carbon dioxide laser and liquid nitrogen.

Juvenile Xanthogranuloma

Juvenile xanthogranuloma (JXG) is a common tumor seen in infants and children. JXG consist of dermal lipid-laden histiocytes with scattered Touton giant cells (wreath-like) and eosinophils. Typically, JXG appear as single or multiple discrete yellow-brown papules on the head and trunk (especially flexural areas) (Fig. 55-29). Lichenoid, plaque and subcutaneous variants have been described. JXG lesions resolve spontaneously over a period of months to several years, leaving few cutaneous sequelae. Hyperpigmentation and atrophic scars remain in some patients. Periocular JXG should raise the suspicion of intraocular lesions and glaucoma, and these patients should be examined by an ophthalmologist. Rarely, JXG can be associated with neurofibromatosis type I, and juvenile chronic myeloid leukemia.

Figure 55-29 Juvenile xanthogranuloma.

Sebaceous Gland Hyperplasia

Sebaceous gland hyperplasia appears as numerous small pinpoint yellow to white papules involving the nose, upper lip, and malar areas. Maternal androgens enlarge the pilosebaceous glands. The vast majority of term infants are affected and, occasionally, preterm infants are affected. This condition resolves by 2 to 6 months of age.

Milia

Milia are common discrete yellow-white papules that are slightly larger than those seen in sebaceous gland hyperplasia, and represent tiny epidermal inclusion cysts. They occur on the forehead, nose, cheeks, chin and forehead. They resolve within the first several months of life. Larger milia can be persistent. Most milia arise spontaneously (primary milia) and can affect 40% of newborns. Milia can result from trauma (secondary milia) and be associated with genetic conditions (epidermolysis bullosa, pachyonychia congenita).

Disorders of Hair and Nails

Hair

Newborns are covered with very fine hair referred to as lanugo. This hair is normally shed and replaced with vellus hair within the first several months of life. Scalp hair undergoes repeated patterns of shedding with regrowth from front to back within the first year of life. Hair can be abundant (hypertrichosis) or absent (alopecia). Examples of genetic conditions associated with hypertrichosis include congenital hypertrichosis lanuginosa, Cornelia de Lange syndrome and Rubenstein-Taybi syndrome. Congenital alopecia can be an isolated inherited condition or it can be associated with a number of the ectodermal dysplasias.

Figure 55-30 Congenital ingrown toenail.

P.1504

Congenital Ingrown Nails

Toenails that grow into the surrounding skin are referred to as ingrown toenails (onychocryptosis). Infants develop painful, red, swollen skin as the distal free edge of the nail becomes embedded into the skin. It is not clear if the distal free edge embeds into the skin because of misalignment of the nail plate or because of underlying thickening of the tissue surrounding the nail (Fig. 55-30). Toenails and fingernails can develop spicules that ingrow into the lateral nail folds. This type of onychocryptosis is thought to be as a result of clipping the nails too short. Rarely, the nail plate can be deviated on the long axis of the nail (congenital misalignment of the hallux nail) and can be inherited in an autosomal dominant manner. Most ingrown toenails spontaneously involute within the first year of life and require no treatment. With significant paronychia, antibiotics and surgical nail avulsion may be required. Infants with bulbous nail folds without signs of infection may respond to daily application of high potency topical steroids.

Anonychia and Micronychia

Anonychia (complete nail absence) and micronychia (small nail) are rare and can be sporadic or associated with a number of underlying genetic conditions such as ectodermal dysplasia, teratogen exposure (hydantoins, alcohol), Coffin-Siris syndrome, amniotic bands, trisomy 13 or 18, and dyskeratosis congenita. In many instances, there are deformities of the underlying phalanx.

Chapter 56

Drug Therapy in the Newborn

Robert M. Ward

Ralph A. Lugo

The developmental uniqueness of the neonate has tremendous impact on drug therapy. This uniqueness and the potential for dramatic and rapid developmental changes beginning shortly after birth defy accurate generalizations, and illustrate the need for age-specific studies in the increasingly premature patients surviving today. These developmental changes affect all aspects of drug action, from absorption and protein binding to receptor interaction and elimination. The impact of these developmental changes on drug action and the use of pharmacokinetics to adjust drug dosages will be outlined to guide the clinician between the Charybdis of ineffective therapy and the Scylla of drug overdose and toxicity (see also Appendix H).

PRINCIPLES OF PHARMACOLOGY APPLIED TO NEONATES

Free-Drug Theory and Protein Binding

Most clinical drug assays measure both bound and unbound drug; however, it is only the nonprotein-bound or free-drug molecules that are active i.e., cross membranes, bind to receptors to exert pharmacologic action, undergo metabolism and excretion (1). Serum protein binding usually is a rapidly reversible process, so that additional drug is released to replace the unbound drug removed by distribution into tissue or by elimination. The rate of release from serum protein binding usually is much faster than the rate of transfer across membranes. Seldom is the rate of release from serum proteins so slow that it limits the availability of drug molecules for transfer across membranes to exert pharmacologic effects (2).

For most drugs in premature infants, the percentage of unbound drug in the circulation is greater than in adults, because both the amount and the binding affinity of circulating proteins are decreased (3). For example, the albumin of term newborns, compared to that of adults, binds less theophylline, warfarin and sulfonamides but similar amounts of diazepam (4,5). Because the effects of a drug are related to the amount of unbound drug reaching the site of action, some drug effects in newborns may be explained only by measuring circulating concentrations of free drug. Furthermore, circulating total drug concentrations that are in the therapeutic range for adults or older children may represent free-drug concentrations that are in a toxic range in the premature neonate (5).

Absorption

In drug treatment, absorption refers to the transfer of drug from the site of administration into the circulation. The rates of drug absorption are related to several factors, beginning with the route of administration and including the same characteristics that influence transfer of any substance across lipid bilayers: degree of ionization, molecular weight, lipid solubility, concentration gradient, and active transport.

Enteral

Enteral drug treatment of neonates may not produce reliable and reproducible circulating drug concentrations for a variety of reasons. Although most studies of enteral drug therapy have been conducted in adults, many of the problems of enteral drug administration identified from these studies are likely to occur in neonates.

Intestinal villi and microvilli increase the surface area of the gastrointestinal tract, so that rates of drug absorption are usually much greater from the intestine than from the stomach. Delayed gastric emptying slows passage of drug into the intestine, which prolongs the absorption phase of many drugs. Elimination begins during this absorption phase, so that delayed gastric emptying reduces the area under the curve (AUC) for circulating drug concentration vs. time. This reduces the desired therapeutic effect for many

may be associated with delayed gastric emptying that reduces the therapeutic effects of drugs administered orally. Few studies have addressed this aspect of drug treatment of newborns (6).

Additional problems, unique to the immature patient, may affect enteral drug treatment of newborns. Neonates, especially premature neonates, malabsorb fat which may alter enteral drug absorption. Elevated right atrial pressure, leading to passive congestion of hepatic and mesenteric circulations, often reduces enteral drug absorption in adults. Prolonged enteral drug administration often is necessary for treatment of infants with chronic disorders. These include bronchopulmonary dysplasia (BPD) and congestive heart failure, which may increase right atrial pressure and cause intestinal venous congestion that decreases enteral drug absorption and bioavailability. Therefore, larger doses may be required to achieve the desired therapeutic response. This phenomenon has been reported with furosemide in an infant with BPD, who required a six-fold higher enteral dose to reach plasma concentrations comparable to a 1 mg/kg dose administered intravenously (i.v.) (6).

Intramuscular

Intramuscular drug absorption is directly proportional to blood flow and the surface area of the drug deposited in the muscle (7). Although intramuscular drug administration is often considered more reliable than enteral, the sick or hypothermic neonate with limited muscle mass and poor perfusion of muscle may not absorb intramuscular doses rapidly or completely. As a result of limited amounts of muscle, injections intended for the muscle may enter subcutaneous tissue, from which absorption is slow and unpredictable. Caustic drugs (e.g., phenytoin, pH = 12) damage surrounding tissues and isolate the dose of drug from blood flow, or precipitate to a chemical form that is absorbed very slowly in what has been described as a depot effect (7). Intramuscular injection sites in neonates may leave sterile abscesses that later require surgical repair. In general, prolonged intramuscular administration of drugs in neonates should be avoided.

Intravenous

Intravenous drug administration is most likely to ensure effective drug therapy in neonates. Although this route of drug treatment is the most reliable, certain problems must be recognized that are unique to neonates. The infusion rate for i.v. fluids in extremely small neonates is so slow that drug doses injected distant from where the i.v. enters the vessel or up the i.v. tubing away from the patient, may not reach the circulation for several hours (8).

The most reliable method for administering medications intravenously to neonates is to use a small-volume syringe pump and micro-bore tubing connected as close to the patient as possible. If the syringe is prepared to contain the exact dose, the tubing must be flushed following drug administration to ensure complete drug delivery. Alternatively, it may be preferable to include overfill in the syringe so that the tubing may be primed prior to drug administration. Thus, once the drug is infused, the tubing will contain extra drug that may be discarded without the necessity of flushing.

Distribution

Distribution is the partitioning of drug from the circulation into various body fluids, organs, and tissues (9). At equilibrium, this distribution is related to organ blood flow; pH and composition of body fluids and tissues; physical and chemical properties of the drug including lipid solubility, polarity, and size; and the extent of binding to plasma and tissue proteins.

Dramatic developmental changes in body composition of newborns influence the distribution of polar and nonpolar drugs within the body. At 24 weeks of gestation, water comprises about 89% of body weight, with 0.1% to 0.5% as fat (10,11). Thus, water-soluble drugs that distribute primarily into extracellular fluid will have larger distribution volumes in premature neonates. By 40 weeks of gestation, the body is approximately 75% water and 15% fat, compared to adults in whom the body is about 65% water and the fat content is variable. The low fat content of the brain of the extremely premature newborn may affect the distribution and effects of centrally active drugs, such as barbiturates and gaseous anesthetics (12).

Metabolism

Many drugs require biotransformation to more polar forms before they can be eliminated from the body. Biotransformation reactions are designated phase I reactions that make the drug more polar through oxidation, reduction, or hydrolysis; or phase II, conjugation reactions, such as glucuronidation, sulfation, and acetylation

(9). The liver is the primary site for biotransformation, however other organs are also involved. As early as 9 to 22 weeks gestation, metabolic enzyme activities of the fetal liver vary from 2% to 36% of adult activity (13). This variation precludes broad generalizations regarding hepatic drug metabolism in premature newborns. Over the past decade, intense research into the biochemistry of drug metabolism has revealed multiple forms of cytochrome P450 with different substrate specificities and different activities during development from the fetus to the adult (14,15,16,17). Clinicians should have an understanding of P450 nomenclature in addition to understanding which isoforms are responsible for metabolism of commonly used drugs. Both induction and inhibition of specific isoforms may require more frequent therapeutic drug monitoring and dosage adjustments.

Cytochromes P450

Quantitatively, the most important of the phase I enzymes are the cytochromes P450, a superfamily of heme-containing proteins that catalyze the metabolism of many lipophilic substances. The cytochrome P450 isozymes are designated as CYPs that are grouped by the degree of identity in their amino acid sequences. CYP is followed in order by (a) an Arabic number representing the gene family for enzymes with greater than 40% identity; (b) a letter which indicates the subfamily for enzymes with greater than 55% identity; and (c) sequential numbering of the P450 enzymes for different isoforms within each subfamily (9,16). Isozymes which are important in human drug metabolism are found mostly in the CYP1, CYP2, and CYP3 gene families. Table 56-1 outlines the P450 isozymes and their common substrates in the newborn.

Research in the early 1970s revealed that newborn infants have significantly reduced total quantities of cytochrome P450 in liver microsomes (18). This hemoprotein increases with gestational age but reaches only 50% of adult values at term (18). Reduced cytochrome P450 in neonates explains the low clearance and significantly prolonged half-lives of theophylline, caffeine, phenytoin, phenobarbital and other substances that are metabolized via cytochrome P450 (5,19,20,21). Although newborns are poor metabolizers of many xenobiotics, specific P450 cytochromes exhibit unique developmental patterns during gestation and postnatal life that invalidate broad generalizations about drug metabolism. Table 56-1 outlines important developmental patterns for many of these enzymes.

TABLE 56-1 DEVELOPMENTAL PATTERNS FOR IMPORTANT CYTOCHROME P450 ENZYMES IN THE NEONATE

Enzymes	Selected Substrates	Developmental Pattern
CYP1A2	acetaminophen, caffeine, theophylline, warfarin	Not present to an appreciable extent in human fetal liver. Adult levels reached by 4 months of age and may be exceeded in children 1–2 years of age. Inhibited by cimetidine and erythromycin. Induced by cigarette smoke, phenobarbital, and phenytoin.
CYP2C9	phenytoin, torsemide, S-warfarin	Not apparent in fetal liver. Inferential data using phenytoin disposition as a nonspecific pharmacologic probe suggest low activity during first week of life, with adult activity reached by 6 months of age and peak activity reached by 3–4 years of age. Metabolism induced by rifampin and phenobarbital and inhibited by cimetidine.
CYP2C19	phenytoin, diazepam, omeprazole, propranolol	

CYP2D6	captopril, codeine, propranolol ondansetron	Low to absent in fetal liver but uniformly present at 1-week postnatal age. Poor activity (approximately 20% of adults) at 1 month postnatal age. Adult competence reached by approximately 3–5 years of age. Metabolism inhibited by cimetidine.
CYP3A4	acetaminophen, alfentanil, amiodarone, budesonide, carbamazepine, diazepam, erythromycin, lidocaine, midazolam, nifedipine, omeprazole, cisapride, theophylline, verapamil, R-warfarin	CYP3A4 has low activity in the first month of life, with approach toward adult levels by 6–12 months postnatally. CYP3A7 is functionally active in fetus; approximately 30% to 75% of adult levels of CYP3A4. Induced by carbamazepine, dexamethasone, phenobarbital, phenytoin, and rifampin. Enzyme inhibitors include azole antifungals, erythromycin, and cimetidine.
CYP3A7	Dehydroepiandrosterone, ethinylestradiol, various dihydropyridines.	

Adapted from Leeder et al. *Pediatr Clin North Am* 1997;44:55–77, with permission.

Ontogeny of Important P450 Cytochromes

Cytochrome P4501A2 is extensively involved in the metabolism of caffeine (1,3,7-trimethylxanthine) (22,23) and theophylline (1,3-dimethylxanthine) (24,25), drugs that are commonly used to treat neonatal apnea and bradycardia (see methylxanthines). CYP1A2 is not significantly expressed in human fetal liver and expression is very low in neonates reaching only 50% of adult activity by 1 year of age (25,26). Metabolically, this limits N-3- and N-7-demethylation of caffeine in the newborn period (23). Caffeine elimination in both preterm and term infants is significantly prolonged (27). Maturation of this pathway to adult levels occurs between four and six months postnatally (28,29). A similar pharmacokinetic trend is noted with theophylline in which 3-demethylation and 8-hydroxylation are catalyzed by CYP1A2 (24,25). Clinically, theophylline clearance and urine metabolite patterns reach adult values by 55 weeks postconceptional age or approximately 4 to 5 months postnatally (30).

Other P450 enzymes which appear to be reduced or absent in the fetus include CYP2D6 and CYP2C9 (14,15,31). The former is responsible for the metabolism of numerous important therapeutic compounds including β -blockers, antiarrhythmics, antidepressants, antipsychotics, and codeine. Although CYP2D6 is absent in the fetal liver and appears to be expressed postnatally (15), activity remains low for an extended period (see Table 56-1) (32). In contrast to the slow development of CYP1A2 and CYP2D6, other enzymes such as CYP2C9 (responsible for the metabolism of nonsteroidal antiinflammatory drugs,

P.1510

warfarin, and phenytoin) develop more rapidly after birth. For example, although CYP2C9 is not significantly present during fetal life (31), phenytoin pharmacokinetic data in newborns suggest rapid enzyme maturation within the first weeks of life (20,33).

For drug metabolism, the most important of the cytochromes P450 is CYP3A, because of the large number of therapeutic substrates for this subfamily of enzymes (see Table 56-1). Additionally, CYP3A accounts for the majority of P450 cytochromes present in the adult human liver (9). Unlike most of the other important cytochromes, CYP3A is functionally present during embryogenesis, primarily as CYP3A7 (34). CYP3A activity is detectable in large amounts as early as 17 weeks gestation, and reaches 75% of adult activity at 30 weeks gestation (15). *In vivo*, CYP3A activity appears to be mature at birth (17,35). Postnatally, there is a poorly understood transition from the fetal CYP3A7 to the predominant adult isoform CYP3A4.

Phase II Reactions

The phase II reactions are known as synthetic or conjugation reactions and function to increase the

hydrophilicity of drug molecules which facilitates renal elimination (9). The phase II enzymes include glucuronosyltransferase, sulfotransferase, *N*-acetyltransferase, glutathione S-transferase, and methyl transferase. Although the ontogeny of phase II reactions as a group is not well studied, developmental changes during infancy influence drug clearance (see Table 56-2).

Most conjugation reactions show low activity during fetal development, although sulfation is relatively active in the fetus (16,36,37). One of the most common synthetic reactions involves conjugation with uridine diphosphoglucuronosyltransferases (UDP-GT). This enzyme system which is comprised of numerous isoforms is also responsible for glucuronidation of endogenous compounds such as bilirubin (38). Although UDP-GT activity for bilirubin develops relatively rapidly after birth (36), the ability of the infant to glucuronidate xenobiotics is significantly limited during the newborn period. Thus, without dosage adjustments, drugs may accumulate to toxic concentrations during the newborn period. A tragic example occurred in the early 1960s when newborns received standard pediatric doses of chloramphenicol and developed fatal circulatory collapse, a condition known as the gray baby syndrome (39,40,41). The clearance of chloramphenicol is low during the neonatal period and dosage adjustments are necessary in preterm and full-term infants to avoid chloramphenicol toxicity (42).

TABLE 56-2 DEVELOPMENTAL PATTERNS FOR IMPORTANT CONJUGATION REACTIONS IN THE NEONATE

Enzymes	Selected Substrates	Developmental Pattern
Uridine diphosphoglucuronosyl-transferase (UDP-GT)	chloramphenicol, morphine, acetaminophen, valproic acid, lorazepam	Ontogeny is isoform specific. In general, adult activity is achieved by 6–18 months of age. May be induced by cigarette smoke and phenobarbital.
Sulfotransferase	bile acids, acetaminophen, cholesterol, polyethylene glycols, dopamine, chloramphenicol	Ontogeny seems to be more rapid than UDP-GT; however, it is substrate specific. Activity for some isoforms may exceed adult values during infancy and childhood (e.g. that responsible for acetaminophen metabolism)
<i>N</i> -Acetyl Transferase 2	hydralazine, procainamide, clonazepam, caffeine, sulfamethoxazole	Some fetal activity present by 16 weeks. Virtually 100% of infants between birth and 2 months of age exhibit the slow metabolizer phenotype. Adult activity present by approximately 1–3 years of age.

Adapted from Leeder et al. *Pediatr Clin North Am* 1997;44:55–77, with permission.

Other drugs used in the newborn period that undergo glucuronidation include morphine, acetaminophen, and lorazepam. The major metabolic pathway of morphine in children and adults is glucuronidation in the 3- and 6-position (43,44). However, neonates have limited ability to glucuronidate morphine and thus require dosage adjustment (45,46,47). Morphine clearance (45,48), in particular 3- and 6-glucuronide formation, are depressed at birth and increase with birth weight (47), gestational age (49), and postnatal age (43,46). Morphine's clearance and half-life begin to approach adult values after the age of 1 month (46,50), although other reports indicate that adult values are not reached until at least 5 to 6 months (45,51). Overall, the maturation of glucuronosyltransferase enzymes is isoform-specific; however, adult activity is usually achieved by 6 to 18 months of age (16).

In contrast to glucuronosyltransferase, the sulfotransferase enzyme system is well developed in the newborn and may compensate for limited glucuronidation, as is the case with the metabolism of acetaminophen. Although acetaminophen is primarily glucuronidated in adults, the half-life of acetaminophen is only moderately prolonged

in term newborns as compared to older infants and adults (52,53,54). In the neonate, this is explained by a relatively large formation rate constant for the acetaminophen-sulfate leading to a greater percent of the dose excreted as the acetaminophen-sulfate conjugate (52,53). Preferential sulfation of acetaminophen continues into childhood (53,55).

Alterations in Biotransformation

Biotransformation reactions, especially those involving certain forms of cytochrome P450, are often inducible before birth through maternal exposure to drugs, cigarette smoke, or other xenobiotic inducing agents. Biotransformation reactions may also be induced by postnatal drug exposure (see Tables 56-1 and 56-2) and may be slowed postnatally by hypoxia/asphyxia, organ damage, and/or critical illness. Additional postnatal changes in hepatic blood flow, protein binding, and/or biliary function may also significantly alter drug elimination. Additional studies in premature neonates are required to generate the population pharmacokinetic data necessary to design safe and effective pharmacotherapeutic regimens.

Excretion

Excretion involves elimination of drug from the body by several potential routes, including the biliary tract, lungs, and kidneys. Both unchanged and metabolized forms of drug may be excreted, but only unbound drug undergoes filtration and tubular transport. Glomerular and tubular function are decreased at birth, both in absolute terms and after normalization to body mass (56,57). Glomerular filtration in newborns averages 30% of the adult rate after normalization to body surface area. Birth accelerates maturation of glomerular filtration through an increase in cardiac output, decreased renal vascular resistance, redistribution of intrarenal blood flow, and changes in the intrinsic function of the glomerular basement membrane (56). Renal tubular maturation seems to proceed more slowly than glomerular maturation after birth (56). This produces an imbalance in glomerular and tubular function that persists for several months. Because most low molecular weight unbound molecules are filtered, tubular reabsorption exerts a profound influence on the elimination rate for many drugs. Additionally, hypoxemia, nephrotoxic drugs, and underperfusion may alter renal function of newborns, which prevents accurate prediction of the rates of drug elimination after birth.

PHARMACOKINETICS

Pharmacokinetics describes the changes in drug concentrations within the body with time. These concepts are presented as a general overview to assist the clinician with dose adjustments and practical interpretation of therapeutic drug monitoring (58,59,60). The more rigorous mathematical intricacies of pharmacokinetics are covered elsewhere (61,62,63,64). Although a drug may penetrate several body fluids and tissues at different rates, the change in its circulating concentration is used to characterize its kinetics and to guide dosages. The rate of removal of drug from the circulation usually fits either first-order or zero-order exponential mathematical equations. These two types of equations describe two different processes that have important implications for dosage regimes.

Rates and Distribution

First-Order Kinetics

Most drugs are cleared from the body with first-order exponential rates. Exponential clearance indicates that a constant fraction or constant proportion of drug is removed per unit of time. This means that the higher the concentration, the greater the amount of drug removed from the body. Such changes in concentration fit exponential equations of the following form:

$$C_t = C_0 - e^{kt} \quad [1]$$

where C_t is the concentration at a particular time t , C_0 is the starting concentration, which is a constant, and k is the elimination rate constant with units of 1/time. First-order indicates that the exponent is raised to the first power ($-kt$ in Eq. 1). First-order exponential equations, such as Eq. 1, may be solved by taking the natural logarithm of both sides.

$$\ln C_t = \ln C_0 + -kt \quad [2]$$

This transforms the equation to that of a straight line ($y = mx+b$). If \ln (i.e., natural logarithm) C is graphed vs. time, the slope is $-k$, and the intercept is $\ln C_0$. If \log i.e., common logarithm C is graphed vs. time, the slope is $-k/2.303$, because $\ln x$ equals $2.303 \log x$. When graphed on linear-linear axes, exponential rates are curvilinear and on semilogarithmic axes, they produce a straight line.

Half-Life

One of the more familiar exponential rates used clinically is the half-life, i.e., the time for a drug concentration to decrease by one-half. Half-life is a first-order kinetic process, because the same proportion or fraction of the drug is removed during equal time periods. At higher concentrations, a greater amount is removed during a single half-life than when the concentration is lower. For example a drug concentration may decrease by 200 from 400 to 200 in one half-life, and decrease by 100 from 200 to 100 in the next half-life (Fig. 56-1).

Half-life can be determined by several methods. If concentration is converted to the natural logarithm of concentration and graphed vs. time, as described in Eq. 2, the slope of this graph is the elimination rate constant, k . Usually at least three concentration-time points are needed to determine the slope accurately; however, in clinical practice, k is often determined from just two concentrations obtained during the terminal elimination phase. To increase the accuracy of the latter, at least one half-life should elapse between concentration-time points. With multiple data points, the slope of $\ln C$ vs. time may be calculated easily by least-squares linear regression analysis. Half-life ($t_{1/2}$) may be calculated from the elimination rate constant, k (1/time), as follows:

$$t_{1/2} = \frac{\text{natural logarithm } (2)}{k} = \frac{0.693}{k} \quad [3]$$

Figure 56-1 Graph method for estimation of half-life. From Ward RM. Pharmacologic principles and practicalities. In: Tausch HW, Ballard RA, Avery ME, eds. *Shaffer and Avery's diseases of the newborn*. 6th ed. Philadelphia: WB Saunders, 1991:289, with permission.

P.1512

Half-life may be determined graphically from a series of drug concentrations graphed on semilogarithmic axes. With multiple data points, the best-fit line is determined either visually or by linear regression analysis. The times corresponding to carefully chosen concentrations are then used to estimate the interval required for the concentration to decrease by one-half. In Fig. 56-1, this is illustrated by the times corresponding to concentrations of 400, 200, and 100, estimated by the horizontal broken line intercepts with the concentration line and the intercepts with the time axis indicated by the vertical broken lines. Note that the concentrations decrease by 50% every 60 minutes, so that $t_{1/2}$ equals 60 minutes.

First-Order Single-Compartment Kinetics

The number of compartments refers to the number of exponential equations required to describe the observed

changes in concentration. These compartments theoretically represent a group of similar tissues, fluids, and/or organs and may be correlated with different anatomic fluids and tissues. Although multiple transfers of drug among tissues and body fluids may be occurring, a drug's clearance may fit first-order, single-compartment kinetics if it distributes rapidly and homogeneously within the circulation from which it is removed through metabolism or excretion. This may be judged visually, if a semilogarithmic graph of a series of concentrations fits a single straight line. Kinetics may falsely appear to be single-compartment if drug concentrations are not measured quickly enough after i.v. administration to detect the initial distribution phase.

First-Order Multicompartment Kinetics

If drug clearance from the circulation is studied carefully, with measurement of concentration several times within the first 15 to 30 minutes after i.v. administration and during the next several hours, two or more rates of clearance often are detected by a change in slope of a semilogarithmic graph of concentration vs. time (Fig. 56-2). The number and nature of the compartments for the clearance of a drug do not necessarily correspond to specific body fluids or tissues. When two first-order exponential equations are required to describe the clearance of drug from the circulation, the kinetics are designated first-order and two-compartment i.e., central and peripheral compartments and are represented by the following equation (58):

$$C = Ae^{-\alpha t} + Be^{-\beta t} \quad [4]$$

In Eq. 4, C is concentration, t is time after the dose, A is the concentration at time 0 for the distribution rate represented by the broken line graph with the steepest slope, α is the rate constant for distribution, B is the concentration at time 0 for the terminal elimination rate, and β is the rate constant for terminal elimination. Rate constants indicate the rate of change in concentration and correspond to the slope of the line divided by 2.303 for logarithm concentration vs. time.

Such biphasic kinetics are observed commonly for drugs that rapidly distribute out of the central compartment (blood volume + extracellular fluid of highly perfused organs) after i.v. administration (58). For such drugs, the initial rapid decrease in concentration is referred to as the alpha distribution phase and represents primarily distribution to the peripheral (tissue) compartments in addition to drug elimination. After the inflection point in the slope and during the terminal (beta) phase of the curve, elimination accounts for most of the change in drug concentration. The alpha distribution rate constant (α) (see Fig. 56-2) can be determined from the slope of the line generated by subtracting concentrations from the beta elimination phase from those during the alpha distribution phase. A more detailed mathematical discussion may be found elsewhere (58,61).

Figure 56-2 Multicompartment first-order exponential kinetics. From Ward RM. Pharmacologic principles and practicalities. In: Tausch HW, Ballard RA, Avery ME, eds. *Schaffer and Avery's diseases of the newborn*. 6th ed. Philadelphia: WB Saunders, 1991:289, with permission.

Although many drugs demonstrate multicompartment kinetics, the intensive blood sampling required to fit data to more than one compartment is not clinically feasible, particularly in newborns. Furthermore, the mathematical complexity of two compartment models makes this kinetic approach clinically impractical. To minimize cost and simplify pharmacokinetic calculations, only two plasma concentrations (peak and trough) are usually obtained for therapeutic monitoring of commonly used drugs, e.g., gentamicin and vancomycin. Accordingly, a one-compartment model is assumed and the elimination rate constant (k) is determined from the slope of these points plotted on a semi-logarithmic scale. Because the elimination rate constant should be determined from the terminal elimination phase, it is important that peak concentrations of multicompartment drugs not be drawn prematurely, i.e., during the initial distribution phase. If drawn too early, the concentrations will be higher than those during the terminal elimination phase (see Fig. 56-2), which will overestimate the slope and the terminal elimination rate constant. Clinically, this is not usually problematic with gentamicin because the initial distribution phase commonly occurs during the 30- to 60-minute infusion (65). Thus, a peak concentration obtained 30 to 60 minutes after the end of infusion usually reflects the terminal phase of elimination. However, with vancomycin, the half-life of the initial distribution phase is approximately 0.5 hours (66). Thus, a peak vancomycin concentration drawn prematurely may lead to error in estimating the pharmacokinetic parameters.

Zero-Order Kinetics

Some drugs are eliminated by a constant amount per unit time, rather than a constant fraction. Such rates are zero-order and the following equation can be used to calculate the change in the amount of drug in the body (61):

$$-dA/dt = k_0 \quad [5]$$

in which dA is the change in the amount of drug in the body (mg), dt is the change in time, and k_0 is the elimination rate constant with units of amount/time. After solving this equation, it has the following form:

$$A = A_0 - k_0t \quad [6]$$

in which A_0 is the initial amount in body and A is the amount of drug in the body (mg) at time t .

Zero-order kinetics also is referred to as saturation kinetics, because it may occur when excess amounts of drug saturate the capacity of metabolic enzymes or transport systems so that only a constant amount of drug is metabolized or transported per unit of time. This may be detected graphically from a serum concentration vs. time plot in which zero-order elimination is linear on linear-linear axes and is curved when graphed on logarithmic-linear (i.e., semilogarithmic) axes. Clinically, zero-order elimination may be observed after administration of excessive doses, or during dysfunction of the organ of elimination without a decrease in dosage. Certain drugs administered to newborns exhibit zero-order kinetics at therapeutic doses, and may accumulate to excessive concentrations (Table 56-3). Some drugs, e.g., phenytoin, may exhibit Michaelis-Menten kinetics, i.e., first-order at low concentrations and zero-order after enzymes are saturated at higher concentrations. For these drugs, a small increment in dose may cause disproportionately large increments in serum concentrations (Fig. 56-3).

Apparent Volume of Distribution

Volume of distribution does not necessarily correspond to a physiologic body fluid or tissue volume, hence the designation "apparent." The apparent volume of distribution (Vd) is a mathematical term that relates the dose to the circulating concentration observed immediately after intravenous administration. It might be viewed as the volume of dilution. For drugs such as digoxin, Vd in neonates may reach 10 L/kg, a physical impossibility. Such a large Vd occurs when drug concentrates outside of the plasma compartment, for example bound to red blood cells or in tissue. This emphasizes the mathematical nature of Vd. The units used to express concentration are amount/volume and may help to remind the reader of the following equation that expresses the relation between dose in amount/kg and the Vd in volume/kg that dilutes the dose to produce the concentration:

$$\text{Concentration change (mg/L)} = \frac{\text{Dose (mg/kg)}}{\text{Vd(L/kg)}} \quad [7]$$

To facilitate canceling units, concentration is expressed with the unconventional units of milligrams per liter rather than micrograms per milliliter, because they are equivalent. This equation serves as the basis for most of the pharmacokinetic calculations, because it is easily rearranged to solve for Vd and Dose. It is also important to note that this equation represents the change in concentration following a rapidly administered intravenous dose. Following an intravenous infusion, e.g., vancomycin or gentamicin, a more complex exponential equation may be required to account for drug elimination during the time of infusion (61).

P.1514

However, such equations are needed only when the drug is rapidly eliminated, i.e., the duration of infusion approaches the drug's half-life. In neonates, who have relatively slow drug elimination, only a small fraction of drug is eliminated during the time of infusion, and such adjustments can be omitted. Accordingly, we may use the simpler and more practical equation to estimate pharmacokinetic parameters.

Figure 56-3 Nonlinear (Michaelis- Menten) kinetics illustrated for a hypothetical drug. As dosage increases above 3 mg/kg/day, there is a disproportionate increase in average plasma concentration as elimination changes from a first-order to a zero-order process.

Knowledge of the apparent distribution volume is essential for dosage adjustments. Vd may be calculated by rearranging Eq. 7.

$$\text{Vd (L/kg)} = \frac{\text{Dose (mg/kg)}}{\text{C (postdose)} - \text{C (predose) (mg/L)}} \quad [8]$$

The concentration after drug infusion, C (postdose), must be measured after the distribution phase to avoid overestimating the peak concentration that would result in an erroneously low Vd. For the first dose, the predose concentration is zero.

Pharmacokinetic Example

To illustrate the practical application of the principles outlined above, we recommend a simple four-step approach: (a) calculate Vd; (b) calculate half-life; (c) calculate a new dose and dosing interval based on a desired peak and trough; (d) check the peak and trough of the new dosage regimen.

For example, gentamicin 2.5 mg/kg every 12 hours was administered i.v. over 30 minutes. The following plasma concentrations were measured on the third day of treatment (presumed steady-state). The predose or trough concentration was 1.8 mg/L; the peak concentration, measured 30 minutes after the end of the infusion, was 4.8 mg/L.

Step 1: Substituting the data into Eq. 8, we calculate Vd.

$$\begin{aligned} Vd \text{ (L/kg)} &= \frac{2.5 \text{ mg/kg}}{4.8 \text{ mg/L} - 1.8 \text{ mg/L}} = \frac{2.5 \text{ mg/kg}}{3.0 \text{ mg/L}} \\ &= 0.83 \text{ L/kg.} \end{aligned}$$

Step 2: At steady-state, trough concentrations remain unchanged from one dose to the next. Therefore, for the purpose of these calculations, steady-state trough concentration may be understood to follow the peak concentration. Thus, the time between the peak and trough concentrations is 11 hours, i.e., 12 hours minus 0.5 hour infusion, minus 0.5 hour to peak concentration. The plasma concentration decreased from 4.8 to 2.4 mg/L in one half-life, and then from 2.4 to 1.2 mg/L in a second half-life. The trough of 1.8 was reached approximately half way between the first and second half-lives. Because 1.5 half-lives elapsed during the 11 hours between the peak and trough, the half-life is approximately 11 hours/1.5 half-lives, or 7.3 hours.

Step 3: A new dosage regimen must be calculated if the concentrations are unsatisfactory. Accordingly, one must decide on a desired peak and trough concentration. If, for example, the desired gentamicin peak and trough concentrations were 6.5 mg/L (5-10 mg/L) and 1.5 mg/L (1-2 mg/L), respectively, then Eq. 8 may be rearranged to solve for the new dose.

$$\begin{aligned} \text{Dose (mg/kg)} &= Vd \text{ (L/kg)} \times [C \text{ (peak desired)} - C \text{ (post desired) (mg/L)}] \quad [9] \\ \text{Dose (mg/kg)} &= 0.83 \text{ L/kg} \times [6.5 \text{ mg/L} - 1.5 \text{ mg/L}] \\ \text{Dose (mg/kg)} &= 4.15 \text{ mg/kg} \end{aligned}$$

Increasing the dose to 4.15 mg/kg (66% increase) will lead to a higher trough if the dosage interval is kept at 12 hours. Because trough concentrations above 2 mg/L are associated with ototoxicity and nephrotoxicity, the dosage interval needs to be increased. Aminoglycosides, in general, are dosed every 2 to 2.5 half-lives for neonates. However, to reduce the risk of administration errors, one should choose a conventional dosage interval that approximates 2 to 2.5 half-lives, i.e., every 8, 12, 18, 24, or 36 hours. In the above example, dosing every two half-lives would require a 15-hour dosage interval that might lead to administration errors. Thus, the dosage interval should be increased to 18 hr, an interval that corresponds to approximately 2.5 half-lives.

Step 4: Mathematically estimating peak and trough concentrations with the new regimen provides a good double check against a math error. Because 18 hours was

P.1515

chosen as the new interval, waiting 18 hours after the previous dose to begin the new regimen is reasonable. At that time, approximately 2.5 half-lives after the measured peak of 4.8 mg/L, we would expect the trough concentration to be approximately 0.9 mg/L (half-life #1: 4.8 mg/L → 2.4 mg/L; half-life #2: 2.4 mg/L → 1.2 mg/L, half-life #3: 1.2 mg/L → 0.6 mg/L, with half of this third half-life occurring at 0.9 mg/L). Using Eq. 7, we calculate that the plasma concentration will increase by 5 mg/L after each 4.15 mg/kg dose. Accordingly, the measured peak concentration will be 5.9 mg/L after the first dose and will decrease to 1.1 mg/L over the next 2.5 half-lives (5.9 mg/L → 2.95 mg/L → 1.48 mg/L → 0.74 mg/L in 3 half-lives, or 1.1 mg/L in 2.5 half-lives). After the second dose of 4.15 mg/kg, the measured peak concentration will be 6.1 mg/L and will decrease to 1.15 mg/L in 2.5 half-lives. Because the trough has not changed from the previous trough, one can conclude that this dosage schedule will meet the desired therapeutic levels. Estimation of concentrations after a fraction of a half-life assumes a linear rather than logarithmic decline in concentrations and is not mathematically correct for first-order, exponential rates in which the amount of drug eliminated decreases as the concentration decreases. However, this approach is suitable for clinical applications, in which only a reasonable estimate of plasma concentration is needed for dosage adjustments.

Therapeutic Drug Monitoring

Circulating concentrations of drugs should be measured primarily to ensure that the treatment regime achieves concentrations that are effective in clinical situations in which drug treatment is critical, response is not immediately apparent (e.g., for culture-proven sepsis), and a good correlation exists between circulating drug

concentration and desired effect. Drug concentrations should be measured to avoid toxicity when they clearly correlate with toxicity in newborns (e.g., for chloramphenicol), to verify toxicity when symptoms correspond to a known drug toxicity, or to investigate symptoms that are unexplained by the disease process. Extrapolation of toxic and therapeutic ranges from adults to neonates has led to some recommendations about therapeutic drug monitoring in newborns (e.g., for gentamicin) that are not well supported by subsequent experience (67).

Several basic requirements must be met to justify therapeutic drug monitoring in newborns and to modify drug treatment accurately based on measured circulating drug concentrations (68).

- Drug analysis using small blood volumes must be accurate.
- Circulating drug concentrations must correlate with both effective and toxic pharmacologic effects. This implies that the circulating total (i.e., free plus protein-bound) drug concentration correlates with the free-drug concentration at the site of drug action, such as the drug receptor or tissue site.
- The therapeutic index, the concentration range between efficacy and toxicity, should be narrow.
- Clinical studies should have established a concentration range for efficacy and toxicity in the population being monitored.
- Pharmacokinetics are variable and unpredictable in newborns.

In the extremely premature newborn, decreased protein binding may significantly affect therapeutic drug monitoring. As a result of unpredictable decreases in protein binding associated with organ dysfunction or immaturity, free-drug concentrations may be much higher than would be predicted from the total drug concentration that usually is measured clinically. Higher percentages of free drug in the newborn may account for signs of toxicity or adequate therapeutic response at paradoxically low total drug concentrations. When available and when therapeutic concentration ranges have been established, as for phenytoin, measurement of free-drug concentrations may be helpful in newborns demonstrating signs of drug toxicity with therapeutic or subtherapeutic circulating total drug concentrations.

Effective drug therapy is measured by response, not by achieving a particular circulating drug concentration. Concentration ranges described as therapeutic are statistical ranges for drug levels that usually are effective and nontoxic. Individual patients may require drug concentrations outside these ranges to achieve optimal drug treatment.

Repetitive Dosing and Drug Accumulation

During most courses of repetitive drug therapy, the doses are administered before complete elimination of the previous one. This leads to accumulation of drug, with increasing peak and trough concentrations until a steady state concentration is reached (Fig. 56-4). The average C_{ss} can be calculated as follows (59):

$$\begin{aligned} \text{Avg } C_{ss} &= \frac{1}{\text{Clearance}} \times \frac{f \times D}{\tau}, & [10] \\ &= \frac{1}{k \times Vd_{(\text{area})}} \times \frac{f \times D}{\tau}, \\ &= \frac{1.44 \times t_{1/2}}{Vd_{(\text{area})}} \times \frac{f \times D}{\tau}, & [11] \end{aligned}$$

In Eq. 10 and 11, f is the fraction of the dose that is absorbed, D is the dose, τ is the dosing interval in the same units of time as the elimination half-life, k is the elimination rate constant, and 1.44 equals $1/0.693$ (see Eq. 56-3). The magnitude of the average C_{ss} is directly proportional to a ratio of τ /half-life and D . (59)

Steady State

Steady-state occurs when the amount of drug removed from the body between doses equals the amount of the

(64,69). Five half-lives are usually required for drug elimination and distribution among tissue and fluid compartments to reach an equilibrium. When all tissues are at equilibrium, i.e., steady-state, the peak and trough concentrations are the same after each dose. However, prior to this time, constant peak and trough concentrations after intermittent doses, or constant concentrations during drug infusions, do not prove that a steady-state has been achieved because drug may still be entering and leaving deep tissue compartments. During continuous infusion, the fraction of steady state concentration that has been reached can be calculated in terms of multiples of the drug's half-life (59). After 3 half-lives, the concentration is 88% of that at steady state. The effect of dosage changes on drug concentrations during chronic treatment usually should not be rechecked until several half-lives have elapsed, unless elimination is impaired or toxic symptoms occur. Drug concentrations may not need to be checked if symptoms improve.

Figure 56-4 The effect of 2 different half-lives on the steady state concentrations of vancomycin during repetitive dosing with the same dose (15 mg/kg and a V_d of 0.9 L/kg. The solid line represents a half-life of 8 hours and the broken line represents a half-life of 16 hours. Peak and trough concentrations increase until steady-state is achieved, but steady-state is achieved by the fourth dose (36 hrs) with the 8 hour half-life, but not until the 7th dose (72 hours) with the 16 hour half-life

Loading Dose

If the time to reach a constant concentration by continuous or intermittent dosing is too long, a loading dose may be used to reach a higher constant concentration more quickly. This frequently is applied to initial treatment with digoxin, which has a 35- to 69-hour half-life in term neonates and an even longer half-life in preterm newborns (70). Use of a loading dose produces a higher circulating drug concentration earlier in the therapeutic course, but the equilibration to reach a true steady-state still requires treatment for five or more half-lives. Loading doses must be used cautiously, because they increase the likelihood of drug toxicity, as has been observed with digoxin digitalizing doses (70).

Special Considerations for Neonates

Intravenous Administration

Intravenous administration of drugs is considered the most reliable route. In neonates, especially those who weigh 500 to 1000 g and receive small volumes of i.v. fluids, i.v. drug administration may not reliably deliver the dose into the circulation (8,69). Because some types of i.v. tubing may contain 12- to 15-mL of fluid and the i.v. infusion rates for 500- to 1,000-g neonates may be 1.5 to 2.5 mL/hour, infusion of a drug into the i.v. tubing several cm from the patient will markedly delay drug administration. This may confound therapeutic drug monitoring by causing the peak concentration to be less than the trough, because the dose has not reached the

patient. For this reason, microbore tubing, which has a volume of 0.5 mL should be used whenever possible and should be connected to a port closest to the patient. Slow delivery of drug to the circulation may prevent the attainment of an adequate peak concentration to enhance drug diffusion into tissue down a concentration gradient. Lastly, filters present potential obstacle to effective i.v. drug treatment. Drugs may adsorb to the filter or settle to the bottom of a reservoir in the filter, out of the main flow of the infusing solution (71).

Exchange Transfusion

Because few studies have evaluated the amount of drug actually removed from neonates during an exchange transfusion, theoretical estimates have been developed (69,72). The amounts removed vary with the individual drug's volume of distribution, rate of distribution, and circulating concentration at the time of the exchange, and the volume of blood exchanged and the rate of the exchange.

CLINICAL TOXICOLOGY

Newborn infants, both full-term and premature, present an alarmingly wide spectrum of susceptibilities to unanticipated, adverse effects from exposure to exogenous chemicals. New drugs, together with unrecognized chemicals ranging from tape remover to plasticizers, are introduced into the care of neonates each year. Prescription drug exposure of the extremely preterm neonate is extensive. In the late 1970s, neonates admitted to a neonatal intensive care unit (NICU) received 1 to 26 drugs, averaging 6.2 drugs per infant (73). This drug exposure was not innocuous, because 30% of infants in the NICU manifested an adverse drug reaction, of which 15% were considered fatal or life-threatening (74). Similar drug exposure of newborns was documented in Boston from 1974 to 1977, in which infants in the intensive care nursery received more drugs (10.4/patient) than any other hospitalized children (75).

P.1517

Several factors increase the susceptibility of newborns and preterm newborns to chemical toxicities. Immaturity of liver and renal function frequently delays drug elimination, which prolongs the exposure of the newborn to a drug and predisposes to drug accumulation during repeated administration. New therapeutic agents often are introduced into treatment of critically ill neonates when all other therapy has failed, although pharmacokinetic data to guide dose and dosing intervals are lacking. Without the guide of pharmacokinetic or concentration-response studies, treatment failure may be considered an indication to increase the dose, rather than the result of administering excess amounts of the drug (76).

Specific enzyme immaturities of the newborn also may place them at risk. Inadequate function of the glucuronosyltransferase system predisposes the newborn to inadequate elimination of chemicals requiring glucuronide conjugation, such as bilirubin. Circulating albumin binds bilirubin at the levels encountered in physiologic jaundice and protects the newborn from bilirubin encephalopathy as long as the blood-brain barrier remains intact (77,78). Failure to recognize the competition of drugs for bilirubin's albumin-binding sites has led to displacement of bound bilirubin and kernicterus (79,80,81). Large doses of chloramphenicol were associated with unexplained cardiovascular collapse in infants in 1959 (40). That same year, a randomized, controlled study of antibiotics for neonatal sepsis revealed that the groups treated with chloramphenicol alone or in combination had a 60% mortality, threefold higher than neonates receiving no antibiotics (41). The no-treatment control group, however, showed the same survival as the alternate antibiotic treatment group. Inadequate glucuronide conjugation of chloramphenicol and decreased tubular secretion of conjugated chloramphenicol combined to reduce chloramphenicol elimination and led to accumulation to toxic concentrations (39). Acute intoxication with high serum chloramphenicol concentrations manifested with jaundice, vomiting, anorexia, respiratory distress, abdominal distention, cyanosis, green stools, lethargy, and ashen color (41).

The preservative, benzyl alcohol, has been implicated in a fatal syndrome in premature infants of cardiovascular collapse and death associated with metabolic acidosis, gasping respirations, thrombocytopenia, hepatic and renal failure, and progressive central nervous system (CNS) depression (82). The minimal intake to produce toxicity was estimated at 130 mg/kg/day (82). Removal of benzyl alcohol as a preservative in the fluid frequently used to flush i.v. catheters in neonates essentially has eliminated this problem. Although many nurseries and pharmacies have excluded all solutions and medications containing benzyl alcohol, the major problem seemed to lie with i.v. solutions and flush solutions. Considering the dose estimated for toxicity, exposure to the small amounts in medications (which can be estimated from the benzyl alcohol concentration and dosing volume) might pose an acceptable risk compared to the benefit of the drug treatment. Propylene glycol (PG), a solvent frequently used with water-insoluble drugs, has also been associated with toxicity in

neonates (83,84). At high doses, propylene glycol is partly metabolized to lactic acid and may cause serum hyperosmolality with a marked osmolar gap, lactic acidosis, seizures, and cardiac arrhythmias (83,84,85,86). Because up to 45% of PG is eliminated renally, patients with poor renal function (including preterm neonates) may be predisposed to PG toxicity. Lorazepam, which is commonly used in neonates, contains propylene glycol and caution must be exercised in prescribing large scheduled doses of lorazepam for sedation of sick neonates.

Dermal exposure to a variety of chemical agents, including isopropyl alcohol, may be hazardous to the newborn (87,88). Toxic epidermal necrolysis was reported in a neonate after prolonged exposure to a commonly used distillate-containing adhesive remover (89). Unintended percutaneous absorption of toxic substances through the permeable skin of neonates has recurred with several substances. This has led to toxicity from methanol (90), isopropanol (91,92), hexachlorophene (93), iodine-containing topical disinfectants (94,95), aniline dye in diapers (96), and topical antibiotics such as neomycin (97). Advantageous and disadvantageous transcutaneous drug absorption by newborns has been reviewed (98). Chemical intoxication of the fetus and newborn has been reviewed in detail (70).

Inadvertent exposure of the neonate to a variety of chemicals may occur with little notice. Phthalate plasticizers accumulate in the myocardial and gastrointestinal tissue of neonates with umbilical catheters and those who receive blood products (99). Although phthalates probably produce minimal acute toxicity, they accumulate in tissues and may exert effects that are not recognized. Since the report by Hillman and colleagues (99), the extent of exposure of NICU patients to plastic products appears to have increased, causing greater exposure to soluble chemicals in the plastic, such as phthalates.

SPECIFIC CLASSES OF DRUGS

Antiarrhythmics

Treatment of cardiac arrhythmias has advanced with increased understanding of the transmembrane ion currents that control both normal and abnormal myocardial depolarization (100,101,102). Developmental changes in these channels are described using both electrophysiological techniques and molecular biological means of investigation (103). Careful interpretation of various studies is needed, however, as a result of species differences in the timing of innervation and in the development of various channels (103,104).

Antiarrhythmic drugs have been classified and reclassified according to the mechanisms responsible for arrhythmias, including effects on ion channels, duration of repolarization, and receptor interaction (Table 56-4) (100,105,106,107). A discussion of the various subtypes

P.1518

of ion channels is beyond the scope of this chapter (100,101,102,108,109). Such classification systems help with analysis of the effects of individual antiarrhythmic drugs and selection of treatment for specific arrhythmias, but drugs and their metabolites may interact with multiple ion channels and more than one antiarrhythmic mechanism (106,110). Drugs within a given class, however, may differ in their effectiveness for an individual patient's arrhythmia. Dosages for drugs used frequently for resuscitation of newborns are listed (see Table 56-5) (111).

TABLE 56-4 ANTIARRHYTHMIC DRUGS BY MECHANISM OF ACTION

Class	Action/Structure	Drugs
IA	Sodium ± potassium channel blockade Phase 0 dV/dt—slowed Conduction slowed (prolonged PR, QRS, and QT) Repolarization usually delayed Anticholinergic	Quinidine Procainamide Dysopyramide
IB	Sodium channel blockade Phase 0 dV/dt, -minimal change Repolarization usually shortened (QT shortened) Fibrillation thresholds elevated	Lidocaine Mexilitine Morcizine
IC	Sodium channel blockade Phase 0 dV/dt, -markedly slowed Repolarization minimally changed, PR and QRS markedly prolonged	Flecainide Propafenone
II	Beta-adrenergic blockade, variable selectivity	Propranolol Atenolol Esmolol
III	Repolarization and Action Potential Prolonged	Amiodarone Sotalol
IV	Calcium Channel Blockade	Verapamil
V	Digitalis Glycosides	Digoxin Ouabain
VI	Purinergic Agonists	Adenosine

Adapted from Grant AO. Mechanisms of action of antiarrhythmic drugs: From ion channel blockage to arrhythmia termination. *Pacing Clin Electrophysiol* 997;20:432–444; Perry JC. Pharmacologic therapy of arrhythmias. In Deal B, Wolff G, Gelband H (eds). *Current Concepts in Diagnosis and Management of Arrhythmias in Infants and Children*. Armonk, NY: Futura Publishing Co., 1998:267–305, with permission.

Drug selection for treatment of arrhythmias should be guided, whenever possible, by more precise identification of the type of arrhythmia. The most frequent arrhythmia requiring management in neonates is supraventricular tachycardia (SVT) (112). In general, SVT arises from either an aberrant conduction pathway or abnormal automaticity in a discrete focus that captures the ventricle (112). Reentrant mechanisms are the most common cause of SVT in neonates and usually involve retrograde conduction from the ventricle via the accessory conduction pathway to the atrium which then depolarizes prematurely. This has been designated orthodromic reciprocating tachycardia (ORT). A variant of ORT arises from a posterior accessory conducting pathway that causes a slower, but incessant form of SVT, permanent junctional reciprocating tachycardia (PJRT). PJRT, left untreated, may cause a cardiomyopathy and CHF. In the Wolff-Parkinson-White syndrome (WPW), the

accessory conduction pathway can be identified during sinus rhythm from early depolarization that creates a beginning shoulder (delta wave) on the QRS complex with a shortened PR interval (112). Unfortunately, almost 50% of reentrant SVT in infants does not show preexcitation overtly during sinus rhythm. When the depolarization returns from the ventricle through the atrioventricular node to cause SVT, it is termed antidromic reentrant tachycardia, and causes a wide complex tachycardia. Reentrant tachycardias, either overt or concealed, can be identified during electrophysiologic studies by being able to be initiated and terminated by atrial or ventricular extrastimulation (110,112).

Nonreentrant SVT is rare in infancy and difficult to treat pharmacologically. SVT caused by a nonsinus node focus of abnormal automaticity is designated Automatic Atrial Tachycardia (AAT) and is difficult to treat medically (110). AAT must be distinguished from sinus tachycardia because the heart rate may gradually speed up and slow down. The p-wave morphology during AAT differs from that during sinus rhythm and the PR interval of conducted beats may lengthen, rather than shorten as the rate increases (110). SVT may also arise from a site of abnormal automaticity within or near the AV node, designated junctional ectopic tachycardia (JET) (110). JET is also quite difficult to treat with the usual antiarrhythmics (113,114). Treatment of SVT may be required in two situations, acute termination

P.1519

of a symptomatic tachycardia and chronic suppression of SVT that has recurred or is likely to recur. Synchronized direct current electrocardioversion terminated SVT in about 50% of cases, but was more successful if P waves were not present (115). Vagal maneuvers, such as stimulation of the diving reflex through ice applied to the face, are still frequently used for the acute termination of SVT, although bilateral carotid massage or pressure on the eyes should be avoided.

TABLE 56-5 DRUGS FOR NEWBORN RESUSCITATION AND ACUTE TREATMENT OF ARRHYTHMIAS

Drug and Formulation	Final Concentration	Dose (Amount/kg)	Dose (mL/kg)
Adenosine 6 mg/2 mL	3 mg/mL	Start: 50 µg/kg rapid IV push, followed by flush of IV catheter; if no response within 0.5–2 minutes, increase dose by 50 µg/kg and repeat until conversion of SVT or AV block, to maximum single dose of 250–500 µg/kg	Dilute 0.5 ml with 2.5 ml saline, infuse 0.1 mL/kg IV for every 50 µg/kg dose

Atropine 10.0%	0.1 mg/mL	IV dosage: 0.01–0.02 mg/kg (minimum dose 0.1 mg); may repeat in 10 min to maximum of 0.04 mg/kg; IT dosage: 0.02–0.04 mg/kg	0.1–0.2 mL/kg IV 0.2–0.4 mL/kg IT
Bicarbonate 0.05 mEq/mL	0.5 mEq/mL	1–2 mEq/kg; treat measured metabolic acidosis; avoid 1.0 mEq/mL formulation in newborns; maintain ventilation	1–2 mL/kg IV
Calcium Gluconate 10%	100 mg/mL (9.3 mg Ca ⁺⁺ /mL)	60 mg/kg infused slowly and stop infusion for symptomatic bradycardia; repeat as needed for clinical effect; extravasation causes tissue necrosis	0.6 mL/kg IV
Calcium Chloride 10%	100 mg/mL (27 mg Ca ⁺⁺ /mL)	20 mg/kg infused slowly and stop infusion for symptomatic bradycardia; repeat as needed for clinical effect; extravasation causes tissue necrosis	0.2 mL/kg IV
Direct Current Defibrillation		1 Watt-sec/kg; increase by 1 Watt-sec/kg if unsuccessful	
Epinephrine 1:10,000	0.1 mg/mL	0.01–0.03 mg/kg IV or IO 0.1 mg/kg IT	0.1–0.3 mL/kg i.v., i.o. 1.0 mL/kg IT
Glucose 10%	100 mg/mL	200–500 mg/kg	2–5 mL/kg IV

Lidocaine 2%	20 mg/mL	0.5–1.0 mg/kg; repeat every 5–10 minutes to maximum of 3 mg/kg	Dilute 0.5 mL 9.5 mL D5W Infuse: 0.5– 1.0 mL/kg IV, IT
Naloxone 0.4 mg/mL	0.4 mg/mL	0.1 mg/kg; dose may be repeated to maintain opioid reversal. This dose is indicated for acute opiate intoxication. Titration to effect with lower initial doses (0.01 mg/kg or 10 µg/kg) should be considered for respiratory depression during pain management. WARNING: May induce acute withdrawal in opioid dependent patients.	0.25 mL/kg IV, IM
Procainamide 100 mg/mL	100 mg/mL	3–6 mg/kg over 5 minutes, repeat to a titrated maximum of 15 mg/kg loading dose, infuse slowly with myocardial dysfunction	Dilute 1 mL + 9 mL D5W, Infuse: 0.3– 0.6 mL/kg IV

* i.v. = intravenous

IT = through endotracheal tube and dose should be diluted in saline or tube flushed with saline after dose

For the acute treatment of SVT, adenosine has been used with moderate success.

Adenosine slows spontaneous heart rate, prolongs the PR interval, and decreases the slope of phase 4 repolarization through activation of A₁-purinoceptors coupled to sarcolemmal potassium channels. In one report, electroconversion was not required for conversion of infant onset SVT during the 6 years after the introduction of adenosine (116). The ventricle is minimally affected by adenosine whose action begins within seconds of administration. With a 9-second half-life, it must be administered as a rapid i.v. infusion over seconds, but it has been administered successfully by intraosseous infusion (117). Its short half-life limits its usefulness to the acute treatment of SVT. Adenosine treatment may be started with 50 to 150 µg/kg doses, with increases in the dose by 50 µg/kg every minute to a maximum of 300 to 350 µg/kg (106,118,119). Because theophylline is a competitive antagonist of adenosine (120), higher adenosine dosages may be required in infants treated with theophylline (121). Adenosine may precipitate bronchoconstriction and wheezing and hypotension as a result of vasodilatation (122).

SVT that has not responded to adenosine may be managed with an infusion of procainamide, a class 1A drug

P.1520

that blocks both sodium and potassium channels (106). Rapid infusion may precipitate hypotension, whereas chronic treatment produces antinuclear antibodies in 50% to 90% of patients associated with a systemic lupus erythematosus-type syndrome (106,122). High concentrations of procainamide may depress myocardial contractility and predispose to congestive heart failure (106). Although more than half of a procainamide dose is excreted unchanged, it is metabolized in the liver to *N*-acetylprocainamide (NAPA), an active metabolite which acts through a different (class III) antiarrhythmic mechanism (106). Acetylation to NAPA involves the *N*-acetyltransferase enzyme system, which is involved in the metabolism of isoniazid. Adults may be phenotyped as fast or slow acetylators (123), however infants between birth and 2 months of age are uniformly slow acetylators as a result of the immaturity of the enzyme system (16). Both NAPA and procainamide accumulate with renal insufficiency. Procainamide levels of 4 to 8 mcg/ml are generally effective for control of arrhythmias.

Lidocaine, a class 1B antiarrhythmic, primarily blocks the fast inward sodium channel, like other local anesthetic antiarrhythmic drugs (106,122). Its effects are much greater on the conducting system and the ventricular muscle than on the atrium. It has active metabolites that also block the sodium channel. Plasma concentrations should be maintained between 2 and 5 µg/mL, because concentrations exceeding 6 µg/mL may produce seizures or respiratory arrest (106,122). Drugs known to decrease hepatic blood flow, such as cimetidine, will decrease hepatic clearance of lidocaine and increase concentrations unless the dose is reduced.

Chronic treatment of SVT is not needed in every patient (110). If the frequency of SVT is rare, not associated with cardiovascular compromise, and is easily terminated with vagal maneuvers, chronic treatment may not be required provided that the child can be monitored adequately at home (110). The presence of WPW, however, is a significant predictor of recurrence of SVT after stopping medications (124). Digoxin

treatment of WPW is controversial, because it has been associated with sudden death in 1% to 5% of patients (110,125). In another series of patients with SVT, digoxin treatment was successful in 65% regardless of whether or not they showed preexcitation (116). A review of patients treated for SVT at Texas Children's Hospital revealed no difference in the success rate for treatment of SVT with digitalis among patients with and without WPW (115).

Propranolol is frequently used to treat neonates with SVT, if digoxin is contraindicated because of the presence of WPW (106). It has special pharmacokinetic features that must be considered in its administration. When administered enterally, propranolol is cleared largely through first-pass extraction by the liver. It is metabolized extensively to an active metabolite, 4-hydroxypropranolol (126). During repetitive doses, hepatic extraction decreases, and plasma concentrations may vary widely at steady-state. If administered i.v., the propranolol dose must be reduced at least tenfold because it bypasses hepatic extraction and produces a dose- and concentration-related decrease in heart rate and cardiac contractility. Propranolol has been used most frequently to treat supraventricular and ventricular arrhythmias. It also has a role in treatment of sinus tachycardia related to hypermetabolic states such as thyrotoxicosis (122). Data on dosing, kinetics, and efficacy in neonates for other beta-adrenergic blocking drugs such as atenolol, nadolol, sotalol, and esmolol are limited.

Verapamil has been used for treatment of SVT with moderate success, but its use in infants younger than 12 months of age has been discouraged (106,127). As a result of its negative inotropic activity and ability to decrease sinus function, verapamil should not be used with beta-adrenergic blocking drugs in infants and children (122). They have been used together successfully in adults.

Amiodarone is a benzofuran compound with structural similarity to thyroxine that was originally synthesized in 1962 and released in the United States in 1985. Because of the associated toxicities, it was approved as a "last resort" drug that should be reserved for refractory, life-threatening arrhythmias (128). During the last few years, much more information has accumulated about both its efficacy and its toxicity. Amiodarone illustrates the limitations of a classification system for antiarrhythmics. It inhibits both the fast sodium channel and the slow calcium channel, has noncompetitive antisymphathetic effects, and modulates thyroid function (129). Amiodarone has a relatively low negative inotropic effect and therefore may be the preferred antiarrhythmic treatment for infants and children with depressed myocardial function as a result of incessant tachycardias or perioperative tachycardias following surgery for congenital heart disease (130). Acutely, amiodarone slows AV node conduction with little effect on the QTc, although during chronic therapy, it lengthens QTc and prolongs the refractory period (129). Although reports are limited in neonates, the following adverse effects have been observed after amiodarone treatment of infants and children: photosensitivity (131,132), corneal deposits (132), gray skin color (132), abnormal liver function tests (132), hypothyroidism (131,132), hyperthyroidism (131,132), accelerated bone maturation (131), delayed longitudinal growth (131), excess weight gain (131), headaches (131), pulmonary infiltrates (133), and sleep disturbances (132). Amiodarone increases the concentration of several drugs, usually by decreasing clearance and volume of distribution, including

digoxin, quinidine, procainamide, phenytoin, and flecainide. Decreased clearance of warfarin by amiodarone may precipitate hemorrhage. Overall, the frequency of adverse effects is greater in adults than in children and greater in older children than in infants.

Amiodarone treatment of refractory and serious arrhythmias in infants and children has been successful with limited acute toxicity. In a multi-center trial, Perry reported a 93% rate of improvement with the compassionate use of amiodarone for life-threatening arrhythmias in 40 patients from 8 centers (134). Several serious and refractory arrhythmias have been successfully treated with amiodarone, including: multifocal atrial tachycardia

P.1521

(chaotic atrial tachycardia) (135,136), ventricular tachycardia as a result of intracardiac tumor (137), and refractory SVT (138,139). In a study by Burri and associates, i.v. amiodarone was reported to be safe and effective therapy for life-threatening incessant tachycardias in infants (130). Twenty-three hemodynamically unstable infants (median age 8 days) with life-threatening tachycardias (17 supraventricular, 6 ventricular) were treated with i.v. amiodarone 5 mg/kg administered over 1 hour followed by 5 µg/kg/min with stepwise increase to 25 µg/kg/min (130). Amiodarone was effective in 83% of infants. Median time to arrhythmia control was 24 h and the median maintenance dose was 15 µg/kg/min (range 5-26 µg/kg/min). Adverse effects were not significant: sinus bradycardia in 2 patients and hypotension in one infant, which resolved after dose reduction. Choreoathetotic movements and elevated liver enzymes occurred in two patients.

Dosages of amiodarone have varied widely from study to study. Initial treatment with amiodarone usually begins with a loading dose (5 mg/kg) followed by an infusion of 10 to 15 mg/kg/day (134) to 7.5 to 13.5 mg/kg/day for 9 to 10 days (140). Larger dosages were required for infants less than 1 year of age in one study (132). Oral treatment alone has been successful in some studies (132,141). In a study by Etheridge and associates, 44 neonates and infants (1.0 = 6µ 1.5 months) with difficult to control tachycardias were treated with oral amiodarone using a 7- to 10-day load of amiodarone at either 10 or 20 mg/kg/day in two divided doses (141). The higher loading dose was used for more difficult to control tachycardias. Oral propranolol (2 mg/kg/d) was added for sustained or symptomatic episodes of tachycardia ($n = 5\mu 25$). Rhythm control was achieved in all patients. Infants were discharged on maintenance amiodarone dose of 5 to 10 mg/kg/day (mean dose 7 = 6µ 2 mg/kg/day) and drugs were discontinued as tolerated. Sixty-eight percent of patients remained free of arrhythmias at one year, despite discontinuation of propranolol and amiodarone. There were no side effects necessitating drug withdrawal.

The prolonged loading dose likely relates to amiodarone's extremely long half-life that has been estimated in adults to exceed 50 days (128). Levels of amiodarone are kept between 0.8 and 2.0 mg/L in adults (132), but there is no clear relationship between levels of amiodarone or its metabolite desethylamiodarone and toxicity or efficacy (142,143).

Newborns with fetal arrhythmias may be treated with amiodarone and require evaluation of potential adverse effects in the nursery. A healthy fetus whose mother was treated with amiodarone for sick sinus syndrome delivered and breast fed with no changes in thyroid function (144). Both neonatal hyperthyroidism and hypothyroidism with or without a goiter have been observed after fetal exposure to amiodarone (145,146,147,148).

Anticonvulsants

Seizures remain a frequent therapeutic problem for neonates admitted to an intensive care unit. They may be caused by a variety of disorders, such as meningitis, inadequate pyridoxal-5-phosphate binding, i.e., pyridoxine dependency, hypoglycemia, hypocalcemia, inborn errors of metabolism, neonatal abstinence from narcotics, or intracranial hemorrhage (149). Because treatment differs according to etiology, causes for seizures outside the brain should always be considered and evaluated. Some noncerebral causes of seizures may produce recurrent seizures that require prolonged anticonvulsant drug treatment, in addition to treatment of the primary metabolic or infectious disorder. Because prolonged seizures per se may harm the brain, treatment should not be delayed (149).

Phenobarbital remains the mainstay of treatment and is effective in approximately one-third of cases; babies who respond tend to have a smaller seizure burden and a relatively normal background electroencephalogram (150,151). Phenobarbital is often ineffective as a first line anticonvulsant in neonates with seizures in whom the background electroencephalogram (EEG) is significantly abnormal (151,152). Although seizures are controlled in some patients with phenobarbital levels of 15 µg/mL, the minimal effective therapeutic concentration should be regarded as 20 µg/mL and many patients may require concentrations as high as 40 µg/mL to achieve seizure control (153). As a result of a volume of distribution of approximately 0.9 L/kg in neonates, a loading dose of 15 to 20 mg/kg is required to reach a minimum concentration of 20 µg/mL (154). A total loading dose of up to 40 mg/kg rapidly achieves therapeutic levels (150). Caution is advised in nonventilated infants because a single loading dose of 40 mg/kg can result in apnea (150). Accordingly, splitting the loading dose into two 20 mg/kg doses is advised.

The half-life of phenobarbital is prolonged at birth, ranging from 43 to 217 hours (155). Consequently, lower doses of phenobarbital (2-3 mg/kg/day) should be used during the first week of life. Phenobarbital clearance increases significantly during the neonatal period and the half-life decreases to approximately 45 hours at 28 days of life (154). Thus, maintenance doses will often need to be increased within the first several weeks after birth (3-5 mg/kg/day). A good correlation has been demonstrated between plasma and brain concentrations of both phenobarbital and phenytoin, so that increasing plasma concentrations should increase the anticonvulsant concentration at the site of action (12).

Concerns have increased about the effects of long-term phenobarbital treatment on cognitive development. When phenobarbital was compared to placebo in two

randomized groups of children treated for 2 years for febrile seizures, the phenobarbital-treated group had significantly lower intelligent quotients (IQs) (156). In a randomized, crossover trial of three anticonvulsants, phenobarbital produced more impairment of neuropsychological performance than did carbamazepine or phenytoin (157). The American Academy of Pediatrics (AAP) Committee on Drugs summarized concerns about the cognitive effects of phenobarbital (158).

Phenytoin has served as the second line anticonvulsant for neonates. Phenytoin and phenobarbital have been

P.1522

shown to be equally but incompletely effective as anticonvulsants in neonates.(151) The severity of the seizure is a stronger predictor of successful treatment than the agent. Painter and associates evaluated phenytoin (15 mg/kg) as an alternative to phenobarbital. Of the 29 babies administered phenytoin as first-line treatment, 45% responded (151). Phenytoin and lidocaine are probably more effective than any of the benzodiazepines as second line, but very few evaluation studies have been reported (150). Disadvantages of phenytoin are its highly variable and nonlinear pharmacokinetics, i.e., exponential elimination decreases with increasing serum concentrations. The latter phenomenon requires considerable caution because small increases in maintenance dose may result in disproportionately large increases in plasma concentrations. The initially prolonged half-life of phenytoin decreases rapidly during the neonatal period from 57.3 =6μ 48.2 hours during the first days of life to 19.7 =6μ 1.3 hours during the fourth week (33). In term infants between 2 and 21 weeks of age, the half-life ranged from 6.6 hours to 15.1 hours (20). However, preterm infants often exhibit prolonged half-lives (15.6 to 160 hours) up to 18 days after birth (20).

Phenytoin is a water-insoluble base and the commercially available injection formulation is prepared using 40% propylene glycol at a final pH of 12. Side effects associated with parenteral phenytoin, caused primarily by its high pH and the propylene glycol content, include burning at the infusion site and severe local cutaneous reactions following infiltration into surrounding tissue (159). Many of these side effects can be avoided in children with the use of fosphenytoin, a phosphorylated prodrug of phenytoin which has few cardiac and local irritation adverse effects (160). The accepted therapeutic serum concentration range for phenytoin (or fosphenytoin converted to phenytoin) is 10 to 20 μg/mL and a loading dose of 15 to 20 mg/kg will achieve a therapeutic concentration (161). To avoid hypotension, arrhythmias, and precipitation during administration, phenytoin should be administered slowly (maximum 0.5-1 mg/kg/min) into an i.v. line containing only saline. Because the drug is caustic to tissues, intramuscular administration should be avoided and intravenous doses should be infused through as large a vein as is available taking care to avoid extravasation.

Interpretation of phenytoin plasma concentrations requires consideration of protein binding. In adults, the unbound concentration of phenytoin is approximately 10% of the total concentration (162). Thus, the therapeutic range for unbound (free) phenytoin is 1 to 2 μg/mL. Because plasma protein concentrations and binding affinity

of albumin are low in newborns, plasma protein binding of phenytoin is reduced in infants. In normobilirubinemic newborns, the free (unbound) fraction of phenytoin is 15% to 20% and in hyperbilirubinemic infants, the free fraction may reach 30% (20,163,164). Thus, despite apparent subtherapeutic total concentrations ($\approx 10 \mu\text{g/mL}$) free concentrations may be within the therapeutic range of 1 to 2 $\mu\text{g/mL}$. Monitoring free phenytoin concentrations may be useful in this circumstance to determine if concentrations are within the therapeutic range. If free concentrations of phenytoin are not available, targeting total concentrations of 6 to 14 $\mu\text{g/mL}$ are appropriate in the immediate neonatal period (20). However, as protein binding normalizes in the weeks to months after birth, the therapeutic range will require readjustment to 10 to 20 $\mu\text{g/mL}$.

As a result of the significant variability in pharmacokinetics during the first weeks of life, a standard dose of phenytoin cannot be recommended and plasma concentrations must be monitored. During the first week of life, doses of 4-8 mg/kg/day may be required (20). However, chronic oral phenytoin therapy in infants often requires much higher doses (161). By the second week after birth, most infants will require at least 8 mg/kg/day divided every 6 to 8 hours (20), however oral doses as high as 17.7 \pm 6 μ 4.3 mg/kg/day and intravenous doses of 25 mg/kg/day have been required to maintain therapeutic concentrations (161,165). Although some have attributed these dose requirements to poor absorption of the oral formulation (161), high doses are also required after intravenous administration (165). Other investigators have demonstrated complete absorption in infants receiving oral doses (166). High oral dosage requirements in infants likely reflects several pharmacokinetic events, including poor and erratic absorption, increased phenytoin metabolism during the first year of life, and hepatic enzyme induction by concomitant treatment with phenobarbital (161,165,166).

Recently, the introduction of fosphenytoin has significantly reduced the potential for the adverse effects usually associated with phenytoin, including pain on administration, extravasation injury, propylene glycol-associated hyperosmolality (83), CNS changes (85,86), acidosis (167), and cardiovascular compromise (168) following rapid intravenous injection (159). Fosphenytoin is a water-soluble prodrug that is rapidly hydrolyzed to phenytoin via blood and tissue phosphatases (169). Because it is an aqueous solution and contains no propylene glycol, it has few pharmaceutical compatibility problems and may be administered by intravenous injection or by intramuscular injection (169). Because fosphenytoin is converted to phenytoin, issues regarding protein binding, therapeutic concentrations, and drug interactions associated with phenytoin must still be considered. There is limited published experience of its use in newborn infants (160).

Benzodiazepines can be used for additional drug therapy beyond phenobarbital and phenytoin to control seizures in the newborn. Diazepam has been used to treat refractory seizures in neonates, but its efficacy is limited by its short duration of action, respiratory depression, prolonged half-life, and metabolism to active metabolites (170). Lorazepam, in a dose of 0.05 to 0.1 mg/kg has been effective for controlling refractory seizures in neonates and has a duration of action up to 24 hours (84,170). Total doses up to 0.15 mg/kg may be necessary to control neonatal seizures

that are refractory to phenobarbital (171). Because metabolism of lorazepam requires glucuronidation, which is poorly developed in newborns, the half-life

of lorazepam in newborns is prolonged (mean 40 hours) and correlates with gestational age (172). The dose of benzyl alcohol associated with lorazepam treatment is low enough not to represent a risk for toxicity (173). Some have reported "seizure-like" stereotypic movements after lorazepam administration (174,175). The cause of this movement disorder is not known.

Recently midazolam has been used in adults and children for treatment of epileptic episodes of various types, including status epilepticus (176,177). A study was conducted in six neonates (aged 1-9 days; gestation, 30-41 weeks) with persistent seizures despite a mean phenobarbital concentration of 50.5 mg/L (178). Seizures were controlled in all patients within one hour of administering continuous intravenous infusions of midazolam (0.1-0.4 mg/kg/hour). Because neonatal seizures are sometimes refractory to high-dose phenobarbital, midazolam may be a valuable adjunctive therapy (178). Care must be taken to avoid rapid bolus doses of midazolam over 1 to 2 minutes that may cause hypotension in infants receiving fentanyl infusions (15) or tonic-clonic movements similar to those reported in older children following lorazepam (179).

Neonatal seizures refractory to phenobarbital have recently been shown to respond to oral administration of carbamazepine (180). Carbamazepine is a first-line anticonvulsant in the treatment of partial seizures with or without secondary generalization in children and adults. Ten preterm infants (gestational age 23 to 34) with neonatal seizures refractory to phenobarbital (plasma concentration ranging from 50-64 mg/L) received 7-15 mg/kg/day in 2 to 3 divided doses to achieve a plasma concentration of 3-12 mg/L. Nine out of the ten patients had excellent results without adverse effects. In another report, 10 full-term neonates with two or more seizures as a result of hypoxic-ischemic encephalopathy were administered 10 mg/kg of carbamazepine as a loading dose (via nasogastric tube) followed by a maintenance regimen of 15 to 21 mg/kg/day (181). Absorption of carbamazepine was excellent and therapeutic levels were reached in 2 to 4 hours with peak levels achieved in 9.2 ± 4.2 hours. The elimination half-life was 24.5 hours. Levels dropped precipitously around 8 to 15 days and declined slowly over the next 3 months. Seizure control was excellent and there were no adverse effects (181).

Of the newer anticonvulsants, lamotrigine is effective in adults and children with generalized and partial seizures. Lamotrigine is a phenyltriazine structurally unrelated to conventional antiepileptic drugs (AEDs). Recently, lamotrigine has been shown to be a useful agent for treatment of refractory seizures, partial seizures, and infantile spasms (182,183). Thirteen infants (≤ 1 year) with a mean age of 3.7 months (five were 2-4 weeks) had either partial seizures or infantile spasms or both (182). Both were significantly reduced ($p < 0.05$) and lamotrigine was well tolerated. The mean apparent clearance was 82% lower in the infants less than 2 months of age compared with those that were 2 to 12 months of age. Lamotrigine is mainly eliminated by hepatic metabolism to an inactive metabolite through glucuronidation (184). Co-

medication with enzyme inducers increases metabolism (184), and although not studied in neonates, one would expect a drug interaction with phenobarbital. The adverse effect which often leads to drug discontinuation is skin reactions. Overall, rash develops in 12% of patients and the risk of rash is approximately 3 times greater in children as compared to adults (184). Other reported adverse effects include leucopenia, agranulocytosis, and hepatic failure.

Topiramate, another one of the newer antiepileptic drugs, is currently approved for adjunctive therapy for the treatment of generalized tonic-clonic seizures and partial seizures, and Lennox-Gastaut syndrome. It differs both structurally and pharmacologically from other classes of AEDs. Topiramate is a sulfamate-substituted monosaccharide D-fructose derivative with limited protein binding (9%-17%) (185). It is primarily eliminated by renal excretion with a small portion metabolized by hydrolysis, hydroxylation, and glucuronidation (185). No studies have been conducted in neonates, although a report of 5 infants (4 term and one born at 36 weeks) exposed to topiramate in utero indicated extensive transplacental transfer and a half-life of approximately 24 hours, which is close to the 20 to 30 hours reported in adults (185).

The decision to continue or to stop treatment with anticonvulsant medications before discharge from the NICU remains controversial. Scher and Painter suggest that anticonvulsants may be discontinued for infants who show no abnormalities of the brain on imaging studies, have an age-appropriate neurologic examination, and have a normal interictal electroencephalogram (186). Up to 30% of neonates with seizures later have epilepsy, but frequently the later seizure pattern takes the form of infantile spasms or minor motor seizures that are not very responsive to phenobarbital and phenytoin (186).

Antihypertensives

The relationship between blood pressure, gestational age, birth weight and postconceptional age was defined by Zubrow and associates in 695 neonates studied over a period of 3 months (187). Based on these data, hypertension in term and preterm infants may be defined as blood pressure above the upper limit of the 95% confidence interval for infants of similar gestational or postconceptual age and size (188). Drug treatment for hypertension should start with a single drug from one of the following classes, angiotensin-converting enzyme (ACE) inhibitors, vasodilators, beta-receptor antagonists, calcium channel blockers, or diuretics (189).

For severe hypertension in the neonate, a continuous intravenous infusion is advantageous because blood pressure fluctuations observed with intermittent dosing are eliminated and the dose may be titrated to keep blood pressure within narrow parameters. Antihypertensive agents that have been used in neonates or infants by continuous infusion include esmolol (190), nitroprusside, and nicardipine (191,192). Small studies have found that

intravenous nicardipine may be effective in treating hypertensive neonates (191,192).

Milou and associates studied 20 neonates (15 preterm) who were administered intravenous nicardipine 0.5 µg/kg/min (maximum 0.74 ± 0.41 µg/kg/min) for 14.6 ± 11.6 days (192). Blood pressure significantly decreased (approximately 20%) after 3, 6, 12, 24, and 48 hours of nicardipine treatment. No hypotension was observed. Gouyon et al. studied 8 preterm infants with systemic hypertension and treated them with intra venous nicardipine 0.5 µg/kg/min (*n* =2) or 1.7 µg/kg/min (*n* =6) (191). The maximum infusion rate was 1.56 ± 0.45 µg/kg/min and the treatment duration was 15.9 ± 10.3 days. Systolic blood pressure significantly decreased after 12 and 24 hours of nicardipine treatment (-17 ± 17% and -21 ± 10%, respectively) and diastolic blood pressure decreased after 24 hours of treatment (-22 ± 16%) No hypotension or other side effects were noted. Hypertensive emergencies are infrequent in neonates, but can be treated with esmolol, hyralazine, labetalol, sodium nitroprusside if renal function is normal, fenoldopam, isradipine, and minoxidil (189). As observed in older patients, thiocyanate and cyanide may accumulate during sodium nitroprusside treatment. Severe prolonged hypotension has been reported in severely hypertensive neonates treated with enalaprilat (189).

Intermittently administered intravenous agents may be useful for patients with mild-to-moderate hypertension. These agents include hydralazine, labetalol, and enalaprilat, (193) although enalaprilat should be used with great caution as a result of the potential for significant and prolonged hypotension (188).

Oral antihypertensives may be used in infants with mild-to-moderate hypertension or in patients being transitioned from intravenous therapy. Angiotensin-converting enzyme inhibitors (e.g., captopril) have a special role in the treatment of neonatal renovascular hypertension that is caused by markedly elevated renin and angiotensin (194). Aortic catheters may distribute microemboli to the kidneys, which increase secretion of renin and angiotensin in response to focal underperfusion. Although captopril may be relatively specific treatment for many cases of renovascular hypertension in neonates, dosage adjustments are difficult because a liquid dosage form is not commercially available. An extemporaneously compounded dosage form containing ascorbate has been shown to be stable for 14 days at room temperature (195). Captopril treatment of neonates should start with doses of 0.01 mg/kg, rather than the earlier recommendations of 0.1 to 0.3 mg/kg/dose, to avoid hypotension and acute renal insufficiency (196). Doses should be increased daily if hypertension persists. Initial captopril treatment may cause a triphasic reaction of hypotension with renal failure, managed by dose reduction, followed by a rise in blood pressure despite increasing doses above the original dose (197). At the start of captopril treatment, hypotension is exaggerated in salt and water-depleted patients (198). As in adults, captopril may be useful for afterload reduction in the treatment of chronic congestive heart failure in newborns (198). Other oral agents that have been used include the vasodilators hydralazine and minoxidil, and the calcium channel blocker isradipine (188). Isradipine can be compounded into a suspension and its successful and safe use has been reported in infants and children (199,200). The use of isradipine suspension allows infants and young children to be treated as readily as older children.

Antimicrobials

Beta-Lactams

Historically, the selection of antibiotics for the treatment of sepsis and infections in neonates has been empiric based on the most frequent pathogens observed in the clinical setting. Ampicillin and an aminoglycosides have been the mainstay for treatment of presumed sepsis and meningitis in the newborn (201). The advantages of this combination include low cost, relatively few problems with resistance (202,203), and a combined spectrum of activity that covers the majority of neonatal pathogens, including Group B *Streptococcus*, *E. coli*, and *Listeria monocytogenes* (201). However, resistance to antimicrobial agents and changes in the pathogens causing neonatal infections must be the focus of ongoing surveillance to respond with the most appropriate antibiotic combination. As antepartum antibiotic use for the prevention of group B streptococcal disease increases, organisms recovered in early onset disease may shift toward *Escherichia coli* resistant to ampicillin (204,205). In a study of 5447 very-low-birth-weight (VLBW) infants born between 1998 and 2000, there was a marked reduction in group B streptococcal sepsis (from 5.9 to 1.7 per 1,000 live births, $p < 0.001$) and an increase in *Escherichia coli* sepsis (from 3.2 to 6.8 per 1,000 live births, $p 0.004$) as compared to VLBW infants born between 1991 and 1993 (205). Most *E. coli* isolates from the recent birth cohort (85%) were resistant to ampicillin. Ampicillin-resistant strains of *Morganella morganii* have also been reported to cause early onset sepsis in babies born to mothers who received intrapartum ampicillin (206).

The use of third-generation cephalosporins (e.g., cefotaxime, ceftriaxone, and ceftazidime) continues to proliferate, primarily as a result of their excellent penetration into cerebrospinal fluid, minimal nephrotoxicity, and broad gram-negative activity, including *Klebsiella sp.* and many gentamicin-resistant isolates (207). When *L. monocytogenes* or *Enterococci* are potential causes of infection, initial empiric therapy with third generation cephalosporins must be combined with ampicillin because the cephalosporins are not active against these pathogens. The choice of third generation cephalosporins over an aminoglycoside will depend on institutional susceptibility patterns. However, because excessive use of extended spectrum cephalosporins is associated with selection for highly resistant, extended spectrum β -lactamase (ESBL) producing organisms (208,209,210,211), many experts favor a regimen of a penicillin and aminoglycoside for primary therapy of suspected

P.1525

sepsis (208). It has been proposed that the biliary excretion of broad spectrum antibiotics promotes overgrowth of resistant strains (especially *Enterobacter* and *Enterococcus*) which can translocate from the intestines into the bloodstream to cause infection (212,213).

Among the cephalosporins, there is considerable experience using cefotaxime in severe neonatal infections (214). Cefotaxime has often replaced gentamicin for coverage of gram-negative bacilli during outbreaks of sepsis caused by gentamicin-

resistant gram-negative bacteria (209,215). Although this combination may increase the relative number of enterobacter isolates and their resistance (209,211, 216,217). The incidence of serious gram-negative infections decreased during a 5-year period when cefotaxime was substituted for gentamicin (215). Ceftriaxone has a very similar spectrum of activity as cefotaxime, with the primary difference being its pharmacokinetic profile. Ceftriaxone was well tolerated in 80 neonates (mean gestational age 34 weeks), although six patients had sonographic findings consistent with 'biliary sludge' which resolved spontaneously within 2 weeks (218). It is believed that ceftriaxone forms a complex with calcium that is poorly soluble in bile resulting in biliary sludge, which appears to be a transient phenomenon (219). Ceftriaxone may also displace bilirubin from albumin binding sites (220,221). An *in vivo* study demonstrated the potential significance of this interaction and the investigators recommended that ceftriaxone be withheld from jaundiced neonates or premature newborns with acidosis, hypoxia, or sepsis who are at increased risk for developing bilirubin encephalopathy (221).

Certain cephalosporins have unique properties that fit clinical problems encountered frequently in neonates, e.g., ceftazidime is considered the drug of choice to treat *Pseudomonas* infections. It should be combined with an aminoglycoside for synergy and to avoid emergence of resistant strains (222,223). A recent study of 1316 cases of suspected cases of sepsis in the newborn (median age ≤ 3 days) found that ceftazidime in combination with ampicillin had a significantly higher cure rate (97%) than ampicillin and an aminoglycoside (66%) (224). No problems with ceftazidime resistance were encountered. Pharmacokinetic data in preterm infants indicate that the ceftazidime dose during the first 2 weeks of life should be based on gestational age and postnatal age-related changes in glomerular filtration rate (225,226). Additionally, exposure of preterm infants to indomethacin or asphyxia in term infants may reduce ceftazidime's clearance and dosage requirements (225).

The ureidopenicillins, ticarcillin and piperacillin, provide broader gram-negative coverage than ampicillin and are particularly suitable for the treatment of late-onset sepsis (227). For treatment of *Pseudomonas* sp. infections, piperacillin is more active *in vitro* than ticarcillin and may be combined with an aminoglycoside for synergy and to decrease the emergence of resistant organisms (228,229,230). When piperacillin is combined with an aminoglycoside such as gentamicin, the combination provides excellent activity against aerobic and anaerobic bacteria encountered after intestinal perforation. Piperacillin dosage requirements are based on both gestational and postnatal age (231).

The most common mechanism for resistance to beta-lactam antibiotics is production of inactivating beta-lactamases (232). Beta-lactamase inhibitors, including clavulanate and tazobactam, were developed to bind irreversibly to enzyme substrate, thereby blocking this mode of resistance and preserving activity of the penicillins against many organisms. As a result, ticarcillin-clavulanate and piperacillin-tazobactam have significantly improved spectra of activity, including beta-lactamase producing strains of gram-positive organisms, methicillin-sensitive *Staphylococcus aureus*, many *Enterobacteriaceae*, fastidious gram-negative bacteria such as *H. influenzae* and *M. catarrhalis*, and many anaerobes (233,234,235). This makes the combination of a

beta-lactam and a beta-lactamase inhibitor an excellent therapeutic alternative for providing broad spectrum antimicrobial coverage in the treatment of late-onset sepsis (236). Furthermore, combination beta-lactam/beta-lactamase inhibitors are less likely to promote development of resistance because of their decreased potency for inducing beta-lactamases and their minimal effect on gastrointestinal flora (236). Generally, piperacillin-tazobactam is more active than ticarcillin-clavulanate against *Enterococcus faecalis* and gram-negative bacilli, including *Pseudomonas aeruginosa* (235). Piperacillin-tazobactam may be a useful combination in the treatment of *Klebsiella pneumoniae* infections in neonates (237).

The carbapenems, imipenem-cilastatin and meropenem, have an extremely broad spectrum of activity, including gram-positive, gram-negative, and anaerobic organisms (238). Both agents are beta-lactamase stable and have activity against penicillin-resistant pneumococci, *E. faecalis*, *L. monocytogenes*, *P. aeruginosa*, and multi-resistant strains of gram-negative organisms (239). Imipenem is combined with cilastatin, a renal dehydropeptidase I inhibitor, which prevents metabolic activation of imipenem to a nephrotoxic compound. Meropenem is more active against gram-negative bacilli and less active against gram-positive cocci (including *Enterococcus* sp) than is imipenem (239). Both agents penetrate into cerebral spinal fluid in the presence of inflammation associated with meningitis (240). Meropenem and cefotaxime were equally efficacious in the treatment of meningitis in 190 children (median age 1 year) (241).

Carbapenems, through their epileptogenic activity, are potentially more neurotoxic than the penicillins and cephalosporins (242). A study of imipenem-cilastatin treatment of bacterial meningitis in 21 infants and children was terminated when 33% developed seizures after antibiotic administration (243). Seizures with imipenem have often been associated with high plasma concentrations associated with renal dysfunction and high doses, or increased susceptibility, such as underlying central nervous system abnormality (239). An additive risk with concomitant theophylline treatment has been reported (244). The safety

P.1526

margin of meropenem appears to be higher and meropenem can be used at higher doses than imipenem-cilastatin (242). More than 1,200 children (ages 3 months-12 years) have been treated in prospective, randomized, clinical trials of meropenem (238). A promising finding is that meropenem does not cause seizures with greater frequency than other antibiotics used to treat meningitis (238,245).

The published experience of imipenem in neonates and in particular in preterm neonates is limited. Nalin and associates assessed the safety of imipenem in 61 children up to 6 months old and noted that 15% developed seizures; however, neonates weighing less than 750 g or those who were critically ill were excluded (246). Stuart and colleagues investigated the safety of imipenem (20-80 mg/kg/day) in 80 neonates at 32 weeks postconceptional age and noted that only 2 patients developed seizures (2.5%), both of whom had documented seizures before commencing imipenem (247). Overall, adverse effects were minimal and no neonate was withdrawn as a result of toxicity. There are currently no studies evaluating the

efficacy or safety of meropenem in neonates.

Both imipenem and meropenem are primarily excreted in the urine (239). Both agents demonstrate age-related pharmacokinetics; thus, the longest half-lives are in premature neonates (248). Although the carbapenems are administered every 6 to 8 hours in adults, plasma concentrations in neonates should exceed the minimum inhibitory concentrations (MICs) for most organisms for 12 hours after a single dose, suggesting that q12h dosing may be appropriate; however, additional studies are required to determine the optimal dose and interval (248).

Aztreonam is a monobactam and shows excellent activity against aerobic gram-negative bacilli, including *P. aeruginosa*, but it is devoid of activity against gram-positive or anaerobic bacteria (249). A limited evaluation of its efficacy and pharmacokinetics has been conducted in neonates (250,251). Ampicillin plus aztreonam was compared to ampicillin plus amikacin in 147 neonates, 60 with documented gram-negative bacterial infections (251). Clinical response was noted in 90% of those who received aztreonam as compared with 72% those who received amikacin. Because aztreonam does not have the nephrotoxic potential of aminoglycosides, it may be considered as an alternative in the treatment of serious gram-negative infections, particularly when there is a concern regarding concomitant treatment with several nephrotoxic agents.

The antistaphylococcal penicillin, nafcillin, has largely replaced methicillin for the treatment of *S. aureus* infections because it has a lower risk of adverse reactions. Nafcillin is eliminated primarily through biliary excretion, which may be impaired in neonates as a result of cholestasis related to prolonged hyperalimentation (252). To reduce vancomycin resistance in hospitals, the anti-staphylococcal penicillins should be used whenever possible.

E. cloacae, *Enterococcus* sp., and *K. pneumoniae* are emerging in neonatal patients as multiply resistant organisms, possibly as a result of the increased use of cephalosporin antibiotics in NICUs (125,253,254,255). This growing problem of bacterial resistance requires that new classes of antibacterial agents be evaluated for the treatment of severe infections in neonates. Because potent and broad spectrum antibiotics have received less study in neonates, they should be used judiciously and with guidance from a specialist in infectious diseases.

Vancomycin

Patterns of antimicrobial use in neonatology have evolved with the changing spectrum of infections and development of new antimicrobial agents. Emergence of infections with beta-lactam-resistant *S. epidermidis*, *S. aureus*, and *Enterococcus* sp., has led to the frequent use of vancomycin in neonates (256). Reports of the increasing prevalence of enterococcal infections in newborns is of significant concern (257), particularly in view of the nationwide 20-fold increase in the percentage of nosocomial enterococci resistant to vancomycin (258). Among vancomycin-resistant strains of enterococci isolated in a pediatric center, the prevalence of *E. faecium* has increased dramatically (259). Forty-two percent of isolates were from the NICU (259). This trend

suggests that future enterococcal infections in neonates may become far more difficult to treat. Although recent studies in newborns demonstrate that prophylactically administered vancomycin reduces infections with coagulase negative staphylococcus (260,261), clinicians must be cognizant of the dangers of overusing (and misusing) antibiotics, particularly vancomycin. One study reported that gram-negative bacteremia was positively associated with the use of vancomycin (odds ratio, 8.1; 95% confidence interval, 3.1 to 20.9), thus reiterating the importance of minimizing the inappropriate and unnecessary use of vancomycin (262). In response to the increasing prevalence of vancomycin-resistant *Enterococcus* (VRE), the Hospital Infection Control Practices Advisory Committee of the Centers for Disease Control and Prevention (CDC) drafted guidelines to prevent the spread of VRE. These guidelines address, among other things, the appropriate use of vancomycin (263). To minimize the pressure for selecting antibiotic-resistant organisms, vancomycin should generally be reserved for methicillin-resistant staphylococci and ampicillin-resistant enterococcal infections (263).

There appears to be a widely held belief that vancomycin is a nephrotoxin. Consequently, a significant amount of resources are allocated to monitoring serum vancomycin concentrations. Although early preparations of vancomycin were impure and high peaks and troughs were associated with nephro- and ototoxicity (264), these toxicities are now relatively uncommon; however, concomitant administration with aminoglycosides or other nephrotoxins may increase this risk (265,266). Despite a poor correlation between vancomycin plasma concentrations and efficacy and toxicity, medical care has evolved to include the monitoring of vancomycin concentrations. The currently accepted therapeutic range for vancomycin was not derived from rigorous scientific evaluation. Because

P.1527

MICs for most *Staphylococcus* sp. were less than or equal to 5 µg/mL and early toxicities most often occurred at serum concentrations less than 30 to 40 µg/mL, desired trough concentrations were designated as 5 to 10 µg/mL and peak concentrations 20 to 40 µg/mL (267). These somewhat arbitrary ranges have become the standard for "therapeutic" vancomycin concentrations, however there are a paucity of data to substantiate these recommendations (268). In the last decade, clinicians have questioned the utility and cost-effectiveness of measuring peak and trough concentrations (268,269,270,271). Because the association between peak concentrations and toxicity is poor, some have recommended measuring trough concentrations only (272), although others have suggested not measuring any concentrations in the majority of children with normal renal function (271). However, in critically ill neonates, one must consider the inherently poor glomerular filtration rate associated with prematurity and compromised cardiovascular function, and the large inpatient variation in the pharmacokinetics of vancomycin (273). Limited data in neonates support adjusting vancomycin dosages in premature or term infants on the basis of trough concentration monitoring alone (274); however, until more data are published, it remains prudent to measure both peak and trough concentrations, particularly in those with poor or changing renal function and those receiving multiple nephrotoxic agents.

Vancomycin clearance in premature infants is directly proportional to postconceptional age, body weight, and surface area (275). Its half-life and volume of distribution range from 3 hours and 0.38 L/kg, respectively, in infants whose postconceptional age is more than 43 weeks to 9.8 hours and 0.74 L/kg in premature infants of 32 weeks gestation (276,277). The reader is referred to a review for a more in-depth discussion of vancomycin pharmacokinetics and dosage recommendations (278).

Adverse effects of vancomycin include thrombophlebitis and infusion-related histamine release, hypotension, and red-man syndrome. Doses of vancomycin should be infused over at least 1 hour, and never in a rapid i.v. bolus dose, to avoid this reaction (279).

Aminoglycosides

Aminoglycosides continue to play an important role in the treatment of severe gram-negative sepsis. Clearance of aminoglycosides is directly related to the glomerular filtration rate, which is quite low and variable in premature and sick newborns; thus, plasma concentration monitoring is essential to maximizing efficacy and minimizing toxicity. Desired peak gentamicin concentrations are between 5 to 10 $\mu\text{g/mL}$ and trough concentrations should be kept 1 to 2 $\mu\text{g/mL}$ (65,280). Therapeutic drug monitoring may be unnecessary during the first 2 to 3 days of therapy while cultures are pending, unless the patient exhibits overt renal dysfunction (67). To reach appropriate peak concentrations, larger initial doses are necessary in premature infants as compared with infants and children (281,282). This is because aminoglycosides distribute primarily into the extracellular fluid compartment, which is larger in premature infants. Accordingly, a 4 mg/kg gentamicin loading dose has been recommended to reach therapeutic peaks more expeditiously (282). Although gentamicin trough concentrations should always be kept less than 2 ($\mu\text{g/mL}$), gentamicin-induced renal toxicity and ototoxicity are uniquely less frequent in neonates than in adults (67).

In recent years, the use of a single, large, daily dose of an aminoglycoside, i.e., "once-daily aminoglycosides" has become commonplace both in adult medicine and in pediatrics. The rationale for this regimen is based on concentration-dependent bactericidal activity of aminoglycosides (283,284). Thus, a peak concentration:MIC ratio of at least 8:1 to 10:1 optimizes bactericidal activity (285). Secondly, the postantibiotic effect (PAE) of aminoglycosides against gram-negative bacteria is longer at increasingly higher serum concentrations (286,287). PAE refers to the continued suppression of bacterial growth after antibiotic exposure, thus permitting trough concentrations to fall below the MIC with reduced risk of bacterial regrowth (287). Aminoglycosides demonstrate a PAE of 1-8 hours when tested against gram-negative organisms at concentrations of 2 to 10 times the MIC (280). Thirdly, longer dosing intervals permit drug-free periods, which may limit the development of adaptive resistance, a phenomenon which occurs when an organism is constantly exposed to aminoglycosides (285). Lastly, the uptake of aminoglycoside into the renal cortex is saturable, resulting in reduced renal accumulation and a ceiling effect regarding nephrotoxicity (280,288).

Several dozen studies, primarily in adults, have evaluated the efficacy and toxicity of once-daily aminoglycoside. The majority of studies demonstrate no difference in efficacy or toxicity between dosage regimens (280). The remainder suggest that once-daily aminoglycoside treatment is superior in either efficacy or toxicity. The reader is referred to extensive reviews and meta-analyses on the subject (280,285,289,290,291).

In neonates, the use of the phrase "once-daily gentamicin" is potentially confusing, because preterm newborns often receive gentamicin every 24 hours, albeit at a much lower dose than the usual 4.5 to 7 mg/kg reported for once-daily dosing of gentamicin in children. Thus, it may be less confusing to use the phrase "extended-interval dosing" to refer to the single, large, daily dose of aminoglycoside. Nonetheless, this dosing regimen has not been well studied in neonates or infants. In a study that compared 4 mg/kg as a single daily dose to 2 mg/kg every 12 hours in 20 term newborns, the mean peak concentration was 10.9 µg/mL for the single daily dose and 7.4 µg/mL for the twice daily dosing (292). Mean trough concentrations were 0.8 µg/mL and 1.0 µg/mL for the two groups, respectively. *In vitro*, the 4 mg/kg once daily dose was significantly superior in bactericidal activity against isolates with high MICs, including *P. aeruginosa*, *E. faecalis*, and *L. monocytogenes*. In another study of 302 term infants, 3.5 to 4 mg/kg administered once daily produced peak concentrations (>6 µg/mL) in 100% of

P.1528

infants as compared with only 45% of those who received 2 to 2.5 mg/kg every 12 hours (292). In the single daily dose group, only one patient (1.2%) had a trough concentration above 2 µg/mL as compared to 4.5% of those receiving the twice daily regimen. In a study of gentamicin 5 mg/kg in predominantly term infants, peak and trough concentrations averaged 10.7 µg/mL and 1.7 µg/mL, respectively (293). As compared to peak concentrations achieved with conventional aminoglycoside dosing, the peak concentrations in this study were more suitable for optimizing bactericidal activity. However, the mean trough concentration was higher than that reported in most adult studies (<1 µg/mL). Because patients with renal dysfunction were excluded from most clinical studies of once-daily aminoglycosides, the toxic effects of these higher troughs are unknown. Furthermore, it is not known whether these trough concentrations are low enough to prevent the development of adaptive resistance.

Although the majority of neonatal studies of extended interval dosing of aminoglycosides has been conducted in neonates of 34 weeks gestation or older (294,295,296,297), recent data have been published in preterm infants as well (298,299,300). Premature neonates have significantly larger aminoglycoside distribution volumes and longer half-lives than infants and children. Thus, achieving serum concentration-time curves consistent with once-daily gentamicin in adults, i.e., peak concentrations more than 10 to 15 µg/mL and trough concentrations less than 1 µg/mL in a 24-hour period, is impossible in most preterm infants less than 34 weeks gestation. This was demonstrated in a study of predominantly preterm infants (gestational age of 14 of 21 infants ≤34 weeks) who received netilmicin 6 mg/kg per day (301). One-third of the infants had 24-hour trough concentrations that exceeded

2 µg/mL and only 2 of 21 infants had trough concentrations less than 1 µg/mL (301). These high trough concentrations may increase the potential for nephrotoxicity; however, increasing the dosing interval to 36 or 48 hours may permit these larger doses to be given although allowing the trough concentrations to fall to less than 1 µg/mL. Such a strategy was published by Rastogi and associates who compared 4.5 to 5.0 mg/kg q48h with 2.5-3.0 mg/kg q24h in 58 very low birth weight infants (300). Ninety percent of peak concentrations in the q48h group were in the therapeutic range (6-12 µg/mL) as compared to 55% in the q24h group ($p < 0.0005$). None of the q48h infants had subtherapeutic peak concentrations after the first dose vs. 36% of q24h infants ($p < 0.005$). Furthermore, 18% of the q24h infants continued to have subtherapeutic peak concentrations even after the third dose. Although this strategy of administering larger doses less frequently was more effective in achieving therapeutic peak concentrations, it is noteworthy that 30% of infants in the q48h group had trough concentrations less than 0.5 µg/mL. This raises concerns regarding the potential for bacterial growth during prolonged periods of extremely low serum concentrations.

In another study, which included 52 VLBW and ELBW neonates, 5 mg/kg q36-48h of gentamicin resulted in higher peak concentrations than 2.5 mg/kg q18 to 24h (8.0 ± 1.7 vs. 5.8 ± 2.2 µg/mL, respectively, $p < 0.01$). Almost one-third of patients in the 2.5 mg/kg group had subtherapeutic peak concentrations (<5 µg/mL) and the mean trough concentration was higher than in the 5 mg/kg group, 1.2 ± 0.74 vs. 0.7 ± 0.5 µg/mL, respectively.

In summary, preliminary data suggest that therapeutic peak concentrations may be more effectively achieved in preterm and term neonates by administering larger doses of aminoglycosides less frequently as compared with the traditional dosing regimens. The potential advantages of this therapeutic approach are numerous, including increased bactericidal activity, longer postantibiotic effects, and reduced potential for developing adaptive resistance. However, more studies must be conducted in preterm infants and those with renal dysfunction to determine the optimal dosage regimen. The endpoints of such studies need to include both safety and efficacy before they are widely adopted.

Antireflux and Promotility Medications

Reflux may occur when the lower esophageal sphincter transiently relaxes and liquid enters the esophagus. A critical review of the evidence for potential sequelae of gastroesophageal reflux (GER) in preterm infants demonstrates that (a) apnea is unrelated to GER in preterm infants (302); (b) failure to thrive does not occur with GER; (c) although GER may cause aspiration, a relationship between GER and chronic airway problems has not been confirmed in preterm infants (303). Certain infants with BPD clearly reflux, aspirate, and have apnea (304,305,306). Many other infants regurgitate feeds without a clear association with symptoms of chronic lung disease or apnea (307). GER is more frequent in more premature neonates (308) and correlates with reduced lower esophageal sphincter tone and inadequate lower esophageal clearance (309,310). Some of the controversy may relate to measurement of GER by

pH probe and the buffering effect of formula on gastric acid that would prevent detection of reflux by a drop in pH. A recent study using impedance found that 34% of reflux episodes were not detected by pH probe measurements (311). Although gastric emptying may be delayed in premature infants, it does not correlate with GER (312).

Despite the debate about whether clinical signs such as gagging and bradycardia and apnea relate to GER, treatment for GER in neonates is frequent in NICUs (304,313,314). Pharmacologic treatment has included cholinomimetics, such as bethanechol, prokinetic drugs, such as metoclopramide and erythromycin, and drugs to reduce gastric acid, such as H₂-antagonists and proton pump inhibitors. Prokinetic agents reduce regurgitation by affecting lower esophageal sphincter, esophageal peristalsis, and gastric emptying time (315). H₂-antagonists available for use in neonates include ranitidine (316), famotidine (317), and cimetidine; although the use of cimetidine is limited by the potential of significant drug interactions by inhibition of

P.1529

hepatic cytochrome P450 isoenzymes and the availability of safer agents.

There are limited studies evaluating the efficacy and adverse effects of these agents in the neonatal population. A blinded, placebo-controlled, crossover trial evaluated bethanechol treatment of GER in 30 infants aged 3 weeks to 12 months with careful manometric measurements (318). Bethanechol improved lower esophageal sphincter tone, decreased vomiting, decreased the number and duration of reflux episodes and improved weight gain. One study confirmed these observations (319) although another study did not (320). As a cholinomimetic, bethanechol may increase bronchial secretions and bronchoconstriction. Reactive airway disease is a relative contraindication to treatment with bethanechol (318).

Metoclopramide, a derivative of procainamide that antagonizes dopamine, stimulates gastrointestinal motility (321) and has been used to treat GER in preterm neonates (322). Through its cholinergic effects, metoclopramide increases gastric fundal and lower esophageal sphincter tone and peristalsis in the esophagus, gastric antrum, and small intestine (321). Consistent with its central dopamine antagonist activities, it may precipitate extrapyramidal symptoms and stimulate prolactin secretion. Facial spasms, opisthotonos, and oculogyric crisis have been observed in children treated with metoclopramide (321). In an uncontrolled study of 6 preterm infants with signs of GER and impaired gastric emptying, metoclopramide (0.1 mg/kg/day) decreased gastric residual volume, improved feeding tolerance, and improved weight gain without dystonic reactions (322). When compared to placebo in a well-designed, prospective, blinded, crossover trial, metoclopramide decreased the length of time that the esophageal pH was less than 4.0 without changing the total number of reflux episodes or the number of prolonged episodes (323). A significant placebo effect was observed on symptom scores reported by parents. Greater efficacy was observed in infants older than 3 months. In a dosage of 0.1 mg/kg/dose four times daily, no side effects were noted (323). In dosages of 0.5 mg/kg/day divided into four doses, metoclopramide actually increased the number of reflux episodes and the time during which the esophageal pH was less than 4. (324) Hyams and colleagues suggested that

infants (mean 3.2 months) with GER may require metoclopramide dose escalation to 1.2 mg/kg/day (325). Although these higher dosages improved efficacy in some studies (325), higher dosages caused more irritability to the point of patients dropping out of the study (324). These higher doses must be used very cautiously, if at all, in preterm infants. Kearns and colleagues found that 30% of preterm infants (31-40 weeks postconceptional age) had delayed metoclopramide clearance (326). Thus, high doses may result in unacceptable toxicity in some preterm infants, particularly as a result of the propensity of metoclopramide to cause dystonic reactions in children (327). Although clearance did not correlate with age, the investigators recommended that oral metoclopramide therapy be initiated at a dose of 0.15 mg/kg every 6 hours in preterm infants more than 31 weeks postconceptional age (326).

As a prokinetic agent, there is considerable evidence that erythromycin exerts its pharmacological effect via direct activation of motilin receptors in the gastrointestinal tract (328). Although there are numerous published reports of erythromycin's use as a prokinetic agent in neonates, the quality of these data are limited by the paucity of randomized placebo-controlled trials (328). The majority of these studies evaluated the effect of erythromycin on feeding intolerance, gastrointestinal transit time, and time to full feeds (328). Costalos and associates studied 21 preterm infants at 32.5 weeks postconceptional age with feeding intolerance in a double blind, placebo-controlled, randomized, crossover study. Treatment with low oral doses of erythromycin (1.5 mg/kg every 6 hours) for 7 days significantly decreased whole gastrointestinal transit time (WGTT) from 15.9 ± 7.2 hr to 10.2 ± 4.6 hr ($p < 0.01$) (329). In a double-blind, placebo-controlled, study of 56 preterm infants (<1,500 g), erythromycin treatment of 12.5 mg/kg every 6 hours orally reduced the time to reach full feeds by 10 days and reduced cholestatic jaundice (presumably because of less parenteral nutrition) (330). In a study of the gastrointestinal effects of erythromycin, Costalos and associates treated 20 preterm infants (median gestational age of 32 weeks; range 26-34 weeks) with erythromycin (10 mg/kg orally every 8 hours for 7 days) in a double-blind randomized, crossover design (331). Erythromycin treatment shortened antral contractility from 70 ± 13 minutes to 31 ± 9.9 minutes ($p < 0.01$) and WGTT was from 49.3 ± 29 hours to 23.1 ± 12.9 hours ($p < 0.01$). In contrast to these studies, Patole et al did not find that erythromycin shortened the time to full feeds in a controlled trial of oral erythromycin treatment using 12 mg/kg/dose every 6 hours administered for 14 days (332). No adverse effects of pyloric stenosis or arrhythmias or sepsis with resistant organisms have been reported in these controlled studies.

An association between erythromycin treatment of infants and pyloric stenosis was first reported in 1976 (333), but more recent cases have supported this association. Following a pertussis exposure in a community hospital, erythromycin prophylaxis was recommended for around 200 neonates born during one month (334,335,336). Erythromycin treatment increased the relative risk by 7-fold for developing infantile hypertrophic pyloric stenosis (IHPS). Using Medicaid or TennCare records in Tennessee from 1985 to 1997 with a cohort of 314,029 enrolled births, erythromycin treatment increased the risk of pyloric stenosis by 8-fold (337). Others have reported the same association with neonatal erythromycin treatment during the first 2 weeks after birth (338). This association has also been observed with maternal treatment with

macrolide antibiotics during breast feeding in a case report (339) and in a population-based cohort study from Denmark (340). Because IHPS has a distinct developmental timing of presentation with a later onset in premature newborns (341), the ELBW infant may not be as susceptible as the term

P.1530

neonate, but treatment of all infants with erythromycin must weigh the risks and benefits.

In summary, there is a lack of published evidence relating to the efficacy of pharmacologic management of GER and additional data are needed regarding the optimal treatment of gastrointestinal dysmotility. Potentially significant side effects are associated with pharmacologic treatment, and debate persists about the efficacy and indications for pharmacologic treatment of these conditions.

Bronchodilators

The use of bronchodilators has increased with the survival of more immature newborns with greater susceptibility to development of BPD. Histologic studies in infants with BPD confirm bronchiolar smooth muscle hypertrophy, which can lead to airway narrowing.(342) Consistent with these anatomic changes, infants with BPD demonstrate bronchodilatation, increased dynamic airway compliance, and reduction in airway resistance in response to β -adrenergic agents and ipratropium, an anticholinergic drug (343,344,345,346,347,348,349,350,351,352,353,354,355,356). Airway responsiveness to bronchodilators develops by two weeks postnatal age in most neonates requiring mechanical ventilation and as early as 26 weeks postconceptional age (357). Consequently, bronchodilator treatment is frequently used in the management of BPD in preterm neonates.

The method of administering bronchodilators may influence efficacy. Aerosolized albuterol may be administered by either nebulizer or metered dose inhaler (MDI) and spacer. Until recently, the former was commonly used in mechanically ventilated patients. Nebulized albuterol (2.5 mg) increased respiratory system compliance (Crs/kg) by 35.3% as compared with a 2.8% improvement following saline placebo ($p < 0.001$) in ventilator-dependent, ELBW infants as early as 5 to 31 days after birth (352). A significant decrease in $p\text{CO}_2$ (<10 mm Hg) was noted in 47% of

measurements. As expected, heart rate increased an average of 17.5 beats/min and persisted for 30 to 120 minutes after albuterol administration. In a study by Wilkie and colleagues, both nebulized salbutamol (albuterol) and ipratropium bromide, improved lung mechanics in ventilator-dependent neonates who were progressing into chronic lung disease (355). These infants, whose gestational ages ranged from 25 to 29 weeks with birthweights of 560 to 1,050 g, demonstrated bronchodilatation as early as 19 days after birth. These findings were confirmed in ventilator-dependent preterm infants who demonstrated dose-related bronchodilatation to nebulized ipratropium alone, and in combination with salbutamol (albuterol), by 18 to 34 days after birth (358). No synergistic bronchodilatation in neonates between an anticholinergic agent and albuterol has been reported (347). Oral administration of

albuterol has also been noted to improve lung function in infants with BPD (354,359).

Nebulization of albuterol has several undesirable effects, including cooling of the inspired gas, higher cost of administration as compared with metered dose inhaler, loss of drug by continuous flow, and inefficient delivery. Previous studies in ventilator models revealed that only 1-3% of nebulized drug is delivered to the patient (250,360,361). Our data in a neonatal ventilator-lung model indicate that only 0.2% of nebulized albuterol is delivered to the lungs of the ventilated neonate (362). Delivery of aerosolized albuterol is markedly improved when it is administered by MDI and spacer (362). When administered by MDI and spacer, both 72 µg of ipratropium and 400 µg of albuterol improved oxygenation and ventilation in 1 week-old, 880 gm neonates by 30 minutes after administration and increased heart rate an average of 23 beats/min (350). In 2 week-old, average 28-week gestation, ventilator-dependent newborns, albuterol improved pulmonary mechanics in 9 of 10 patients (344). Seven of 10 patients responded after one MDI actuation (100 µg), and two of the remaining three patients after 200 µg (344). Improvement in pulmonary resistance was maximal at 30 minutes and lasted three hours. Albuterol treatment was associated with a significant tachycardia (mean 180 beats/min).

Beta agonists also improve pulmonary function of nonventilated infants with BPD. Nebulized isoproterenol markedly improved airway resistance and specific airway conductance in nonventilated infants with BPD at 41 weeks postconceptional age (348). Today, albuterol is the preferred agent over isoproterenol as a result of its greater selectivity for β₂ receptors. Gappa and colleagues reported a significant reduction in airway resistance following albuterol administration by either nebulizer or MDI in spontaneously breathing infants (postconceptional age 37.1 ± 2.3 weeks) with BPD (345). Administration of the latter was facilitated by attaching the MDI to a holding chamber and face mask and allowing the infant to breathe for 30 seconds between puffs.

Choosing between albuterol delivery by nebulizer or MDI requires careful consideration of the differences in delivery efficiency, convenience and ease of use, disturbance to the patient, and adverse effect profile. In a recent survey of NICUs, 57% of centers administer albuterol by MDIs at least some of the time, although 19% of centers use MDIs exclusively (363). In most cases, MDIs are the preferred method of administration as a result of their greater efficiency in drug delivery (345), short delivery time, and reduced administration costs. Additionally, MDIs obviate the need to change ventilator flow rates and do not cause potentially troublesome cooling of ventilator gas. On the other hand, MDI dosages can only be changed in fixed increments.

Diuretics

Several classes of diuretic drugs are available, including osmotic agents such as mannitol, carbonic anhydrase inhibitors such as acetazolamide, thiazides such as chlorothiazide, high-ceiling or loop diuretics such as furosemide, and potassium-sparing diuretics such as spironolactone (364). The last three classes are used

treatment of neonates, both for acute fluid overload and for chronic therapy of BPD and congestive heart failure. Distinct differences in mechanisms of action and potency should guide selection of specific drugs (365,366).

Thiazides are sulfonamide diuretics whose major action is to block sodium and chloride cotransport in the first portion of the distal tubule, which causes a natriuresis (364,365,366). Thiazide-induced diuresis produces a greater loss of sodium and potassium per urine volume than does a diuresis induced by loop diuretics, although only a moderate amount of sodium is excreted (364). Among diuretics, thiazides are relatively unique in that they decrease the renal excretion of calcium, although magnesium excretion is increased. In high doses, thiazides may inhibit carbonic anhydrase with a potency equal to that of acetazolamide. They also may induce hypoglycemia, hypercholesterolemia, and hypertriglyceridemia (364). Thiazide elimination occurs through the renal tubular organic acid transport system, and may be inhibited by other organic acids such as probenecid. The diuretic action of thiazides depends on secretion into the renal tubular fluid, so that competitive inhibition of the transport of a thiazide by another organic acid may blunt its diuretic effect.

Spironolactone, the potassium-sparing diuretic commonly used for treatment of newborns, is a 17-spironolactone steroid that competitively antagonizes mineralocorticoids, predominantly aldosterone (364,366). Because aldosterone increases sodium reabsorption and potassium secretion, increased aldosterone secretion may be suspected by the ratio of urine sodium to potassium. Similarly, effective antagonism of aldosterone by spironolactone may be detected by an increasing urine sodium to potassium ratio. The appropriate dose of spironolactone relates to the concentration of aldosterone, because it acts through competitive inhibition. Spironolactone is available only for enteral administration and undergoes extensive first-pass hepatic metabolism to an active metabolite, canrenone.

The most serious toxicity of spironolactone is hyperkalemia during cotreatment with potassium supplements (366). Spironolactone increases calcium excretion and, in older males, may produce gynecomastia as a result of an antiandrogen effect. In rats exposed to high doses of spironolactone for prolonged periods, tumors may develop, but this has not been reported in humans to date (364). Other side effects include rashes, diarrhea, and vomiting.

Alternate potassium-sparing diuretics that do not work through aldosterone inhibition, such as triamterene and amiloride, rarely are administered to neonates. Their potassium-sparing action probably occurs through inhibition of the electrogenic sodium transport in the distal nephron (364).

Among the three loop diuretics in clinical use in the United States, bumetanide, ethacrynic acid, and furosemide, furosemide is the best studied in neonates. All three are organic acids, but furosemide and bumetanide are sulfonamides. All three diuretics induce diuresis by inhibiting the chloride pump in the ascending limb of the loop of Henle. Their diuretic effects require secretion into the tubular fluid by the organic acid

transport system that may be competitively inhibited by other organic acids such as probenecid or penicillin (365,367). Because of these similarities in action, there is almost no reason to use two loop diuretics simultaneously. Patients who are resistant to furosemide, however, may still respond to bumetanide likely as a result of its greater potency (366). Loop diuretics produce excretion of dilute urine, with an increase in free-water excretion compared to sodium excretion (368).

Calcium excretion is increased by furosemide (366). This contributes to renal parenchymal calcification, nephrolithiasis, and osteopenia during chronic treatment of neonates with furosemide. Cholelithiasis has also been observed during chronic furosemide treatment. Although furosemide is highly protein bound, it appears unlikely that doses administered to neonates produce high enough concentrations to displace bilirubin (365).

As might be expected for a drug eliminated by renal tubular secretion, the half-life of furosemide in neonates is long and variable, ranging from 4.7 to 44.9 hours (369). During repetitive dosing, Vert and colleagues demonstrated an inverse relationship between postconceptional age and furosemide half-life (369). Petersen and colleagues have confirmed this prolonged half-life for furosemide in preterm neonates during the first few weeks after birth (6). They also noted that some neonates have poor absorption of orally administered furosemide, leading to an inadequate diuretic response. The prolonged half-life does not support the current clinical practice of administering furosemide every 6 to 8 hours in neonates.

The effects of furosemide on lung function, both acutely and chronically, have been studied in neonates with BPD (370) and in neonates recovering from hyaline membrane disease (371). In patients with BPD, pulmonary compliance improved after a single dose of furosemide. Prolonged treatment improved pulmonary compliance, pulmonary resistance, and oxygenation without an effect on transcutaneous PCO₂ (370). In a controlled study of preterm neonates recovering from hyaline membrane disease, furosemide improved pulmonary compliance by 2 hours after administration (371). This improvement persisted for 4 hours and then returned to baseline by 6 hours. Chronic furosemide treatment for 4 days produced a further improvement in alveolar-arterial difference in partial pressure of oxygen (AaDO₂).

One prospective, controlled study of newborns has found that furosemide treatment increases the frequency of patent ductus arteriosus, presumably as a result of the release of prostaglandin (PG) E₂ that accompanies diuresis (372). Other investigators have administered furosemide with indomethacin to blunt the oliguric response to indomethacin without loss of indomethacin-induced ductal closure (373). Indomethacin blocks the natriuretic response to furosemide and the increase in renal blood flow that furosemide produces (374).

Both furosemide and ethacrynic acid may produce ototoxicity (364). Furosemide-induced hearing loss occurs

after large doses (1,000 mg in adults) administered i.v., especially to patients with

renal failure who would be expected to have poor clearance of the drug (375). This transient ototoxicity correlates with changes in electrolyte concentrations in the middle ear fluids, endolymph and perilymph, that reduce endocochlear potentials (375). Compared to furosemide, bumetanide caused a similar frequency of adverse effects, except for ototoxicity, which appeared to be less with bumetanide (376).

Both thiazides and furosemide may produce allergic interstitial nephritis (364). The most frequent adverse effects associated with treatment of newborns with loop diuretics reflect their actions that frequently lead to hypochloremic, hypokalemic alkalosis. Electrolyte monitoring is needed at the start of treatment to detect excessive sodium depletion to serum values less than 120 mEq/L.

Although seldom used as a diuretic, methylxanthines may produce significant diuresis, natriuresis, and choliuresis (377).

Histamine₂ Receptor Antagonists

Acid suppressant therapy is commonly used in critically ill patients to prevent acute gastric mucosal damage (AGMD) and its severe complications, such as hemorrhage or perforation (378,379,380). Studies evaluating the risk of AGMD in critically ill infants and children are few in number and discrepant in results, thus making the issue of stress ulcer prophylaxis controversial (381,382). A small study in critically ill preterm infants (median gestational age 29.7 weeks) endoscopically demonstrated a high prevalence (94%) of asymptomatic esophageal and gastric lesions, including macroscopic esophagitis and gastritis together with ulceration (383). In children, a histamine₂-antagonist, in particular ranitidine, has been the agent of choice to treat these lesions and prevent the development of gastric hemorrhage (384).

Histamine₂ receptor antagonists inhibit histamine-induced gastric acid secretion (385). A series of structurally related compounds have been developed to block the histamine₂ receptor, including cimetidine, ranitidine, and famotidine. Although all of these drugs are used clinically, patients report adverse effects more often with cimetidine than ranitidine (386). Adverse effects most commonly reported by adults include diarrhea, nausea, vomiting, and constipation. In newborns, the most important undesired effect of cimetidine is its inhibition of the elimination of numerous drugs metabolized by cytochrome P450 (CYP) isoenzymes, including those metabolized by CYP1A2, CYP2C9, and CYP2D6 (387). Cimetidine, like other drugs with an imidazole structure, such as ketoconazole and metronidazole, binds to cytochrome P450 and reduces its activity (388). In newborns, one of the most frequently encountered and troublesome drug-drug interactions during cimetidine therapy is its inhibition of theophylline metabolism (CYP1A2) (389). This drug interaction requires vigilance and careful monitoring of theophylline concentrations to prevent toxicity. Other potential interactions include decreased clearance of propranolol, phenytoin, lidocaine, nifedipine, and diazepam (388). Drugs such as lorazepam, which require conjugation for elimination, are not affected by cimetidine treatment. Ranitidine, in which the imidazole ring is replaced with a furan ring, binds much less to liver microsomes and

cytochrome P450 with approximately one tenth the affinity of cimetidine (388). Because of its greater potency and longer duration of effect, ranitidine is administered less frequently than cimetidine. Because ranitidine has at least three to four times the molar potency of cimetidine, it has minimal effects on cytochrome P450 in usual clinical doses (390,391). Accordingly, it is often the preferred agent in newborns and infants for suppression of histamine₂ receptor mediated acid secretion.

In a randomized, controlled study of 23 mechanically ventilated, preterm and full-term newborns (mean gestational age 32 weeks), 5 mg/kg/day of ranitidine markedly decreased the risk for endoscopically proven gastric mucosal lesions (384). In a case report, ranitidine provided effective treatment for a preterm neonate with a life-threatening upper gastrointestinal hemorrhage after indomethacin (392). In this preterm newborn, an infusion of 0.2 mg/kg/hour resulted in high concentrations with a half-life of approximately 5.5 hours, which is greater than twice the elimination half-life reported in older children (248).

To determine the optimal dosage requirement of ranitidine, many investigators have used gastric pH as a surrogate endpoint. The validity of this endpoint is based on adult data that demonstrate that maintaining gastric pH above 4 reduces the risk of stress ulceration and gastric hemorrhage in critically ill patients (393). Kuusela and associates studied intraluminal gastric pH in 16 preterm and term infants who received three different bolus doses of ranitidine: 0.5 mg, 1.0 mg, and 1.5 mg per kg of body weight to keep the intraluminal gastric pH greater than 4 on a 24-hour basis (316). Preterm infants needed significantly smaller doses of ranitidine than term neonates to keep their gastric pH greater than 4. The required optimal dose of ranitidine for preterm infants was 0.5 mg/kg/body weight twice a day and 1.5 mg/kg three times a day for term infants (316). Kelly and associates found that ranitidine infused at 0.0625 mg/kg/hour was sufficient to increase and maintain gastric pH above 4 in 10 premature neonates (median gestational age 27.5 weeks) who were receiving dexamethasone (394). Fontana and associates studied the pharmacokinetics of ranitidine in 27 term infants during the first day after birth and reported that concentrations greater than 100 ng/mL and 200 ng/mL could be expected for at least 12 hours after a single intravenous bolus dose of 1.6 mg/kg and 3.3 mg/kg, respectively (395). The same average concentration could be maintained at steady-state with an intravenous infusion rate between 0.03 and 0.06 mg/kg/hour based on their reported mean half-life of 207 minutes (395).

Famotidine is an H₂-antagonist that is not well studied in neonates and infants.

Advantages over ranitidine and

P.1533

cimetidine include its potency, relatively longer elimination half-life, and lack of interaction with the cytochrome P450 isoforms. The pharmacokinetics and pharmacodynamics of intravenous famotidine were evaluated in 10 infants (5-19 days of age) (396). After a 0.5 mg/kg infusion of famotidine, the terminal elimination half-life was 10.5 ± 5.4 hours. Six of the nine infants who had intragastric pH monitoring maintained a gastric pH =.μ 4 until the final 24-hour sampling point. Orenstein and

associates evaluated the safety and efficacy of famotidine in 35 infants (1.3-10.5 months of age) in a randomized, placebo-controlled trial evaluating famotidine 0.5 mg/kg and 1.0 mg/kg once daily for up to 8 weeks in the treatment of GERD (317). No serious adverse events were reported. Eleven of 16 patients had nonserious, possibly drug-related adverse experiences. The investigators concluded that a possibly efficacious famotidine dose for infants is 0.5 mg/kg, however dosage individualization may be required based on response. Larger placebo-controlled evaluations of famotidine in infants are warranted.

Inotropes

Although inotropy refers specifically to myocardial contractility, inotropic drugs improve cardiac contractility, increase cardiac rate, and alter vascular tone (397,398). Cardiac output is determined by preload, contractility, and afterload and represents stroke volume \times heart rate. The inotrope should be selected according to its specific pharmacologic properties and the specific cardiovascular abnormality to be corrected. Despite frequent administration of inotropes to newborns, they have received limited study in this population.

Shock occurs when blood flow and oxygen supply are inadequate to meet tissue demands. The same principles apply to the myocardium. Increasing cardiac wall stiffness increases myocardial oxygen consumption and may decrease flow during diastole. Inotropic drug treatment for the failing heart must balance increasing myocardial oxygen consumption against the increase in cardiac output that provides more oxygenated blood through the coronary circulation to the myocardium. Disproportionate increases in myocardial wall stiffness from increased contractility and increased afterload may impede coronary flow and worsen myocardial ischemia. Conversely, excess peripheral vasodilation may reduce the blood pressure to a level in which there is too little pressure to maintain coronary flow during diastole.

Specific receptor interactions, cardiovascular effects, and controlled clinical trials of inotropic drugs in newborns should guide their clinical use (Table 56-6) (398,399,400). Dosages for drugs used frequently in newborn resuscitation are indicated in Table 56-5. All the inotropes should be dosed to effect. Prolonged infusion of catecholamines has been shown to down-regulate receptors which reduces their effects.

Isoproterenol is a direct-acting, potent, pure beta-adrenergic agonist whose usefulness is limited by tachycardia and peripheral vasodilation. Tachycardia and diversion of blood flow to the extensive vasculature in muscle may steal perfusion away from more vital organs and extend myocardial infarction (401). Isoproterenol is most effective for raising heart rate, for instance in the treatment of complete heart block. Epinephrine stimulates all adrenergic receptors directly, but its vascular effects vary among organs, with β_1 stimulation usually exceeding β_1 vasoconstriction so that peripheral vascular usually falls (398). The effects of epinephrine infusions of 0.05 to 2.6 μ g/kg/min were described in thirty-one 23 to 30 week gestation, hypotensive newborns who had not responded to treatment with three 10 to 15 ml/kg infusions of

crystalloid and 15 µg/kg/min infusions of dopamine (402). Epinephrine normalized blood pressure in all, increased heart rate an average of 10 beats/min, improved urine output in 5 of 6 patients with oliguria, but it increased the base deficit an average of 3 mEq/L. No controlled trials have compared epinephrine treatment of hypotensive premature newborns to dopamine or dobutamine as initial treatment.

Dopamine, the immediate precursor of norepinephrine, is unique among inotropes because it dilates renal, coronary, and mesenteric vascular beds of adults at low doses through activation of the D₁-dopaminergic receptors (398). Dopamine exerts some of its effects through release of endogenous norepinephrine, which may become depleted during prolonged infusions (398). Peripheral infusions of dopamine do not cross the blood-brain barrier to interact with CNS dopamine receptors. Extravasation of dopamine may cause severe ischemic tissue damage, which may be treated by local infiltration of diluted phentolamine (403).

The dose-response in neonates for dopamine to raise blood pressure appears to start at 2 µg/kg/min, but the upper limit of its dose response in neonates has not been defined. At high concentrations, dopamine's alpha₁ receptor activity is reported to cause vasoconstriction to predominate in all circulations (397). This effect appears to vary with development and clinical condition. Studies of renal vascular resistance in newborn animals infused with 32 to 50 µg/kg/minute of dopamine have not detected this effect (404,405). Similarly high-dose (30-50 µg/kg/min) infusions in oliguric, hypotensive, near-term newborns improved urine output and increased heart rate suggesting that the alpha₁ vasoconstrictor effects that are expected at high dosages may not predominate and reduce renal perfusion in all newborns (406).

The regional blood flow effects of dopamine have been studied in premature newborns using Doppler measures of blood flow velocity to derive a pulsatility index (PI) that provides indirect evidence of vascular tone. The greater the degree of initial vasoconstriction in the renal arteries, the greater the degree of vasodilation by dopamine, measured as a decrease in PI (407). Although dopamine did not change flow in the cerebral or mesenteric arteries, it increased aortic blood pressure without changing aortic PI suggesting this occurred through peripheral vasoconstriction. A related study of dopamine in hypotensive

P.1534

P.1535

preterm newborns with PDA's estimated both pulmonary and systemic blood pressures after dopamine treatment using Doppler blood flow velocities (408). In this study of 18 neonates, pulmonary/systemic artery mean blood pressure ratio decreased or remained the same in 9 and increased in 9. In 2 patients with lower baseline PA BP, the rise in PA pressure was sufficient to reverse ductal flow and create a right to left shunt. For the 9 neonates whose mPAP/mSBP increased, the increase was similar in magnitude to the decrease in the other 9 (+17% vs.- 19%). This unpredictability of PA responses implies that dopamine needs to be used carefully with frequent reevaluation of its effects.

TABLE 56-6 RELATIVE CARDIOVASCULAR RECEPTOR INTERACTIONS OF INOTROPES AND THE ASSOCIATED EFFECTS

CARDIOVASCULAR RECEPTOR INTERACTIONS AND EFFECTS

Dobutamine is the product of directed structural manipulation of dopamine and isoproterenol to produce hydroxyphenyl-isobutyl-dopamine (dobutamine), an inotrope designed to increase contractility with a minimum of tachycardia and vasodilation (409). Initially, dobutamine was thought to possess balanced vascular α and β activities. Later study demonstrated that dobutamine exists in two enantiomeric forms, with different receptor activities (410). The (-) isomer is a potent α_1 -agonist that increases cardiac contractility, whereas the (+) isomer is a potent α_2 -antagonist. The (+) isomer is several-fold more potent for β receptors than the (-) isomer. Overall, dobutamine is more selective for β_1 than for β_2 receptors. With infusions at less than 20 $\mu\text{g}/\text{kg}/\text{minute}$, dobutamine increases cardiac output and contractility with minimal changes in peripheral resistance and modest increases in heart rate (411). In neonates, dosages of 5 and 7.5 $\mu\text{g}/\text{kg}/\text{minute}$ increased cardiac output without changing heart rate or blood pressure (412). The lack of vasoconstriction may limit dobutamine's usefulness in patients with severe hypotension, but may be useful in patients with cardiogenic failure in whom cardiac function may worsen with increased afterload.

The effectiveness of dopamine and dobutamine to raise blood pressure have been studied in hypotensive, premature newborns with RDS (413,414,415,416). In this specific group of neonates without asphyxia or sepsis, dopamine is more effective than dobutamine for treatment of hypotension unresponsive to volume expansion. This likely relates to the peripheral vasodilating effects of dobutamine and the vasoconstricting effects of dopamine.

The effects of dobutamine and dopamine on systemic blood flow were compared using SVC blood flow velocity (416). Dobutamine increased SVC blood flow velocity more than dopamine, although dopamine raised blood pressure to a greater degree. This would be consistent with effects of dobutamine in adults in whom it lowers systemic vascular resistance although increasing cardiac output.

Phosphodiesterase inhibitors represent a relatively new class of inotropic drugs for newborns, although they have been used extensively since the 1980s to treat adults and older children, especially following cardiac surgery (417,418,419). These drugs increase cardiac output through a combination of increased contractility and decreased afterload without receptor interactions. In contrast to catecholamines that increase intracellular cyclic adenosine monophosphate (cAMP) through activation of adenyl cyclase, these newer bipyridine compounds increase cAMP by inhibition of cyclic nucleotide phosphodiesterase.

The first of these drugs approved and used in the United States was amrinone which has been studied in neonates and infants (420,421,422,423,424). Rapid redistribution of amrinone after cardiac surgery creates complex pharmacokinetics in adults that require a higher loading and infusion dosages to maintain therapeutic concentrations (425). Neonates have a smaller distribution volume and lower clearance of amrinone than infants, despite equal rates of n-acetylation,

leading to a half-life of 10.7 hr vs. 6.1 hr for infants (426). In infants, amrinone increases cardiac index more than nitroprusside alone likely as a result of the combination of increased cardiac contractility and vasodilation (421). The use of amrinone has been limited, however, as a result of reversible thrombocytopenia with a frequency of 20% (417) to 44% in a pediatric study (427). The latter study found that thrombocytopenia correlated with the AUC of N-acetylamrinone, but not that of amrinone (427).

Milrinone represents the next generation of bipyridine phosphodiesterase inhibitor to be marketed in the United States to augment cardiac output. In an open-labeled study of 10 neonates with low cardiac output after cardiac surgery, milrinone treatment with a 50 µg/kg loading dose and infusion of 0.50 µg/kg/min for 30 minutes increased heart rate, decreased average atrial pressures, systemic and pulmonary arterial pressures and increased cardiac index more than 20% in 9/10 patients by an average of 48% (428). As would be predicted systemic and pulmonary vascular resistances decreased, as well. A more definitive, multi-centered, placebo-controlled, dose-response study of milrinone was conducted in 238 infants greater than 35 weeks postconceptual age undergoing cardiac surgery (419). In this study, high-dose milrinone (75 µg/kg over 60 minutes followed by 0.75 µg/kg/min for 35 hours) was superior to low dose milrinone (25 µg/kg over 60 minutes followed by 0.25 mcg/kg/min for 35 hours) and to placebo for prevention of low cardiac output state (9.6% in high dose, 17.7% in low dose, and 26.7% in placebo) (419). In a comparison of milrinone and amrinone treatment of adults during cardiopulmonary to prevent low cardiac output state, no differences were noted (429). As with amrinone, milrinone has a lower clearance in infants than in children (430). As with amrinone, milrinone has been associated with the development of thrombocytopenia in infants and children (430). Before adopting widespread treatment of premature neonates with milrinone, the kinetics must be studied in this population. The phosphodiesterase inhibitors, however, may provide an important new treatment for low cardiac output in neonates that avoids adrenergic receptor down-regulation, and depletion of endogenous catecholamines.

Digoxin, despite its long history, remains a useful drug for the chronic enteral treatment of congestive heart failure, although the phosphodiesterase inhibitors may take its place. The efficacy of digitalis for the treatment of congestive heart failure varies according to myocardial dynamics (431). In a study of 21 infants with congestive heart failure

P.1536

as a result of ventricular septal defects, digoxin improved 12 clinically, but only 6 improved by echocardiographic measurements (432). The digoxin serum half-life averages 35 hours (range 17-52 hours) in term newborns and 57 hours (range 38 to 88 hours) in premature (birth weight range of 1,150-2,230 gm) newborns (433). This likely reflects the dependence on renal excretion for most of the

elimination of digoxin (434) and suggests that premature neonates require a smaller digoxin maintenance dose (435).

Digoxin toxicity, like efficacy, is not defined by a specific concentration, but by signs and symptoms such as emesis, arrhythmias, or conduction abnormalities, such as complete heart block (436). Various drugs may increase digoxin concentrations, such as antibiotics that reduce inactivation by gut flora (437), spironolactone that reduces its clearance (438), and amiodarone that may either reduce the clearance or increase the bioavailability of digoxin (128). Life-threatening arrhythmias as a result of excessive digitalis concentrations may be treated successfully with antidigoxin Fab antibody fragments (439).

Older assays for therapeutic monitoring of digoxin cross-reacted with an endogenous molecule, digoxin-like immunoreactive substance (DLIS), which was increased in the circulation of preterm newborns, pregnant women, and patients with renal failure (440,441). DLIS has been identified as having both the structure (442) and function of ouabain (443). The cross-reactivity of the newer assays has been eliminated.

Methylxanthines

Methylxanthines, including caffeine, theophylline, and aminophylline (an ethylenediamine complex of theophylline) are commonly administered to preterm neonates to treat apnea of prematurity and to aid in weaning from mechanical ventilation. The proposed mechanisms of actions of methylxanthines include (444): (a) increased central neural drive; (b) adenosine receptor blockade, thereby inhibiting adenosine's potent respiratory depressant effects (445); (c) improved respiratory muscle function, particularly diaphragmatic contraction (446); and (d) natriuresis. The often cited mechanism of increased cyclic AMP through phosphodiesterase inhibition does not explain the *in vivo* effects of theophylline because this mechanism requires concentrations which are usually toxic ($\approx 20 \mu\text{g/mL}$) (447). Other factors which may contribute to the action of methylxanthines include catecholamine release that increases cardiac output and improves oxygenation, and increased blood glucose which may reduce the frequency of apneic spells (444).

Theophylline

The effectiveness of theophylline in the treatment of neonatal apnea was first documented over two decades ago (448,449,450). Theophylline increases minute ventilation, reduces PaCO_2 , increases central respiratory drive, and significantly reduces the frequency of apnea (444,449,451,452,453). Additionally, theophylline may promote extubation of infants recovering from respiratory distress syndrome (454).

The desired plasma concentration of theophylline in the treatment of apnea is approximately 5 to 15 µg/mL (455), although concentrations as low as 2.8 to 3.9 µg/mL have been reported to be effective (456). To achieve and maintain therapeutic concentrations, a loading dose of 5 to 6 mg/kg of theophylline is administered followed by a maintenance dose of 2 to 4 mg/kg/day in two to four divided doses (444). Note that the therapeutic range to treat apnea is lower than the commonly accepted therapeutic range to treat asthma in older patients (10-20 µg/mL). This is as a result of reduced protein binding and higher free concentrations of theophylline in neonates as compared to adults (5). Because the unbound fraction of drug in plasma is considered pharmacologically active, a greater response may be expected in the newborn than in the adult, despite the same plasma concentrations. For example, at a total theophylline plasma concentration of 17 µg/mL, approximately 44% is unbound and pharmacologically active in the adult as compared to 64% in the full-term infant (5). Thus, 17 µg/mL of theophylline in a newborn would be equivalent to 24.7 µg/mL total theophylline concentration in the adult. Despite achieving therapeutic concentrations of theophylline, about 25% of infants with apnea may not respond (444).

Metabolism of theophylline (1,3-dimethylxanthine) and caffeine (1,3,7-trimethylxanthine) via demethylation is primarily mediated by cytochrome P4501A2 (CYP1A2) (22,23,24,25). However, because expression of CYP1A2 is low in neonates, clearance of these agents is significantly reduced, especially in preterm infants (23,34). Newborns, unlike adults, are able to hepatically methylate theophylline to caffeine, and plasma caffeine/theophylline ratios may reach 0.3 to 0.4 at steady-state (457,458,459). Thus, both compounds may contribute to theophylline's therapeutic effects (459,460). Changes in theophylline kinetics during maturation of infants born at gestations of 25 to 30 weeks were studied with stable isotopes (461). This technique allows more accurate determination of the elimination phase by monitoring concentrations for prolonged periods although continuing administration of the unlabeled medication. Theophylline half-life correlated best with postnatal age, rather than postconceptional age. As would be expected, the theophylline half-life varied inversely with postnatal age as follows:

$$\log t_{1/2} \text{ (hours)} = 1.72 - 0.00565 \times \text{postnatal age (days)}. \quad (12)$$

Clinically, theophylline clearance and urine metabolite patterns reach adult values by 55 weeks postconceptional age or approximately 4 to 5 months after birth (30). As a result of the significant interindividual variability in clearance and protein binding, theophylline plasma concentrations should be monitored and doses should be adjusted to maintain therapeutic concentrations.

When monitoring theophylline concentrations, one must consider factors that alter theophylline clearance. Theophylline's metabolism is increased and its half-life

shortened by inducing agents, such as anticonvulsants (462). Metabolism is delayed by viral infections, such as influenza (359), and numerous interacting drugs, including erythromycin and cimetidine (463). Ranitidine was also noted to reduce theophylline clearance, although this interaction is less significant and less predictable than with cimetidine (464,465).

Adverse effects of theophylline include irritability, sleeplessness, natriuresis, hyperglycemia, hyperreflexia, tremor, seizures, hypertension, tachycardia, and cardiac arrhythmias (466,467). Tachycardia is the most common side effect associated with aminophylline. Theophylline relaxes the gastroesophageal sphincter of adults and probably has the same effect in newborns. If apnea occurs as a result of gastroesophageal reflux, theophylline treatment may worsen this problem.

Caffeine

Caffeine and theophylline have similar efficacy in treating or preventing apnea and bradycardia in premature infants (468,469,470). However, caffeine has fewer associated adverse effects and a more favorable therapeutic index than aminophylline (466,467,471). Additionally, caffeine has a longer half-life, thus permitting a convenient once or twice daily dosage schedule.

Apnea was reduced by administering caffeine citrate 20 mg/kg followed by 5 to 10 mg/kg/day once or twice daily to 18 preterm infants with a mean gestational age of 27.5 weeks (472). The average number of episodes were reduced from 13.6 to 2.1 episodes per day. Note that caffeine citrate doubles the weight of the administered drug, so that 20 mg/kg is equivalent to 10 mg/kg of caffeine base. Subsequent pharmacokinetic studies from the same group led to the current dosing recommendation of 10 mg/kg of caffeine base, followed by a maintenance dose of 2.5 mg/kg/day given as a single daily dose (27). More recently, Scanlon and associates reported that "high dose" caffeine (50 mg/kg caffeine citrate loading dose followed by 12 mg/kg/day) improved apnea more rapidly than the standard dose (25 mg/kg loading dose followed by 6 mg/kg/day) without increasing adverse effects (473).

Effective caffeine concentrations for the treatment of apnea of prematurity range from 5 to 25 µg/mL (467). Previous reports suggest that caffeine plasma concentrations of up to 50 µg/mL may be tolerated without significant adverse effects (27,473). Caffeine is noted to have minimal metabolic effects in the newborn infant (474). In a study of 12 premature neonates, 20 mg/kg caffeine citrate did not increase excretion of electrolytes or catecholamine metabolites, however glucose concentrations were lower in formula fed infants after caffeine administration (474). Infants who received continuous glucose infusions had no change in plasma glucose concentrations. Caffeine's wide therapeutic index reduces the necessity for the close plasma concentration monitoring that is

required with theophylline. Similar to theophylline, approximately one-third of patients do not respond to treatment with caffeine (444).

As a result of limited biotransformation, caffeine elimination in the neonate is dependent on renal clearance. Unchanged caffeine comprised about 86% of the methylated xanthines and methyluric acids in the urine of infants less than 1 month of age (466). As a consequence of limited biotransformation, the half-life of caffeine is significantly prolonged and may exceed 200 hours in preterm infants (27). Similar to theophylline, the half-life of caffeine in preterm infants decreases after birth (475,476). In 34 preterm infants 25 to 32 weeks gestation with a mean postnatal age of 4.8 ± 0.7 days, the half-life of caffeine was markedly reduced from 129.8 hours to 93.5 hours ($p < 0.005$) by treatment day 7 (476). Even full-term infants, who were exposed to caffeine transplacentally, have prolonged half-lives, ranging from 31 to 132 hours (477). In general, adult values for the caffeine half-life are reached at approximately 60 weeks postconception or 4 to 6 months postnatally (28,29).

Muscle Relaxants

Muscle relaxants are commonly administered to neonates during mechanical ventilation and anesthesia for surgical procedures (478). Nondepolarizing muscle relaxants, which competitively inhibit acetylcholine at the motor end-plate, have become the mainstay for neuromuscular (NM) blockade in the NICU. Although pancuronium has been used extensively in treatment of neonates, the use of the shorter acting nondepolarizing agents, vecuronium and atracurium, has increased in recent years.

Pancuronium is a long-acting neuromuscular blocker with an average duration of action in neonates of 60 to 120 minutes following a 0.05 mg/kg dose (478). Pancuronium is primarily excreted by the kidney (60-80%) with approximately 15% hepatically metabolized to an active metabolite (479). Its predominant renal elimination requires that caution be used to avoid accumulation in premature neonates or infants with poor renal function. Pancuronium does not cause histamine release, however tachycardia and increased systolic blood pressure as a result of vagal blockade are characteristic (480,481).

Pancuronium dosage requirements for neonates increase with postnatal age, and decrease with prematurity (482). Treatment during the first week after birth required a dose of 0.03 mg/kg, compared to 0.09 mg/kg by 2 to 4 weeks after birth. Dose reductions were required not only for prematurity, but also for acidosis and hypothermia. By monitoring muscle twitch to determine neuromuscular blockade, others have shown that newborns have widely variable dosage requirements of pancuronium (483). Generally, larger doses of pancuronium are required for muscle relaxation in infants than in adults, presumably as a result of a larger volume of distribution. Repeated administration of pancuronium to

active metabolite and long half-life, which is related to immaturity of liver and renal function.

Vecuronium and atracurium are intermediate-acting neuromuscular blockers with a shorter duration of effect than pancuronium. In contrast to pancuronium, vecuronium, and in large part atracurium, have little to no cardiovascular effects (481). In neonates, 0.03 mg/kg of vecuronium produces a 30 to 40 minute duration of action as compared to 20 to 30 minutes after 0.15 to 0.3 mg/kg of atracurium (478). Vecuronium's effects are much longer in neonates and infants than in children and adolescents (484). A 0.1 mg/kg dose maintained neuromuscular blockade by analysis of muscle twitch for more than 58 minutes in infants and 18 minutes in children, aged 3 to 10 years (484).

Vecuronium is 20% renally excreted unchanged and the remainder is excreted in the bile (485). Vecuronium's limited renal excretion has often led to its choice in patients with renal dysfunction; however, its active metabolite (3-desacetylvecuronium) may accumulate in renal failure and result in prolonged neuromuscular blockade (480). Although repeated administration of vecuronium carries a lower risk than pancuronium of prolonged neuromuscular blockade, this phenomenon has been reported in neonates both with and without renal failure (486,487). The latter occurred in a 2-month old infant as a result of vecuronium accumulation at doses of 1.67 µg/kg/min for 5 days followed by 0.83 µg/kg/min for 2 days. The infant required 48 hours to regain full neuromuscular function. Lower doses may be required in some neonates and infants and monitoring of the neuromuscular junction may reduce the use of excessive doses.

Atracurium does not rely on renal or hepatic elimination and undergoes a spontaneous, nonenzymatic, ester hydrolysis at the pH of body fluids (Hoffmann elimination). The breakdown products are not pharmacologically active, making this an excellent agent for use in patients with renal and/or hepatic dysfunction (488). Unlike pancuronium and vecuronium, atracurium has the potential for histamine release that may result in cutaneous flushing and/or hypotension. Neonates appear to be more sensitive to atracurium than older children (489) and infusion requirements are approximately 25% lower than older children to maintain 90% to 95% neuromuscular blockade (490).

Neuromuscular blockade for several days may produce prolonged muscle weakness. Several metabolic factors and other drugs may enhance neuromuscular blockade, including acidosis and hypokalemia, and treatment with magnesium and aminoglycoside antibiotics (478). The contribution of drug accumulation at the myoneural junction or alteration of the myoneural junction requires more study. Monitoring of muscle fiber twitch during prolonged paralysis may be helpful for

evaluating and avoiding this side effect.

Prostaglandins and Prostaglandin Inhibitors

During the last 25 years, understanding of the pharmacology and physiology of the eicosanoids has expanded dramatically from PGE₁ and PGF₁ α to thromboxane and prostacyclin, products of the cyclooxygenase pathway, and leukotrienes, noncyclized products of the lipoxygenase pathway. Better understanding of leukotrienes has helped to account for previously recognized biologic mediators such as slow-reacting substance A, which is the same as leukotriene C. Despite the enormous variety of functions mediated through the eicosanoids, PGE₁ and PGE₂ are the most frequently used eicosanoids in newborn medicine (491). They have been used primarily to maintain patency of the ductus arteriosus, and occasionally, for pulmonary vasodilation in the treatment of persistent pulmonary hypertension of the newborn (PPHN). The effectiveness of PGE₁ for maintaining ductal patency has been confirmed in various studies, including a multicenter collaborative investigation (492).

Prostaglandin E₁ usually has been administered by continuous venous or arterial infusion (493). Dosages generally have started at 0.1 µg/kg/minute and have been associated with a variety of adverse reactions, including cutaneous vasodilation, edema, hypotension, apnea, fever, irritability, seizures, hypoglycemia, diarrhea, disseminated intravascular coagulation, osteolysis, hypercalcemia, and thrombocytopenia (493). By reducing starting dosages to 0.05 µg/kg/minute, side effects, in particular apnea, are reduced. If oxygenation is maintained, dosages can be tapered to 0.01 µg/kg/minute (494).

Prolonged treatment with PGE₂ is needed for patients with ductal-dependent cardiac malformations awaiting transplantation. Oral PGE₂ also is effective for maintaining ductal patency and oxygenation (494). Patients who were changed from the i.v. to the oral route, however, did have a significant decrease in PaO₂. Oral treatment utilized doses of 35 to 65 µg/kg/hour by gastric drip, with a slow increase in dosing intervals from 1 to 4 hours during the second and third week of treatment. This is consistent with recent reports of treatment of adults with PGE analogues for healing of ulcers (495).

Closure of the patent ductus arteriosus with cyclooxygenase inhibitors also is an integral part of neonatal pharmacology. Ductal patency after birth is maintained by PGE₂, the secretion of which is inhibited by rising oxygen tension (491). Ductal closure was first achieved with oral indomethacin in large dosages (2.5-5 mg/kg) (496). Since that report, indomethacin has been formulated in an i.v. preparation and used in a multicenter collaborative trial that demonstrated the efficacy of treatment with a 0.2 mg/kg loading dose, followed by 0.1 to 0.25 mg/kg/doses

every 12 hours for a total of three doses (497). This study also illustrated the side effects of cyclooxygenase inhibition in neonates, including oliguria, increased serum creatinine, and transient mild bleeding.

Infants with intracranial hemorrhage were excluded from the collaborative study (497). Subsequent studies have found that early indomethacin treatment actually decreases the risk of intracranial hemorrhage (498). When the presence of an intracranial hemorrhage was not a contraindication to indomethacin treatment, it has not been

P.1539

shown to cause extension of intracranial hemorrhages (499,500). These studies do not indicate that intracranial hemorrhage should be a contraindication for indomethacin treatment, although some physicians follow the approach used in the multicenter collaborative trial and avoid administration of indomethacin to neonates with intracranial hemorrhages (497).

Developmental changes in the pharmacokinetics of indomethacin have been defined for preterm infants (501). Lower average indomethacin concentrations were noted in patients who did not sustain ductal closure after treatment with indomethacin. Indomethacin clearance increased with both postnatal age and body weight. A correlation between individual indomethacin levels and ductal closure was not found, however, possibly relating to variation in rates of PGE₂ production among patients.

The optimal length of indomethacin treatment for low-birth-weight neonates has not been settled. After initial treatment with two doses of indomethacin, once-daily doses of indomethacin have been continued for 5 additional days in 22 infants with birth weight under 1,500 g (502). The group that was treated for a sustained period of time had no patent ductus 3 days after ending treatment and fewer intraventricular hemorrhages. The ductus reopened eventually in almost one-half of this group, but at a much older age. Longer courses of indomethacin need more study, but may be more effective for ductal closure.

The neonate who is several weeks old and has a symptomatic patent ductus arteriosus presents a therapeutic dilemma. McCarthy and colleagues reported failure of ductal closure in infants who were 37 to 40 weeks postconceptional age at the time of indomethacin treatment (503). Efforts to maintain effective indomethacin concentrations in older patients with patent ductus arteriosus, by higher doses administered more frequently, have not ensured ductal closure (504).

The renal effects of indomethacin in premature infants are quite similar to those observed in symptomatic adults (505). In premature infants, indomethacin decreases urine flow, glomerular filtration rate, and free-water clearance, which combine to decrease renal electrolyte excretion (506). Oliguria during indomethacin treatment of premature infants has been improved with dopamine (507) and with furosemide (371). In adults, salt depletion and hypovolemia

accentuate the adverse effects of nonsteroidal antiinflammatory drugs on renal function (505,508,509). Seri and colleagues found that dopamine prevented a decrease in urine flow and increased sodium excretion (507).

The rate of indomethacin infusion has a significant effect on its cardiovascular effects. When indomethacin was infused over 0.2 to 4 minutes, cerebral blood flow velocity decreased 48% to 75% (510). When indomethacin was infused over 20 minutes, cerebral blood flow velocity was not reduced (511). A similar reduction in mesenteric blood flow occurs when indomethacin is administered over 20 seconds or less, and this can be prevented by slow infusion over 30 to 35 minutes (512). It is too early to determine whether the common practice of discontinuation of feeds during indomethacin treatment is unnecessary when doses are administered more slowly.

Pulmonary Vasodilators

Because the pulmonary vasculature of many neonates is in parallel with the systemic vasculature, through patency of the ductus arteriosus and foramen ovale, an effective pulmonary vasodilator must dilate the pulmonary vasculature more than the systemic vasculature (513). Endothelium-derived relaxing factor (EDRF) was shown to be involved in control of the perinatal pulmonary circulation as it dilates after birth (514,515). EDRF was shown to have the same properties as nitric oxide (NO) (516). NO dilates pulmonary arteries selectively through release of cyclic guanosine monophosphate (cGMP) (517,518). Infants with persistent pulmonary hypertension of the newborn (PPHN) have lower circulating cGMP likely as a result of inadequate NO production needed to dilate the pulmonary vasculature after birth.(519) The selectivity of NO for the pulmonary vasculature derives from its administration by inhalation and inactivation by binding to hemoglobin as soon as it enters the blood stream. This same binding, however, may induce methemoglobinemia at higher doses of NO (520). NO is a highly reactive compound whose dose must be carefully monitored to avoid potentially severe or even lethal toxicity (517).

Improved oxygenation and a reduced need for ECMO have been demonstrated in randomized, controlled trials of NO treatment of near term neonates with respiratory failure (521,522,523,524,525). A meta-analysis of 12 controlled trials found that NO improves oxygenation in about 50% of term and near-term neonates and significantly reduced the need for ECMO (525). No improvement in outcome was demonstrated for infants with diaphragmatic hernia. Although NO has been used to treat a variety of disorders (526), when respiratory failure is accompanied by pulmonary disease and severe infiltrates, NO treatment is less successful, possibly because inhalational delivery does not reach the pulmonary vasculature (527). Dose-response studies indicate that neonates achieve maximum improvement in oxygenation at 20 ppm (528) to 40 ppm (529,530,531). Prolonged treatment longer than 10 days has been associated

with pulmonary toxicity demonstrated by detection of nitrotyrosine (532). Platelet function has been reduced during NO treatment of adults, likely through increased cGMP, and this may represent a risk for neonates (533). In the critically ill, neonatal population treated with NO, long-term outcome should be evaluated in comparison to control, comparably sick infants not exposed to NO. From a randomized, controlled study of NO treatment in 248 neonates, evaluation at 1 year showed no increase in mortality, reactive airway disease, chronic lung disease, or developmental delay in the NO treated group (534).

Although NO was approved for the near term neonate with pulmonary hypertension, preterm neonate less than 32 weeks gestation have been treated with NO (535). A group of 70 infants born at 23 to 31 weeks gestation with

P.1540

hypoxic respiratory failure defined by aAO_2 less than 0.22, were randomized to treatment with 5 ppm NO or no treatment and pulmonary blood flow velocity was measured by Doppler. NO treatment increased pulmonary blood flow and significantly improved oxygenation with a 71% increase in aAO_2 .

Several other drugs have been used for treatment of PPHN, including tolazoline, PGE_1 , PGI_2 , PGD_2 , acetylcholine, isoproterenol, chlorpromazine, nitroprusside, and sildenafil (536). None of these have proven to be selective for the pulmonary vasculature. Although tolazoline has been reported to improve oxygenation in approximately 60% of patients, high mortality persisted, and adverse effects occurred at an unacceptably high rate (76). Improvement in oxygenation was recently reported in 72% of forty-three ELBW neonates with birth weight less than 750 gm treated with slow bolus tolazoline infusions of 0.5 to 2.0 mg/kg (537). Inappropriately high prolonged infusion doses of tolazoline, used without the guidance of kinetic studies, may have contributed to the high rate of adverse effects associated with tolazoline treatment (76). Despite this recent report of efficacy of tolazoline in ELBW neonates, it has been removed from production.

Investigations of the mechanisms through which NO controls neonatal pulmonary vascular tone and which control NO production in the pulmonary vasculature point to potential, new alternatives for treatment of PPHN (515,517). Inhibition of phosphodiesterase 5 increases cGMP and dilates pulmonary arteries. Despite hopes that sildenafil, a phosphodiesterase 5 inhibitor, would be a specific pulmonary vasodilator, a small randomized study in infants following cardiac surgery found that sildenafil reduced systemic and pulmonary vascular resistance and worsened oxygenation and the aAO_2 gradient (538). Studies of prostacyclin administered via the airway have shown promise in a small number of neonates with PPHN, but controlled studies are needed to evaluate the efficacy of this prostanoid (539,540). For now, inhaled NO remains the only selective pulmonary vasodilator in neonates. Alternate drug treatment may still be successful at

improving pulmonary perfusion in patients with PPHN, but their effectiveness must be confirmed in appropriate controlled trials.

Respiratory Stimulants

Doxapram has been administered to newborns both i.v. and orally, to treat apnea that was unresponsive to methylxanthines (see Methylxanthines) (541).

Doxapram is a general stimulant of the CNS respiratory center, along with the entire cerebrospinal axis. Originally, doxapram was administered by continuous i. v. infusion for treatment of apnea of prematurity (542,543). When administered enterally, only 10% to 12% of the doxapram dose is absorbed (544). Despite poor absorption when administered enterally, doxapram decreases apnea of the newborn (545). Side effects observed during enteral administration included occult blood in stools, necrotizing enterocolitis, and premature teeth buds. Seizures have been associated with high circulating concentrations, although Alpan and colleagues suggest that the ratio of effective to convulsive concentration is 1:70 (542). Seizures have been observed in two neonates treated with doxapram, but these were thought most likely to reflect intraventricular hemorrhages (543).

Steroids

The use of dexamethasone for the prevention and treatment of BPD in ventilator-dependent neonates increased for several years until concerns about neurologic damage began to emerge (546,547,548,549,550). Treatment was based on efforts to reduce pulmonary inflammation associated with the pathogenesis of chronic lung disease (547,551,552,553,554,555). Randomized, placebo-controlled studies have documented that dexamethasone reduces ventilator settings, oxygen requirement, and facilitates extubation of ventilator-dependent neonates at 14 to 35 days of age (556,557,558,559,560,561,562,563). Although the beneficial respiratory effects of dexamethasone have usually been attributed to its antiinflammatory activity, other factors may contribute to respiratory improvement such as increases in vitamin A and retinol binding protein.(564) The most common dexamethasone dosage regimen used was 0.5 mg/kg/day divided into two daily doses and tapered over a period of 7 to 42 days (556,557,558,559,560). These dosages, however, were not based on pharmacokinetic studies in premature newborns.

Dexamethasone is a pure glucocorticoid, without mineralocorticoid activity, but with approximately 25 times more antiinflammatory potency than cortisol (565). Such comparisons, however, do not consider pharmacokinetic differences in the elimination rates between endogenous corticosteroids, such as cortisol, and the halogenated steroid, dexamethasone, that has a very low clearance in ELBW neonates (566,567). This reduced clearance is likely to produce much greater

areas under the concentration-time curve and progressive accumulation with repetitive dosing at intervals less than one half-life.

The onset and duration of treatment of preterm neonates has varied widely with initiation of treatment within hours of birth (547,563,568) within the first week (561,569) or after 3 weeks (562). The duration of treatment has ranged from less than 48 hours to 42 days. As more randomized studies were completed, meta-analyses have shown that early treatment for less than 48 hours did not reduce death or BPD (570) although treatment for longer periods reduces duration of intubation, BPD, death or BPD at 36 weeks, PDA and severe ROP (563). Similar findings but without an effect on ROP were noted with later treatment at 7 to 14 postnatal days (561).

Early reports of adverse effects of dexamethasone treatment of neonates showed poor growth and weight gain during treatment (558,560,571,572,573,574,575), hypertension (572,573,576,577,578,579,580), hypothalamic-pituitary-adrenal (HPA) axis suppression (581,582,583,584,585,586), hypertrophic cardiomyopathy (587,588,589), gastrointestinal hemorrhage and perforation

P.1541

(579,590,591,592), and hyperglycemia (572,576,579). Many adverse effects are reversible on drug discontinuation, however some may be severe or even life-threatening. Some degree of HPA-axis suppression is often evident following dexamethasone regimens of 14 to 42 days (581,582,583,584,585,586). Adrenal suppression may persist for months, so this population may require a prolonged steroid taper (581). During this period, Byyny found that stresses such as surgery or infection may require temporary administration of exogenous glucocorticoids at two to three times the maintenance dose (593). The effect of a short course of dexamethasone on the HPA-axis is more controversial. Some investigators reported that 7 days of dexamethasone had no effect on adrenal responsiveness to ACTH (594, 595). Others reported hyporesponsiveness to both ACTH and corticotropin releasing hormone following as little as a 7-day course of dexamethasone (596,597,598), although this effect appears short-lived and not clinically significant (596). A sufficient number of controlled trials of postnatal dexamethasone treatment are now published to allow meta-analysis of adverse effects that show significant increases in: gastrointestinal bleeding and perforation, hyperglycemia, hypertension, growth delay and hypertrophic cardiomyopathy (561,562,563).

The beneficial respiratory effects of postnatal treatment of preterm neonates with dexamethasone are offset by concerns about neurologic impairment. Stark and associates reported reduced head sizes at 36 weeks postmenstrual age in a controlled trial of dexamethasone treatment beginning within 12 hours of birth with a relatively low dose (0.15 mg/kg/day) for 3 days followed by a 7 day taper (599). The controlled trial of early dexamethasone treatment by Yeh et al showed developmental delay at school age (550). Concern was also raised by Shinwell in a

multi-center, controlled study of dexamethasone treatment beginning within 12 hours after birth that showed a significant increase in neurologic injury associated with dexamethasone treatment, even in preterm newborns with normal cranial ultrasound studies (549). Animal studies have shown that prolonged dexamethasone treatment may adversely affect brain growth (600,601,602). Other controlled trials, however, beginning within 3 to 10 days after birth have not shown an increase in neurologic damage (569,603). Cummings and associates reported an improved neurological outcome with a 42-day dexamethasone regimen as compared with an 18-day treatment regimen or placebo (557). One-year and three-year follow-up studies have not demonstrated any long-term neurological benefits or adverse effects associated with steroid treatment during infancy (229,604). The largest meta-analyses of controlled studies of postnatal steroid treatment of neonates with long term follow-up have not found a significant correlation between treatment and adverse neurologic outcomes (561,562,563).

The National Institute of Child Health and Human Development Neonatal Network retrospectively correlated postnatal steroid treatment with reduced Bayley II scales of motor and mental development at 18 to 22 months adjusted age (605). Such correlations point to the need for, and the importance of, controlled studies because postnatal steroid treatment may simply be a marker for the extremely ill neonates with severe hypotension, severe lung disease, or other conditions or treatments that lead to neurologic damage. Opinions about the adverse effects of dexamethasone treatment of neonates have led to significant debate (606,607,608) and even a policy statement of warning by the AAP (609).

Accurately attributing long-term neurologic impairment to treatment with a single drug, dexamethasone, is difficult in this critically ill, immature population that is treated with a plethora of medications during their months of NICU care. The study must be large enough to achieve equipoise in acuity between the control and treated groups, include similar rates of elective steroid treatment contamination outside the study assignments, and similar distributions of other factors that can cause brain injury, such as sepsis and hypotension.

Continued dexamethasone treatment requires better pharmacokinetic study to determine the optimal dosing interval, because current empiric schedules are likely to cause significant drug accumulation. Regardless of the difficulties with study of this issue, enough concern has been expressed that treatment with dexamethasone should be reserved for significantly ill infants in whom treatment benefits are carefully weighed against potential neurologic harm and the adverse effects indicated above.

Recognition of the contribution of low cortisol secretion to chronic lung disease in extremely preterm neonates (610,611,612) and to adrenal insufficiency with hypotension and oliguria (613,614,615,616), have led to studies of steroid treatment of neonates with hydrocortisone (cortisol). In a randomized, placebo-

controlled study of 40 extremely premature neonates, prophylactic hydrocortisone treatment (1.0 mg/kg/day) increased survival without supplemental oxygen at 36 weeks adjusted age, decreased days on the ventilator and need for oxygen at discharge (617). The effects seemed to be greater in infants with chorioamnionitis. None of the adverse effects associated with systemic steroid treatment were increased by hydrocortisone treatment. Specifically, there was no increase in sepsis, IVH, ROP, GI perforation, NEC, hyperglycemia, hypertension, or PDA.

Hydrocortisone and prednisolone treatment of premature neonates have been compared to dexamethasone. The hydrocortisone study was a retrospective controlled study conducted in 2 neonatal centers to determine short and long-term outcomes of hydrocortisone treatment, started at 5 mg/kg, at one center and dexamethasone treatment, started at 0.5 mg/kg, at the other center (618). Doses were then tapered over 21 to 22 days. Both steroid treatments reduced the need for oxygen. Dexamethasone, but not hydrocortisone, increased blood urea concentrations and blood pressure and reduced weight gain. Long-term outcome evaluated at 5 to 7 years showed that dexamethasone, but not hydrocortisone, was associated with a greater frequency of needing special education. If the potency of dexamethasone is at least 25-fold that of hydrocortisone

P.1542

and if it persists longer in the circulation, the steroid equivalent dosage of dexamethasone is much larger than that of hydrocortisone which may explain its greater toxicity (565). In the prednisolone study, 45 consecutively delivered premature newborns at gestational age less than 30 weeks who were at risk of developing CLD were treated with methylprednisolone and the outcomes compared to historical dexamethasone-treated, matched controls (619). Doses were tapered from 0.6 to 0.2 mg/kg q6h with each dose maintained for 72 hours. No differences in CLD were noted, but the methylprednisolone-treated group had faster weight gain, less frequent glucose intolerance, and less frequent cystic periventricular leucomalacia. Again, just as in the hydrocortisone study, the dosages in cortisol equivalents are much greater in the dexamethasone treated group without considering probable differences in rates of clearance and areas under the concentration-time curve (565).

This assumes that hydrocortisone is effectively cleared in extremely premature neonates by the usual endogenous enzymes. This needs more study, because current treatment with 2 to 3 doses/day is based on that assumption. This will also help to determine the lowest hydrocortisone dose needed to achieve the desired effects.

Inhaled Steroids

Concern for the adverse effects associated with intravenous dexamethasone has

prompted study of treatment of neonates with aerosolized topical corticosteroids, such as beclomethasone, budesonide and fluticasone to prevent BPD. In theory, administration of topical steroids to the lung should minimize systemic drug exposure, thus reducing the potential for systemic adverse effects, but it may also reduce efficacy. Controlled treatment trials have analyzed success of extubations, indices of lung inflammation, measures of lung function, and need for additional steroid treatment. In a placebo-controlled study of 161 ventilated neonates, beclomethasone reduced airway inflammation after 8 and 15 days of treatment assessed by measurement of interleukin-8 levels in tracheal aspirates (620). An earlier study by Groneck and associates in 7 beclomethasone-treated patients did not find a significant decrease in IL-8A levels compared to 9 patients treated with systemic dexamethasone (621). A meta-analysis of 12 randomized, controlled trials of inhaled steroid treatment of preterm neonates to reduce chronic lung disease helps to resolve some of these differences (622). In this meta-analysis, Halliday found that inhaled steroid treatment begun within 2 weeks of birth reduced the need for later dexamethasone treatment (622). More importantly treatment begun after 2 weeks of age was associated with more successful extubations and measurable improvements in lung function. Adverse effects of inhaled steroids appeared to be minimal.

The effects of systemic steroids and inhaled steroid were compared in an earlier meta-analysis that found only 2 randomized studies with a total of 294 subjects that met their criteria for inclusion (623). The frequency of death or chronic lung disease at 36 weeks adjusted age was not different between the two modes of steroid administration. The need for supplemental oxygen was longer in the inhaled steroid group indicating lower efficacy. As might be expected, adverse effects of hyperglycemia, gastrointestinal hemorrhage and perforation were less in the inhaled steroid group. The authors caution that neither inhaled steroids, nor systemic steroids, can be recommended as standard practice for ventilated preterm infants without additional study. The lower rate of adverse effects associated with inhaled steroids treatment supports such study. If higher doses of inhaled steroids are tested, potential toxicities from chlorofluorocarbon propellants, including bronchospasm and cardiac toxicity, must be evaluated (624,625,626).

Vitamin E

Vitamin E refers to several chemically related compounds, differing in degrees of methylation, desaturation, and oxygen content, classified generically as tocopherols (627). The oxygen molecules and aromatic ring conjugation allow interconversion between hydroxyl and quinone forms, so that vitamin E functions as an antioxidant. Alpha-tocopherol is the primary, naturally occurring member of this group.

The clinical administration of vitamin E to premature neonates is based on its

antioxidant activity, low vitamin E concentrations in many preterm neonates at birth, and animal studies suggesting that vitamin E protects against oxidant injury to the lung and eye. Initial favorable effects of vitamin E on BPD (628) were not confirmed in a subsequent randomized, double-blind study by the same investigators (629).

For prevention of retinopathy of prematurity (ROP), a prospective, double-blind, randomized trial reported that 100 mg of vitamin E per day reduced the severity, but not frequency of ROP (630). Studies of tocopherol in a kitten model of ROP, in doses of 50 to 1000 mg/kg/day, revealed a high frequency of mortality with lethargy, weight loss, and seizures (631). Livers were enlarged and extensively vacuolated with fat in the vitamin E-treated animals.

In 1984, the CDC and Bodenstein separately described infants with a new symptom complex that included pulmonary deterioration, thrombocytopenia, liver failure, ascites, and renal failure leading to death in some cases (632,633). These symptoms were attributed to a specific brand of alpha-tocopherol acetate, E-Ferol, which had begun to be administered i.v. to prevent oxidant injury to eyes and lungs. This syndrome ceased after the use of E-Ferol was discontinued. It was never completely clear whether the toxicity was a result of alpha-tocopherol, the polysorbate emulsifiers, or an unknown contaminant (634,635). Sepsis, necrotizing enterocolitis, and intraventricular hemorrhage also have been attributed to treatment of neonates with vitamin E (627). The AAP Committee on Fetus and Newborn (COFN) concluded that pharmacologic doses of vitamin E should be regarded as experimental, and not routinely indicated for infants weighing under 1,500 g

P.1543

(636). The COFN recommends 5 to 10 IU of vitamin E per day for preterm infants, provided through supplemented formulas or supplemental vitamins (348).

DRUG EXCRETION IN BREAST MILK

Over 50% of newborn infants are breast-feeding at the time of discharge (637). Although almost all drugs and chemicals present in the maternal circulation may enter human milk, the extent of transfer is quite variable. Maternal intake of prescription medications, over-the-counter medications, illicit drugs, and exposure to a multitude of environmental substances may expose the breast-feeding infant to a complex mixture of potentially harmful chemicals.

The nature of human milk influences its drug content. Human milk has been described as a suspension of fat in a protein-mineral-carbohydrate solution (638). The lactose secreted in milk is synthesized from glucose by the alveolar cells of the breast, in a process that requires alpha-lactalbumin. Milk contains a variety of proteins, including alpha-lactalbumin, lactoferrin albumin, lysozyme, and immunoglobulin A, all of which may bind drugs during transport into milk (638).

The lipid within milk is maintained in the aqueous phase in milkfat globules surrounded by lipoprotein membranes. Milk is iso-osmotic to plasma, with an average pH of 7.2.

Several factors affect drug transfer into milk, including molecular weight, lipid solubility, maternal plasma protein binding, and extent of ionization. These are similar factors to those that influence transfer of molecules across any lipid bilayer membrane. Because milk usually is acidic to maternal plasma, and non-protein-bound, nonionized molecules are free to cross membranes, the Henderson-Hasselbach equation may be used to estimate drug distribution between maternal plasma and milk (639). This predicts that organic bases ($pK_a = \mu 7.4$) will reach a higher concentration in milk than in maternal serum. Many quantitative studies of human milk drug excretion have estimated that approximately 1% to 2% of a maternal drug dose will appear in milk (640).

The AAP Committee on Drugs has written policy statements about the transfer of drugs and chemicals into humans since 1983. The latest revision in 2001 updated information about transfer of chemicals into milk and included sections that address smoking, the presence of breast implants, and the use of psychoactive drugs during breast feeding (641). The information is presented in tables that indicate the relative risk to the breast feeding infant. The full text of this statement is available at <http://aapolicy.aapublications.org>.

Chapter 57

Anesthesia and Analgesia in the Neonate

Sally H. Vitali

Anthony J. Camerota

John H. Arnold

Despite the widespread use of potent analgesic agents in adult patients and older children, it is remarkable that, until recently, systemic analgesia and sedation were rarely administered to neonates. An analysis of neonatal anesthetic practice published in 1985 revealed that only 23% of preterm infants undergoing patent ductus arteriosus ligation received adequate intraoperative anesthesia (1). In a retrospective survey of opioid use in a single institution, only 14% of 933 neonates received opioid analgesia after a variety of surgical procedures (2). However, in a 1995 questionnaire, all neonates received either systemic opioids and/or regional anesthesia for major surgery (3). Although appreciation and management of operative and postoperative pain in neonates has improved, use of analgesia for nonoperative painful procedures remains limited. Despite evidence that premedication reduces the pain and physiologic instability associated with awake direct laryngoscopy and endotracheal intubation in neonates, surveys in the United States, Canada, and Great Britain indicate that premedication is rare even in nonemergent intubations in neonatal intensive care units (4,5,6,7). Circumcision is another known source of neonatal pain that can be reduced with premedication, but a 1998 survey of residency programs teaching circumcision training practices indicated that 26% of programs teaching circumcision provided no training in anesthesia and analgesia for the procedure (8). A recent consensus statement by the American Academy of Pediatrics and Canadian Pediatric Society recognizes the recent improvement in neonatal pain assessment and management but concludes that "prevention and treatment of unnecessary pain attributable to anticipated noxious stimuli remain limited" (9).

Although adequate anesthesia and analgesia were not given to neonates in the past because of the belief that they could not feel pain, there is overwhelming evidence that pain perception and physiologic responses to stress occur in neonates of all gestational ages (10). It is broadly accepted that anesthesia and analgesia in the neonatal population have important clinical and physiologic consequences and may have long-term psychologic impact. Control of the stress response in the perioperative period may improve the outcome of infants after cardiac surgery (11,12). Appropriate analgesia and sedation are proven means of reducing catabolism associated with surgery and recovery from surgery, illness, and injury (13). Human and animal studies have found compelling evidence that early pain and stress affect nociception and behavioral responses to pain later in life, but the conflicting results of these studies leave the nature and mechanism of these long-term effects largely unexplained (14,15). Given that critically ill preterm neonates have been reported to experience as many as 488 painful procedures during their stay in neonatal intensive care units, pain and its management may have profound implications for the health of these children (16).

As these data are assimilated and accepted, there is often a discrepancy between the growing understanding of neonatal pain and actual clinical practice. A survey of British pediatric anesthetists found that only 5% routinely prescribed systemic opioids to neonates postoperatively, although 80% of the respondents believed that neonates feel pain (17). There are probably several reasons for the lag in changing clinical practice to match current knowledge, but a crucial element may be the lack of standard guidelines for the use of drugs, doses, and schedules that can be applied to various clinical situations by the practitioner at the bedside. The International Evidence-Based Group for Neonatal Pain summarized the current evidence for a set of standard guidelines in 2001; the impact of these guidelines on clinical practice remains to be studied (18).

P.1558

This chapter reviews the rapidly developing field of neonatal anesthesia and analgesia, summarizes the relevant pharmacokinetic and pharmacodynamic data, and highlights practical considerations for the most commonly used agents.

PAIN PERCEPTION

In addition to the ethic arguments for preventing needless human suffering, the risks and benefits of using anesthesia and analgesia to prevent pain and stress must be physiologically evaluated. Pivotal aspects of this physiologic rationale are based on one question: Does the neonate feel pain?

Components of the pain system may be traced from sensory receptors in the skin to sensory areas in the cerebral cortex and used as a framework to study its development (4). The density of nociceptive nerve endings in newborn skin, labeling of specific proteins (e.g., GAP-43) produced by axonal growth cones, reflex activity and receptive fields of primary afferent neurons, and development of synapses between primary afferents and interneurons in the dorsal horn of the spinal cord indicate the anatomic and functional maturity of the peripheral pain system during fetal life (19,20). Cellular and subcellular organization in the dorsal horn, with maturation of primary afferent terminations, occur during later in gestation and postnatally (21,22). In the dorsal horn, various neurotransmitter and neuromodulatory substances associated with pain (e.g., substance P, somatostatin, calcitonin gene-related peptide, vasoactive intestinal peptide, met-enkephalin, glutamate) appear during early gestation (23).

Lack of myelination in neonatal nerves or central nerve tracts is offset completely by the shorter interneuronal and neuromuscular distances traveled by the impulses.

Quantitative neuroanatomic data show that nociceptive nerve tracts in the spinal cord and central nervous system undergo complete myelination during the second and third trimesters of gestation (10). Subcortical foci associated with nociception are characterized by a high density of opioid receptors during the middle of gestation, with a differential reduction in binding capacities during the third trimester (24). Development of the fetal neocortex begins at 8 weeks of gestation; by 20 weeks, each cortex has a full complement of 109 neurons. Arborization of dendritic processes in the cortical neurons is followed by synaptogenesis with incoming thalamocortical fibers by 24 to 26 weeks of gestation. Functional maturity of the cerebral cortex is suggested by fetal and neonatal electroencephalographic patterns, cortical somatosensory-evoked potentials, studies of

regional cerebral metabolism, early behavioral development, and the specific behavioral responses of neonates to painful stimuli (10,25).

Endorphinergic cells in the anterior pituitary are responsive to corticotrophin-releasing factor stimulation *in vitro* and show increased β -endorphin production during fetal and neonatal life. Endogenous opioids and other hormones (e.g., catecholamines, steroid hormones, glucagon, growth hormone) are secreted by the human fetus in response to stress, leading to catabolism and other complications (12,26). Significant changes in cardiovascular parameters, transcutaneous partial pressure of oxygen, and palmar sweating have been observed in neonates undergoing painful clinical procedures. These physiologic changes are closely associated with behavioral responses of newborns to pain. Neonatal behavioral responses are characterized by simple motor responses, precise changes in facial expression associated with pain, highly specific patterns of crying activity, and a variety of complex behavioral changes. These neonatal responses suggest integrated emotional and behavioral changes correlated with pain, and they are retained in memory long enough to modify subsequent behavior patterns (10).

The surgical stress responses of neonates can be inhibited by potent anesthesia, as demonstrated by randomized trials of halothane anesthesia in term neonates, fentanyl anesthesia in preterm neonates, and sufentanil anesthesia in neonates undergoing cardiac surgery (12,27,28). These results imply that the nociceptive stimuli during surgery are at least partially responsible for the marked stress responses of neonates and are prevented by the provision of adequate anesthesia. In these trials, the reduction in surgical stress responses was associated with significant improvements in clinical outcome, supporting the use of potent anesthetic agents for newborns undergoing surgery. In contrast, a recent randomized, double-blind study of fentanyl bolus, fentanyl infusion, and fentanyl-midazolam infusion in infants less than 6 months old undergoing cardiac surgery found that these anesthetic regimens did not blunt the metabolic and hormonal responses to surgical stress, yet no adverse postoperative outcomes were observed. These findings indicate that improvements in clinical outcome observed in previous trials may have been related to factors other than reduction in surgical stress (29).

In recent years, the concept of blunting the pain response in neonates to improve physiologic parameters has been extended from the operating room to the intensive care unit. High-dose narcotic anesthesia for the first postoperative night after complex cardiac surgery reduces mortality (6,30,31). Using narcotics during painful procedures, such as tracheal suctioning, has been shown to reduce concomitant hypoxemia (32). Fentanyl infusions have been shown to decrease plasma stress hormone levels in preterm infants (33). A multicenter pilot study of 67 premature infants randomized to midazolam (0.2 mg/kg loading dose followed by 0.02 to 0.06 mg/kg/hour infusion), morphine (0.1 mg/kg loading dose followed by 0.01 to 0.03 mg/kg/hour infusion), or 10% dextrose for up to 14 days of mechanic ventilation showed improvement in pain scores and neurologic outcome in the morphine-treated infants, but a much larger trial will be required before this practice can be universally recommended (34).

ANESTHESIA

Anesthesia is classically defined as a drug-induced state that includes analgesia,

The provision of anesthesia to infants undergoing surgical procedures has gone through a remarkable transition coincident with the development of new intravenous agents and more sophisticated monitoring techniques. As recently as 1985, there was considerable debate about whether neonates feel pain, and sophisticated researchers advocated the use of minimal anesthesia in neonates undergoing surgical procedures, citing the dangers of anesthetic administration to this population (35,36,37). Beginning with the landmark paper of Robinson and Gregory (38), practitioners of neonatal and pediatric anesthesia have proclaimed the importance of providing adequate anesthesia, particularly to ill preterm infants (38,39). In modern anesthetic practice, adequate anesthetic depth and control of the neonatal stress response can be achieved without undue risk to the infant.

The appropriate anesthetic technique is dictated by the preoperative condition of the patient, planned surgical procedure, and skills of the anesthetist. The encounter between the anesthesiologist and neonate usually occurs in the setting of a surgical emergency, and a general anesthetic with control of the airway is most often the technique of choice. General anesthesia is provided using a combination of inhaled and intravenous agents and muscle relaxants. The inhaled agents include an inorganic gas (e.g., nitrous oxide) and volatile liquids (e.g., halothane, enflurane, isoflurane, sevoflurane, and desflurane). Delivery of potent inhaled agents by means of the respiratory system offers a reliable route of administration and excretion with the ability to rapidly alter anesthetic concentrations in the central nervous system.

Inhaled Anesthetics

Each of the inhaled anesthetic agents has unique effects on the cardiovascular, respiratory, and central nervous systems, which are not exhaustively reviewed here (Table 57-1). The volatile anesthetics produce dose-dependent decreases in mean arterial blood pressure, particularly in premature infants, due to direct myocardial depression, and decreases in systemic vascular resistance due to exaggerated depression of the baroreceptor reflex (40,41,42). Nitrous oxide produces minimal alterations in myocardial performance or systemic vascular resistance, due in part to direct stimulation of the sympathetic nervous system (43). However, if combined with a potent volatile agent or opioids, nitrous oxide significantly depresses myocardial contractility (44). If ventilation is carefully controlled, nitrous oxide has insignificant effects on pulmonary vascular resistance (45).

TABLE 57-1 SYSTEMIC EFFECTS OF INHALED ANESTHETICS
--

	Myocardial Function	Heart Rate	Systemic Vascular Resistance	Cerebral Blood Flow
Halothane	--	--	+/-	++
Enflurane	-	+	-	+
Isoflurane	-	++	--	+/- ^a
N ₂ O	+/-	+/-	-/-	+/-
Desflurane	-	++	--	+/- ^a
Sevoflurane	-	+/-	+/-	+/- ^a

^a In doses <1.0 minimum alveolar concentration.
 ++, greatly increased; +, moderately increased; +/- no consistent effect; -, moderately decreased; --, greatly decreased.

All inhaled agents increase the respiratory rate, reduce tidal volume and functional residual capacity, decrease the ventilatory responses to hypoxemia and hypercapnia, and decrease bronchial smooth muscle reactivity. These agents produce a dose-dependent increase in cerebral blood flow despite simultaneous depression of cerebral metabolic oxygen requirement. At high concentrations, isoflurane and desflurane induce an isoelectric electroencephalographic pattern; this property is not shared by the other inhaled anesthetic agents.

Although halothane is most frequently associated with perioperative hepatic dysfunction, other inhaled agents and intravenous anesthetics may result in hepatic necrosis (46). True halothane-induced hepatitis is a rare event, occurring in approximately 1 of 30,000 patients. It is seen most commonly after repeated administration and is probably mediated by an immune mechanism involving an intermediate oxidative metabolite (47,48). The inhaled agents produce dose-related decreases in renal blood flow and urine output due to effects on cardiac output and systemic vascular resistance. Fluoride-induced nephrotoxicity is a potential complication of prolonged exposure to the fluorinated hydrocarbons (e.g., enflurane, isoflurane), although it is of practical concern only during prolonged administration of enflurane and sevoflurane (49,50).

Two newer inhaled anesthetics, sevoflurane and desflurane, are gaining popularity due to their low lipid solubility (51). This property allows for rapid induction of anesthesia as well as a short recovery time. Sevoflurane has the advantage of providing a smooth, less irritating induction of anesthesia that rivals that of halothane, with less risk of hepatitis and fewer hemodynamic effects (52,53). The drawbacks are the biotransformation of sevoflurane into potentially toxic Compound A (2-fluoromethoxy-1,1,3,3,3-pentafluoro-1-propene) and the accumulation of fluoride ions (54,55). As in adults, inhaled sevoflurane has been shown to prolong the QTc interval in infants, an

P.1560

effect that lasts at least 60 minutes into the postoperative period (56). Desflurane does not undergo biodegradation *in vivo* or *in vitro*, but its irritating effects on the airway prevent its role as an induction agent (57,58).

Opioid Anesthesia

Morphine and the synthetic opioids have been a consistent adjunct to the volatile agents throughout the history of anesthesia. High-dose opioids have become the preferred anesthetic technique for cardiac surgical procedures in adults and children (59,60). The virtues of opioids include minimal effects on myocardial performance, ablation of pulmonary vascular responses to nociceptive stimuli, and preservation of hypoxic pulmonary vasoconstriction (61,62,63).

Because of their wide margin of safety in ill infants with congenital heart disease, opioid anesthesia is often effective in ill preterm infants with cardiopulmonary instability undergoing surgical stress. Fentanyl, sufentanil, and remifentanil are the most popular agents due to their negligible effect on cardiovascular function, but if combined with other anesthetic agents, these opioids may be associated with significant hemodynamic instability. Morphine anesthesia may increase plasma histamine concentrations and decrease vascular resistance, and it is not recommended as a primary anesthetic for ill neonates (64).

The elimination half-lives of most opioids are variable but significantly prolonged in the neonate (Table 57-2) and may be further prolonged by any compromise of hepatic blood flow (65,66,67,68,69,70). The exception to this rule is the synthetic opioid remifentanil; a recent study in children showed that clearance was as much as twice as rapid in infants from birth to 2 years than in older children, and half-life was similar in all age groups studied (71). Premature infants have an even more prolonged morphine clearance than term newborns that shortens with postconceptual age (72). Prolonged postoperative respiratory depression may occur if these important pharmacokinetic variables are ignored in the perioperative period.

Regional, Neuraxial, and Local Anesthesia

Regional anesthetic techniques have become increasingly popular in the pediatric and neonatal populations (73). General anesthesia may be associated with an increased incidence of postoperative apnea in the preterm infant (74). This may be a particularly difficult issue in the day-surgery setting, where former preterm neonates commonly present for minor surgical procedures (e.g., circumcision, herniorrhaphy). It is in this population that regional or local anesthetic techniques may be particularly advantageous. The use of spinal anesthesia for herniorrhaphy decreases the need for postoperative mechanic ventilation in former preterm infants matched for gestational age at birth and incidence of bronchopulmonary dysplasia (75). Epidural anesthesia has been shown to reduce the need for postoperative ventilation after both esophageal atresia repair and Nissen fundoplication (76,77).

TABLE 57-2 ELIMINATION HALF-LIVES OF OPIOIDS

TABLE 57-2 ELIMINATION HALF-LIVES OF OPIOIDS	

	Opioid Relative Dose	Preterm	Neonate	Child
Morphine	0.1 mg	9–10 h	6.8 h	2.2 h
Fentanyl	1–5 µg	6–32 h	4.2 h	3.5 h
Sufentanil	0.2–1 µg	N/A	12.3 h	2.3 h
Alfentanil	5–25 µg	N/A	8.8 h	1.4 h
Remifentanil	0.25–1 µg	N/A	3–10 min	3–10 min
N/A, unknown.				

Spinal anesthesia consists of injection of an anesthetic agent into the subarachnoid space. The technique is easy to perform and safe (78,79). The most frequent local anesthetic agents are hyperbaric lidocaine, tetracaine, and bupivacaine. Side effects of spinal anesthesia, such as dural puncture headaches and hemodynamic compromise, are common in adults but surprisingly uncommon in infants or children (78,80).

Epidural anesthesia consists of a single injection or repeated injections through an epidural catheter of an anesthetic agent into the potential space between the dura mater and ligamentum flavum. The advantage epidural has over spinal anesthesia is the potential for long-term, continuous, or intermittent administration of anesthetics. Although the epidural space can be approached at any level, for most infants, a lumbar or caudal epidural blockade is used. Caudally inserted epidural catheters can also be advanced to the thoracic region and dilute local anesthetic solutions applied for thoracic-level anesthesia in infants, but radiographic confirmation of tip placement has been shown to be important for safety (81). Caudal epidural blockade with bupivacaine is used most frequently for postoperative pain relief after lower abdominal and lower extremity procedures. Compared with older children and adults, infants and toddlers require higher doses of local anesthetic and demonstrate a shorter duration of effect. Combining local anesthetics with an epidural opioid (fentanyl, hydromorphone), clonidine, or ketamine prolongs the duration of analgesia (82). Several case reports have suggested that epidural clonidine may contribute to postoperative apnea in the former preterm infant (83,84,85). Caudal anesthesia has been sufficient as

P.1561

the sole anesthetic technique for lower abdominal procedures (86). Caudal epidural blockade may be used in combination with general anesthesia in infants during abdominal procedures. Complications rarely result from improper placement of the needle and injection of the anesthetic agent into a vein, the dura, the subarachnoid space, or sacral marrow.

Local anesthetics may be used to block peripheral nerves in infants undergoing limited surgical procedures (e.g., orchiopexy, herniorrhaphy, circumcision). These techniques are simple to perform, have limited complications, and significantly decrease the need for postoperative analgesia (87,88,89).

Local anesthetic toxicity is manifested by effects on the cardiovascular system (e.g., myocardial depression, arrhythmias) and central nervous system (e.g., delirium, seizures) (90,91). In premature infants, the subtle behavioral changes that precede cardiovascular collapse and generalized seizures may be difficult to recognize. The reduced protein binding and prolonged elimination of local anesthetics in this population make the neonate susceptible to toxic effects at lower doses, decreasing the therapeutic index. Careful attention to total administered dose (particularly with field blocks) and monitoring of cardiovascular parameters during the administration of any local anesthetic are essential.

The topical anesthetic EMLA, a eutectic mixture of 2.5% lidocaine and 2.5% prilocaine, has shown efficacy in neonatal circumcisions (92,93), but two randomized, controlled trials have shown that dorsal penile nerve block is more effective than EMLA (94,95). EMLA is not effective in reducing pain with heel sticks, perhaps owing to the incidental vasoconstriction associated with EMLA which may require more vigorous squeezing to obtain a blood sample (96). Oral sucrose has been shown to be more effective than EMLA as analgesia for neonatal venipuncture in two randomized, controlled trials (97,98). Although methemoglobinemia is a potential side effect of EMLA, it appears to be safe even in preterm infants (99,100). A newer topical agent, amethocaine, in a 4% gel, avoids the possibility of methemoglobinemia, and its vasodilatory effects on the skin may facilitate blood sampling (101).

Propofol

Propofol, as a loading dose of 2 to 4 mg/kg, acts as a complete anesthetic with a short recovery period, similar to or even briefer than the lipid-soluble pentothal. A continuous infusion of 50 to 100 mg/kg/minute maintains anesthesia and may, when discontinued, have a shorter recovery time than that of inhalation agents. However, prolonged infusions lead to lipid deposition and persistent anesthetic effects of propofol, even with discontinuation. A recent study of propofol infusions in neonates, infants, and children showed that most newborns and children have similar propofol pharmacokinetics as adults, but that elimination is prolonged in children after cardiac surgery and in low-birth-weight infants (102). Postoperative emesis and analgesic requirements may be reduced with propofol versus pentothal-halothane. Pain at the infusion site has limited the enthusiasm for propofol. Pain can be alleviated by adding 0.2 mg/kg of lidocaine for every 3 mg/kg of propofol. The incidence of hypotension with propofol is comparable to similar agents.

Prolonged propofol infusion (3 to 5 days) has been linked to metabolic acidosis, heart failure, and death in critically ill children. Associated with these have been lipemic serum and fatty infiltration of the liver (103). Propofol may be used during the course of some anesthetics, but a recent, unpublished clinical trial showed a significantly increased mortality in children sedated with propofol, and as a result, its use for sedation of children younger than 16 years is contraindicated (104).

ANALGESIA

Opioids

The provision of adequate analgesia for painful diseases and procedures should be of utmost concern to the neonatologist (105). Despite widespread misgivings about their potential side effects, systemic therapy with opioid analgesics remains the mainstay of treatment for severe pain in neonates. The administration of opioids produces profound analgesia and sedation through specific activity on μ 1, δ , and other opioid receptors in the brain and spinal cord (106).

The dosage and mode of administration of opioids should be carefully titrated to avoid undertreatment of pain or oversedation (Fig. 57-1). Continuous intravenous infusion of opioids provides an effective alternative to intermittent intravenous doses, with constant blood levels and minimal fluctuations in analgesia. Nearly all opioids have prolonged half-lives in neonates (Table 57-2), and continuous infusions can result in a slow accumulation of the drug over time, with high blood levels that may not be considered or detected immediately. In addition, morphine has an active metabolite that can accumulate in renal insufficiency, compounding the narcotic effect. Despite this disadvantage, continuous intravenous infusion is ideal for providing a constant level of analgesia if appropriate precautions are observed.

A newer agent, remifentanil, is quickly degraded by red cell and tissue esterases, giving it an elimination half-life of about 3 minutes. Unlike the other opioids, its brief duration of action is maintained, even after prolonged continuous infusions (107). A study of remifentanil pharmacokinetics in neonates showed a similar half-life as in older children (71).

Alternative modes of administration are rarely indicated in neonates. Subcutaneous morphine or fentanyl, given as a lozenge or transdermally, is not routinely used in neonates because precise documentation of their efficacy and safety is not available. The transdermal route may be an attractive future alternative to intravenous infusions in premature neonates, particularly because the permeability

P.1562

of preterm skin is 102 to 103 times greater than the skin of term neonates (108). Oral or rectal opioids can be used in the neonate, but only if the same close monitoring provided for intravenous opioid analgesia can be given to these patients. The oral bioavailabilities of commonly used opioids are listed in Table 57-3, although these data have been derived mostly from older children and adults. The pharmacokinetics of oral opioids have not been studied in neonates, but the onset and duration of action are likely to be delayed, and close monitoring should continue for at least 24 hours after the last dose.

Figure 57-1 Modes of opioid administration. **A:** Patients given intermittent intravenous boluses every 4 hours experience deep sedative effects at peak levels after a dose, with prolonged periods of pain between doses. **B:** Patients given intramuscular injections experience less fluctuation in opioid effects but undergo alternate periods of pain and analgesia. **C:** Patients receiving continuous infusions of opioids experience constant analgesia but are at risk for a slow build-up in plasma levels, resulting in sedation or toxicity. (Adapted from Berde CB. Pediatric postoperative pain management. *Pediatr Clin North Am* 1989;36:921-940, with permission.)

Opioid side effects include respiratory depression, tolerance and dependence, alterations in chest wall compliance, decreased gastrointestinal motility, and nausea. Exogenously administered opioids may alter endogenous opioid receptor physiology and possibly influence subsequent behavioral development (24,109,110). Chronic opioid administration also has immunosuppressive effects through both direct (immune cell

receptors) and indirect (centrally mediated) mechanisms (111). However, these agents are probably the most suitable and effective analgesics currently available for treatment of severe pain in neonates.

All opioids produce dose-related respiratory depression characterized by decreased ventilatory and behavioral responses to hypoxemia and hypercarbia. The carbon dioxide response curve is displaced to the right and resting partial pressure of carbon dioxide rises. Clinically, the respiratory rate decreases with an incomplete compensatory increase in tidal volume. It is not widely appreciated that standard doses of morphine (0.1 mg/kg) almost abolish the ventilatory response to hypoxemia. In patients with airway obstruction or atelectasis after surgery, blunting of hypoxic drive can lead to dangerous hypoventilation. Opioid-induced respiratory depression can be reversed with naloxone, but the effect of this drug diminishes within 30 minutes, and repeated dosing may be required, particularly after the use of morphine or methadone (112). It was long believed that newborn infants were more prone than older children or adults to opioid-induced respiratory depression, perhaps because of an immature blood-brain barrier (113). It has been shown that opioid-induced apnea is less common in neonates than in older infants and children at similar plasma concentrations (114,115). Neonates conjugate morphine into morphine-6-glucuronide and morphine-3-glucuronide. Compared with infants and older children, however, the neonate produces less of the 6-glucuronide metabolite. Morphine-6-glucuronide is a more potent analgesic than morphine itself, and it induces less apnea. The more plentiful metabolite in the neonate, morphine-3-glucuronide, may actually antagonize the effects of its parent molecule, morphine (116,117). This may partially explain the susceptibility of the neonate to morphine-induced apnea.

Tolerance occurs if there is a reduction in the clinical effects of a drug with repeated administration. The rate of development of tolerance to the analgesic effects of opioids is extremely variable. There is evidence that tolerance may develop more rapidly in the absence of nociceptive stimulation (118). Dependence is the requirement for continued drug administration to prevent withdrawal symptoms, including agitation, dysphoria, tachycardia, tachypnea, piloerection, nasal congestion, temperature instability, and feeding intolerance. Tolerance and dependence have been described in neonatal and pediatric patients during the therapeutic use of opioids (119,120,121,122). Although tolerance to opioids may appear to develop more rapidly in neonates than at other ages, it is likely that tolerance to the sedative and cardiovascular effects of opioids may precede a tolerance to their analgesic effects (123). The predominance of the antagonistic morphine-3-glucuronide metabolite in infants may help explain their more rapid development of tolerance to morphine (124). Opioid

P.1563

tolerance may develop more rapidly with continuous infusions as compared with intermittent dosing (123,125). The development of physical dependence is quite variable, and withdrawal symptoms have been observed in infants in whom opioid administration was discontinued abruptly after periods of administration as short as 5 days (121). Fear of precipitating the abstinence syndrome should not inhibit the appropriate administration of opioids because withdrawal symptoms can be effectively managed by gradually tapering the opioid dosage over 5 to 7 days (Fig. 57-2).

TABLE 57-3 RECOMMENDED DOSAGES AND ORAL/PARENTERAL RATIOS FOR OPIOIDS

Drug	Routes of Administration	Parental Dosage (mg/kg)	Frequency (Parenteral)	Oral/Parenteral Ratio	Frequency (Oral/Rectal)
Morphine \	IM, IV, ^a SQ, po, pr, neuraxial ^b	0.05–0.2	q 1–2 h IV; q 2–4 h IM or SQ	3–6	q 4–6 h ^c ; q 8–12 h ^d
Meperidine	IM, IV, SQ, po	0.5–1.5	q 1–2 h IV; q 2–4 h IM or SQ	4	q 4–6 h
Codeine	IM, IV, ^a SQ, po	0.5–1.0	q 2–4 h	1.5–2	q 4–6 h
Hydromorphone	IM, IV, SQ, po, pr	0.02–0.04	q 2–4 h	2–4	q 4–6 h po; q 6–8 h PR
Methadone	IM, IV, SQ, po	0.05–0.2	q 12–24 h	2	q 24 h
Fentanyl	IM, IV, TM/TD, ^e neuraxial ^b	0.0005–0.003	q 1–2 h		

IM, intramuscular; IV, intravenous; po, oral; pr, rectal; SQ, subcutaneous; TM/TD, transmucosal/transdermal.

^aIV administration may be associated with significant histamine release and possible hypotension.

^bNeuraxial (i.e., epidural, subarachnoid) administration can be performed only by qualified and experienced anesthesiologists.

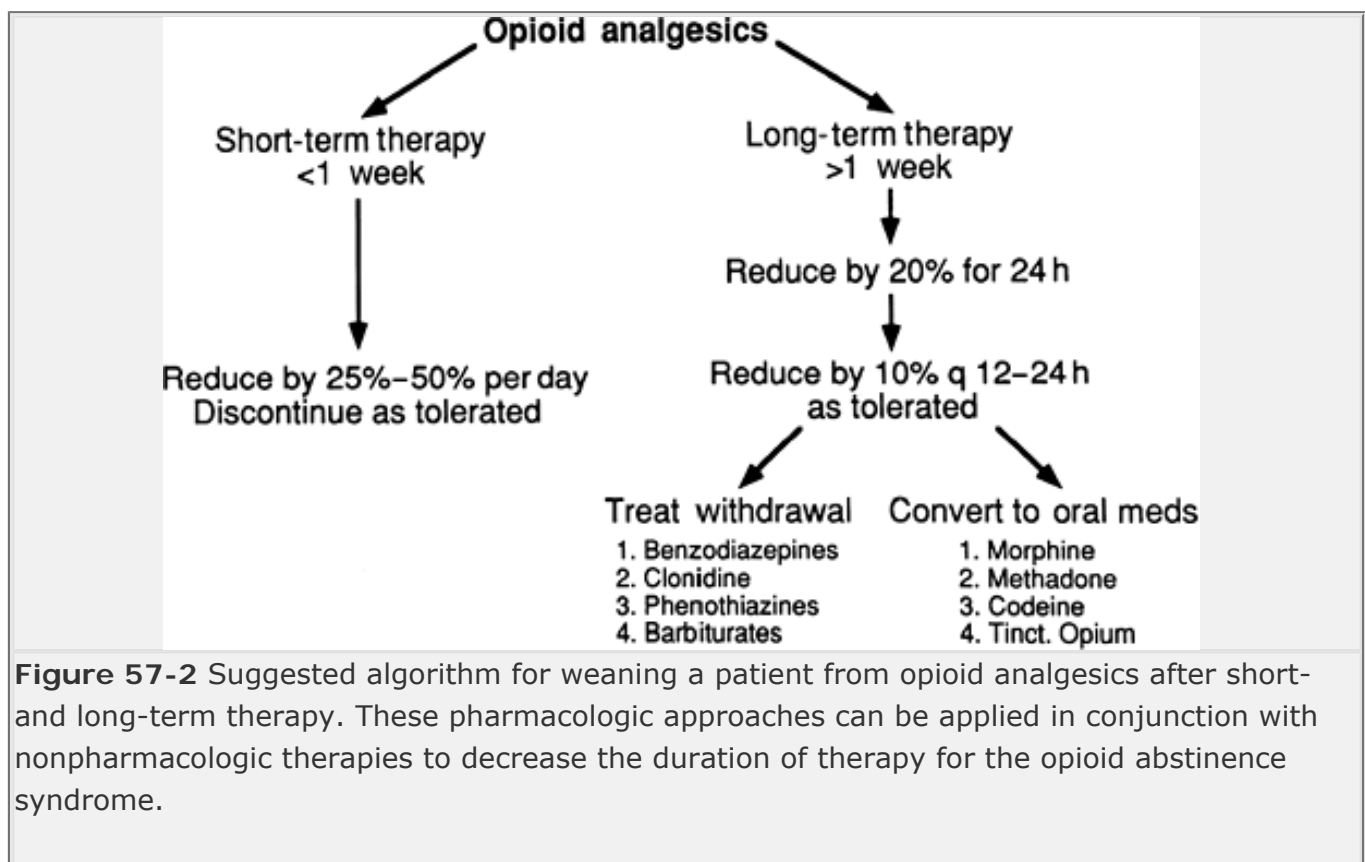

^cPertains to regular oral preparations (e.g., MSIR, Roxanal; tablets and oral solutions).

^dPertains to slow-release oral or rectal preparations (e.g., MS Contin, Duramorph, Roxanol SR).

^eTM/TD preparations have not been standardized for use in full-term or preterm neonates.

Dependence is a set of physiologic responses that should be differentiated from addiction, which is a behavioral syndrome of compulsive drug seeking. Addiction is extremely rare in patients of all ages receiving opioids for pain or sedation, and fear of addiction should not affect the appropriate treatment of acute pain or agitation in neonatal intensive care.

Opioids increase airway resistance, and there is much debate about the effect of histamine release on bronchial smooth muscle and whether histamine-releasing agents such as morphine are contraindicated in patients with reactive airway disease (126). Although intravenous morphine releases greater amounts of histamine than fentanyl, precipitation of bronchospasm has not been reported after the administration of morphine (64). Intravenous morphine has been used frequently in patients with severe asthma requiring mechanic ventilation, based on evidence that it might inhibit bronchoconstriction and mucous hypersecretion (127,128,129).

Chest-wall rigidity is a well-described complication of opioid administration and has been documented in patients receiving large doses of fentanyl, sufentanil, or alfentanil (44,130,131). The administration of 30 mg/kg of fentanyl in tracheostomized patients produced a minor increase in total lung compliance, suggesting that inability to maintain a mask airway during fentanyl administration is due to supraglottic obstruction and not chest-wall rigidity (132,133). Rigidity has occurred at an average dose of 15 to 17 mg/kg of fentanyl (132,133). There are no controlled data available in term or preterm neonates receiving fentanyl. However, clinical experience indicates that chest-wall rigidity may occur at significantly lower opioid doses in the neonate. The mechanism that mediates this phenomenon may involve μ_1 opioid receptor modulation of gamma-aminobutyric acid pathways in the spinal cord. Rigidity on induction of anesthesia is avoided by pretreatment with a subrelaxant dose of pancuronium (0.01 to 0.02 mg/kg) and by slow intravenous infusion of the opioid (130, 134,135).

All opioids delay gastric emptying, decrease intestinal motility, produce nausea by direct

stimulation of the chemoreceptor trigger zone, and increase common bile duct pressure. Impaired absorption of enteral nutrients is undesirable in neonates, and opiate-induced ileus may increase the risk of regurgitation and aspiration of gastric contents. One case report described a newborn given

P.1564

morphine who developed a reversible and nonobstructive dilation of the common hepatic duct that resolved after morphine was discontinued (136). Although such side effects are mediated by means of μ opioid receptors, they may occur with high doses of opioids devoid of μ_2 activity (e.g., fentanyl) as a result of nonspecific effects on all opioid receptors.

Nonopioid Agents

There are many nonopioid agents available for the treatment of mild pain or use as adjuvants for decreasing the doses and potential side effects of opioid drugs. Various other analgesic agents can be used systemically for providing sedation or in combination with regional and topical analgesia to produce effective analgesia while minimizing the side effects of any single agent.

Acetaminophen

Acetaminophen (N-acetyl-p-aminophenol) is used commonly in all age groups as an antipyretic and analgesic. Its use in neonates has been limited by misconceptions about its metabolism, excretion, and potential for hepatotoxicity. Experimental data and clinical experience have supported the relative safety and analgesic efficacy of acetaminophen in newborn infants, without the significant side effects on platelet aggregation, the ductus arteriosus, or the gastric mucosa, commonly seen with aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs) (137).

The hepatic metabolism of acetaminophen occurs primarily by sulfation or glucuronidation, but a small fraction is oxidized by the cytochrome P450 mixed-function oxidase system into an arene compound (i.e., a reactive metabolite), which is conjugated with glutathione before excretion (138,139). In acute toxicity, the hepatic stores of glutathione are depleted rapidly, and this reactive metabolite binds irreversibly to membrane proteins, leading to liver cell necrosis. In the newborn or fetal liver, this metabolic pathway is seven to ten times slower than in the adult liver and occurs well after the development of glutathione synthesis, mediating a protective effect in fetal hepatocytes (140). These experimental data have been substantiated by the absence of hepatic dysfunction in clinical reports of neonatal poisoning with acetaminophen (141,142). The clinical use of acetaminophen in term or preterm neonates should not be overly restrained by concerns about its potential hepatotoxicity.

Acetaminophen has many potential advantages as an analgesic in neonates. It has approximately the same analgesic efficacy as 0.5 to 1.0 mg/kg of codeine, and the analgesia is generally thought to be additive to that provided by opioids. It is effective at reducing pain after circumcision but does not reduce the pain with heel stick (143,144). Recent data from a randomized, double-blind, controlled trial indicate that prophylactic use of rectal acetaminophen up to 40 mg/kg for elective cleft-palate repair had no opioid-sparing effect in the immediate postoperative period and failed to produce therapeutic serum acetaminophen levels, calling into question both the dosing of rectal acetaminophen in the operative period and its additive effects with the opioids (145). Acetaminophen produces no respiratory depression, and tolerance to acetaminophen-induced analgesia has not been reported. It can

be given rectally in doses of 20 to 25 mg/kg, avoiding the need for intravenous lines in infants who cannot be given oral medications.

Nonsteroidal Antiinflammatory Drugs

The NSAIDs are a group of drugs with many actions, including potent analgesic and antiinflammatory properties. The antiinflammatory effects are mediated through inhibition of prostaglandin synthesis by means of the cyclooxygenase pathway. Several NSAIDs have been used in pediatric patients, although data pertaining to neonates are scarce and come from uncontrolled clinical reports (146). Indomethacin and ibuprofen are the most commonly prescribed NSAIDs, but drugs such as ketorolac tromethamine, tolmetin, and naproxen are being used with increasing frequency.

The toxicity of NSAIDs limits their potency and clinical usefulness as analgesics (147). Major toxicity is related to gastrointestinal bleeding, hepatotoxicity, blood dyscrasias, decreased renal and splanchnic perfusion, and severe skin reactions. Because of the chemical diversity of NSAIDs, adverse reactions to a particular NSAID do not predict similar reactions to other drugs in the class. Significant advantages include the low incidence of side effects in judicious analgesic doses (Table 57-4), absence of respiratory depression or sedative effects, relatively long duration of analgesia, and lack of tolerance or potential for abuse. Selective cyclooxygenase-2 (COX-2) inhibitors are designed to avoid the gastrointestinal and antiplatelet side effects of the classic NSAIDs, but these have not been studied in infants or children.

NONPHARMACOLOGIC TECHNIQUES

Neonatal pain may be reduced by using a variety of nonpharmacologic methods. Several studies have shown that intraoral sucrose or glucose is effective for reducing pain associated with procedures such as heel stick, circumcision, venipuncture, and subcutaneous injection in term and preterm infants (148,149,150,151,152). The antinociceptive effects of sucrose appear to be opioid receptor mediated. Sucrose's antinociceptive properties in rats can be reversed with naltrexone administration (153). However, neonates born to mothers on methadone do not appear to derive analgesic benefits from sucrose (154). Infant formula and its components (protein, fat, sucrose, but not lactose) also have shown antinociceptive properties (155). In a randomized, controlled trial, breastfeeding has been shown to reduce pain associated with newborn heel stick as much as sucking glucose on a pacifier (156).

TABLE 57-4 RECOMMENDED DOSES FOR NONSTEROIDAL ANTI INFLAMMATORY DRUGS

Drug	Dosage (mg/kg)	Routes of Administration	Frequency
Acetaminophen	10–15	po, pr	q 4–6 h
Aspirin	10–15	po	q 4 h
Choline-magnesium trisalicylate	10–15	po	q 6–8 h
Ibuprofen	5–15	po, pr	q 6–8 h
Naprosyn	5–7	po	q 8–12 h
Tolectin	5–7	po	q 8–12 h
Ketorolac tromethamine	0.3–0.6	po, IM, IV	q 6–8 h

Facilitated tucking, by holding the neonate's extremities flexed and close to the trunk, lowered the heart rate and produced less crying (157). Nonnutritive sucking, enhanced by the use of a pacifier, reduces the physiologic response to circumcision pain and is synergistic with the effects of intraoral glucose or sucrose (151,158). Clearly, nonpharmacologic techniques to reduce pain should be sought whenever possible because of their effectiveness coupled with a rarity of side effects.

SEDATION

The goals of sedation in the intensive care unit include analgesia for painful diseases and procedures and compliance with controlled ventilation and routine care. The ideal agent would not have hemodynamic or pulmonary side effects and would not be associated with the production or accumulation of toxic metabolites. It would have a short duration of action and a high therapeutic index. The wide variety of medications and combinations of agents that have been used suggests that no single agent meets this ideal standard. Opioids have become exceedingly popular due to their relatively high toxic-to-therapeutic ratio, reported lack of side effects, and potent analgesic properties. Although opioids are considered the mainstay of sedation in the intensive care setting, tolerance to their sedating effects may occur rapidly, and adequate sedation for prolonged periods can be ensured only by administration of adjuvant sedative agents (121,159).

Benzodiazepines

The benzodiazepines have a variety of desirable clinical effects that include hypnosis, anxiolysis, anticonvulsant activity, anterograde amnesia, and muscle relaxation. The amnestic properties of benzodiazepines may be affected by the clinical status of the patient before administration. In the presence of a painful stimulus, the benzodiazepines may produce hyperalgesia and agitation (159,160,161,162). These problems usually do not occur if benzodiazepines are combined with opioids.

Benzodiazepines act on specific receptors, located mainly in the cerebral cortex, hypothalamus, cerebellum, corpus striatum, and medulla oblongata, which are coupled to gamma-aminobutyric acid receptors by means of a common chloride channel in synaptic membranes (163). Early pharmacokinetic data showed that the half-lives of diazepam and its active metabolites were markedly prolonged in neonates (164). Diazepam is used commonly for sedation in neonates, with doses of 0.1 to 0.3 mg/kg given every 4 to 6 hours. Doses as high as 50 mg/kg/day have been used to treat neonatal tetanus, with a low incidence of side effects (165). Diazepam has no analgesic effects, and it causes respiratory depression and mild hypotension, both of which are potentiated by opioids and other sedatives. Prolonged use may produce tolerance and withdrawal. In preterm neonates, doses as high as 0.5 mg/kg were associated with cardiovascular stability and no alteration in cerebral blood flow (166).

Lorazepam is five to ten times more potent than diazepam. In doses of 0.05 to 0.1 mg/kg, therapeutic levels may persist for 24 to 48 hours. Oral administration results in reliable absorption, with maximal plasma concentrations in 2 to 4 hours. Although lorazepam is insoluble unless combined with an organic solvent, it is suitable for intramuscular or intravenous injection and causes much less tissue irritation than diazepam (167). Lorazepam

is glucuronidated to form inactive metabolites. Its elimination half-life is 10 to 20 hours, but clinical effects may be prolonged because of its pharmacodynamic differences from the other benzodiazepines. The cardiovascular and respiratory effects of lorazepam are similar to those of diazepam. Lorazepam should be used judiciously for sedation in the intensive care setting because of prolonged effects on mental status and respiratory drive. Unlike the other benzodiazepines, it contains polyethylene glycol 400 in propylene glycol, which causes an elevated osmolar gap,

P.1566

metabolic acidosis, and can be nephrotoxic when large amounts of lorazepam are given as a continuous infusion, particularly in patients susceptible to renal injury (168). Lorazepam infusions can lead to significant metabolic acidosis and acute renal insufficiency in term and preterm infants, and some guidelines advise to avoid these infusions in infants under 6 months of age. There have been case reports of lorazepam triggering myoclonus and seizures in neonates (169).

Midazolam, a water-soluble and shorter-acting benzodiazepine, has been used in neonates requiring sedation, alone or combined with opioid analgesics such as fentanyl. Loading doses of 0.2 mg/kg and continuous infusions of 0.4 mg/kg/minute of midazolam were used in patients weighing as little as 3 kg and provided good sedation without any apparent adverse effects (170). At the benzodiazepine receptor, midazolam has twice the binding affinity of diazepam and inhibits gamma-aminobutyric acid reuptake. The pharmacokinetics of midazolam in neonates are characterized by rapid redistribution, plasma clearance of 6.9 mL/kg/minute, and elimination half-life of 6.5 hours, which is significantly longer than the elimination half-life reported for older infants and children (171,172).

After prolonged intravenous therapy with midazolam, a withdrawal syndrome has been described in infants, which is characterized by agitation, poor visual tracking, constant choreoathetoid and dyskinetic movements of the face, tongue, and limbs, and depression of consciousness (173,174,175). Midazolam may be used intermittently as premedication for specific invasive procedures in doses of 0.05 to 0.2 mg/kg, for short-term sedation by continuous infusion (less than 12 hours) at rates of 0.025 to 0.05 mg/kg/hour, or for longer term sedation of the intubated patient at rates starting at 0.05 mg/kg/hour. After 12 hours, the 1- and α -hydroxymidazolam metabolites that have longer half-lives begin to accumulate, and midazolam's duration of action is prolonged. The respiratory depression and hypotension caused by benzodiazepines are synergistic with the similar effects of potent opioids. Midazolam and fentanyl given by rapid intravenous injection may cause severe, life-threatening hypotension and cardiorespiratory arrest (176). This combination should be used with extreme caution in neonates and only with close monitoring in an intensive care unit.

Flumazenil, a short-acting benzodiazepine antagonist, can be used as a bolus of 10 mg/kg followed by an infusion (5 mg/kg/minute) to reverse the effects of the benzodiazepines. Rapid reversal of the benzodiazepines can trigger seizures in susceptible patients.

Barbiturates

Phenobarbital has long been used as an anticonvulsant in newborns and children, although its routine use for sedation has been discouraged because of several drawbacks. Phenobarbital has hyperalgesic effects and may increase the requirement for analgesia, and rapid tolerance to its sedative action invariably occurs (177). It has a prolonged elimination half-life in neonates (5 to 6 days), and it may increase the risk of intraventricular hemorrhage in

premature neonates (178,179). Phenobarbital has no specific antagonist, and prolonged use is associated with microsomal induction of hepatic enzymes and with a withdrawal syndrome. Its advantages in neonates include increased bilirubin metabolism, relatively mild cardiovascular and respiratory depression, and familiarity with its usage in preterm and term neonates. In ventilated preterm neonates, the changes in mean arterial pressure and intracranial pressure associated with endotracheal suctioning were blunted with phenobarbital therapy (180). A neonatal dose-response study found increasing degrees of sedation and feeding difficulties with increasing serum phenobarbital concentrations. These responses were greater in preterm neonates than in term neonates (181). Loading doses of 5 to 20 mg/kg and maintenance doses of 2.5 mg/kg every 12 hours, given orally or intravenously, are generally used for sedation.

Pentobarbital is a shorter-acting barbiturate than phenobarbital with a half-life of 19 to 34 hours in adults. It is useful as an adjunct for sedation of the intubated infant and child, particularly when tolerance has led to rapid escalations of narcotic and benzodiazepine infusions to continue an appropriate and safe level of sedation. One clinical practice guideline for sedation of the intubated infant and child suggests adding intermittent doses of 2 to 6 mg/kg of pentobarbital every 4 hours when infusions of morphine and midazolam begin to exceed 0.5 mg/kg/hour each. Pentobarbital is associated with both tolerance and withdrawal and is generally discontinued in a "last-on, first-off" fashion when sedation is being weaned. Pentobarbital causes more hypotension than most other sedatives used in the infant and child; slower infusions over 15 to 30 minutes reduce this side effect. Like lorazepam, pentobarbital is mixed in propylene glycol, and continuous infusions may precipitate metabolic acidosis and nephrotoxic effects, particularly in patients susceptible to renal injury.

Chloral Hydrate

Chloral hydrate is used frequently as a sedative in doses of 25 to 50 mg/kg or as a hypnotic in doses of 50 to 100 mg/kg for short procedures in neonates and for infants with chronic lung disease (182). Higher doses may be required after repeated use in neonates because of the slow development of tolerance. The advantages of chloral hydrate include ease of administration (e.g., oral syrup, rectal suppositories), although repeated doses can be irritating to the enteral mucosa; lack of respiratory depression; lack of other side effects (e.g., emesis, changes in vital signs or behavior) with usual therapeutic doses; and familiarity with its use in newborns and older infants (183,184). However, an infant who received 165 mg/kg of chloral hydrate over 16 hours developed the toxic reactions of respiratory depression and lethargy (185). Other reports have documented complications such as direct hyperbilirubinemia, decreased tidal volume, hypertriglyceridemia, acute

P.1567

laryngeal edema, and cardiac arrhythmias (e.g., supraventricular tachycardia) in neonates and infants (186,187,188,189,190). One of its metabolites, trichloroethylene, has been described as carcinogenic with chronic exposure (191).

The sedative action of chloral hydrate may be mediated by generalized neuronal depression, similar to other halogenated hydrocarbons. A precise mechanism of action is unknown, and there is no specific antagonist. The pharmacokinetics of chloral hydrate are not clearly defined in neonates. Onset of clinical effects after oral dosage occurs at 30 minutes, and its duration of action is usually 2 to 4 hours, depending on the exact doses used.

Ketamine

Ketamine is a dissociative anesthetic that has been used as an induction agent for anesthesia, analgesic for conscious sedation, premedication before induction of anesthesia, and sedative for critically ill patients. There is a broad range of experience with this agent in older patients, but limited experience in infants and newborns (192,193). Ketamine has been used to provide anesthesia in the spontaneously breathing, nonintubated newborn and causes less neonatal neurobehavioral depression than thiopental after maternal administration for vaginal delivery (194,195). Ketamine produces reliable serum levels within 1 minute when administered intravenously or within 5 minutes when administered intramuscularly, and it is rapidly redistributed, with awakening occurring in 10 to 15 minutes. In neonates, the elimination half-life is significantly longer than 130 minutes, which has been reported in older children and adults (196,197). Extensive hepatic biotransformation necessitates higher doses when administered orally or rectally.

Tolerance and hepatic enzyme induction have been demonstrated during chronic administration of ketamine. Cross-tolerance with opiates has been demonstrated in animals, but convincing evidence from human studies is lacking (198,199). The precise site of action of ketamine is unknown, despite suggestions that ketamine may interfere with excitatory transmission by means of N-methyl-D-aspartate receptors (200). The anesthetic effects of ketamine have been attributed to electrophysiologic dissociation between the thalamoneocortical and limbic systems. Other clinical effects at anesthetic plasma concentrations include catalepsy, nystagmus, hypertonicity, and nonpurposeful movements. Ketamine is a potent stimulator of the cardiovascular system, presumably by means of central sympathetic effects and inhibition of catecholamine reuptake (201). Compared with isoflurane, halothane, and fentanyl, ketamine had the least effects on mean arterial pressure in ill preterm neonates undergoing surgery (202). Pulmonary vascular resistance does not appear to be altered in infants with or without preexisting pulmonary hypertension (203). For critically ill patients with moderate hypovolemia, low doses of ketamine (i.e., 0.5 to 1 mg/kg) are safer than barbiturates as rapid induction agents before tracheal intubation.

CLONIDINE

Clonidine is an α_2 -adrenoreceptor agonist, and its receptor activation in the locus coeruleus of the brain leads to decreased sympathetic outflow and a resulting antihypertensive effect. In addition to its antihypertensive actions, clonidine has both sedative and antinociceptive effects as well. The mechanisms for these effects are less well understood, but both appear to be mediated through α_2 -receptor action because they are blocked by α_2 -antagonist drugs (204). Animal data has shown that the same potassium channels activated by μ opioid receptor agonists are also activated by α agonists, and these effects seem to be mediated via different G-proteins (124). Clonidine has been used as a component of epidural anesthesia because of its synergistic effects with local anesthetics. In addition, oral or transdermal administration at initial doses of 5 μ g/kg/day is useful as an adjunct for sedation of the critically ill infant and child. Transdermal delivery is limited in the neonate because the smallest patch (TTS-1 providing 100 μ g/day) can be halved for the 10-kg child but cannot easily be quartered. An oral suspension of clonidine is not commercially available but can be prepared by guidelines in the literature; dosing of 5 μ g/kg/day divided into two or three times per day is effective. Doses which provide sedative and analgesic effects without accompanying hypotension are easily achievable (205). The mild antihypertensive effect contributes to the usefulness of clonidine in combating narcotic, benzodiazepine, and barbiturate withdrawal syndromes.

SUMMARY

The proper approach to sedation includes an individualized regimen, which ensures analgesia with careful consideration of the important pharmacokinetic and pharmacodynamic differences in the neonatal population. Analgesia and sedation are needed for neonates undergoing stressful or painful procedures required for essential monitoring and therapy in intensive care. Safe and effective techniques are available that can be used in a variety of clinical circumstances. As the International Evidence-Based Group for Neonatal Pain concluded in their recent consensus statement, universal attention to standard guidelines for neonatal pain control “will not only improve the clinical care provided to all neonates, but may also have a positive impact on their subsequent health and behaviors during childhood and adolescence” (18).

Chapter 58

The Infant of the Drug-Dependent Mother

Enrique M. Ostrea Jr.

J. Edgar Winston Cruz Posecion

Maria Esterlita-Uy

T. Villanueva

The problem of drug abuse has reached epidemic proportions during the past two decades, with increases not only in the number of drug users but also in the types of drugs abused. Equally alarming is the increase in the proportion of drugs users among women of childbearing age or are pregnant, because the effects of drugs on the pregnancy and fetus can be far reaching. In this chapter, the latter will be addressed. Existing information in the literature on the maternal, neonatal, and long-term complications in infants of drug use during pregnancy will be consolidated plus a brief historical and epidemiologic perspective of the problem. There will be many instances in which the data presented are conflicting. This reflects the limitations of studies on human population, because of the influence of many confounding factors especially multiple drug use, socioeconomic status, environmental factors, parental education and psychopathology.

EPIDEMIOLOGY

In 2001, the National Household Survey on Drug Abuse estimated that 15.9 million (7.1%) Americans of age 12 years or older were current illicit drug users (1). This represents an increase from 6.3 percent in 1999 and 2000 (Table 58-1). Between 2000 and 2001, statistically significant increases were also noted for the current use of marijuana (4.8%-5.4%), cocaine (0.5%-0.7%), psychotherapeutic drugs (1.7%-2.1%) and hallucinogens (0.4-0.6%). Current heroin use was estimated at 0.1%. Marijuana was the most commonly used illicit drug.

Approximately 56% consumed only marijuana, 20% used marijuana and another illicit drug, and the remaining 24% used an illicit drug but not marijuana in the past month. Thus, about 44 percent of current illicit drug users in 2001 (7 million Americans) used illicit drugs other than marijuana and hashish, with or without using marijuana as well.

The rate of drug use substantially varied by age. Among youths 12 to 17 years of age, 10.8% were current illicit drug users which tended to increase with age and peaked at age 18 to 20 years (22.4%). By race, the rate of current illicit drug use

was 7.4% for blacks, 7.2% for whites (6.1%), and 6.4% for Hispanics. The rate was highest among American Indians/Alaskan natives (9.9%). As in prior years, men continue to have a higher rate of current illicit drug use than women (8.7% vs. 5.5%). Illicit drug use remains highly correlated with educational status and employment. Those who did not complete a high school education had the highest rate of use (7.6%) compared to college graduates (4.3%). Similarly, the rate of illicit drug use was 17.1% among unemployed adults (18 years of older) compared to 6.9% of full time employed adults. Among pregnant women, aged 15 to 44 years, 3.7% reported using illicit drugs. The rate was highest among pregnant women aged 15 to 17 years (15.1%). Rates of illicit drug use among pregnant women aged 18 to 25 and 26 to 44 years were 5.6% and 1.6%, respectively. The rates of current illicit drug use were similar for white (4.0%), black (3.7%), and Hispanic (3.3%) pregnant women. However, the true prevalence of illicit drug use among pregnant women is difficult to determine, as a result of significant underreporting of drug use by these women. One study, based on a survey using maternal history, urine toxicology, or both, of predominantly urban hospitals, gave an estimate of drug use among pregnant women as 0.4% to 27%; cocaine use ranged from 0.2% to 17%. With the use of a more sensitive drug screening method (e.g., meconium drug test), a 44% prevalence of illicit drug use was found among pregnant women in a high risk center in contrast to 11% by maternal self-report and 30% of the infants were positive for cocaine (2). The association of illicit drug use with HIV infection in pregnant women is high. Use of hard drugs was 42% in a cohort of HIV-infected pregnant women and was further associated

P.1573

with positive maternal HIV culture at delivery and perinatal transmission (3).

TABLE 58-1 ILLICIT DRUG USE AMONG PERSONS 12 YEARS OR OLDER BY DRUG (1999–2001)

	1999	2000	2001
Any illicit drug	6.3%	6.3%	7.1%
Marijuana	4.7%	4.8%	5.4%
Psychotherapeutic	1.8%	1.7%	2.1%
Cocaine	0.7%	0.5%	0.7%
Hallucinogen	0.4%	0.4%	0.6%
Inhalants	0.3%	0.3%	0.2%

NARCOTICS

The term "opiate" or "narcotic" refers to any natural or synthetic drug that has morphine like pharmacologic actions. The natural opiates include morphine and codeine, whereas the synthetic opiates include heroin, methadone, propoxyphene (Darvon), pentazocine (Talwin), meperidine (Demerol), oxycodone (Percodan, Tylox, Vecodine, Percocet), hydromorphone (Dilaudid), and fentanyl (Immovar, Sublimaze). Chronic use of narcotics, even in therapeutic doses, results in addiction, which is characterized by psychological and physical dependence on the drug.

HISTORY

Opium use probably dates back to about 6,000 years. One of the earliest references to opiate complications in the perinatal period was made by Hippocrates, who mentioned "uterine suffocation" as possibly secondary to opium use. By the late nineteenth and early twentieth century, reference to the passively addicted neonate is evident from reports describing the diffusion of morphine through the placenta and transmission through the breast milk (4). The naturally occurring opiates, morphine and codeine, are derived from the seeds of the unripe poppy plant, *Papaver somniferum*, and were consumed for their narcotic and analgesic properties. Heroin (diacetylmorphine), a semisynthetic opioid, was first introduced in 1874. It became popular because of the rapid onset of its central nervous system (CNS) effects. By 1950, heroin had supplanted morphine as the drug of choice among abusers (5). It is available illicitly in bags containing up to 40 to 50 mg of the active ingredient, cut or diluted variably with quinine, lactose, starch, lidocaine, or even powdered milk. Methadone was first synthesized in 1945. It is longer-acting than heroin, and can be administered orally. These properties render it the drug of choice for replacement therapy of heroin addicts undergoing detoxification. Because Dole and Nyswander (6) advocated the use of methadone in maintenance treatment programs, it has become the most widely used and studied opiate in pregnancy. However, methadone treatment of the opioid dependent pregnant woman has also led to significant withdrawal in the infant (7).

Almost all narcotics taken by the pregnant woman cross the placenta and enter the fetal circulation. Thus, the fetus is chronically exposed to these drugs and can develop problems in utero and after birth. Although the development of passive addiction is the most commonly known fetal complication of morphine, many other important problems are encountered (Table 58-2).

ANTENATAL PROBLEMS

Intrauterine asphyxia is perhaps the single greatest risk to the fetus of a drug-dependent woman based on reports of a high incidence of stillbirths, meconium-

stained amniotic fluid, fetal distress, non reactive stress test, low Apgar score, and neonatal aspiration pneumonia (8,9,10,11,12). The predisposition of the fetus to asphyxia underscores the need for repeated evaluation of fetal well-being during the course of the pregnancy of the drug dependent woman. Fetal asphyxia may be secondary to a number of factors. Studies using methadone in a fetal lamb model suggest that opiates affect both quiet and rapid-eye-movement (REM) sleep, which lead to a hyperactive state that causes a 20% increase in fetal oxygen consumption (13). Sleep disturbances, consisting of more REM and less quiet sleep, have been observed in newborn infants chronically exposed in utero to low doses of methadone with or without concomitant heroin usage (14,15). Another possible cause of fetal asphyxia is fetal withdrawal, which usually coincides with the mother's withdrawal. Fetal withdrawal leads to fetal hyperactivity, increase in catecholamine release, increase in oxygen consumption and, if not adequately compensated for, fetal asphyxia (16). In a lamb model, withdrawal was induced in the morphine-exposed fetal lamb by the administration of naloxone, an opiate antagonist. Manifestations included immediate bradycardia associated with transient increases in systolic and diastolic blood pressure, rapid, continuous deep breathing movements, increased total body movements, eye movements and neck tone, and desynchronization of electrocortical activity (15). A high incidence of preeclampsia, abruptio placentae and placenta previa in the pregnant addict also predispose to placental insufficiency and fetal distress (7).

Meconium-stained amniotic fluid is frequently encountered in the pregnant addict and is a manifestation of fetal distress (7). Aspiration of meconium as a result of fetal distress may account for the increased frequency of meconium aspiration syndrome and persistent pulmonary hypertension of the newborn after birth.

Intrauterine infection is another risk in the fetus of a drug addict. Because of the life-style of the pregnant addict of

P.1574

P.1575

P.1576

trading sex for drugs, she is predisposed to infections, particularly of sexually transmitted diseases such as syphilis, gonorrhea, hepatitis and HIV infection, all of which can be transmitted to her fetus (2,17,18). During delivery or before labor, the increased incidence of premature membrane rupture in the pregnant addict further exposes the fetus to the risk of nonspecific infections (7). Opiates may also compromise immune functions in the fetus through its adverse effect on cell-mediated and humoral immune responses (19,20).

TABLE 58-2 SUMMARY OF PERINATAL AND LONG TERM COMPLICATIONS ASSOCIATED WITH FETAL EXPOSURE TO DRUGS

Drugs	Antenatal	Intrapartum	Neonatal	Long Term
Narcotics (morphine, heroin, methadone)	Stillbirth	Fetal distress	Prematurity	Persistence of withdrawal
	Spontaneous abortion	Low Apgar score	Low birth weight	Child neglect and abuse
	Fetal asphyxia	Neonatal depression	Small-for-gestational-age (SGA)	Sudden infant death Syndrome (SIDS)
	Maternal infection	Meconium stained fluid	Aspiration pneumonia	Psychomotor delay
	Premature rupture of membranes (PROM)		Meconium aspiration	Strabismus/nystagmus
			Persistent pulmonary hypertension (PPHN)	Behavior problems, e.g., hyperactivity, aggression, inattention, impulsiveness, short attention span
			Transient tachypnea	Language problems
			Hyaline membrane disease	Preschool — problems in perception, short term memory and organization
			Minor congenital anomalies	
			Altered sleep pattern	
			Thrombocytosis	
			Abstinence syndrome	
			Abnormal Brazelton Neonatal Assessment Scale (BINAS)

intoxication

Alcohol	Spontaneous abortion Aneuploidy Stillbirth Breech presentation IUGR Abnormal fetal heart rate pattern Decreased fetal breathing, eye and body movement	Abruptio placenta Premature labor Precipitous or dysfunctional labor Meconium stained fluid	Prematurity Low birth weight SGA, symmetric Abstinence syndrome Facial dysmorphism Fetal alcohol syndrome Fetal alcohol effect Abnormal BNAS Abnormal EEG in sleep state	Growth deficits in weight, length, head circumference Low Bayley scores Low Fagan scores Hyperactivity and attention deficit Language problem Behavior problem Poor academic achievement (low aptitude score) Adolescent: difficulty in tasks involving manipulation of information, goal management, attention, memory, calculation, estimation test Fine tremors Disrupted sleep patterns Poor abstract/visual reasoning, poor memory and verbal skills at age 3—4 yrs Poor motor skills, short length of
Marijuana			Prematurity Increase in male births Abnormal BNAS	

Nicotine	Spontaneous abortion Stillbirth Placental decidual necrosis and calcification	Abruptio placenta Premature labor	Decrease in birth weight, length, head circumference Congenital heart defect, aortopulmonary septum defect, cheilognathopalatoschisis, deformities of the extremities, polycystic kidney, gastroschisis, skull deformities Persistent pulmonary hypertension Abnormal BNAS	play at age 3 years Abnormal attention behavior Small risk for SIDS Low test scores in cognitive, psychomotor, language and general academic achievement, including reading, mathematics Risk for prepubertal onset conduct disorder and adolescent onset drug dependence Sudden infant death syndrome
Phencyclidine	Intrauterine growth retardation,	Precipitous labor Meconium stained fluid	Drug intoxication (irritability, tremors, hypertonicity, poor attention, bizarre eye movements, staring spells, hypertonic ankle reflexes, depressed grasp and rooting reflexes. Sudden, rapid change in level of consciousness, with lethargy alternating with irritability)	Temperament and sleep problems

Amphetamine, methamphetamine	Fetal death Retroplacental hemorrhage	Prematurity Neonatal death Drug intoxication (abnormal sleep patterns, tremors, poor feeding, hypertonia, sneezing, high-pitched cry, frantic fist sucking, loose stools, fever, yawning, tachypnea, hyperreflexia and excoriation)	Decrease in IQ at 4 years (Terman Merrill method) Aggressive behavior and peer- related problems Poor academic performance and various behavioral problems in adolescent children
Caffeine	Small risk for spontaneous abortion Reduced fetal growth	Cardiac arrhythmias Potential abstinence syndrome, (jitteriness, irritability, vomiting)	

NEONATAL PROBLEMS

Prematurity and Low Birth Weight

Infants born to mothers on heroin have a higher incidence of prematurity, low birth weight, small for gestation, and small head circumference (between the 3rd and 5th percentile) than drug-free control subjects (20,21,22,23,24 and 25). One mechanism for the fetal growth restriction in narcotic addiction may be the effect of opiates stimulating opiate kappa receptors which inhibit acetylcholine release in the placenta. Acetylcholine is responsible for increasing placental blood flow through vasodilatation and facilitating the transport of amino acids across the placenta (26).

On the other hand, the birth weight of infants whose mothers were on methadone have varied from being higher (27) or lower (24) than the infants of untreated pregnant addicts, or not significantly different from the general newborn population (22). Higher birth weights probably reflect the good prenatal care that the woman receives in a methadone program. On the other hand, studies on pregnant rats exposed to methadone have shown their offspring to have significantly lower body weight, length, head diameter, and organ weight (28), and impaired brain development (29) and thermoregulation (30) compared to non-methadone-exposed pups. Women who reduced their methadone dose during pregnancy delivered infants of significantly higher birth weight than those whose methadone dose remained the same or were increased (31). A meta-analysis of opiate use and birth weight showed a mean reduction of 489 g associated with heroin use, 279 g with methadone use and 557 g on combined heroin and methadone use. These findings suggest that concurrent use of heroin although on methadone treatment counteracts the birth weight advantage gained from methadone alone (32).

Low Apgar Score

There is a high incidence of low Apgar score in infants of drug-dependent mothers. This may be related to intrauterine asphyxia (see Antenatal Problems) or to the effects of narcotics which the mother received before delivery. Not infrequently, the pregnant addict will obtain a heroin fix before entering the hospital, which can depress the infant. Significantly large amounts of morphine have been found in the urine and cord blood of infants born to these women (6). Caution must therefore be exercised with the use of narcotic antagonists to reverse the respiratory depression in drug-dependent infants, because the narcotic antagonists can precipitate an acute withdrawal in the infant.

Others

In addition to withdrawal, other problems are seen with increased frequency in the infant of a drug-dependent mother: jaundice, aspiration pneumonia, meconium aspiration, persistent pulmonary hypertension of the newborn, transient tachypnea,

hyaline membrane disease, congenital malformations, and infections (7). These problems are significant because they are the principal causes of death in these infants.

Aspiration pneumonia, hyaline membrane disease, and transient tachypnea are the leading pulmonary problems in the infant of the drug-dependent mother. About 30% of aspiration pneumonia is as a result of meconium aspiration (7). Transient tachypnea may be secondary to the inhibitory effects of narcotics on the reflex clearing of fluid by the lungs (33). The high incidence of hyaline membrane disease among infants of drug-dependent mothers is likely as a result of prematurity. What has been reported as a protection among premature, drug-dependent infants from hyaline membrane disease is due primarily to the increased incidence of small-for-gestational-age infants in this group (7,34). Thus, the factors that cause a fetus to be small for gestational age are probably more important determinants of the infant's risk for developing hyaline membrane disease than is the direct action of narcotics (e.g., heroin) in accelerating pulmonary maturation (35). Meconium aspiration, persistent pulmonary hypertension of the newborn and hyaline membrane disease account for more than 50% of the deaths among infants of drug-dependent mothers (7).

In general, opiates are not teratogenic to the fetus. Most reports do not show an increase in the frequency of congenital anomalies (11,30), and in one study, although an increased frequency of malformations was found (7,36), the malformations were minor (e.g., skin tag) and no consistent pattern of malformation was observed. Animal studies, however, have shown a dose-related teratogenic effect of narcotics on the CNS of the developing hamster, which can be blocked by narcotic antagonists (37). *In vitro* studies have also shown opiates to impair deoxyribonucleic acid (DNA) repair and cause chromosome aberration with hyperdiploidy (38).

There is an altered sleep pattern in infants of drug dependent mothers, characterized by more rapid eye movement associated sleep than quiet sleep (39,40). In term infants exposed to opiates, abnormal auditory brainstem evoked response show decreased conductance time for waves I-III (41,42). Abnormal heart rate and breathing patterns have also been observed (43,44). The respiratory

P.1577

rates are higher with low end tidal volume PCO_2 and a shift to the left in their breathing response to CO_2 (45). These abnormalities have been suggested to increase their predisposition to the sudden infant death syndrome (see Long-Term Outcome).

There is an increased incidence of jaundice in the infants of drug-dependent mothers, which is likely related to the high incidence of prematurity in this group (7). Although induction of liver enzymes by morphine has been demonstrated in animals (45), the dose of morphine used was exceedingly high (250 mg/kg); a situation unlikely to be paralleled in a clinical setting. A significant thrombocytosis, occasionally exceeding 1,000,000 platelets per mm^3 , was reported in infants of mothers receiving maintenance doses of 40 to 90 mg of methadone per day. Onset was by the second week of life, with counts remaining high for over 16 weeks. The thrombocytosis, and associated increased circulating platelet aggregates, may play a role in the

development of the focal cerebral infarctions and germinal matrix and subarachnoid hemorrhages which were encountered in some postmortem examinations of the infants (46). The incidence of intraventricular hemorrhage in the opiate exposed infant is not increased (47). Cranial ultrasound have shown slit like ventricles and small intracranial diameter (48).

Along with the high incidence of infection in the pregnant addict is a correspondingly high incidence of infection in her infant. Although some of the neonatal infections are nonspecific in nature, such as sepsis, omphalitis, necrotizing enterocolitis, and gastroenteritis, many are related to the life style of the mother and include hepatitis and venereal diseases, e.g., syphilis, gonorrhea, herpes simplex, group B streptococcal, and HIV infections (2,7,17,18).

Neonatal Narcotic Withdrawal or Abstinence Syndrome

The onset of withdrawal usually occurs within the first 72 hours after birth, commonly within the first 24 to 48 hours. In a few instances, the onset may appear soon after birth, particularly if the mother has begun to experience withdrawal before delivery. Reports of withdrawal occurring after the first or second week may be secondary to withdrawal from other drugs, e.g., phenobarbital, beside the narcotics (49). Many factors, such as amount of narcotics used by the mother, timing of the last dose before delivery, character of the labor, type and amount of anesthesia or analgesia given to the mother, and the maturity and nutritional status of the infant, influence the onset of withdrawal (7).

Withdrawal in the infant usually peaks by about the third day of postnatal life and decreases in intensity by the fifth to seventh day. The duration of withdrawal is related to its severity. When drugs are used to treat the withdrawal, relapse may occur if treatment is discontinued abruptly. The withdrawal manifestations, although they may improve within a week, do not completely disappear until about 8 to 16 weeks of age (see Long-Term Outcome).

The severity of the withdrawal is influenced by several factors. It is less severe in the preterm infants as a result of their neurologic immaturity or reduced total exposure to narcotics (50). Withdrawal is significantly related to the amount of narcotics that the mother used during pregnancy. With methadone, a high maintenance maternal methadone dose during pregnancy or the dose at the last methadone intake is associated with more intense withdrawal (7,51,52,53). Almost half (46%) of these infants were treated for narcotic withdrawal; with the methadone dosage correlating both to the duration of hospitalization and neonatal abstinence score (32).

Buprenorphine, a potentially safer, opioid, maintenance drug than methadone, has been shown to lead to lower incidence of abstinence syndrome in both the mother and infant and lower mean weight reduction in the infant (54,55,56,57,58). Neither the infant's gender, race, and Apgar score nor the mother's age, parity, and duration of heroin intake correlated to the severity of withdrawal (7). Similarly, manipulation of the environment such as reducing the amount of light or noise in the nursery did not

ameliorate the severity of withdrawal in the infants (7). Adults experience abdominal cramps, palpitation, nausea, and other discomforts while undergoing withdrawal. It is likely that similar discomforts are also experienced by the infant which may nullify any potential benefits from light or noise reduction in the nursery.

Neonatal narcotic withdrawal is associated with noradrenergic hyperactivity and the manifestations involve the central nervous system, the respiratory, gastrointestinal, vasomotor and cutaneous systems (Table 58-3).

Central Nervous System Signs. Neurologic signs predominate and appear early. The findings are those of CNS excitability, such as hyperactivity, irritability, tremors, sneezing and hypertonicity. Occasionally, fever may accompany these increased neuromuscular activities.

Hyperactivity manifests almost as incessant movements of the extremities. When the infant is supine and unrestrained, the movements assume a jerky, purposeless, en masse nature, apparently perpetuated by unchecked, proprioceptive stimuli. When placed in the prone position, the motor behavior becomes more organized. There are crawling movements, which may actually lead to the infant's displacement from the crib, and other motions such as chin lifting, head movement from side to side, chest elevation, and hand-to-mouth facility. The latter usually soothes the infant, indicating the usefulness of pacifiers. Hyperirritability manifests almost as incessant crying with shrill, high-pitched outcries. The infant's muscle tone is exaggerated and sometimes, an opisthotonic position is assumed. This makes the infant difficult to hold as a result of its failure to mold to the body of the holder. Sleep is also disturbed. Tremors and myoclonic jerks are frequent, and are sometimes sustained. To distinguish tremors from seizures, the former can be abolished by restraint of the tremulous extremities. The reflexes of the infant (e.g., Moro, traction response, weight bearing, placing, stepping, crawling, and Landau) are all exaggerated. The infant's

P.1578

responses to stimuli, such as sound and light, are also increased disproportionately. In premature infants, the neural hyperexcitability is more episodic. The infants appear restless and overactive for short periods and then lapse into periods of lethargy and inactivity. Sustained tremors usually are not seen in premature infants until they mature to a point when sufficient tone is present in the upper and lower extremities. Electroencephalographic (EEG) tracings on the addicted neonate may be abnormal and show high-frequency dysynchronous activity suggestive of CNS irritability.

TABLE 58-3 MANIFESTATIONS OF NEONATAL NARCOTIC WITHDRAWAL

TABLE 58-3 MANIFESTATIONS OF NEONATAL NARCOTIC WITHDRAWAL	

Central nervous system

- Hyperactivity
- Hyperirritability-excess crying, high-pitched outcry
- Increased muscle tone
- Exaggerated reflexes
- Tremors
- Sneezing, hiccups, yawning
- Short, nonquiet sleep
- Fever

Respiratory system

- Tachypnea
- Excess secretions

Gastrointestinal system

- Disorganized sucking with reduced pressure
- Vomiting
- Drooling
- Sensitive gag
- Hyperphagia
- Diarrhea
- Abdominal cramps

Vasomotor system

- Stuffy nose
- Flushing
- Sweating
- Sudden, circumoral pallor

Cutaneous system

- Excoriated buttocks
- Facial scratches
- Pressure-point abrasions

From Ostrea EM, Chavez CJ, Stryker JS. The care of the drug dependent woman and her infant. Lansing, MI: Michigan Department of Public Health, 1978:30, with permission.

Respiratory Signs. Infants in withdrawal may be tachypneic, with irregular respirations. Alkalosis as a result of hyperventilation may result. Fluid loss may also be increased.

Gastrointestinal Signs. The suck of the infant is disorganized, reduced in rate and sucking pressure (59) and poorly coordinated with swallowing. Consequently, milk frequently drools around the corners of the infant's mouth. The infant appears incessantly hungry, which, when unfulfilled, leads to mounting agitation, persistent crying, hyperactivity, and exhaustion. Proper positioning of the infant to enhance hand-to-mouth facility may be extremely soothing. Vomiting and diarrhea are often observed. This may lead to dehydration, electrolyte imbalance, and excoriations

around the buttocks (see Complications).

Vasomotor Signs. Significant vasomotor instability manifests as stuffy nose, flushing, mottling, sweating, and episodes of sudden, circumoral pallor.

Cutaneous Signs. Because of hyperactivity, facial scratches and abrasions on pressure points may be observed on the infant's skin. Excoriations of the buttocks can occur if diarrhea is present.

Complications

The complications associated with neonatal drug withdrawal are related to its severity. Abnormalities in serum electrolytes and pH and dehydration may occur secondary to vomiting and diarrhea. Weight loss may be profound, not only as a result of increased fluid loss and hyperactivity, but also to poor and ineffective oral intake. Aspiration pneumonia may occur, as a result of vomiting, incoordinate sucking and swallowing. Respiratory alkalosis can result from tachypnea. In some instances, convulsion may be observed. However, it should be noted that convulsion is a more frequent manifestation of narcotic compared to nonnarcotic withdrawal (see Nonnarcotic Abstinence Syndrome).

Mortality

The mortality rate among infants born to drug-dependent mothers used to be as high as 50%. With early recognition and treatment of the withdrawal syndrome and prevention of its complications, the mortality from neonatal withdrawal is almost negligible. Nonetheless, overall mortality among infants of drug-dependent mothers remains high. In one report, mortality rate was 27 per 1,000 live births compared to 12 per 1,000 live births in the general population (7). The causes of death were related to immaturity, prematurity, hyaline membrane disease, meconium aspiration, persistent pulmonary hypertension of the newborn (PPHN) and major congenital malformations. Pulmonary problems (e.g., meconium aspiration, PPHN, hyaline membrane disease) accounted for more than 50% of the deaths.

Neonatal Neurobehavioral Abnormalities

By the Brazelton Neonatal Assessment Scale, the manifestations of neonatal withdrawal such as hypertonicity, hyperirritability, hyperactivity, and increased hand-to-mouth facility can be demonstrated. Some other fine behavioral abnormalities are also found that could affect early infant-caregiver interaction (60). For instance, congenital addiction seems to affect those behavior systems which are associated with arousal and early development of mother-infant bonding. Although the addicted infant is more likely to elicit caregiver consolation because it cries more often, it is less easy to cuddle, because of increased tone. It is also less readily maintained in an alert

state through handling and less responsive to visual stimuli, although auditory evoked

responses are better integrated. Because cuddliness, alertness, and visual regard are the primary means by which the infant initiates and maintains interaction with its mother, the impairment of these behavior patterns may have a profound effect on the early infant-mother bonding (61).

Long-Term Outcome

Persistence of Withdrawal. The withdrawal of infants from narcotics may persist for 8 to 16 weeks (62,63), but are usually milder than the initial course and consist of mild irritability, tremors, hypertonicity, sneezing, hiccups, and regurgitation. The persistence of withdrawal is related directly to its initial severity and is more prolonged in those infants who had severe withdrawal and were treated with drugs for withdrawal. Thus, although drug treatment may ameliorate the manifestations of withdrawal, it does not shorten its duration. It is important therefore that the mother is made aware that the infant's withdrawal may persist for sometime, albeit manageable, once the infant is discharged from the nursery. Otherwise, she may become alarmed when the infant continues to manifest withdrawal at home. The unwarned mother may also misinterpret the infant's irritability as hunger and over feed the infant which can then lead to diarrhea and vomiting. The mother also should be instructed on how to reduce the infant's discomfort by swaddling and cuddling the infant. Additionally, she should be reassured that the infant's withdrawal will eventually subside without the use of medications. In most instances, the mother who is well informed can cope with the situation successfully.

Child Abuse and Neglect and Sudden Infant Death Syndrome. The high incidence of child abuse and neglect constitutes one of the serious problems in the infants of drug addicted mothers (64,65). Thermal burns, usually from cigarette burns, traumatic ecchymoses, and hematoma have been observed in 8% of infants during the first 8 months of life (58). About 8.3% of the infants have to be placed in alternative care environment because of maternal neglect, abandonment or maternal death. Many factors contribute to the risk of child abuse. The persistence of withdrawal for some weeks, feeding problems, abnormal sleep patterns and periods of restlessness in the infant can generate undue tension in the mother, whose tolerance for frustration is already low. Thus, the mother, unable to cope with the situation, may simply withdraw from her infant and avoid any contact or may abandon or injure the infant.

There is a four to fivefold increase in the incidence of sudden death syndrome in infants of opiate-dependent mothers (66,67). This complication is observed whether the infant is cared for by the mother or in an extended family or foster home. The cause is not clear, although its occurrence is significantly higher in those infants who had moderate to severe than mild withdrawal after birth (66,67). Abnormal breathing patterns, control of breathing and exposure of the infant to maternal smoking have been implicated as contributory causes to sudden infant death syndrome (SIDS) (44).

Growth and Psychomotor Development

In general, the physical growth of the congenitally addicted infant has shown a catch

up in growth when adjusted for sex, race, maternal education and smoking. At 12 months of age, the growth in terms of weight, head circumference and length of the infants have been observed to fall within the 10th to the 90th percentile on the growth chart. Similarly, the percentage of addicted infants whose growth parameters were below the 10th percentile did not differ significantly from the nonaddict group (68). However, some studies have reported retardation in the weight, length, and head circumference at age 3 to 6 years (69,70,71,72 and 73). A high incidence of transient or minor motor deficits, poor motor coordination, and abnormal eye findings, such as nystagmus and strabismus have also been observed in these infants in the first year of life (71,74,75).

The mental and cognitive performance of the opiate exposed infants have been shown to be comparable to the control, non drug exposed group (63,68,76,77). Within the first year, infants of narcotic addicts have been shown to manifest some difficulty in regulating their behavior, but otherwise had normal developmental scores except in early language development (69,70 and 71,78). However, at preschool age, compared to controls, i.e., children at similar environmental risk and sociodemographic background, the addicted children performed less well in terms of perception, short-term memory, and organization, but did just as well on objective tests of activity and attention (70).

Behavioral problems have been observed among the opiate exposed infant and have persisted even in late childhood. These consisted of hyperactivity, aggressiveness, inattention, impulsiveness, short attention span and lack of concentration and inhibition (63,78,79,80,81,82). This leads to learning problems in school, truancy and suspension (64). However, these problems are probably more the result of environmental and emotional deprivation of the infant than from the effects of in utero drug exposure. These include significant psychopathology in the mother (or parents) with or without comorbid alcohol abuse, and negative parenting behavior which contribute to poor infant rearing. The problems are further compounded by arrest or incarceration of the mother and her treatment for emotional disorders (64,65,83,84). The mother is also more socially isolated and less likely to pursue vocational or educational attainment. Thus, the addicted mother needs assistance in parenting. Someone should be available to help her in the care of her child (often the maternal grandmother) and that a visiting or public health nurse and a social and protective service worker should actively participate in the follow up of the mother and her infant (85,86 and 87). Alternative measures of

P.1580

placement of the child into a more favorable home environment have sometimes resulted in better behavioral functions of the child (81).

NONNARCOTIC HYPNOSEDATIVES

Nonnarcotic Abstinence Syndrome

Infants born to women who have used nonnarcotic hypnosedatives during pregnancy

(Table 58-4) can become addicted to the drugs and manifest withdrawal, as well. The manifestations of nonnarcotic withdrawal in the neonate are similar to those of narcotic withdrawal (88). In a few instances (e.g., with barbiturate withdrawal or ethchlorvynol withdrawal), hyperphagia has been described as a prominent manifestation.

Although the manifestations of withdrawal from narcotic and nonnarcotic drugs are similar, major differences exist (58).

In adults, the rate of developing physical dependence to the nonnarcotic hypnosedatives does not increase with the drug dose, as it does with narcotics. Rather, prolonged and continuous administration of large and partially incapacitating doses are necessary, over months or years, to produce addiction to nonnarcotics, especially if the drugs are taken orally. The situation is different in the newborn infant. Passive addiction in the fetus and infant have been observed even with therapeutic doses of nonnarcotic drugs used by the mother during pregnancy. For instance, a pregnant woman who is treated with phenobarbital for epilepsy can induce serious addiction in her fetus, although she herself, may not be addicted to the drug (49).

The manifestations of the nonnarcotic abstinence syndrome are more frequently intense and life threatening compared to narcotic withdrawal. The occurrence of convulsion is also more frequent.

Most of the withdrawal from narcotics is seen within the first 3 days of postnatal life, as a result of the short half-life of most narcotics. In contrast, withdrawal from the nonnarcotics, particularly phenobarbital, may be observed at 7 to 10 days after birth as a result of the slow clearance of the drug in the infant.

TABLE 58-4 NONNARCOTIC DRUGS

Hypnosedatives

Barbiturate

Nonbarbiturate sedatives and tranquilizers

Bromide

Chloral hydrate

Chlordiazepoxide (Librium)

Diazepam (Valium)

Ethchlorvynol (Placidyl)

Glutethimide (Doriden)

Ethanol

Unlike the narcotics, neonatal addiction to many of the nonnarcotic hypnosedatives has been induced by physicians who prescribe the drug to the mother, totally unaware of its addicting potential on the fetus (58).

BARBITURATES

Barbiturates have been used in clinical medicine for many years, but its addiction potential has only been recently recognized. In adults, the frequent association of barbiturate use with alcohol may have contributed to the delayed recognition of its addicting potential because of the ability of barbiturates to control the withdrawal from alcohol (89,90).

Barbiturates are classified, based on their duration of their action, as ultrashort, intermediate, and long acting. The intermediate-acting barbiturates are most frequently abused (e.g., secobarbital [Seconal], pentobarbital [Nembutal], amobarbital [Amytal], butobarbital [Butisol]). The abuse of the long-acting barbiturates (e.g., phenobarbital) is not as common as the abuse of the shorter-acting forms. Phenobarbital, however, is more frequently involved in withdrawal syndrome in the newborn because it is used frequently by the mother for insomnia, for the relief of anxiety, as an anticonvulsant, or for sedation when toxemia of pregnancy occurs.

Passive addiction of the fetus to barbiturates can occur after its prolonged exposure to the drug *in utero* (49,91). Barbiturates cross the placenta readily and establish high levels in both the maternal and cord blood. Relatively high levels of barbiturates have been found in the fetal brain, liver and adrenal glands (92). The manifestations of barbiturate withdrawal in the neonate are similar, regardless of the type of barbiturate used by the mother; however, the onset of withdrawal may differ. Withdrawal typically occurs within a day after birth with intermediate-acting barbiturates (93), and from 3 to 7 days after birth with the long-acting barbiturates (91).

Barbiturates are metabolized principally by the liver, although a significant portion may be excreted unchanged by the kidney. In adults, up to 30% of the total dose of phenobarbital ingested is excreted unchanged in the urine (94). The half-life of phenobarbital prenatally administered to infants is almost twice that in the adult, and varies inversely with the extent of the prenatal exposure to the drug (95). Phenobarbital levels in the arterial cord blood have ranged from 77% to 100% of maternal levels depending on the duration of maternal treatment, gestational age and cord pH in the infant (96).

The signs of withdrawal from barbiturates in neonates are similar to those described in adults. The infants are overactive and restless, with excessive crying, twitching, hyperactive reflexes and hypertonicity. They also manifest diarrhea, vomiting, and poor sucking ability. When tonic-clonic convulsions occur, the EEG patterns show diffuse, paroxysmal, high-voltage, slow-wave bursts, similar to those seen in adults (91). A subacute phase of hyperphagia, episodes of prolonged crying, episodic irritability, hyperacusis, and sweating have been described (91). These

P.1581

manifestations may last from 2 to 6 months. A combination of phenobarbital-phenytoin treatment of the mother has also been observed to predispose to smaller occipitofrontal circumference in the infants compared to phenobarbital monotherapy alone (97). Cognitive functions in infants exposed to phenobarbital, *in utero*, did not differ from controls, except for a higher incidence of learning problems (98).

Recognition of the abstinence syndrome from phenobarbital is essential for the proper management of the infant. An awareness of late onset withdrawal in infants exposed in utero to long-acting barbiturates should alert the clinician to follow these infants closely during the first 2 weeks of life.

CHLORDIAZEPOXIDE AND DIAZEPAM

Chlordiazepoxide (Librium) and diazepam (Valium) are widely used for their hypnosedative effects. Abuse and dependence on these drugs have been reported in adults. During pregnancy, benzodiazepines cross the placenta with relative ease, resulting in significant drug levels in the serum and tissues of the fetus (99). Placental transfer of diazepam can occur from the sixth week of gestation and accumulate in the fetal tissues during organogenesis (100). Mean levels of diazepam were found to be markedly higher in the umbilical cord serum than in the maternal serum after a single intravenous injection of 10 mg of diazepam (101).

An acute withdrawal syndrome from chlordiazepoxide or diazepam was observed in the newborn infant (102,103). A presumptive diagnosis of chlordiazepoxide withdrawal was made in a set of twins born to a mother who used chlordiazepoxide (20 mg per day) during the second and third trimesters of her pregnancy (102). The withdrawal occurred on day 21 of life, and consisted of severe irritability and coarse tremors. However, in three reports of neonatal withdrawal from diazepam, the onset of withdrawal occurred within 2.5 to 6 hours after birth and consisted of tremors, irritability, hypertonicity, vigorous sucking, vomiting, and diarrhea (103). The dose of diazepam used by the mother up to the time of birth ranged from 15 to 20 mg per day. In all three cases, phenobarbital was effective in controlling the withdrawal in the infant, although the drug had to be administered for a prolonged period (13-25 days). In another report, a mother used narcotics and diazepam during pregnancy. There was an initial good response of the infant to treatment for narcotic withdrawal but the withdrawal manifestations intensified at 7 to 14 days of life. The late withdrawal was attributed to prenatal diazepam exposure (104). Late third trimester use and exposure to diazepam during labor has been associated with the floppy infant syndrome, or marked neonatal withdrawal. The manifestations varied from mild sedation, hypotonia and reluctance to suck, to apneic spells, cyanosis and impaired metabolic responses to cold stress. These signs may persist from a few hours to months after birth (105). High dose, intravenous administration or prolonged duration of diazepam therapy in mothers has also caused significant depression in the newborn with poor muscle tone (101,106). In one report, infants prenatally exposed to diazepam had lower birth weight compared to controls, but eventually showed catch up growth by eight months of age (107). Congenital malformations are uncommon with antenatal diazepam exposure although a case has been reported of an omphalocele-exstrophy-imperforate anus-spina bifida complex occurring in a infant whose mother took 30 mg of diazepam daily for affective disorder during the entire pregnancy (108). Offspring of rats who were treated with chlordiazepoxide during the critical period of neural development showed significant deficits in learning acquisition and retention (109). In general, most studies involving first trimester use of benzodiazepines have shown the

majority of infants to be normal at birth and have normal postnatal development (105).

OTHER HYPNOSEDATIVES

Hypnosedatives, which used to be popular in the past, have been associated with adverse effects in the newborn infants. These include chloral hydrate (110), bromide (111,112 and 113), ethchlorvynol (114,115,116,117,118 and 119), and glutethimide (120). A withdrawal syndrome and growth retardation have been reported in newborn infants after the use of bromides by the mother during pregnancy (111,112). Studies on rat pups whose dams were given sodium bromide, ad libitum, showed significant delay in postnatal development, permanent deficits in body weight, brain weight and protein content of brain tissue but with an increased size of the olfactory glomeruli (113). Ethchlorvynol (Placidyl) was introduced in 1955 as a nonbarbiturate, non addicting hypnotic for the treatment of insomnia (114,118). However, subsequent reports of addiction to ethchlorvynol have been reported (115,116 and 117). An abstinence syndrome from ethchlorvynol was observed in a newborn infant, which consisted of extreme jitteriness, irritability, and hyperphagia (119). The drug that was taken by the mother was within the recommended therapeutic dose. The onset of withdrawal in the infant occurred during the second day of life. No convulsions were noted because the infant received phenobarbital treatment early in the course of the abstinence syndrome. Glutethimide (Doriden) was first introduced in 1954 as a nonbarbiturate hypnosedative, allegedly free of addicting properties. As in the case of most nonbarbiturate hypnosedatives, this led to its widespread use, particularly as a substitute drug for the treatment of alcohol addiction (120). Since then, numerous reports of acute and sometimes fatal intoxication with the drug in adults and the occurrence of physical dependence have been reported (120,121 and 122). Glutethimide is structurally related to phenobarbital.

A possible case of neonatal withdrawal to glutethimide was reported in a pregnant heroin addict who supplemented her habit with 2 to 3 g of glutethimide three or

P.1582

four times a week to get a desired euphoric effect (123). Within 8 hours of birth, the infant exhibited signs of withdrawal from narcotics that were readily controlled with chlorpromazine. However, on the tenth day of life, while on a tapering dose of chlorpromazine, the infant suddenly manifested diarrhea, fever, tachypnea, irritability, hypertonicity, and diaphoresis. It was presumed that the unusual recurrence of withdrawal on the tenth day of life may have been secondary to withdrawal from glutethimide.

DIFFERENTIAL DIAGNOSIS

Withdrawal from the narcotic and nonnarcotic hypnosedatives should be distinguished from hypoglycemia, hypocalcemia, hypomagnesemia, sepsis, meningitis, subarachnoid hemorrhage, infectious diarrhea, and intestinal obstruction. Blood chemistry, white cell count and differential, cerebrospinal fluid examination, radiographic examination, and

cultures should be performed as indicated by the clinical circumstances.

Infants whose mothers were on tricyclic antidepressants and lithium during pregnancy for psychiatric conditions may manifest toxicity similar to withdrawal, such as irritability, tachycardia, respiratory distress, sweating, and convulsions (124,125,126,127 and 128). Likewise, maternal intake of phenothiazines (e.g., chlorpromazine) may induce extrapyramidal dysfunctions in the newborn infant, such as tremors, facial grimacing, increased muscle tone, cogwheel rigidity, increased reflexes, and torticollis, all of which can resemble the withdrawal syndrome (129,130). The prenatal history and the identification of the corresponding drug in the infant's serum or urine are necessary to establish the diagnosis.

COCAINE

Types

Cocaine is an alkaloid that is extracted from the leaves of the *Erythroxylon coca* bush. Its chemical name is methylbenzoylecgonine, and is the only known, naturally occurring local anesthetic. Cocaine was first extracted and identified by the German chemist, Albert Niemann in 1860. The drug is extracted from the leaves of the coca plant by a series of solvent extractions. Coca paste is the first extraction product of cocaine and contains about 80% cocaine (131,132). The paste can be smoked by applying it to tobacco or marijuana. Cocaine hydrochloride is the most common available form of cocaine. In its acid state, cocaine HCl is a white powder that is soluble in water and can be snorted or injected. Cocaine HCl usually is adulterated with starch, glucose, phencyclidine (PCP), heroin, or amphetamines, and its purity ranges from 20% to 80% (131-132).

An alkaloidal base of cocaine can be obtained from cocaine HCl ("free-basing") by alkalinizing the aqueous solution of cocaine HCl and then extracting the cocaine alkaloid base using volatile organic solvents, such as ether. The gummy cocaine residue, called "rock," has a lower melting point than cocaine HCl and can be smoked using a special pipe. Crack cocaine is the most popular, abused form of the drug. Crack cocaine is produced when cocaine HCl is mixed with ammonia, water, and baking soda and heated. The resulting paste, once dried, forms a hard, rocklike substance that can be smoked. The term "crack" is derived from the crackling sound that is produced when crack cocaine is prepared or smoked.

When taken orally, cocaine HCl has a peak effect at between 45 minutes and 90 minutes. Intranasal administration of cocaine, i.e., snorting has a peak effect in 15 to 30 minutes, and lasts from 60 to 90 minutes. Smoking cocaine ("crack" cocaine) provides the most rapid delivery of the drug to the body. Peak effect is within 60 to 90 seconds, but the high lasts only for about 5 to 10 minutes. The intense high is followed by a down period as the effect of the drug wears off. The down period may be so unpleasant that more of the drug is used to re-experience the high, or other drugs, e.g., alcohol are used. Thus, cocaine use promotes the abuse of other drugs (131).

Cocaine is metabolized by plasma and hepatic esterases into three major water-soluble metabolites, ecgonine methyl ester, benzoylecgonine, and ecgonine, although other minor metabolites are also present. The half-life of cocaine in adults depends on the route of administration—an average of 0.6 hour after intravenous administration, 0.9 hour after oral use, and 1.3 hours after intranasal use. The metabolites can be found in the urine 72 hours after administration. In infants, metabolites can be found for up to 2 weeks after administration (132,133).

Pharmacology

The neuropharmacologic effect of cocaine is secondary to its effect on three neurotransmitters: norepinephrine, dopamine, and serotonin. Cocaine inhibits the reuptake of norepinephrine and dopamine (134), which accumulate at the synaptic cleft, leading to prolonged stimulation of their corresponding receptors. Therefore, the effects of norepinephrine stimulation (e.g., tachycardia, hypertension, arrhythmia, diaphoresis, tremors) and dopamine stimulation (e.g., increased alertness, euphoria or enhanced feeling of well-being, sexual excitement, heightened energy) are experienced. Cocaine also decreases the uptake of tryptophan, which affects serotonin biosynthesis. A diminished serotonin level is associated with diminished need for sleep, because serotonin regulates the sleep-wake cycle (132).

Adverse Effects on Pregnancy

Studies in pregnant sheep have shown that maternal blood pressure becomes elevated within 5 minutes after cocaine infusion (135,136 and 137), coupled with an increase in uterine vascular resistance and decrease in uterine blood

P.1583

flow. Fetal heart rate and blood pressure also increase, but fetal partial pressure of oxygen (PO_2) and oxygen (O_2) content decrease as a consequence of the reduced uterine blood flow. Thus, oxygen availability to the fetus is impaired. The cocaine-induced uterine vasoconstriction is mediated solely by adrenergic stimulation because adrenergic blockade by phentolamine does not ablate the response. Pregnancy can potentiate the toxic effects of cocaine, because progesterone can increase the adrenergic sensitivity of the receptors or delay cocaine metabolism (137).

At serum levels found in humans, cocaine per se has no effect on human and animal umbilical arteries. However, cocaine enhances the umbilical artery vasoconstrictor action of catecholamines and serotonin, presumably by increasing the sensitivity of the α -adrenergic receptors of arterial smooth muscle (138).

Overall, the cardiovascular effect of cocaine on the materno- fetal circulation is maternal hypertension, increase in uterine vascular resistance, decrease in uterine blood flow, decrease in oxygen transport to the fetus, and fetal hypoxemia.

Obstetric Effects

A characteristic profile has been observed in the pregnant women who abuse cocaine: multigravid, multiparous, service patient and with little to no prenatal care (3). The life-style of prostitution, with little attention to personal health care, contributes to these attributes. The women are also older (mean age of 33 years), of low income and are more likely to smoke cigarettes, drink alcohol and use another drug, beside cocaine. In the United States, the majority of cocaine users are Afro-American, with a high incidence of suicidal ideation and emergency room visits (139,140,141). The pregnant addict is generally of poor health, as a result of poor nutrition and vitamin deficiency, and is at high risk for infection, particularly hepatitis, syphilis gonorrhea and HIV infection (142,143). Cocaine use and HIV infection have also noted to be significant risk factors for maternal pneumonia (144).

Maternal use of cocaine has been associated with a number of obstetric complications. Spontaneous abortion occurs in 25% to 38% of pregnancies of cocaine-using women (145,146,147). The rate of stillbirth is five to ten times higher among pregnant women who continue to use cocaine late in the third trimester. This may be secondary to placental abruptio, placental infarcts or hemorrhage (145,148). Fetal anuria, anasarca and neonatal gastrointestinal hemorrhage were reported in association with maternal use of cocaine and indomethacin during pregnancy (149,150).

There is a tenfold increase in the incidence of abruptio placenta and vaginal bleeding with cocaine use during pregnancy (17,145,146,147,148,151,152,153), although some studies do not show this association (2,154,155). One of the latter was a study based on a large obstetric population and the use of a more sensitive test to detect cocaine exposure in the infants (3).

An increased occurrence of premature labor and premature rupture of the membranes have been observed among pregnant women who use cocaine (145,156,157 and 158). There is a belief among these women that cocaine will shorten the duration of their labor. Although one study does not support this belief (159), another has shown a significant decrease in the duration of labor in women who used cocaine compared to nonusers or to those who only used opiates during the pregnancy (3).

There has been no observed increase in the incidence of amnionitis, abnormal presentation, eclampsia, preeclampsia, or placenta praevia in pregnant women who abuse cocaine (145).

Placental Transfer

Because of its low molecular weight and high lipid solubility, cocaine crosses the placenta by simple diffusion (147). However, the fetal concentration of cocaine is only one-fourth to one ninth that of the mother. Nonetheless, the elimination of cocaine and its metabolites is much slower in the fetus than in the mother; thus, the risk of cocaine toxicity in the fetus is increased.

Effects on the Neonate

The cocaine-exposed infant is at risk for a number of complications. Cocaine decreases

placental perfusion, which leads to poor gas exchange and fetal oxygenation (135,136 and 137). Fetal hypoxemia in turn leads to fetal distress, meconium staining of the amniotic fluid, and low Apgar score. Meconium staining has been observed in 23% of the births in cocaine-abusing women—approximately twice the incidence among nondrug users (3,145). There is also an increased incidence of premature birth (145,156,157,160,161,162,163,164 and 165) and intrauterine growth retardation (147,155,158,161,166). These rates are about three to four times higher than in nonusers. Numerous studies have also reported lower birth weights and smaller body length and head circumference in infants exposed to cocaine during pregnancy compared to controls

(17,147,150,152,157,160,161,163,164,167,168,169,170,171,172,173 and 174).

Somatic growth deceleration seems to be evident after 32 weeks of gestation (171).

In a meta-analysis study, maternal cocaine use was not only associated with low birth weight in the infants but that the effect is increased with heavier drug use (175). The dose related, negative effect of cocaine on head circumference may reflect specific central nervous system insult that interferes with prenatal brain growth (176). Again, maternal smoking, alcohol and opiate use (177) and lead exposure (178) are important contributing factors for these reduced growth parameters in the infant.

Cocaine use during pregnancy has been associated with an increased incidence of the congenital malformations in animals, such as neural tube defects, skeletal deficits (e. g., camptodactyly, bradydactyly) and hydrocephalus (145,158,179,180). It is suggested that fetal vascular disruption secondary to vasoconstriction may lead to these defects (181). On the other hand, congenital malformation is not

P.1584

increased among cocaine exposed newborn infants. A previously reported increase in the rate of genitourinary malformations was not subsequently substantiated by renal ultrasound study of 100 term infants who were exposed to cocaine during pregnancy (182). In a large, blinded, prospective and systematic study of infants, an increased incidence of congenital abnormalities was not observed among prenatally cocaine exposed infants (183,184).

Maternal cocaine use during pregnancy has been associated with a number of multiorgan dysfunctions in the infant (185) (Table 58-5). Neurologic abnormalities have included seizures (186), transient dystonia (187), hypertonia/ hypereflexia and tremors (188,189 and 190), and transient abnormal EEG suggestive of CNS irritability (191). Problems of low arousal, poor quality of movement, high excitability, poor attention, hypertonia, jitteriness and non optimal reflexes have also been observed (192,193,194,195 and 196). The infant's cry is characterized as few, short and less crying in the hyperphonation mode (197). These acoustic cry characteristics which reflect reactivity, respiratory and neural control have also been found to be compromised in marijuana, opiate and alcohol exposed newborn infants (192). The sleep pattern of the infant shows more wakefulness, more frequent arousals and a higher proportion of active compared to quiet sleep (198,199 and 200).

Abnormal hearing tests have been consistently observed among prenatally cocaine exposed infants. The auditory brainstem evoked response shows prolonged interpeak

and absolute latencies suggesting abnormal neural transmission (201,202,203,204). There is also impaired auditory information processing with impaired habituation to novel stimulus (205).

TABLE 58-5 REPORTED COMPLICATIONS INVOLVING SPECIFIC ORGAN SYSTEMS IN COCAINE EXPOSED NEWBORN INFANTS

Central nervous system

- Cerebral infarction
- Mobius syndrome
- Seizures, tremors
- Hypertonicity/hyperreflexia and transient dystonia
- Abnormal head ultrasound, e.g., echolucencies in basal ganglia, ventricles, periventricular and germinal matrix cyts
- Abnormal EEG
- Abnormal sleep pattern
- Abnormal cry

Sensory organs

- Abnormal brainstem auditory evoked response
- Increased auditory startle response
- Retinal hemorrhage and tortuosity and dilatation of iris vessels

Cardiovascular system

- Transient tachycardia
- Hypertension and diminished stroke volume and cardiac output
- Atrial and ventricular arrhythmia

Respiratory system

- Apnea
- Abnormal breathing pattern, e.g., periodic breathing

Genitourinary system

- Renal ectopia

The incidence of severe intraventricular hemorrhage among preterm infants is not increased with cocaine exposure (206). Recent studies however, have shown dose-related increase in the incidence of mild periventricular-intraventricular hemorrhage, specifically in the caudothalamic groove, echolucencies in the basal ganglia and caudate nucleus, ventricle dilatation and germinal matrix or subependymal cysts (207,208,209 and 210). An increased flow velocity in the anterior cerebral artery has been shown in these infants and is consistent with the vasoconstrictive effects of cocaine (211). Although high resolution single photon emission computed tomographic scans have shown normal cerebral blood flow in 21 infants with confirmed cocaine exposure (212), cerebral infarction and hemorrhage has been reported in an infant whose mother had taken a large amount of cocaine during the intrapartum period. A Mobius syndrome was observed in an infant born to a mother with heavy use of cocaine and alcohol. It was suggested that cocaine-induced vasoconstriction at a critical time of cerebrovascular development produced a vascular disruption sequence

leading to the syndrome (213). The vasoconstrictive effect of cocaine on the cerebral circulation is prominent in utero because the fetus is more consistently exposed to the drug. Postnatally, this may no longer be observed as cocaine exposure is discontinued and is evidenced by a significant drop in arterial blood pressure and cerebral blood flow velocities in the second compared to the first day of the infant (214).

In the cardiovascular system, asymptomatic cocaine exposed infants showed either decreased (215,216) or increased (217,218) heart rate variability after birth and are related to the effect of cocaine on the autonomic nervous system either through sympathetic stimulation or vagal suppression. However, the effect is transient and the vagal tone eventually recovers as cocaine exposure ceases after birth (215,216). A decrease in cardiac output and stroke volume and increase in arterial blood pressure have been reported in cocaine exposed infants (219,220) and atrial and ventricular arrhythmias (221) and transient ST segment elevation (221,222). In children, sustained arrhythmias which may result from an increased number of potential initiating premature beats, may be associated with congestive heart failure, cardiopulmonary arrest and death (223).

In the respiratory system, abnormal breathing patterns have been observed in the cocaine exposed infants, e.g., high respiratory rate, decreased end tidal PCO₂ and shift to the left of the breathing response curve to CO₂ (44). There have also been described increased apnea density and periodic breathing (219). The failure in animals to ventilate adequately in the presence of hypoxia, after prenatal exposure to cocaine, may indicate retardation of development of their ventilatory control system (224). In preterm infants with respiratory distress syndrome, cocaine exposure was associated with less frequent use and fewer doses of surfactant and with less frequent intubation (225).

P.1585

Other findings in the neonate which are attributed to in utero cocaine exposure include: elevation in serum myoglobin and creatine kinase secondary to tremors (226) and decreased jaundice because cocaine is a strong inducer of the glutathione-S transferase family of enzymes that is closely associated with bilirubin transport (ligandin) in the liver (227). An increased incidence of early onset necrotizing enterocolitis and intestinal perforation, not related to necrotizing enterocolitis, have been observed which may be secondary to the vasoconstrictive and ischemic effect of cocaine on the gastrointestinal tract (228,229). Eye findings of retinal hemorrhages (230) and dilated and tortuous iris vessels have been reported (231). Retinal, vascular, disruptive lesions which consisted of blot full-thickness hemorrhages with rounded domed contours suggestive of venous occlusion and retinal ischemia have been described (230,231,232). These lesions took longer to resolve compared with those hemorrhages as a result of birth trauma.

Neonatal Neurobehavioral Assessment

By the Neonatal Brazelton Assessment Scale (NBAS), cocaine- exposed newborns

exhibited significantly depressed performance on the habituation clusters, including lower state regulation and greater depression. During sleep-wake behavior observations, the infants showed difficulty in maintaining alert states and self-regulating their behavior, and spent more time in indeterminate sleep and had decreased periods of quiet sleep and increased levels of agitated behavior, including tremulousness, mouthing, multiple limb movements, and clenched fists. (233,234,235,236,237,238 and 239). There is a dose-response relationship between cocaine fetal exposure and performance on the NBAS (233,234,235,236,237,238 and 239,192). High urinary norepinephrine, dopamine, and cortisol levels were noted during these conditions (239). A significant negative correlation was observed between serum norepinephrine concentration and orientation cluster score for the cocaine-exposed newborns (240). Similarly, a significant negative effect was observed between cocaine concentration in meconium and the cluster scores on motor and regulation state (234). An increase in the infant's auditory startle response has also been observed (241). Two neurobehavioral syndromes have been described in these infants: an excitable state, which may be as a result of the direct neurotoxic effects of the drug and a depressed state that may be indirect effects of intrauterine growth retardation (242).

Cocaine use during pregnancy has not only caused significant medical problems in the infant, but has been an economic burden, as well. Increased hospitalization costs have resulted from prematurity and adverse birth outcome, prolonged stay while awaiting home and social evaluation of foster care placement and laboratory fees (243,244,245,246,247 and 248). Cocaine exposed infants had longer length of hospital stay (249), more likely to be admitted to a neonatal intensive care unit, be treated for congenital syphilis and discharged to a person other than the mother (250).

An abstinence syndrome has not been commonly observed with cocaine exposure. Reports of withdrawal-like manifestations with cocaine may be related to polydrug abuse, particularly opiates or cocaine toxicity.

Long-Term Outcome

In terms of physical growth, the infants prenatally exposed to cocaine showed catch up in weight and length (251), although head circumference still tended to be smaller (252,253) than control infants. Strabismus, high blood pressure and hypertonicity were noted particularly during the first year of life (188,254,255). Hypertonia, both symmetrical and peripheral, were also noted during infancy but disappeared by 24 months (188,256).

Difficulties in early language development, lower verbal comprehension and reasoning and poor recognition memory and information process have been more consistently reported (251,252,257,258,259 and 260). The infants also showed lower scores in the Fagan Intelligence tests (261), Bayley Scales of Infant Development (262,263), language skills (264,265,266), cognitive functions (267), and visual attention (268). Behavior problems dealing with attention deficits and distractibility have been noted (269). The adverse effect of cocaine on the child's attention processing (270) and

expressive language (271) were noted even up to school age. These may indicate the long lasting disruption of the brain systems subserving arousal and attention as noted in the neonatal period (270,272). Cocaine exposure is not associated with differences in play behavior of the infant at 18 and 24 months (273) despite previous report to the contrary (274). However, behavior problems dealing with attention deficits and distractability have been noted (269).

Many of the adverse long term outcome in the infants are not exclusively the effects of prenatal cocaine exposure alone but the influence of other important factors as well, such as aberrant parental behavior and interaction with the child (275), poor home environment (255,276), poor caregiving skills (276,277,278,279 and 280), abnormal maternal psychological functions (279), and low socio-economic status (280,281,282,283 and 284). In a meta-analysis study, which controlled for many of these confounding factors, many of the reported adverse effects of cocaine on the growth and development of infants were not observed except for decreased attentiveness and emotional expressivity (285).

As in the opiate exposed infant, there is increased risk to SIDS and child abuse with prenatal cocaine exposure (198). The risk however, is not specific for cocaine exposure alone but to intrauterine exposure to illicit drugs in general (286). The chaotic home environment and a high incidence of depression, emotional and physical neglect, inadequate skills and poor self esteem in the mother are important contributing factors for child abuse and neglect (255). Perinatal drug abuse including cocaine, opiate and cannabinoid has not been associated with increased infant mortality within the first two years of life except among the low birth weight infants (287).

Cocaine Exposure During Infancy and Childhood

The exposure of the infant to cocaine can be ongoing after birth through breastfeeding, intentional administration of the drug by caregivers, accidental ingestion of cocaine or cocaine contaminated household dust via normal hand to mouth activity or passive inhalation of cocaine smoke during freebasing activities of adults (288). Cocaine and benzoylecgonine have been found in the hair, saliva, skin and urine of these children (258,289). The incidence of passive cocaine exposure in ill infants younger than 1 year old seeking medical care through the emergency services may be as high as 1 in 3 to 6 infants (290). Morbidity from postnatal cocaine exposure have included seizures, drowsiness and unsteady gait, diarrhea and shock from intoxication and sometimes, death (291,292,293 and 294). Two major age-related patterns have been observed: in children less than 5 years of age, seizures (focal or generalized) and obtundation and in older children, delirium, dizziness, drooling, and lethargy (295). Thus, afebrile seizures in infants and young children should include a consideration of cocaine intoxication. The development of upper and lower respiratory tract symptoms also correlate significantly with cocaine exposure (290).

ALCOHOL

The use or abuse of alcohol during pregnancy has serious effects on the fetus and newborn. The adverse effects of alcohol on the offspring have been observed for centuries, although the fetal alcohol syndrome (FAS) was not defined as a medical entity until 1973 (296,297). Infants born to alcoholic parents may have dysmorphic features and are subsequently observed to have a higher than expected incidence of delayed growth and development and of neurologic disorders (298,299). Excellent reviews on this topic have been written (300,301 and 302).

Epidemiology

Almost half of Americans aged 12 or older (48.3%) reported being current drinkers of alcohol in a recent survey of the National Household Survey on Drug Abuse (1). This is equivalent to an estimated 109 million people. The rate of alcohol use and the number of drinkers have increased from 2000, when 104 million, or 46.6% of people aged 12 or older reported drinking in the past 30 days. Approximately one fifth (20.5%) of persons aged 12 or older participated in binge drinking at least once in the 30 days prior to the survey. Although the number of current drinkers increased between 2000 and 2001, the number of those reporting binge drinking have not changed significantly. Heavy drinking was reported by 5.7 percent of the population aged 12 or older, or 12.9 million people. These 2001 estimates are similar to the 2000 estimates.

Alcohol use during pregnancy is a significant public health problem. Among pregnant women aged 15 to 44 years in 2000 and 2001 combined, 12.9 percent used alcohol and 4.6% were binge drinkers (1). These rates were significantly lower than the rates for nonpregnant women of that age (49.8 and 20.5%, respectively). A variety of programs have been developed to prevent drinking during pregnancy, such as public service announcements and beverage warning labels, which strive to increase public knowledge about fetal alcohol effects. Selective prevention approaches to women of reproductive age involve screening all pregnant women for alcohol consumption and counseling for those who drink (303). It has been shown that knowledge among pregnant adolescents about drinking especially those with specific knowledge of FAS drank less before pregnancy (304). Among drinkers, general knowledge was significantly related to a decrease in drinking between prepregnancy and first trimester, and between first trimester and third trimester (303).

Widely used terms such as "light," "moderate," and "heavy" alcohol consumption are unstandardized. Attempts to standardize these terms resulted in considerable agreement for the following operational definitions: "light" drinking as 1.2 drinks/day; "moderate" as 2.2 drinks/day and heavy drinking as 3.5 drinks/day (305).

Although most of the women who report alcohol use are light drinkers, those who drink heavily are more likely young, white, single, to have higher education and income and to be employed outside the home (306,307). However, women who drink during pregnancy, and particularly those who continue to drink through the third trimester are different. They are older, more likely black, have higher rates of illicit drug use, less education and lower social status (306). They also have higher levels of

psychopathology such as depression, psychopathic deviance, schizophrenia and social introversion (308). In one survey, almost half (45%) of all pregnant women drank alcohol during the first three months before finding out they were pregnant (307).

Alcohol consumption and pregnancy in the adolescent group has also been increasing the past years (308). Although adults have significantly higher average daily volume of alcohol prior to pregnancy than adolescents, this was no longer significant during pregnancy. The rate of binge drinking (5+ drinks/occasion) during the first trimester was higher in pregnant teenagers (309,310). Binger drinkers are more likely to be young, white and with heavier use of tobacco, marijuana and cocaine compared with nonbinge drinker (309,311). Offsprings of these binge drinkers may be at higher risk for intermittent high peak alcohol exposure further into the pregnancy than those of adult drinkers (310).

The concept of moderate consumption of ethanol has evolved over time from considering this level as nonintoxicating and noninjurious, to encompassing levels defined as statistically normal in particular populations (312). Moderate consumption of alcohol may be defined as >2 drinks/week to 2 drinks per day (313). A meta-analysis showed no association between moderate alcohol intake during the first trimester of pregnancy and increased risk of

P.1587

fetal malformation (313). It was also not noted to be associated with intrauterine growth retardation (314) and abnormal child development at 18 and 42 months of age (315). On the other hand, one study has shown a 7-point decrease in the general cognitive index on the McCarthy scales at preschool age in offspring of women with moderate alcohol consumption during pregnancy (316).

Metabolism and Placental Transfer

Ethanol is an anxiolytic analgesic with a depressant effect on the central nervous system (301). It is absorbed rapidly by diffusion across the mucosa of the stomach (20%) and intestines (80%). The absorption rate is not affected by pregnancy, but blood alcohol levels may be higher in pregnancy (300). Alcohol is usually cleared from the bloodstream within 1 hour in adults and 2 hours in newborns. Approximately 95% is metabolized by the liver and 5% is eliminated by the kidneys and lungs. Ethanol is metabolized to acetaldehyde and then to acetate. Acetaldehyde is more toxic than ethanol itself. Acetaldehyde levels are frequently elevated in chronic alcoholics and in children with alcohol related birth defects (317). Genetic predisposition to alcohol and its effects may be present. The alcohol dehydrogenase 2 genotype (ADH2-1/3) is found to be more prevalent among black women who reported high alcohol use during pregnancy. There is also subsequent higher percentage of affected infants carrying this genotype (318). There is an unimpeded bidirectional placental transfer of ethanol during pregnancy. Alcohol is distributed rapidly and nearly equally in maternal and fetal tissues (319). Fetal ethanol is eliminated by maternal hepatic biotransformation. Ethanol has been detected in amniotic fluid and constitutes an additional reservoir for fetal exposure (301,320,321).

Maternal alcohol abuse is difficult to assess by laboratory tests. Biological markers which have been studied include: increased levels of mean cell volume, gamma-glutamyl transferase, carbohydrate deficient transferrin, hemoglobin acetaldehyde adducts (322,323,324) and decreased hepatic levels of glutathione (325). In the infant, fatty acid ethyl esters in meconium are promising biomarkers of fetal exposure to alcohol (326,327,328,329).

Ethanol has been implicated in the impairment of normal placental function. It affects or interferes with the transport of amino acids across the placenta to the fetus (330). Placental expression of epidermal growth factor and placental growth factor is also altered in alcohol abusing women (331). Ethanol has also been found to inhibit DNA synthesis, protein synthesis (332), inhibit phospholipase A2 (333), decrease PGI2 production (334), and increase HCG production in the placenta (335).

Effects on Pregnancy

An increased incidence of spontaneous abortion, abruptio placentae, and breech presentation have been observed among women who abuse alcohol during pregnancy.

The incidence of spontaneous abortion among alcoholic pregnant women ranges between 18.8% to 52% of pregnancies (300). In a large, prospective study of 12,127 pregnant women, alcoholic women were found to have a 2.3 times higher incidence of three or more spontaneous abortions than nonalcoholics (336). The single variable that correlated highly with spontaneous abortion was an extremely heavy episode of drinking during the early first trimester. In another cohort of 24,768 singleton pregnancies, the risk ratio for stillbirth among women who consumed more than 5 drinks/week during pregnancy was 2.96. The increased risk of stillbirth was independent of other alcohol effects like prematurity, low birthweight, or malformations (336). Other reports, however, do not show an association of alcohol consumption with an increased risk for spontaneous abortions in nonheavy drinkers (338) nor an increased risk of stillbirths even among women classified as problem or heavy drinkers (336, 338,339 and 340). However, the risk of abruptio placenta is increased (341,342).

Studies in nonhuman primates have shown that an increase in spontaneous abortion occurred only when blood alcohol levels reached approximately 200 mg/dL (343,344,345,346,347 and 348).

An increase in the frequency of aneuploidy was found in abortuses of women who consumed two or more drinks per week (347). Although in mice, preovulatory alcohol exposure did not increase the incidence of abortion (348) or aneuploidy, (349), alcohol administration shortly after ovulation resulted in a 7.5% incidence of aneuploidy. Ingestion shortly after mating also resulted in a 15% incidence of aneuploidy (350). Alcohol administration to mating female mice 2 hours after ovulation resulted in a significant increase in fetal death associated with aneuploidy. Another study showed that successful fertilization of such eggs after a single "binge," consequently resulted in the production of aneuploid embryos, which had a very high chance of being spontaneously aborted during the first trimester. Those relatively few aneuploid

conceptuses that survived to term invariably showed moderate to severe degrees of mental retardation, craniofacial and other abnormalities and having a significantly reduced life expectancy (351). These studies raise the possibility that the high rate of spontaneous abortions among alcoholic women may be as a result of a single episode of heavy drinking around the time of conception (352).

Fetal alcohol syndrome is strongly associated with breech presentation. Seventy percent of infants with FAS were breech births (300). In other studies, 9 of 23 (39%) infants born to heavy drinkers were delivered as breech (353); however, only 3 of 59 infants of moderate drinkers had breech presentation (354). Thus, it appears that heavy consumption of alcohol increases the incidence of breech births.

Effects on the Fetus

Animal studies have shown that in utero alcohol exposure may cause fetal malnutrition and chronic fetal hypoxia by

P.1588

inducing hypoglycemia at high blood alcohol levels (301). Alcohol decreases adrenergic receptors on the hepatic plasma membrane, resulting in reduced epinephrine-induced stimulation of glycogen phosphorylase activity and interference with carbohydrate metabolism and prenatal and postnatal growth. Low concentrations of somatomedin C and high growth hormone levels have been noted in infants of alcoholic mothers (355). A dose dependent contraction of the human umbilical cord, in vitro, and decreased fetal placental flow, *in vivo*, have been demonstrated with alcohol exposure and may further contribute to fetal hypoxia (356). Abnormal fetal heart rate patterns (357), decreased fetal breathing (358), decreased fetal eye movements, disorganized behavioral state organization (359) and decreased fetal movements (360) have all been described with alcohol use during pregnancy. There also is a reduction in the amount of neurotransmitters in the human brain, a decrease in the myelination process and decreases in fetal hippocampal nitric oxide synthase activity (361,362,363,364,365 and 366).

Effects on the Newborn Infant

Prematurity

The incidence of prematurity ranges from 46% to 52% in infants with FAS (365,367). The relationship between alcohol exposure and preterm birth in which FAS is not a factor is not as clear. Several reports indicate increased preterm delivery in alcohol abusers (368,369,370,371 and 372). This may be as a result of an associated increase in congenital anomalies, rather than directly to alcohol itself. Nonetheless, heavy alcohol consumption during pregnancy (i.e., six or more drinks per day) has been associated with an approximately threefold increased risk of preterm delivery (373).

Growth and Morphology

Maternal alcohol consumption has been associated with an increased risk for infants with low birth weight and with length and head circumference below the tenth percentile, if the mother's drinking took place during the early first trimester of pregnancy (302,375). Similarly, birth weight, length, and head circumference have been reported to be significantly reduced in the offspring of women who drank continuously throughout pregnancy (376,377,372,374). Abnormalities in fetal brain development have also been described (378,379). In rat pups, an increased vulnerability of brain development was observed (decreased brain to body weight ratio) when the pups were exposed to alcohol especially in the third trimester compared with other times in the pregnancy (380). The low birth weight was influenced both by dose and duration of alcohol exposure. Moderate or light drinking has been associated with a decrease in the birth weight of the infants (381). The birth weights, however, are within the range of normal, have no biologic significance, and often cease to achieve statistical significance when other risk factors, such as smoking, are taken into account. There are also a few reports that show no association between alcohol use and the infant's birth weight. In a group of healthy, full-term infants, no growth difference was noted between those exposed and those not exposed to alcohol (381,382 and 383).

Some minor morphologic malformations in the infant have been observed with alcohol use during pregnancy (382,383,384,385 and 386). On the other hand, other reports have failed to demonstrate this phenomenon (381,387,388 and 389). In a large prospective birth defects study involving 32,870 women, light and moderate drinkers were not found to have an increased rate of malformations in their offspring compared to nondrinkers (390).

Newborn Withdrawal

Withdrawal from alcohol occurs in infants but is rarely observed, because the withdrawal may be confused with withdrawal from narcotics or other drugs that are used together with alcohol. The withdrawal from ethanol has been described to occur within 12 hours of birth and may manifest as abdominal distention, opisthotonus, convulsions, tremors, hypertonia, apnea, and cyanosis. The infants are irritable, have restless sleep, and engage in exaggerated mouthing behavior (391,392).

Neurobehavioral Effects

Alcohol-exposed infants have been found to habituate less well to aversive stimuli as measured by the Neonatal Behavioral Assessment Scale (393,394), exhibit changes in their reflexive behavior, state control, and motor behavior, (381,395), and have increased irritability (396) and depressed range of state (397). These effects, however, have not been universally observed (386). Timing of prenatal exposure to alcohol, especially in early gestation, also had deleterious effects on neurobehavioral tests (398).

Sleep cycling and arousal have been studied as a measure of neurophysiologic

development, integrity, and maturation. Infants of mothers who drank heavily throughout pregnancy showed a greater amount of restless sleep and more bodily movements (399,400). Electroencephalographic power spectra analyses of the infants showed hypersynchrony of the EEG and an increase in the integrated power in all sleep states, particularly with active sleep (401,402). Electro-encephalographic maturation also was affected by maternal binge drinking (403).

Animal studies have shown that the deleterious effect of ethanol on brain development is a result of ethanol's potential to interfere with neuronal migration, trigger widespread neuronal apoptosis by blockade of NMDA glutamate receptors and excessive activation of GABA (404) and induce loss of myelinated axons in the CNS (405).

Breast-Feeding and Alcohol

Alcohol is distributed in breast milk; however, the amount ingested by the infant is only a small fraction of the amount consumed by the mother (300). Short-term alcohol con

P.1589

sumption by lactating women had an immediate effect on the odor of their milk and the feeding behavior of their infant (406). The infants sucked more frequently during the first minute after their mothers had consumed alcohol, but consumed significantly less milk. The postnatal growth was not affected in breastfed infants whose mothers consumed alcohol during lactation (407). In animal studies, ethanol has been shown to block the secretion of oxytocin, thereby preventing milk ejection (408). A similar effect has been observed in normal women (409).

Long-Term Effects of Prenatal Alcohol Use

Growth

Growth deficits were found in infants at 6.5 to 18 months of age and were related to alcohol use during the second and third trimesters of pregnancy (410,411). These children continued to be smaller in weight, length, and head circumference at 3 years of age, even after controlling for nutrition, current environment, exposure to alcohol during lactation, and other significant covariates. Variations in growth retardation have been observed. Growth retardation at 8 months of age, but not at subsequent evaluations (412), and significant effects on height and head circumference in children at 6 years of age have been reported (386). Some catch up growth after 8 months of age have been observed whether the children were exposed to alcohol in the first and second trimester or throughout gestation (413,414 and 415). However, head circumference remained smaller among children who were exposed throughout pregnancy (416). On the other hand, there are reports which show no effects of prenatal alcohol exposure on the infants' growth at 1 and 2 years of age (417,418).

Behavioral and Cognitive Effects

Infants of mothers who drank throughout pregnancy showed less improvement in reflexes and autonomic regulation over the first month of life than infants of women who stopped drinking or who never drank (419). At 6 to 8 months of age, these infants had significantly lower Bayley mental and motor scores (420,421 and 422) slower reaction time, longer fixation time, lower scores in elicited play and longer periods of toy exploration which may indicate slower cognitive processing (423,424,425). At 13 months of age, infants of women who drank during pregnancy did less well on the mental index and on the verbal comprehension and spoken language cluster scores derived from the Bayley Scales (417,426,427). Antenatal reports of alcohol use was a reliable predictor of poorer cognitive performance on Bayley Scales and symbolic play, slower processing speed on the Fagan Test of Infant intelligence and slower reaction time in infants tested from 6 to 13 months of age (428). Fried and Watkinson found that infants exposed to alcohol prenatally evidenced no deficits at 12 months of age (429). However, at 24 months of age, they performed more poorly than nonalcohol-exposed controls on the Bayley Mental Scale and the Reynell Language Scale. At 36 months of age, the language development of the exposed children continued to be affected, but at 48 months of age no significant relationships were found (430). Again, others have found that prenatal alcohol use did not significantly predict Bayley mental or motor scores at either 8 or 18 months of age (431).

Alcohol use during pregnancy was associated negatively with IQ at 4 years of age (432). At 4 years of age, children who were exposed prenatally to moderate drinking were less attentive and more active during naturalistic observations at home (433), and were less attentive and had longer reaction times on a vigilance task in a laboratory setting (434). Prepregnancy alcohol exposure also was related to increased fine motor errors, increased time to correct the errors, and poorer gross motor balance (435). Preschool children who were exposed to alcohol throughout gestation (with a range of 2-9 drinks per day) were more likely to show hyperactivity, language problems and motor deficits compared with those whose mothers stopped drinking by the second trimester (436). Difficulty in management, tantrums and eating problems were reported in 3 year old children prenatally exposed to alcohol. In children evaluated between 2 to 12 years of age, alcohol exposure during any part of pregnancy appeared to be associated with poorer academic achievement, although exposure during the third trimester appeared to be associated with lower aptitude scores (416).

Attention, distraction, and reaction time on a continuous performance task at 7 years of age continued to be negatively related to alcohol exposure during pregnancy (437). Children with any prenatal alcohol exposure were more likely to have higher scores on Externalizing (aggressive and delinquent) and Internalizing (anxious/depressed and withdrawn) compared with non exposed controls (372). Intelligence quotient effects persisted at 7.5 years, with a decrement of 7 IQ points with exposure to more than 1 ounce of alcohol per day during pregnancy (438). Achievement scores were related to binge drinking before pregnancy. Evaluation during adolescence showed difficulties in

tasks which involve manipulation of information, goal management (439), attention, memory (414), calculation, and estimation tests with intact reading and writing ability (430). Again, the inconsistencies regarding the long-term effects of prenatal alcohol exposure on the child's development may lie in the difficulty in separating the teratogenic effects of alcohol from the effects of the disordered environments, both interpersonal and structural, that often accompany alcohol and drug use (440,441).

With regards to alcohol ingestion by the infant through breast feeding, a slight but significant negative effect was observed in these infants on their motor development as measured by the Bayley scales psychomotor developmental index (PDI) but not on the mental developmental index (410).

Fetal Alcohol Syndrome

The Fetal Alcohol Study Group of the Research Society on Alcoholism defined three specific criteria for the diagnosis

P.1590

of FAS (300). An infant must exhibit an abnormality from each category to qualify for a diagnosis of FAS:

Prenatal or postnatal growth retardation, i.e., weight, length, or head circumference <the 10th percentile when corrected for gestational age.

CNS involvement, which includes signs of neurologic abnormalities (e.g., irritability in infancy, hyperactivity during childhood), developmental delay, hypotonia or intellectual impairment (e.g., mental retardation)

Characteristic facial dysmorphism (at least two of the three must be present)

Microcephaly, i.e., head circumference <3rd percentile

Microphthalmia or short palpebral fissures

Poorly developed philtrum, thin upper lip, i.e., vermillion border, and flattening of the maxilla.

Physical findings of smooth philtrum, thin upper lip and short palpebral fissure have a 100% sensitivity in diagnosing FAS (442,443). Presence of some, but not all, of these features is defined as alcohol-related birth defects (ARBD), or fetal alcohol effects (Table 58-6). Current criteria for diagnosis of FAS depend on recognition of subtle physical anomalies, growth retardation and nonspecific developmental aberrations which may change with time and varying degrees of severity which is affected by patient's age, or racial background. Under diagnosis of FAS usually occurs when complete patterns of abnormalities cannot be substantiated or when there is clinician's

fear of stigmatizing the mother and child (444).

Incidence

The incidence of FAS has been estimated at 1 to 3 per 1000 live births. Fetal Alcohol Spectrum Disorders (FASD) (which include FAS) are estimated to occur in about 1 in 100 births (445). The reported rate in the United States is 2.2 per 1000 live births (300). Prevalence estimates vary, depending on geographic location and specific population studied (446). The highest reported incidence of FAS occurs in the Native American and black population and those with low socioeconomic status. In a review of North Dakota FAS registry, 80.6% of FAS cases were native Americans and 18.2% were Caucasians and with more female than male infants (61.4% vs. 38.6%). Maternal characteristics include older maternal age, lower educational level, fewer months of prenatal care, fewer prenatal visits and less prenatal weight gain (447). Sokol and associates, in a prospective study of 8,331 pregnancies, identified 25 cases of FAS (448). Four significant prenatal risk factors were identified: black race, high parity, percentage drinking days, and positive Michigan Alcoholism Screening Test. In the absence of any of these factors, the probability of a child being afflicted with FAS was 2%; in the presence of all four, the probability was 85.2%.

Among alcohol-abusing women, the incidence of FAS in the world literature is 71 per 1000 live births, and in the United States, from 24 to 42 per 1000 live births (299). The National Institute on Drug Abuse (NIDA) estimated that approximately 7.62 million babies (18.6%) were exposed to alcohol during gestation (449). One factor that has been associated with an increase in the risk of FAS is the history of previous siblings with FAS in the family. It is estimated that the risk of a younger sibling having FAS, given an older sibling diagnosed as having FAS, is increased by 406 times, so that the incidence of FAS occurring in this group is 771 per 1,000 live births (300). Older siblings are not as likely to be severely affected as younger siblings (300). There is a higher risk of FAS with increasing maternal age and parity. This may be as a result of increase in maternal body fat-to-water ratio and a faster rate of alcohol metabolism in chronic drinking women (450).

Alcohol has the most teratogenic effect during organogenesis and development of nervous system (451). Teratogenesis is grossly dose related (394,452) although threshold dose is still not known. Estimates of 21 ounces of absolute alcohol per week around the time of conception may be a critical dose (422,452).

Alcohol-Related Birth Defects

Alcohol-related birth defects may account for as many as 5% of all congenital anomalies (301). Alcohol-related birth defects result from variable dose exposures at variable gestational times, and are offset by the genetic background. These determinants place the fetus at a higher risk for possible adverse outcome. The frequency of ARBD is 3 to 5 per 1000 live births. Table 58-6 shows the various dysmorphic features that may be observed in the infant after prenatal alcohol exposure.

Follow-Up of Infants with Fetal Alcohol Syndrome

Postnatal growth retardation and retarded motor performance are hallmarks of prenatal alcohol exposure, especially of FAS. A 10-year follow-up of patients diagnosed to have FAS showed that the children continued to be growth retarded with respect to weight, height, and head circumference. Weight-for-height was especially decreased (453,454). Long-term study of children with FAS showed that the characteristic craniofacial malformations of FAS diminished with time but the microcephaly and, to a lesser degree, short stature, and underweight persisted in boys. In female adolescents, body weight normalized (455,456,457). Significant differences in facial features between exposed and nonexposed infants were mostly evident only up to 3 months of age (457). However, mental retardation persisted ranging from near normal to severe (458,459). The long-term neurobehavioral effects of FAS, which consisted of attention and memory deficits, poor adaptability and organization did not improve with age (460). Significant adaptive behavior defects in adolescent and adults with FAS and FAE particularly in areas of socialization and communicative skills also persisted (456). Behavioral problems

P.1591

included general spatial memory deficit and distorted spatial arrangement (461), profound verbal and learning deficits (462), stereotyped behaviors, irritability, hyperactivity, attention deficits tremulousness, and hyperdistractibility (367,461,462,463,464,465 and 466). The excess psychopathology (hyperkinetic disorders, emotional disorders, sleep disorders, abnormal habits and stereotypes) strongly persisted over time (466). Speech may be delayed or impaired and may be partly as a result of hearing impairments (464,465,466,467,468,469,470 and 471).

TABLE 58-6 ALCOHOL AND FETAL DYSMORPHOGENESIS^c

Central nervous system

Neurobehavioral Intellectual impairment (i.e., mild to moderate mental retardation),^a low IQ (65–70), hypotonia,^b developmental delay, poor coordination, cognitive and sensory deficits, attention deficits, hyperactivity and irritability in infancy, hyperactivity in childhood,^c language disabilities and sleep–wake cycle disturbances, electroencephalogram hypersynchrony, delayed or deficient myelination, corpus callosum hypoplasia, echolalia, cerebral palsy

Craniofacial

Head

Microcephaly,^a Dandy–Walker malformation, anencephaly, porencephaly, meningocele, spasmus nutans

Eyes

Ocular retinal tortuosity, ptosis, strabismus, epicanthal folds, myopia, retinal coloboma, astigmatism, steep corneal curvature, anterior chamber anomalies, sensorineural hearing loss

Ears

Poorly formed conchae and posterior rotation of the ear and eustachian tube

Nose

Short, upturned^b hypoplastic philtrum^a

Mouth

Dental malalignments, small teeth with faulty enamel, retrognathia in infancy^a or relative prognathia in adolescence, cleft lip or cleft palate, malocclusions, prominent palatine ridges, thinned upper vermilion,^a a poor suck reflex

Maxilla

Hypoplastic^b

Cardiovascular

Heart	All cardiac defects (57%), particularly ventricular septal defect, atrial septal defects, murmurs, tetralogy of Fallot, double-outlet right ventricle, dextrocardia, patent ductus arteriosus, and great vessel anomalies
Pulmonary	
Chest	Pectus excavatum, bifid xiphoid
Lungs	Pulmonary atresia, atelectasis, upper respiratory infections
Gastrointestinal	
Abdomen	Inguinal and abdominal hernias, diastasis recti, gastroschisis, hepatic fibrosis, childhood cirrhosis, extrahepatic biliary atresia, hyperbilirubinemia in childhood
Urogenital	
Renal	Hydronephrosis; small rotated kidneys; aplastic, dysplastic, or hypoplastic kidneys; horseshoe kidneys; ureteral duplications; megaloureter, cystic diverticula; vesicovaginal fistula, pyelonephritis
Dermatologic	
Dermatoglyphic	Aberrant fingerprint and palmar creases, hemangiomas in one-half of the cases, disproportionately diminished adipose tissue, ^b abnormal whorls on scalp, hirsutism in infancy, nail hypoplasia, poor proprioception
Orthopedic	
Skeletal	Polydactyly, radioulnar synostosis, talipes equinovarus, dislocated hip, scoliosis, Klippel-Feil syndrome, limited joint movement, lumbosacral lipoma, shortened fifth digit, syndactyly, camptodactyly, clinodactyly, flexion contractures
Endocrinology	
Congenital	DiGeorge syndrome

^a Feature seen in 80% of patients.

^cFrom Pietrantoni M, Knuppel RA. Alcohol in pregnancy. *Clin Perinatol* 1991;18:93.

Slow growth of the head circumference indicates slow brain growth in children with moderate to severe FAS (443). Neurologic findings by MRI showed significant reduction in the cerebellar vermis (472), cerebral vault, basal ganglia and diencephalon. The basal ganglia changes may relate to behavioral findings seen in these children (473). Another study has shown mildline anomalies such as complete callosal agenesis, hypoplastic corpus callosum, cavum septum pellucidum and cavum vergae which are associated with greater number of facial anomalies (408,474).

Ophthalmologic abnormalities are also found in children with FAS. These consist primarily of fundus anomalies and optic nerve hypoplasia (475,476 and 477). These defects have been attributed to competition of ethanol with retinol at the same ADH-binding sites (478). Other eye findings include strabismus, blepharoptosis, epicanthus, cataract, glaucoma, persistent hyperplastic primary vision and increased tortuosity of retinal vessels with smaller number of vascular branching (476,479).

P.1592

Four types of hearing disorders are associated with FAS: (a) developmental delay in auditory maturation, (b) sensorineural hearing loss, (c) intermittent conductive hearing loss as a result of recurrent serous otitis media, and (d) central hearing loss (480). Seventy-seven percent of children with FAS have conductive hearing loss secondary to recurrent, serous otitis media. Twenty-seven percent have sensorineural hearing loss and 100% have central hearing function injuries. Majority of the patients have associated speech pathology, expressive language defects and receptive language defects (481). The craniofacial abnormalities may also increase the susceptibility to peripheral hearing disorders (482).

MARIJUANA

Marijuana is the most widely used illicit drug among women of childbearing age in the United States (483). In 2001, marijuana was used by 76% of current illicit drug users, 56% of whom consumed marijuana exclusively. The number of new users continues to rise with about 2.4 million new users reported in 2000 (1). In 1999 and 2000 about 2% to 2.8% of pregnant women in the United States were current marijuana users. The majority were young mothers between the ages of 15 and 25 years old. The incidence of marijuana use during pregnancy is notably lower than that of non pregnant women of the same age group. This trend seems to persist amongst new mothers up to one year after the delivery.

There are some common terminology pertaining to marijuana: (a) cannabis refers to the crude material from the plant, *c. sativa*, (b) marijuana refers to a mixture of crushed leaves, twigs, seeds, and sometimes flowers of the plant, (c) sinsemilla is a variety of high-potency marijuana originally grown in northern California, and

(d) hashish is a resin obtained by pressing, scraping, and shaking the plant in hash oil, to produce a potent extract (484,485). Cannabis contains more than 400 chemicals, of which 61 are unique to cannabis and are referred to collectively as cannabinoids. The primary psychoactive component is δ -9-tetrahydrocannabinol (THC). Other cannabinoids, however, such as cannabidiol and cannabinol, also have biologic activity and potentially can affect the fetus (486,487).

Placental Transfer

Tetrahydrocannabinol is highly bound to the lipoprotein fraction in blood. Studies using radiolabeled THC have shown that tissues with high blood flow show a rapid uptake of the drug. Tetrahydrocannabinol gets into the placenta within minutes of administration; however, the placenta may retard THC passage to the fetus. In rats, the placenta contained ten times more radiolabeled THC than fetal serum (488), and fetal rat THC serum levels were well below the maternal serum levels (489). In humans, however, the concentrations of THC in maternal and fetal sera essentially are identical (490).

Effects on Pregnancy

Based on a large perinatal study, no significant differences were observed between marijuana users and control subjects matched for amount of alcohol consumption, cigarette use, and family income regarding several birth outcome measures, such as miscarriage rate, presentation at birth, Apgar status, and the frequency of complications at birth (491,492). In another prospective, multicenter, cohort study no significant association was found between marijuana use during pregnancy and preterm delivery or abruptio placenta (493). Severe nausea and vomiting have often been observed in pregnant women who discontinued marijuana during the first trimester (494), which is consistent with the known antiemetic effect of the drug. Higher levels of blood carboxyhemoglobin and tar have been reported with marijuana smoking compared to regular cigarettes. Low blood levels of folate and ferritin have also been reported in pregnant women with high serum levels of PCP, cocaine, and cannabinoids (494). Studies on marijuana use during pregnancy have shown infrequent adverse pregnancy outcomes except for a higher incidence of precipitous or dysfunctional labor and meconium staining compared to controls (494).

Effects on the Fetus and Newborn Infant

A reduction by 0.8 weeks was observed in the gestational age of infants of heavy marijuana users (six or more times/week) compared to infants of nonusers although in some studies, a 25% prematurity rate was reported (492,495). However, this effect was not consistently observed (496,497,498 and 499).

Most studies did not show an increase in the incidence of major or minor malformations in the offspring with prenatal marijuana exposure (498,499 and 500). In the few reported cases of malformations, the confounding variables of poor nutrition, little prenatal care, low socioeconomic status, and other factors that may have interacted to produce these abnormalities were not controlled for (501).

There seems to be an increase in the gender ratio of male-female offspring in marijuana users. In animals, litters from dams fed 50 mg/kg of THC showed a significant increase in the proportion of male offspring, ranging from 57% to 61% (411,412). In a study of women who smoked marijuana during pregnancy, heavy use similarly was associated with a significant increase in male over female births (497).

Most studies do not show a significant effect of prenatal marijuana use on fetal growth and weight. In animal studies, reduced birth weights among the drug-exposed offspring were observed (489), but appeared to have resulted largely from the reduced maternal food and water intake rather than the effect of the drug (502).

There is equivocal relationship between prenatal marijuana use and neurobehavioral outcome of the offspring (503). Prenatal marijuana exposure has been associated with increased fine tremors in the infant, accompanied by exaggerated and prolonged startles, both spontaneous

P.1593

and in response to mild stimulation. Poor visual but not auditory stimuli habituation (503) and decreased ability to regulate state and disrupted sleep patterns (504) have also been noted. Elevated serum norepinephrine levels were observed among these infants (505). Again, there are also reports that have not found altered neurobehavioral patterns in marijuana-exposed offspring (399, 497,506).

Long-Term Outcome

After controlling for confounding variables, prenatal marijuana use was found to be associated with increased infant weight at 12 months and increased height at 24 months of age (429). One report, however, found no effect on infant growth at 12 months of age (497). Assessment of growth from birth up to 6 years failed to demonstrate any independent effect of marijuana (507). In general, there has been no observed adverse effect of antenatal marijuana exposure on infant motor and mental development at 12 months of age, as determined by the Bayley Scales of Infant Development (429,497). Global IQ was not also affected (508). However, women who used marijuana prenatally were found to be less involved with their children at 24 months of age and provided less stimulating home environment. From a preschool sample, no effect of prenatal marijuana use on IQ

scores was found at 4 years of age. However, contrasting observations have also been published. There are reports, among infants at age 36 to 48 months, of poor abstract/ visual reasoning and poor memory and verbal outcome in association with heavy prenatal marijuana use (257,429,430,503). Follow-up studies on children with prenatal exposure to marijuana also showed increased fearfulness, poorer motor skills, and shorter length of play at age 3 years (509). Additionally, attention behavior and visual analysis/hypothesis testing appeared to be negatively associated with in utero cannabis exposure (508). No effects on language development have been reported. Abnormal sleep patterns in infants which persisted at 3 years of age have raised concerns about potential neural alterations or disruptions (509). Others have reported frequent maternal cannabis intake as a small risk factor for SIDS (511). Drug interactions may play a role in the effect of marijuana exposure. There is an increased risk for FAS if the mother reported marijuana use in addition to alcohol (512).

NICOTINE AND SMOKING

Cigarette smoke contains about 4,000 chemical compounds. Most are found in the gas phase of cigarette smoke and include carbon monoxide, carbon dioxide, nitrogen oxide, ammonia, hydrogen cyanide, and other compounds. A smaller number of undesirable compounds are in the particulate phase of cigarette smoke (e.g., nicotine and tar). Tar is what remains after the moisture and nicotine are subtracted. It consists primarily of polycyclic aromatic hydrocarbons (e.g., nitrosamines, aromatic amines, polycyclic hydrocarbons) and numerous other compounds, including metallic ions and radioactive compounds (513).

Absorption and Metabolism

Nicotine is the most studied compound in cigarette smoke, and is primarily responsible for the pharmacologic effects of smoking. It is absorbed readily from the lungs, almost with the same efficiency as intravenous administration. Blood nicotine levels vary depending on the amount of nicotine delivered. The amount of nicotine delivered depends on the duration and intensity of inhalation, the number of inhalations per cigarette, the presence or absence of filters, the brand of the cigarette (which affects the composition of the tobacco), how densely the tobacco is packed, and the length of the column of tobacco (513).

Nicotine is distributed rapidly throughout the body. It reaches the brain within 8 seconds after inhalation. Peak concentrations of nicotine in plasma after a cigarette is smoked are typically between 25 to 50 ng/mL. The course of elimination of nicotine is multiexponential. After a single cigarette, concentrations decline rapidly, i.e., over 5-10 minutes, primarily reflecting distribution. After long-term smoking, the elimination half-life of nicotine is approximately 2 hours (513).

Nicotine is metabolized mainly in the liver but also in the kidneys and lungs. The

two main metabolites are cotinine and nicotine-1'-*N*-oxide. Cotinine has few or no cardiovascular or subjective effects. It is cleared more slowly than nicotine, with a half-life of about 19 hours. Cotinine concentrations in the plasma and breast milk of mothers and in the urine of their infants have been reported to reflect the smoking habits of the mothers during pregnancy (514). Thus, it is a better measure of overall intake than nicotine itself. Nicotine crosses the placenta and also is excreted in the milk of lactating women (513). There is a close correlation between nicotine concentration in the mother's plasma and milk after smoking (514). Cotinine, the principal metabolite of nicotine, has been detected in breast milk, particularly in the colostrums in women who smoked actively during pregnancy. Cotinine has also been detected in amniotic fluid and placenta (515).

Incidence

An estimated 66.5 million Americans reported current use of tobacco products in 2001, representing a smoking rate of 29.5% for the population age 12 and older (1). Tobacco is still widely used by women of childbearing age. Based on 2000 and 2001 combined data of the National Household Survey on Drug Abuse, 19.8% of pregnant women aged 15 to 44 smoked cigarettes in the past month compared with 29.5% of nonpregnant women of the same age group. The trend has increased from 1999 and 2000 in which 17% of pregnant women were current smokers (1). Pregnant

P.1594

women aged 15 to 25 were twice as likely to have smoked cigarettes in the last month compared to women aged 26 to 44. Most of those who smoked during pregnancy were Caucasian. About 23.6% of current smokers smoked during the first trimester, 23.8% continued to smoke during the second trimester and 17% up to third trimester (1).

Spontaneous Abortion

The relationship between cigarette smoking and spontaneous abortion has been documented in both animal and human studies. When other risk factors are controlled, women who smoke cigarettes during pregnancy are 1.2 to 2 times more likely to have a spontaneous abortion than those who do not smoke (516). The higher rate of abortion was noted in women who smoke one-half of a pack per day compared to nonsmokers. The mechanism for this association has not been completely elucidated, although studies support the theory that this may be as a result of the vasoactive effects of nicotine on the umbilical arteries (517). Nicotine decreases prostacyclin production in the umbilical artery and reduces its capacity for vasodilatation, thereby affecting fetal nutrition and oxygen transport especially in conditions causing asphyxia (518). Other studies attribute the higher rate of abortion to abnormalities in placental development, and dysfunction of

hormones that sustain pregnancy (519,520).

Placental Effects

An increased incidence of placental abruption, and an increase in fetal death as a result of abruption, were seen among women who smoke more than ten cigarettes per day (521). Maternal smoking was associated with the finding of decidual necrosis on pathologic examination. Extensive placental calcification occurred significantly more often in smokers than in nonsmokers (46% vs. 14%) (518). Intervillous blood flow was reported to be reduced acutely during smoking, and for 15 minutes afterward (520).

Apgar Scores

Several studies have noted that maternal cigarette smoking during pregnancy is associated with low Apgar score; however, other risk factors were not controlled for (522). When potentially confounding factors were controlled for, no significant independent association was noted between cigarette smoking and Apgar score (523).

Preterm Birth

Maternal smoking has been reported to be a risk factor for preterm labor and delivery (524). The incidence of preterm labor and birth increases with the number of cigarettes smoked per day (525,526). or nicotine levels in maternal hair (524). However, other studies have shown no effect of smoking on length of gestation (527).

Fetal Death and Neonatal Mortality

Epidemiologic studies have shown a significant effect of smoking on late fetal death and neonatal mortality. Among first-born infants, there was a 25% greater risk for fetal death and neonatal mortality for less than one-pack-per-day smokers and a 56% greater risk for more than one- pack-per-day smokers, compared to the nonsmokers (528). For second or higher births, a 30% greater risk of late fetal death and neonatal mortality was noted in maternal smokers compared to nonsmokers. Maternal smoking had a relative risk for late fetal death of 1.4 and a relative risk for early neonatal mortality of 1.2 (529).

Effects on Fetus and Newborn

Animal models have been designed to prove that nicotine is a neuroteratogen. Nicotine targets specific neurotransmitter receptors in the fetal brain, leading to a decrease in the number of cells and subsequently to altered synaptic activity. The

adverse effects of nicotine involve multiple neurotransmitter pathways that alter not only immediate developmental events but also the eventual programming of synaptic competence. These defects may eventually lead to disabilities in learning and cognition which appear later in childhood or adolescence. Alterations in the development of the autonomic nervous system may lead to increased susceptibility to hypoxic-ischemic brain injury, stillbirth and SIDS (530).

Numerous studies have examined the association between smoking prior to or during pregnancy and birth weight and have consistently demonstrated a decrease in birth weight (531) of approximately 200 g, and an increased percentage of low-birth-weight (LBW) infants. (423,526,532,533 and 534). Additionally, a dose-response relationship has been demonstrated between the number of cigarettes smoked and the decrease in birth weight (535,536) and the percentage of LBW infants (537). These findings remain consistent after controlling for confounding variables (423). Race is an important factor. In Caucasian mothers, the incidence of LBW babies ranged from 4.8% for women who did not smoke, to 8% for women who smoked 1 to 10 cigarettes per day, and to 13.4% for women who smoked more than 20 cigarettes per day. For black women, the incidence of LBW babies ranged from 8.3% for women who did not smoke, to 13.5% for women who smoked 1 to 10 cigarettes per day, to 22.7% for women who smoked more than 20 cigarettes per day (537). One study demonstrated that serum nicotine levels were more strongly correlated with reduced birth weight than with smoking history (538). This indicates the importance of using biochemical markers in studies of pregnancy outcome.

Studies comparing infant birth weights showed that mothers who quit smoking during pregnancy have infants with higher birth weights than do mothers who continued to smoke during pregnancy, although the overall birth weight was still about 179 g lower compared to nonsmoking

P.1595

mothers (537). The difference in birth weight was highly significant when smoking was discontinued by as late as 16 weeks of gestation, compared to persistent smokers. However, even beyond 16 weeks of gestation, cessation of smoking was still found to be associated with infants with higher birth weights than the offspring of persistent smokers (536). Pregnant women who switched to low tar or low nicotine containing cigarettes continue to have increased risk of having a small for gestational age infant (539).

Attention has been recently focused on the role of environmental tobacco smoke exposure (ETS) as a potential risk factor for low birth weight infants. In one review, infants with ETS exposure in utero were 1.5 to 4 times more likely to be born with low birth weight. ETS was associated with a 25 to 90 g reduction in birth weight and infants born to mothers with ETS exposure were 2 to 4 times more likely to be born small for gestational age (540).

The nature of the growth deficit in terms of newborn body composition, was assessed by examining the anthropometric indices of subcutaneous fat deposition and lean body mass in infants of smokers and nonsmokers. There was no difference between the two groups of infants in the skinfold measurements or in the calculated cross-sectional fat area of the upper arm. These results suggest that the reduction in birth weight of infants whose mothers smoke is due primarily to a decrease in the lean body mass of the newborn, whereas deposition of subcutaneous fat is relatively unaffected (541,542).

Besides birth weight, length and head circumference were also found to be smaller for infants of smoking mothers (533,543), especially among those who continued to smoke to the third trimester (544).

Various studies assessing the association between cigarette smoking during pregnancy and congenital malformations have shown conflicting results. The British Perinatal Mortality Survey, in a study of 17,418 subjects, demonstrated that maternal smoking was associated with congenital heart defects, even after maternal age, parity, and social class were controlled for (545). Other reported deformities included cheilognathopalatoschisis, deformities of the extremities, polycystic kidney, aortopulmonary septum defect, gastroschisis, and skull deformities (546). However, the United States Collaborative Perinatal Project, in a study of 50,282 subjects, did not observe these findings (547,548). The inconsistency of reports suggests that cigarette smoking per se may not be a cause of congenital malformations in infants (549).

Active, and passive, smoking during pregnancy has recently been reported as an independent risk factor for the development of persistent pulmonary hypertension of the newborn (550).

Neurobehavioral Effects

Several studies have investigated the impact of cigarette smoking during pregnancy on newborn behavior and on later child development (550,551). Offspring of mothers who smoked during pregnancy have been observed to perform less well on the Brazelton Neonatal Behavioral Assessment Score in items such as habituating to sound or orienting to a voice, compared to offspring of nonsmoking mothers. Other studies indicate poorer performance with head turning and sucking, lower visual alertness, more crying, tremors and startles, and increased lability of color and problems with arousal and behavioral regulation (552,553). Most of the studies, however, do not demonstrate a clinically significant effect on neonatal behavior that can be attributed independently to maternal cigarette smoking alone.

Long-Term Outcome

Long-term follow-up evaluation of children's cognitive and developmental functions indicate that when sociodemographic factors were controlled for, children exposed to cigarette smoke in utero performed less in tests of cognitive, psychomotor, language, and general academic achievement, including reading and mathematics. Although the differences were statistically significant between the two groups, they were small compared to other factors that affected the children's performance (509,554,555,556,557). Children of mothers who smoked during pregnancy have been shown to be at a higher risk for prepubertal onset conduct disorder and, adolescent onset drug dependence (558).

Sudden Infant Death Syndrome

Several studies have reported that maternal cigarette smoking significantly increases the likelihood of sudden infant death syndrome (559,560,561 and 562). It is proposed that nicotine affects catecholamine metabolism in the brain causing an attenuated response to hypoxia which later causes disturbances in respiratory and cardiovascular control mechanisms (560). Maternal smoking has also been associated with increased incidence of central apnea among infants (561). Mothers of infants who died from the sudden infant death syndrome were more likely to smoke cigarettes either during pregnancy or after their baby was born.

PHENCYCLIDINE

Phencyclidine (PCP) was first introduced in 1957 as a dissociative anesthetic. Despite its wide margin of safety in humans, its clinical use was discontinued after reports of adverse effects that include agitation, confusion, delirium, and persistent hallucinations. Other untoward effects noted with its use were feelings of paranoia, impending death, outbursts of bizarre, agitated, or violent behavior, and a psychosis mimicking schizophrenia. It remains popular as a drug of abuse as a result of its sedative and hallucinogenic effects, its synthesis from readily available precursors, low cost, and variety of routes of administration. Most users smoke PCP; others sniff or snort the powder, drink

P.1596

the liquid form mixed with lemonade or alcohol, or inject it intravenously (563,564,565 and 566).

Placental Transfer and Metabolism

Placental transfer of PCP has been studied in the pig, mouse, rabbit, and humans. In piglets, serum levels of PCP were ten times higher than in the sow (567,568); in fetal rabbits, similar high serum levels were found that reached a peak 2 hours after parenteral administration of the drug to the doe (569). In the mouse, there was almost a tenfold higher concentration of PCP in fetal tissue than in maternal

blood (569), and PCP appeared in the pup's brain as early as 15 minutes after subcutaneous injection to the dam (564). Phencyclidine also has been detected in amniotic fluid and umbilical cord blood at high concentrations (570).

Phencyclidine appears rapidly in breast milk, appearing within 15 minutes of maternal administration. By 3 hours, the ratio of levels in milk to those in plasma is approximately ten to one (569).

Phencyclidine is lipophilic. It is stored in body fat and in the CNS for a prolonged period and is released slowly into the bloodstream. The major routes of elimination involve metabolism of PCP in the liver and excretion in the urine and feces (571). The half-life of the drug in the body usually is about 3 days, although it has been found in the urine as long as 8 days after last use (572). The half-life of PCP in the fetus is approximately twice that in the mother (569).

Mode of Action

Phencyclidine has strong, centrally mediated effects in animals and humans, and influences many different neuronal systems. It inhibits the uptake and increases the release of monoamines in the brain, interacts with cholinergic and serotonergic systems, and antagonizes the neuronal stimulation caused by the excitatory amino acid, *N*-methyl aspartate (563). Phencyclidine may produce a general enhancement of neurotransmitter release by blocking voltage-sensitive potassium channels, and thus might act at several different loci (573).

Incidence

The abuse of PCP first occurred in 1970, peaked in 1979, and then declined by 1981 (574). National surveys, however, have indicated that PCP abuse is again on the rise, especially in large urban areas.

The prevalence of PCP abuse during pregnancy has not been firmly established, because most reports have come from urban areas and could not be generalized to a national level.

Between 1981 and 1982 in Cleveland, 7.5% of 2327 pregnant women gave a history of PCP use, although only 0.8% could be confirmed by maternal urine screening (575,576). In 1983, a study from Los Angeles reported that 12% of a random sample of 200 newborns had measurable quantities of PCP in their cord blood (570). In 1995 and 1996 about 2.6% of pregnant women admitted having used PCP in their lifetime although 0.2% admitted having used it in the last year. In 2000 and 2001, there were 16,000 women of reproductive age (aged 15 to 44) who were current users of PCP (1). Although the number of new users of hallucinogens continues to rise, it is due largely to the use of methylenedioxymethamphetamine (MDMA) or ecstasy, a member of the so called club drugs.

Growth and Morphology

Animal studies indicate that maternal weight gain is lower in PCP-exposed mice. The birth weights of exposed pups were approximately 7% lower than those of nonexposed pups (564). In most human studies, no significant difference in the birth weight and length and head circumference was observed in PCP-exposed newborns compared to matched controls (577,469,5). In another study, two of five preterm and none of seven term PCP-exposed newborns were small for gestational age. All 12 newborns were normocephalic (579). However, in other studies, intrauterine growth retardation, precipitous labor and neonatal drug withdrawal/intoxication and longer hospital stay were observed among PCP-exposed newborns that were comparable, if not less pronounced (580,581) than cocaine effects (581).

There was also a higher incidence of meconium stained amniotic fluid and less incidence of premature delivery (581). In both animal and human studies, PCP has not been shown to be teratogenic, and no reports of congenital malformations attributable to PCP have as yet been made. Some animal studies have shown either neurodegenerative or antiapoptotic changes in various regions of the brain which resulted in decreased motor coordination and hyperactivity in newborn pups (582). Drugs like PCP have also been shown to produce widespread apoptotic neurodegeneration throughout the developing brain when administered to immature rodents during the period of synaptogenesis which is known as the growth spurt period in the developing brain. This eventually resulted in decreased brain mass and perhaps may also account for the neurobehavioral disturbances seen in the postnatal period (583).

Neurobehavioral Effects

Early case reports of PCP-exposed newborns showed abnormal neurobehavioral findings in the infants. These included irritability, tremors, hypertonicity, poor attention, bizarre eye movements, staring spells, hypertonic ankle reflexes, and depressed grasp and rooting reflexes (576,577,584). One of the most characteristic features in infants is a sudden and rapid change in level of consciousness, with lethargy alternating with irritability. The behavioral outcome of these newborns has been attributed

P.1597

to PCP intoxication, rather than to withdrawal (580). The very low threshold of stimulation, coarse, flapping tremors, and rapid changes in state are similar to behavior reported in children and adults intoxicated with PCP (577).

Long-Term Outcome

The Bayley psychomotor and mental development indices of PCP-exposed infants at 3 months and at 1 year (585) of age were not statistically different from those of controls (577). In one study however, temperament and sleep problems were noted at 12 months of age (585). At 9 and 18 months of age, fine motor development, adaptive or playing behavior, language skills, and personal-social development as determined by the Gesell Developmental Evaluation were within normal range. PCP exposure reportedly, does not affect Bailey Scores during the first 2 years of life (586). These findings are consistent with the interpretation that the observed PCP effects on infants at birth result from acute intoxication rather than from morphologic CNS damage.

AMPHETAMINES

The amphetamines are a group of chemically related sympathomimetic amines that have both CNS stimulant and peripheral α and β actions (587). Since their synthesis in the 1880s, therapeutic uses have included the treatment of exogenous obesity, narcolepsy, hyperkinesia, and depression. There is a very strong abuse potential because of their psychic effects, which include a decreased sense of fatigue, wakefulness, alertness, mood elevation, self-confidence, and often euphoria and elation.

Epidemiology

After initial epidemics of abuse of speed in the 1950s and 1960s, there was a decline in the abuse of amphetamines with the emergence of other drugs of abuse (e.g., heroin, crack cocaine). Lately, a resurgence of amphetamine use in epidemic proportions has occurred, particularly in Japan and parts of Asia, Hawaii, and areas of the West Coast. Of the estimated 356,000 women of reproductive age who were current users of stimulants in 1999-2000 about 4000 (1.12%) of these women were pregnant (1).

Methamphetamine

Methamphetamine is the methylated derivative of amphetamine, and is prepared through the reduction of ephedrine or pseudoephedrine. The ease of its synthesis, its availability and affordability, and a state of prolonged high have made it an increasingly popular drug of abuse. Ice, the form of methamphetamine that can be smoked, is claimed to produce an intense euphoria. High doses may cause aggressive behavior, arrhythmias, severe anxiety, seizures, shock, strokes, abdominal cramps, insomnia, and death. Chronic use can produce paranoid psychosis.

Effects on Pregnancy

Outcomes of pregnancies in 52 self-reported intravenous methamphetamine abusers were studied; these patients used other drugs as well (588). The infants had significantly lower birth weight, length, and head circumference than infants of non-drug-users. There was no significant difference, however, in the frequency of pregnancy complications such as pregnancy-induced hypertension, peripartal hemorrhage, chorioamnionitis, syphilis, and hepatitis.

No significant increase in the frequency of major congenital anomalies has been associated with methamphetamine use during pregnancy (588,589), although clefting and cardiac anomalies have been reported (590).

Higher incidence of prematurity, intrauterine growth retardation, and smaller head circumference have been reported in infants of mothers who abused cocaine and methamphetamine (591,592). A higher incidence of retroplacental hemorrhage also was noted (591). Fetal and neonatal deaths from maternal methamphetamine abuse have been reported (593).

Effects on Neonates

An infant of a known amphetamine addict manifested after birth with diaphoresis, episodes of agitation alternating with lassitude, meiosis, and vomiting (594). Infants exposed to both cocaine and methamphetamine were described as having abnormal sleep patterns, tremors, poor feeding, hypertonia, sneezing, a high-pitched cry, frantic fist sucking, tachypnea, loose stools, fever, yawning, hyperreflexia, and excoriation (591). Cranial ultrasound performed on term neonates exposed to cocaine, methamphetamine (or cocaine and a narcotic) showed a higher incidence of cranial abnormalities similar to the incidence of infants at risk for hypoxic ischemic injury. The abnormalities include intraventricular hemorrhage, cavitary lesions, echodensities associated with necrosis, mostly found in basal ganglion, frontal lobes and posterior fossa. This is probably related to the vasoconstrictive property of these drugs (595). Brain proton magnetic resonance spectroscopy of children with in utero exposure to methamphetamines showed abnormal energy metabolism but no visible structural abnormalities (596).

Long-Term Effects

Long-term, prospective follow-up of 65 children of women who abused amphetamines and also used alcohol and smoked cigarettes during pregnancy revealed that, at 1 year of age, somatic growth was normal, although illness and accident rates were increased (597). At 4 and 8 years of age, somatic growth and general health still were normal (598,599). Prenatal amphetamine and or cocaine exposure has been reported as a risk factor for later subtle neurologic

abnormalities. Developmental screening at 4 years of age, using the Terman Merrill method, revealed significantly lower IQs (484,598), but IQ and psychomotor development were within normal limits by 8 years of age (599). Aggressive behavior and peer-related problems also were noted (599). Poor academic performance and various behavioral problems have been reported among adolescent children who were exposed to amphetamines *in utero* (600).

CLUB DRUGS (ECSTASY, GHB, KETAMINE)

The illicit use and abuse of club drugs such as methylenedioxymethamphetamine or MDMA (ecstasy), gamma hydroxybutyrate (GHB) and ketamine hydrochloride have increased during the past decade. These club drugs are chemical substances used recreationally by young people during all-night dance parties. In 2001, an estimated 8.1 million (3.6%) of Americans aged 12 or older had tried ecstasy at least once in their lifetime compared to 6.5 million with the highest percentage occurring in the 18 to 25 age group. Use of this drug has been rising steadily since 1992 (1). There is growing concern about its potential toxicity and their effects on human pregnancy because it is being used by a significant number of women of child bearing age. Only a few data are available regarding the effects of these drugs on the fetus.

An animal study on the effect of exposure to ecstasy in utero during the maturation phase suggest that it does not produce damage to 5-HT nerve terminals in the fetal rat brain in contrast to the damage seen on the brain of the mother. This may be as a result of ecstasy being metabolized into free radical producing entities in the adult brain but not in the immature brain or, alternatively, this may be as a result of more effective or more active free radical scavenging mechanisms being present in the immature brain (601). In a prospective follow-up of 136 babies exposed to ecstasy in utero one study indicated that the drug may be associated with a significantly increased risk of congenital defects predominantly cardiovascular and musculoskeletal anomalies (602). There is still much to be learned about the effects of these club drugs on the fetus and the newborn, much less is known about its long-term effects in children. Clinical and basic science research data have remained limited.

CAFFEINE

Caffeine (1,3,7 trimethylxanthine) is a mild CNS stimulant, which is the most widely used psychoactive drug in the world. It is found in coffee (the most important source of caffeine in the American diet), tea, chocolate, cocoa and in numerous prescription and over-the-counter medications (603).

Caffeine is readily absorbed from the digestive tract and is rapidly distributed to all tissues. It easily crosses the placenta and is found in breast milk. Caffeine has several proposed mechanisms of action. One is that it inhibits phosphodiesterase

thereby causing intracellular accumulation of cyclic adenosine monophosphate (cAMP). It may also block adenosine receptors and cause increased release of calcium ions from the terminal cisternae of the sarcoplasmic reticulum (604). The major effects of caffeine, as with other xanthine derivatives, are: CNS stimulation, emesis, cardiovascular effects, diuresis, and smooth muscle effects leading to vasodilatation or bronchodilatation (604).

Teratogenicity, Spontaneous Abortion, and Prematurity

Caffeine is teratogenic when given in high concentrations to experimental animals causing limb and facial anomalies. However, no correlation exists between caffeine consumption in humans and birth defect (605). In rodents, caffeine causes malformations usually at high doses not seen in humans. Maternal caffeine consumption during gestation affects the hematologic parameters in both rat and human infants (605,606). Overwhelming evidence indicates that caffeine is not a human teratogen and that caffeine appears to have no effect on preterm labor and delivery (527,607,608,609). However, there is a small but statistically significant increase in the risk for spontaneous abortion and low birth weight infants in pregnant women consuming more than 150 mg caffeine per day. However, the possible contribution of maternal age, smoking and ethanol, however, could not be excluded (610).

Fetal and Neonatal Effects

Most of the reported effects of maternal caffeine consumption on fetal growth and development are on their adverse effects on birth weight and IUGR. Caffeine ingested in large amounts (>7 cups of coffee/day or >300 g of caffeine/day) during pregnancy causes a dose dependent decrease in birth weight of about 6.5% (606,607 and 608,611,612). The risk for low birth weight is further increased by concomitant use of alcohol, nicotine and illicit drugs (612). Other studies however have reported no adverse effects especially with moderate maternal consumption (614) or when other confounding variables like maternal smoking (615), cannabis (417), alcohol (616), and other socioeconomic factors are controlled for. Pregnant mothers are therefore advised to consume coffee or caffeinated beverages in moderation. Elevated levels of maternal third trimester serum paraxanthine, which reflects caffeine consumption, was associated with a higher risk of reduced fetal growth, particularly among women who smoked (617).

Neurobehavioural Effects

Maternal caffeine consumption has been reported to induce long term effects on sleep, locomotion, learning

abilities and anxiety among experimental animals. More studies are needed to confirm these observations among human infants (606). Other effects reported include cardiac arrhythmias (618,619) and a possible withdrawal syndrome, characterized by jitteriness, irritability and vomiting (620). It is postulated that these withdrawal signs are caused by a tripling of the half life of caffeine during the last 2 trimesters of pregnancy resulting in a much higher caffeine blood levels in both the mother and the fetus. This is further aggravated by the neonate's inability to metabolize caffeine efficiently (606,621).

Caffeine, during or after pregnancy was not found to be an independent risk factor for SIDS after adjustment for maternal age, education, parity, and smoking during pregnancy (622).

DIAGNOSIS OF DRUG EXPOSURE

Methods to Detect Drug Exposure in the Mother and Infant

The identification of drug exposure in the mother or her neonate is not easy. Mothers rarely fully admit to the use of drugs, because of fear of the consequences stemming from such an admission. Even with maternal cooperation, information on the type and extent of drug use often is inaccurate (3). Similarly, many of the drugs to which the fetus is exposed in utero do not produce immediate or recognizable effects in neonates (623). There are a number of methods used to detect prenatal drug exposure.

Methods to detect substance abuse in a pregnant woman or intrauterine drug exposure in a neonate ideally should address not only the types of drug abused, but also the amount, frequency, and duration of drug exposure. Two general methods are used to achieve this: maternal interview and laboratory tests.

Maternal Interview

Maternal interview has the greatest potential for providing comprehensive information on the type, amount, frequency, and duration of drug use. Two types of maternal interview generally are used.

Routine Interview. The routine interview forms an integral part of the obstetric history, which is obtained either prenatally or when a woman is admitted in labor. The accuracy of the data obtained by this method depends on the attention devoted to the interview. Cursory interview often results in underreporting of drug use, whereas the incidence increases threefold to fivefold if a more organized protocol is used (17,624). There are many elements inherent to routine history

taking that affect its accuracy. Maternal fear of the consequences of admission, underestimation of drug use even by those who admit to the use of drugs, and physical discomfort experienced by the woman, particularly if in labor, all affect the accuracy of her self-report. Under these circumstances, the reporting of drug abuse by the mother can be as low as one fourth of the true incidence (3).

Structured Interview. A structured interview is a highly organized interview, frequently using a standard questionnaire. Examples of this are the Khavari Alcohol Test (625), or its modification (626), and the Cahalan Volume Variability Scale (627). The structured interview is more accurate because more time is spent with the patient and the interview frequently is conducted in a more favorable environment than is the routine interview, i.e., it is not conducted when the mother is in labor. Structured interviews frequently are used as research tools. On the other hand, structured interviews are expensive and time-consuming to conduct, and are not practical for routine clinical use when dealing with patients who present in labor and have received little or no prenatal care. Interview directed at drug use at the time of conception (or when the woman first learned that she was pregnant) has a higher degree of accuracy and correlates more to pregnancy and neonatal outcome than interview on drug use during pregnancy as a result of the stigma associated with the latter (628).

Laboratory Tests

Most of the laboratory tests for drug detection are used simply for screening purposes. Confirmation with the use of another, unrelated procedure is usually needed if results are to withstand further scrutiny. It is apparent that as more confirmatory tests are done, the testing process becomes more expensive. Thus, the extent to which further tests are carried out after the initial screen is determined by the reasons that initiated the test.

Various analytical procedures are used for drug detection: thin-layer chromatography, immunoassays, high-performance liquid chromatography (HPLC) and gas chromatography for screening and gas chromatography-mass spectrometry (GCMS) for confirmation. A good review of the use and limitations of these procedures has been published (629).

Specimens for Drug Testing

Urine. The testing of biologic fluids for drugs is by far the most common method used to detect drug abuse in a pregnant woman, or intrauterine drug exposure in a neonate. There are several limitations to this method, however. Identification of drugs in biologic fluids will differentiate only those who have been exposed to drugs vs. those who were not. The test cannot provide information on the amount, frequency, duration, or the time of last drug use. Among the biologic fluids, urine has been most often tested owing to several advantages (630): urine

collection is easy and noninvasive; drug metabolites in urine usually are found in higher concentrations than in serum, as a result of the concentrating ability of the kidneys; large volumes of urine can be collected; urine is easier to analyze than blood because it usually is devoid of protein and other cellular constituents; the metabolites in urine

P.1600

usually are stable, especially if frozen; and urine is amenable to all of the drug-testing methods mentioned above.

However, there are several drawbacks to the use of urine for testing. Foremost is the high rate of false-negative results (14,509). In the mother, unless collection is watched closely, urine easily can be substituted with a clean specimen. Urine samples can be tampered with by dilution or by the addition of ions, such as salt, which may interfere with the testing methods. Drug metabolites in urine also reflect only very recent use of the drug, so that negative results may occur if the woman abstains from the use of the drug a few days before testing (630). In the infant, the incidence of false-negative urine tests also is high, ranging from 32% to 63% (631,632,633 and 634). Urine specimens must be obtained as close to birth as possible to reflect the infant's intrauterine exposure to drugs. The later after birth that urine is collected and tested, the higher is the likelihood of a false-negative test. Collection of the requisite volume of urine for both the screening test and the confirmatory test from an extremely small or very sick infant may also be difficult. The cutoff concentration for positivity used by the laboratory can also influence the detection rate (635). Recent abstention by the mother from the use of drugs may result in a negative urine test in the infant. The detection rate for drugs in the urine also can improve if a battery rather than a single test is used (634).

Meconium. The concept behind meconium drug testing was based on studies in pregnant rhesus monkeys which received morphine throughout gestation; a high concentration of morphine and its metabolites were found in the gastrointestinal tract or "meconium" of their fetuses (636). It was postulated that the drug accumulated in meconium as a consequence of fetal swallowing of amniotic fluid which contained drugs originating from fetal urine or from the excretion of drug metabolites through the bile. Subsequent studies in pregnant rats further showed that the concentration of morphine and cocaine in meconium were related to the dose, timing and duration of drug administration to the dam (637,638).

Meconium drug testing has been adapted to various analytical methods which included radioimmunoassay, EMIT, FPIA, HPLC and GCMS (639). The original analysis of meconium for drugs was by radioimmunoassay and the recovery of morphine and benzoylecgonine which were spiked in meconium ranged from 84% to 97% and 70% to 100%, respectively (640). The use of radioimmunoassays, which can detect both parent drug and its metabolites, e.g., Coat-a-Count (DPC, Los Angeles, CA) result in a higher detection rate compared to those tests which

are specific only for the metabolites. A radioimmunoassay-based meconium drug testing kit, called Mectest (Meco Industries, Walnut, CA) is approved by the FDA for the testing of cocaine, opiate and cannabinoid in meconium and exhibits high sensitivity, specificity and precision. The detection limit is 7.62 ng/mL for cocaine, 27.8 ng/mL for opiate and 5.3% ng/mL for cannabinoid.

The concentration of drugs in meconium can change if meconium is left at room temperature for 24 hours: 25% decrease in cocaine, 62% increase in morphine and 30% decrease in cannabinoid. The increase in morphine is as a result of the endogenous hydrolysis of morphine glucuronide into morphine in meconium from the action of β glucuronidase and the higher sensitivity of the radioimmunoassay for morphine compared to its glucuronide. On the other hand, drugs are stable in meconium, if frozen, for as long as 9 months.

Meconium drug testing has also been adapted to other drug testing methods such as EMIT or enzyme multiplied immunoassay technique and FPIA or fluorescence polarization immunoassay (641). However, when compared to radioimmunoassay, the sensitivity of enzyme immunoassay for cocaine, opiate and cannabinoid detection is lower, although its specificity is still 100%. With EMIT and FPIA, the cutoff concentrations for meconium drug testing are 50 ng/mL for cocaine, 100 ng/mL for morphine and 25 ng/mL for cannabinoid (642). Meconium has also been tested for methamphetamine and phencyclidine using EMIT and the detection limits are 730 and 100 ng/g meconium, respectively (642). Meconium drug testing has been adapted to HPLC (642,643,644 and 645), and GC/MS analysis (646,647,648,649 and 650) and the detection limit by HPLC is 50 ng/g meconium for benzoylecgonine and 500 ng/g meconium for morphine and amphetamine. By GCMS, the limit of detection is 11 ng/mL for cocaine and its metabolites, 5 ng/g meconium for morphine, codeine, hydromorphine, and hydrocodone and 2 ng/g meconium for cannabinoids. Fatty acid esters of ethanol have also been analyzed in meconium by GCMS and their concentrations have correlated well to maternal alcohol use during pregnancy (326,327,328 and 329). Likewise, nicotine metabolites (cotinine and trans 3'-hydroxycotinine) have been measured in meconium by radioimmunoassay and GCMS (651).

A number of clinical studies using the meconium drug test have demonstrated major advantages of meconium drug testing over urine testing in newborn infants. These include the ease and noninvasiveness of meconium collection which is particularly useful in anonymous, drug prevalence study; high sensitivity and specificity of the test; large window for detecting intrauterine drug exposure to as early as the 16th week of gestation, reliability of testing meconium samples even for those obtained beyond 24 hours after birth and positive correlation between concentration of drugs in meconium and the amount of drug use by the mother during gestation (141,638,651,652,653,654,655,656 and 657). The main disadvantage of meconium drug testing is the nonhomogeneity of meconium which requires preparative procedures to produce the analyte. In, one report

using GCMS for drug analysis, maternal urine, infant urine and meconium analysis yielded equivalent results (658).

Hair. Hair analysis has been one of the recent additions to drug testing (659). The test is based on the principle that illicit substances and their metabolic products are incorporated from the serum into the hair follicle and grow into the cuticle and hair shaft. The drug, once deposited in the hair shaft, remains for an indefinite period. As the hair grows at the rate of 1 to 2 cm month, the deposited drugs follow the

P.1601

growth of the hair shaft. The section of the hair closest to the scalp is the most recently exposed portion. Sectional analysis can be performed by month to provide information on the duration and time of drug use. The information on the chronicity of drug use makes hair analysis advantageous compared with urine or other body fluid testing. Furthermore, quantitative detection of drugs in hair has been correlated with the amount of drug use in the past.

Hair has been analyzed to detect opiates (660), cocaine (661), PCP (662), methamphetamine, antidepressants, and nicotine (663) by radioimmunoassay (659), GCMS (664), HPLC (665), and collisional spectroscopy (666).

The validity of hair analysis for drug detection has been demonstrated both in the mother and her neonate (664). Although hair analysis has exciting potential, there are some significant drawbacks to the use of hair for testing in women (667). Patients who are not chronic drug users may not be detected by this technique, because drug deposition in hair relies on serum levels during hair growth. The expense of the test mounts with the number of drugs being screened for, and has limited its usefulness in prenatal clinics. The quantity of hair necessary to perform the drug screen, i.e., a pencil-sized diameter plug of hair from the posterior scalp, may be difficult to collect in some newborn infants. Use of hair dye, bleach, and other cosmetic agents by the woman may modify the amount of drug in hair, but should not totally eliminate its presence because the drug is incorporated into the hair shaft. Some ethnic groups weave hair from other individuals into their own hair, and this creates the potential for false test results. Because of misconceptions about cosmetic effects, some patients may refuse hair testing. Hair can also be passively exposed to drugs that can be smoked (e.g., cocaine, marijuana).

Others. Other types of specimens have been tested for drugs. These include perspiration, nail clippings, menstrual blood, gastric juice, semen, and saliva (668,669 and 670). The use of these specimens for drug detection has been uncommon, however.

<p>TABLE 58-7 ASSESSMENT OF THE CLINICAL SEVERITY OF NEONATAL NARCOTIC WITHDRAWAL</p>
--

Sign	Mild	Moderate	Severe
Vomiting	Spitting up	Extensive vomiting for three successive feedings	Vomiting associated with imbalance of serum electrolytes
Diarrhea	Watery stools < four times per day	Watery stools five to six times per day for 3 days; no electrolyte imbalance	Diarrhea associated with imbalance of serum electrolytes
Weight loss	<10% of birth weight	10%–15% of birth weight	>15%
Irritability	Minimal	Marked but relieved by cuddling or feeding	Unrelieved by cuddling or feeding
Tremors	Mild tremors when twitching	Marked tremors or stimulated	Convulsions twitching when stimulated
Tachypnea	60–80 breaths/min	80–100 breaths/min	>100 breaths/min; associated with respiratory alkalosis

TREATMENT

Initial management of the infant is directed toward the antenatal and neonatal complications that are associated with maternal drug abuse such as asphyxia, fetal distress, prematurity, meconium aspiration, and congenital malformation. Additionally, the infant should be routinely tested for syphilis and HIV disease, be assessed for drug withdrawal, undergo drug testing and receive social service referral.

Narcotic Withdrawal

The infant of an opiate-dependent mother should be observed closely for withdrawal. The severity of the withdrawal can be assessed by several clinical scoring systems (671,672). We use a system that evaluates the infant specifically on manifestations that are life-threatening: vomiting, diarrhea, weight loss, irritability, tremors, and tachypnea (Table 58-7). With this system, drugs are used to treat the withdrawal if there is moderate vomiting, diarrhea, or weight loss; or any severe criterion.

Both narcotic and nonnarcotic drugs have been used to treat narcotic withdrawal (673) (Table 58-8). Narcotics are preferred, however, because their action is more physiologic for an abstinence state. Although the neurologic manifestations of withdrawal may be controlled successfully by nonnarcotic drugs, narcotics are

more effective in relieving the non-CNS manifestations (e.g., diarrhea).

Among the narcotic drugs, paregoric, laudanum, and sometimes methadone are used. We prefer to use tincture

P.1602

of opium or laudanum, United States Pharmacopeia (USP) over paregoric, because paregoric contains camphor, a CNS stimulant. Laudanum USP is available in a standard 10% solution, contains 1.0% morphine, and must be used with caution. Laudanum USP must be diluted 25-fold to a concentration of 0.4% to reduce its morphine content to a level equivalent to the amount present in paregoric. Laudanum USP (0.4%) can be given at the same dose as paregoric, i.e., 3-6 drops every 4-6 hours.

TABLE 58-8 TREATMENT OF NEONATAL WITHDRAWAL SYNDROME^a

Drug	Dosage
Paregoric	0.1–0.4 mL/kg (2–6 drops) every 4 to 6 h, PO
Laudanum (0.4%)	0.1–0.4 mL/kg (2–6 drops) every 4 to 6 h, PO
Chlorpromazine	0.55 mg/kg every 6 h, PO or IM
Phenobarbital	Loading dose: 16 mg/kg/day PO Maintenance dose: 2–8 mg/kg/day PO
Methadone	0.05–1.0 mg/kg every 6 hours, PO with increases of 0.05 mg/kg until signs are controlled.

^a From Osborn DA, Cole MJ, Jeffrey HE. Opiate treatment for opiate withdrawal in newborn infants. *Cochrane Database Syst Rev* 2002; CD002059, with permission.

The aim of treatment with drugs is to render the infant comfortable, but not obtunded. Thus, the drug should be titrated, starting with the smallest recommended dose and increased accordingly until the desired effect is achieved. Once the infant is asymptomatic, the drug can be tapered slowly until it is completely discontinued which usually takes between 4 to 6 days. The infant should be observed for a day or two after discontinuance of the drug for possible recurrence of withdrawal manifestations ("rebound" phenomenon). Overall, it will normally take between 10 to 14 days from the time that pharmacologic treatment is initiated up to the time that the infant is discharged home without the need for medication. When the infant is discharged from the nursery, the mother should be instructed to anticipate some mild jitteriness and irritability that may persist in the infant for 8 to 16 weeks, depending on the initial severity of the withdrawal.

In view of their hyperirritability, infants manifesting withdrawal should be swaddled, placed in a prone position, and cuddled more often. Swaddling, particularly with the infant's extremities flexed and hands placed in front of its mouth, enhances the infant's hand-to-mouth facility and is soothing. A similar soothing action can be achieved with a pacifier.

The frequency of diarrhea and vomiting should be noted, and the infant's weight checked at least every 8 hours. Temperature, heart rate, and respiratory rates should be recorded every 4 hours. Laboratory examinations to detect serum electrolyte or pH imbalance should be done as indicated.

There are only a few studies which have compared the efficacy of the different pharmacologic agents for the treatment of neonatal opiate withdrawal and these are reviewed in a meta-analysis study (674). The conclusion is that opiates, as compared to supportive care only, appear to reduce the time to regain birth weight and reduce the duration of supportive care, but increase the duration of hospital stay. There was no treatment failure. When compared to phenobarbital, opiates reduced the incidence of seizures, but overall, no evidence of treatment failure. When compared to diazepam, opiates reduced the incidence of treatment failure.

Nonnarcotic Withdrawal

A cross reaction exists between the different drugs belonging to the alcohol-hypnosedative group (see Table 58-4). Each drug is effective in treating withdrawal from any of the drugs belonging to this group (1). Thus, barbiturates can be used to treat withdrawal from nonbarbiturates, including alcohol, or vice versa.

The two drugs that have been used commonly during the neonatal period for this purpose are phenobarbital, 3 to 5 mg/kg/day in divided doses every 6 hours, and chlorpromazine, 1 to 2 mg intramuscularly every 8 hours. Chlorpromazine also has been used successfully at a dose of 2 to 3 mg/kg/day in divided doses every 6 hours (12). Although chlorpromazine does not belong to the group of nonnarcotic drugs that can cause withdrawal manifestations, its ability to ameliorate the signs and symptoms of withdrawal may be secondary to its capacity to suppress REM sleep, which is exaggerated during the state of withdrawal (14).

During the treatment of withdrawal, attention also should be focused on the nutrition and the fluid and electrolyte balance of the infants, particularly if vomiting, diarrhea, hyperpyrexia, and hyperhidrosis occur. Appropriate intravenous fluids may be required to correct deficits or prevent the occurrence of fluid and electrolyte imbalances in the patients.

Maternal Support

The addicted woman has some serious impediments to a successful mothering role. She has meager past mothering experience to rely on; often there is little or no support from a father or husband because frequently she is single, and, finally, the neurobehavioral abnormalities and withdrawal in her infant may hamper the gratifying feedback that she wishes to experience from her infant.

Thus, the mother and child should have early and repeated contacts. A staff member also should have repeated and relatively brief contacts with the mother, to describe the status of the child and to reassure her that, with the disappearance of withdrawal, the infant will feed more vigorously and will respond better to maternal ministrations.

P.1603

On the other hand, should it be decided that the infant will be placed in a foster care home, it should be remembered that the infant will need human contact for its normal growth and development. As part of its care in the nursery, the child should be stimulated appropriately through frequent handling or fondling by the staff professionals.

Breast-Feeding

Most drugs taken by the mother will cross into her breast milk. The concentration of illicit drug in the breast milk will depend on the amount and time of drug intake by the mother. In general, breastfeeding is discouraged in the pregnant addict who has not been compliant in her attendance in her drug treatment program because of the potential presence of multiple drugs of abuse in her breast milk. On the other hand, compliant mothers, even on methadone treatment, can safely breast-feed because the amount of methadone in breast milk is less than 5% of the maternal dose (675). If the mother is HIV positive, there is the danger of HIV transmission through the breast milk and breast-feeding is not recommended.

DRUG-ADDICTED WOMEN AS INFANT CAREGIVERS

The ability of the drug-addicted woman to perform her functions as a mother and provide adequate care for her infant has been seriously questioned on many occasions. Frequently, these women have been denied their maternal rights and responsibilities soon after the infant's birth on the basis of their unstable homes, life-styles, and their emotional and psychological weaknesses. Evidence suggests that this practice may be unnecessary and counterproductive in many cases. A study that determined outcome of infants on the basis of the type of caregiver showed that the outcome, measured by growth, development, frequency of medical illnesses, and child abuse, for infants cared for by the mother with the help of a caregiver (e.g., either a husband or relative) was better than the

outcome for infants in foster home care (74). Thus, with proper guidance and supervision, the addict mother may be capable of providing adequate care for her infant, particularly because most of these women desire to fulfill their mothering functions. It has been reported that mothers who had full time responsibility for child care had significantly higher levels of maternal adaptation than part time mothers (676). Similarly, although a high incidence of problems suggestive of child abuse (e.g., cigarette burns, hematoma) were noted in infants who were cared for exclusively by the mother, very few of these complications were noted in infants whose mother had help available. Thus, it is important that when allowing the mother to care for her infant, someone should help her at home (often the maternal grandmother) in the care of the infant to ensure its better care and protection. Likewise, the drug dependent mother needs assistance in parenting which can be given through a regular follow up of the mother and infant by a visiting or public health nurse and the social and protective service worker. Such interventions have been proven to be beneficial (85,86 and 87). In appropriate circumstances, alternative measures of placement of the child into known favorable home environment have also resulted in better behavioral functions of the child (81).

Social Service Referral

All infants of drug-dependent mothers should have a social service referral to assess the adequacy of parenting and care at home. The discharge of the infant to the mother's care is the primary objective, unless serious conditions dictate otherwise. The care of the infant by the mother, with the help of a support person, usually a grandmother or other relative, has, in our experience, been the best arrangement for a favorable outcome for the infant. The discharge of the infant to a person other than the mother (e.g., foster parent) or an agency should be resorted to only when it is apparent that the infant will be neglected, poorly cared for, or abused. Most mothers hesitate to admit to the use of drugs during pregnancy because of fear that their infants will be taken away from them. They should be assured otherwise; in fact, they should be encouraged to be responsible for the primary care of their infants. The social worker and physician also should advise the mother about available medical and social services in the community, such as substance abuse counseling and family planning services.

Potential Child Abuse

As part of child protection laws that are operative in many states, infants born to drug-dependent mothers are considered as potentially abused and are required by law to be reported to child protection agencies. Many of these agencies require a positive drug screen in the infant before they will take action on the reports. The precautionary measure intended in the referral of the infant to the child protection agencies is useful if the intent is to ensure the adequacy of care of the infant at

home. It is when punitive measures are taken against the mother that the outcome may become counterproductive.

FOLLOW-UP

The infant of the drug-dependent mother is at risk to many long-term problems (see Drug Addicted Women as Infant Caregiver and Potential Child Abuse) and to ongoing exposure to drugs in the household as a result of accidental ingestion or passive exposure, particularly to crack cocaine (see above). Follow-up of these infants should be planned not only to assess their medical well-being but to ascertain that further risks to drug exposure are prevented and that appropriate interventions are initiated.

Chapter 59

Medical Care After Discharge

Judy Bernbaum

Once the high-risk infant is discharged from the hospital, his or her many special care needs do not cease. Although they still require well-child care, many of these infants have needs that are far from routine. Special attention must be given to their growth and nutrition, immunizations, vision and hearing, and sequelae of illnesses experienced during the neonatal period. While premature infants have a higher likelihood for long-term sequelae and continuing medical problems than term infants do, many of the issues discussed specifically about prematurity apply to term infants as well.

EXPECTATIONS OF GROWTH

Growth patterns are a valuable indicator of an infant's well being. Aberrant growth may reflect the presence of chronic illness, feeding difficulties, inadequate nutrition, or social- emotional difficulties. Preterm infants are at particular risk for growth disorders. Many infants with chronic illness, while at an age when rapid growth is expected, have high caloric requirements but are unable to meet them because they have impaired feeding abilities. It is crucial to monitor nutritional intake closely and to interpret growth rates with a complete understanding of the infant's past history, current problems, and expectations for growth.

Many factors affect the growth of a preterm infant, including gestational age, birth weight, severity of neonatal illness, caloric intake, current illnesses, environmental factors in the home, and heredity. Caloric requirements for a healthy preterm infant generally exceed those of a term, normal-birth-weight infant, especially during rapid catch-up growth. Chronic illnesses that increase caloric expenditure add to an infant's daily requirements. Malabsorption after necrotizing enterocolitis (NEC) or chronic emesis from gastroesophageal reflux disease (GERD) may impair growth through increased losses. In contrast, decreased intake may be caused by fatigue, hypoxemia, oral motor dysfunction, or reflux esophagitis. Finally, infants with intrauterine growth retardation caused by congenital infections, chromosomal abnormalities, or other syndromes may never achieve normal growth (1,2,3,4).

Patterns of Growth

When the growth of a low-birth-weight (LBW) infant is evaluated, the gestational age should be considered. Growth parameters should be plotted on growth curves that have been developed using low-birth-weight preterm infants exclusively (5). Measurements should be plotted according to the infant's adjusted age until approximately 2.5 years of age, when the age difference becomes insignificant. Various patterns of growth emerge from different groups of patients.

Healthy, LBW, appropriate-for-gestational-age (AGA) infants generally experience catch-up growth during the first 2 years of life, with maximal growth rates between 36 and 40 weeks of gestational age. Little catch-up growth occurs after 3 years of age. Head circumference usually is the first parameter to demonstrate catch-up growth and often plots at a higher percentile than do weight and length. Increases in weight are followed within several weeks by increases in length. Rapid catch-up head growth must be distinguished from pathologic growth associated with hydrocephalus. An imaging study may be indicated if the infant's history or symptoms suggest hydrocephalus. Insufficient brain growth, a head circumference falling more than two standard deviations below the mean, indicates that the infant is at risk for significant developmental disability.

Growth velocities for weight and height vary considerably. Some preterm infants show growth on curves between the 75th and 97th percentiles by 3 months adjusted age, whereas others remain on low curves well beyond the child's first year. It is helpful to evaluate an infant's weight gain in comparison to gains in length. Low weight for length or a decline in all growth parameters suggests inadequate

P.1619

nutrition. Weight percentiles significantly greater than length percentiles indicate obesity. Obesity may occur in a preterm infant whose parents overfeed their previously underweight baby. It is common to see an infant who was formerly failing to thrive rather abruptly become obese when the medical problems resolve but the diet

remains high in calories.

Growth of the small-for-gestational-age (SGA) infant is influenced strongly by the cause of the intrauterine growth retardation. Overall, LBW-SGA infants demonstrate less catch-up growth than LBW-AGA infants, but if they do, acceleration starts by 8 to 12 months of adjusted age (2). Approximately 50% of LBW-SGA infants are below average in weight at 3 years of age, whereas only 15% of LBW-AGA infants remain below average weight at the same age (4). Symmetric SGA infants with birth head circumference similar in percentile to birth weight are less likely to demonstrate catch-up growth than are those asymmetric SGA infants whose birth head circumference was at a significantly higher percentile than their weight. As with AGA infants, head circumference is normally the first parameter to demonstrate catch-up, followed by weight and then by length.

Because of the wide range of growth that is considered normal during the first several years of life, it is best to analyze trends in growth rather than make assumptions based on single measurements. When abnormalities are noted in growth trends, investigation of the infant's nutritional status during hospitalization, the results of cranial sonography studies, and the status of continuing illnesses should be undertaken to identify a possible cause.

Nutritional Requirements

Traditionally, although somewhat controversial, the goal for preterm infants is to achieve a growth rate approximating that expected while *in utero* had they not been born prematurely (4). Because weight gain is suboptimal during acute illness, all efforts should be made to promote catch-up growth once the medical condition is stable. The nutritional needs of the preterm infant during the first few months of life exceed those of a term neonate and may continue for the entire first year of life even if there are no exceptional medical or feeding problems. Appropriate choices for many preterm infants include breast milk and routine infant formulas, but because many preterm infants continue to have increased caloric requirements, breast milk and routine formulas often need to be supplemented with either carbohydrates or fats. Formulas can be concentrated somewhat to increase their caloric density, allowing the infant to consume more calories per unit volume. There are now commercially available premature growth formulas tailored to address the unique protein, fat and caloric needs of the growing preterm infant for the first year of life (6,7,8). Most infants do not tolerate feedings with caloric densities greater than 30 kcal/oz. Infants given feedings concentrated beyond 24 kcal/oz should be monitored for symptoms of intolerance such as vomiting and diarrhea and for hyperosmolar dehydration secondary to insufficient free water intake. Whole cow's milk is poorly tolerated and should be avoided. When caloric additives or concentrated formulas are used, care should be taken to maintain an appropriate caloric distribution of nutrients with a ratio among carbohydrates-fats-protein of approximately 40-50-10 (6).

Caloric requirements for adequate growth vary. Healthy preterm infants generally require 110 to 130 kcal/kg per day, but some infants with chronic disease may require up to 150 kcal/kg per day (9). Caloric intake should be increased as tolerated until weight gain is satisfactory.

Often infants with ongoing illness or those just recovering from their long hospitalization will be unable to consume the volume of formula or breast milk needed to provide them with the calories they need for catch-up or even maintenance of their ideal growth rate. It is not uncommon to suggest offering up to one-half of their daily calculated needs by continuous feedings (by tube) through the night and allowing them to feed the remainder orally during the day. Taking that approach often decreases the need to consume large volumes by oral feeding and allows the infant to increase volumes as tolerated during the day, after which nighttime volumes can begin to be decreased.

FEEDING PROBLEMS

Although unusual in term infants, feeding disorders are relatively common in preterm infants. Most feeding problems occur in the neonatal period, but many infants demonstrate recurrent or chronic problems with sucking and swallowing (10). Unrecognized, these problems may lead to significantly impaired nutritional intake and negatively affect the parent-infant relationship. Infants at risk for development of feeding problems include those with a delay in initiating oral feedings during the neonatal period and those with immature oral motor skills related to prematurity. Additionally, those with transient neurologic immaturity or more permanent neurologic deficits are at highest risk. Additional risk factors for development of feeding dysfunction include chronic lung disease, tracheostomy, gastroesophageal reflux, and repeated exposure to noxious, albeit life-sustaining, equipment secured around the area of the nose and mouth. These include suction catheters, endotracheal tubes, naso- or orogastric tubes, and oxygen cannulas. Frequently, many feeding difficulties can

be avoided and transition to all oral feedings can be enhanced by offering nonnutritive sucking opportunities during gavage feedings (10).

Oral reflexes that allow normal feeding and protect the airway from aspiration may be hypoactive or hyperactive in preterm infants. Abnormal reflexes such as a tongue thrust or hyperactive gag can further complicate successful and pleasurable feeding. A hyperactive gag is particularly troublesome because the infant may manifest oral hypersensitivity and be unable to tolerate the nipple or spoon on the tongue and resist any oral stimulation. Other causes of hypersensitivity or tactile defensiveness include the noxious stimuli mentioned above.

P.1620

The evaluation of a possible feeding disorder includes a detailed history of feeding behaviors and nutritional intake, a physical examination with assessment of oral motor reflexes, and observation of a feeding. If an infant with chronic lung disease desaturates during feeding, increasing the supplemental oxygen during feeding can improve feeding behavior (11,12). Evaluation of the type of nipple and the size of its hole may show that the hole is too small, causing fatigue, or too large, making it difficult to control the flow. There are now a large variety of nipples available that can specifically be chosen for the individual infant's needs. Indications for radiologic evaluation include suspected aspiration during feeding or an anatomic abnormality such as a tracheoesophageal fistula.

All of these conditions are amenable to therapy if identified early. Treatment of underlying medical problems, the most common of which is gastroesophageal reflux, often helps ameliorate the feeding problems. A pediatric speech pathologist or occupational therapist trained in feeding techniques can assess an infant and develop an appropriate feeding program once a problem has been defined.

Feeding an infant is normally a relaxing, nurturing act that plays a role in parent-infant bonding. In the presence of a feeding disorder, feedings may become a major source of stress, frustration, and anxiety for the infant, parents, and physicians.

IMMUNIZATIONS

Most preterm infants should receive the same immunizations as the term infant and on similar schedules. However, special consideration should be given to the preterm infant with the following vaccines or regarding certain infectious diseases (13,14).

Diphtheria, Tetanus, Pertussis

The American Academy of Pediatrics (AAP) recommends that full doses of DtaP vaccine be administered to prematurely born infants at the appropriate postnatal i.e., chronologic age. A large percentage of preterm infants demonstrate inadequate protection if given a reduced dosage of DTaP vaccine at the routine intervals. Fewer side effects occur in preterm infants who receive full-dose vaccine than in their full-term counterparts, and the use of acellular pertussis vaccine should obviate any concerns in this regard. The same contraindications to immunizing full-term infants against pertussis apply to preterm infants. Most importantly, infants with bronchopulmonary dysplasia (BPD) are at highest risk for serious sequelae if they contract pertussis. Therefore, the pertussis component of this vaccine should not be withheld. Similarly, the pertussis component should also be given to any child with cerebral palsy or other muscle tone abnormalities. If an infant has an underlying seizure disorder, the decision to withhold pertussis should be reviewed with the individual's neurologist.

Polio, Haemophilus Influenzae Type b, Pneumococcal, Varicella, and Measles-Mumps-Rubella Vaccines

The AAP Committee on Immunization Practices recommends that full-dose inactivated, enhanced potency polio (IPV), haemophilus influenzae type b (Hib), pneumococcal, varicella, and measles-mumps-rubella (MMR) vaccines be administered at the appropriate chronologic age.

Influenza

Infants with chronic pulmonary disease (e.g., BPD) or cardiac disease with pulmonary vascular congestion are at high risk for the development of serious illness if infected with an influenza virus (14). Infants with influenza

have presented with symptoms of sepsis, apnea, and lower airways disease. To protect vulnerable infants, immunization with influenza vaccine is indicated for household contacts, including siblings, primary caretakers, and home care nurses and hospital personnel. For infants older than 6 months chronological age, two doses of split virus vaccine should be given 1 month apart between October and December, followed by an annual dose. It is now recommended that influenza vaccine be given to all infants under 2 years of age (13,14). Older siblings under 9 years of age who have not received previous influenza vaccines also require two doses initially. However, adults and older siblings with natural immunity or who have received previous immunizations need only one yearly dose.

Respiratory Syncytial Virus

Preterm infants, especially those with underlying chronic lung disease, are particularly at high risk for serious sequelae after becoming infected with respiratory syncytial virus (RSV) during the late fall and winter months. Many will require re-hospitalization and re-intubation for respiratory failure and are often left with worsening lung disease requiring increased support with supplemental oxygen, bronchodilators, or and/or diuretics. Attempts at developing a vaccine to protect against RSV have been unsuccessful; however, an anti-RSV monoclonal antibody (Synagis®) has been approved for use in high-risk infants (15,16). Monthly intramuscular injections are necessary to provide passive protection throughout the RSV season. Synagis® is expensive; thus, its use should be limited to those infants most at risk. According to the guidelines set forth by the AAP (14), those who should be considered to receive monthly injections include the following:

- Children under 24 months with BPD who require:
 - Supplemental oxygen
 - Have required oxygen within 6 months of RSV season
 - Are currently requiring mechanical ventilation
 - Are being treated with bronchodilators or diuretics
-
- P.1621
- Premature infants without BPD may benefit if gestational age is:
 - Between 29 and 32 weeks until they are 6 months of age
 - Less than 28 weeks until they are 12 months of age.
 - Premature infants between 32 and 35 weeks of age who are at high risk for developing severe sequelae if they develop RSV disease including:
 - multiple births, attendance in daycare, exposure to older siblings (especially if in day care or school), and living in crowded conditions.

Hepatitis B

For infants with birth weights below 2,000 g born to hepatitis B surface antigen-negative women, it is advised to delay the initiation of hepatitis B vaccine until just before initial hospital discharge, provided the infant weighs more than 2,000 g or until 2 months of age when other immunizations are given (13).

SPECIALIZED CARE

In addition to routine well-child care, the preterm infant may require specialized follow-up for the monitoring, detection, and management of sequelae from neonatal problems. The remainder of this chapter is devoted to a discussion of these special needs.

Retinopathy of Prematurity

Retinopathy of prematurity (ROP) (see Chapter 54) is a disorder that interrupts the normal vascularization of the developing retina. Although it has been reported in term infants, ROP is mainly a disease associated with prematurity and, in particular, with those less than 32 weeks gestation. The incidence and severity of ROP increase with decreasing gestational age. Most cases of ROP resolve spontaneously, but even with complete resolution, scarring of the retina may occur. Generally, the more severe the disease, the longer it takes for resolution. An infant with ROP affecting Zone 1, however, is at a much greater risk for permanent visual sequelae than one who has the disease affecting Zone 2 or 3 (17,18). According to recommendations in the AAP Guidelines for Perinatal Care (19), infants with a birth weight of less than 1,500 g or with a gestational age of 28 weeks or less, and selected infants between 1,500 and 2,000 g with an unstable clinical course who are believed to be at high risk by their attending pediatrician or neonatologist should have an ophthalmologic examination for ROP. The initial examination should not take place before 4 to 6 weeks chronologic age or, alternatively, within the 31st to 33rd week of postconceptional age, whichever is later. Prior to this, the yield for identifying ROP is low. If only one examination is possible, it should be at 7 to 9 weeks of age to catch the peak period of occurrence. A schedule of follow-up visits is based on the retinal findings and should be determined by the examining ophthalmologist. All infants with immature fundi or any stage of ROP require close monitoring until the eyes have matured or the ROP has completely resolved. Thereafter, follow-up to assess for refractive errors should be at 1 year of age and before kindergarten, or earlier for any clinical concerns. Infants with resolving (incompletely resolved) ROP need careful follow-up because some revert to active disease.

Sequelae of ROP depend largely on the extent of retinal scarring. As much as 80% of stage 3 ROP resolves spontaneously without significant scarring, but, even in infants with fully regressed ROP, there may be subtle retinal changes resulting in refractive errors, strabismus, or amblyopia. Additionally, an infant left with moderate scarring can experience retinal tears, late retinal detachment, nystagmus, glaucoma, cataracts, vitreous hemorrhage or membranes, and severe scarring that can lead to blindness (19). Services for visually impaired children are available on county and state levels. Early identification of a child with visual handicaps to such programs is essential to provide the child and family with the services and resources they need.

Hearing Problems

The incidence of sensorineural hearing loss in preterm infants is generally reported to be between 1% and 3%. Several factors place these infants at particular risk for hearing loss, including hypoxia, hyperbilirubinemia, infections, unstable blood pressure, environmental noise, and ototoxic drugs. According to the Joint Committee on Infant Hearing, Year 1999 Position Statement where the Universal Newborn Hearing Screening (UNHS) Program is described, all infants should have access to hearing screening using a physiologic measure before hospital discharge or have access to and be referred for screening before one month of age (20). However, all newborns or infants who require neonatal intensive care should receive hearing screening before discharge from the hospital. All infants who do not pass the initial screen or any subsequent re-screening should begin appropriate audiologic and medical evaluations to confirm the presence of hearing loss before 3 months of age. All infants with confirmed permanent hearing loss should receive services before 6 months of age in interdisciplinary intervention programs that recognize and build on strengths, informed choice, traditions, and cultural beliefs of the family. All infants who pass newborn hearing screening but who have risk indicators for other auditory disorders and/or speech and language delay should receive ongoing audiologic and medical surveillance and monitoring for communication development. Infants with indicators associated with late-onset, progressive, or fluctuating hearing loss and auditory neural conduction disorders and/or brainstem auditory pathway dysfunction should be monitored.

Depending on the screening technology selected, infants with hearing loss less than 30 dB or with hearing

loss related to auditory neuropathy or neural conduction disorders may not be detected in a universal newborn hearing screening program.

All infants, regardless of newborn hearing screening outcome, should receive ongoing monitoring for development of age-appropriate auditory behaviors and communication skills. Passing an initial hearing screening does not preclude the possibility of a later, acquired hearing loss. Absent or abnormal responses to auditory stimulation, delays in speech development, poor articulation, or inattentiveness should raise the suspicion of a hearing loss that requires a more thorough evaluation. All infants who do not pass an initial hearing screen should be referred to an audiologist for further testing and intervention. In general, an infant with a sensorineural hearing loss should have a repeat audiologic evaluation performed every 3 months for 1 year after initial diagnosis, every 6 months during the preschool period, and yearly while in school.

In hearing tests, zero-decibel (dB) represents the level at which response to a sound should occur 50% of the time. If sound is not heard at this level, the decibel level is raised until the sound is audible 50% of the time. Responses above 15 dB are indicative of some degree of hearing loss (Table 59-1).

Children with moderate to profound hearing loss are at high risk for delayed onset of language, problems with articulation, language impairment, and alterations in voice quality. Cognitive delays may be encountered as a result of a loss of auditory input or a language delay. Behavior problems often are experienced and include inattentiveness, overactive or aggressive behaviors, and immature peer relations.

Hearing aids can be fitted early in infancy to avoid acoustic deprivation. With auditory stimulation being provided, language acquisition may proceed more normally. Along with hearing amplification, language stimulation therapy (sign language) should be provided.

For those children whose hearing loss cannot be improved by hearing aids, different modes of communication are necessary. These include sign language, alternate methods of gesturing or word spelling, language boards, or computer-assisted communication devices. The latter two methods are particularly useful for a child who is limited motorically as a result of cerebral palsy.

TABLE 59-1 CLASSIFICATION OF HEARING LOSS

Hearing Loss (dB)	Description
0–15	Normal
16–25	Borderline–mild
26–40	Mild
41–55	Mild–moderate
56–70	Moderate–severe
71–90	Severe
91 and above	Profound

Necrotizing Enterocolitis

Survivors of NEC, especially those who required surgical intervention, may have problems after discharge. The most common complications include strictures or adhesions and short bowel syndrome (SBS).

Strictures or adhesions of the small or large intestines may develop within 2 weeks to 2 months after the acute episode of NEC. Symptoms of complete or, more commonly partial, intestinal obstruction include vomiting, abdominal distention, constipation or obstipation, or hematochezia. Lower gastrointestinal bleeding may be the only symptom of stricture formation without any other symptoms of obstruction being evident. Intermittent or persistent problems with constipation or obstipation are the more common symptoms that an infant may experience well into the first year of life. Management of significant strictures or adhesions generally involves surgical resection, but those with minimal symptoms may be treated conservatively. Stool softeners are useful in preventing obstipation or constipation.

Short bowel syndrome often results from decreased intestinal length or function. Necrotizing enterocolitis requiring significant bowel resection is one of the most common causes of SBS. The associated symptoms are caused by decreased digestion and absorption of nutrients by a smaller intestinal surface area and a more rapid transit time. Most often, evidence is seen of carbohydrate, protein, fat, vitamin, and mineral malabsorption and an increase in colonic water secretion. Occasionally, SBS is associated with a decreased enterohepatic circulation

and gallstones. The resultant problems of SBS constitute a syndrome of chronic diarrhea, malabsorption, growth retardation, and vitamin and mineral deficiencies. The prognosis of SBS is reasonably good if more than 25 cm of small bowel without an ileocecal valve, or more than 15 cm of small bowel with an ileocecal valve, remains after surgery (21). If long-term total parenteral nutrition (TPN) is needed, complications with its use will affect the child's prognosis.

Gastroesophageal Reflux

Gastroesophageal reflux (GER) refers to a condition in which gastric contents reflux into the esophagus and cause subtle or overt signs and symptoms. Although it can develop in full-term infants, GER occurs more commonly in preterm infants. Symptoms develop from incompetence of the lower esophageal sphincter often complicated by poor stomach emptying. Recurrent, nonprojectile emesis is the most common presenting symptom of GER. Usually, an infant will vomit within 1 to 2 hours after a feeding. An infant may experience several small-volume emeses after a feeding or only one or two large-volume emeses. Some children, however, have no significant emesis but reflux into the esophagus or mouth and then re-swallow. Many infants will present with arching of the trunk during or after a feeding. Infants also may present with Sandifer's syndrome, a condition in which an infant cranes his or her

P.1623

neck in various directions, attempting to stretch the esophagus and reduce the discomfort associated with reflux. An infant with this presentation may be misdiagnosed as having dystonia or a neurologic abnormality.

Failure to thrive or dehydration may result from chronic vomiting. Additionally, many of these infants avoid or refuse feedings because they quickly learn to associate feeding with the discomfort of GER and its related esophagitis.

Apnea and bradycardia are complications of GER. Occasionally, GER will worsen if an attempt is made to treat apnea and bradycardia with caffeine because this medication tends to decrease lower esophageal tone, exacerbating symptoms of GER. The physician should consider an evaluation for GER in an infant when his or her apnea or bradycardia worsens, fails to respond to, or worsens with, traditional medical therapy, other causes are ruled out, or if symptoms persist beyond 44 weeks of adjusted age (22).

Aspiration pneumonia is a serious sequela of GER. If acute in onset, symptoms are overt, so GER-related aspiration is more likely to be suspected and diagnosed. If chronic, unrecognized aspiration may cause or exacerbate underlying reactive airways disease. The possibility of GER should be considered in infants with BPD whose disease worsens or fails to improve even in the absence of other signs and symptoms of GER (23).

The evaluation of GER should be individualized. A clinical assessment is sufficient if the history and observation of a feeding present a classic picture of reflux. A technetium-labeled milk scan is helpful to document suspected aspiration and will be able to assess gastric emptying. A pH-thermistor study is useful to document the amount and the degree of acid reflux and any associated apnea or bradycardia. Because of the high false-positive and false-negative rates, a barium swallow and upper gastrointestinal series are of limited value except for documenting underlying anatomic abnormalities (24).

Management of GER depends on the severity of the reflux and its associated symptoms. Simple medical management, successful in 80% of patients, includes thickening formula with cereal, keeping the infant in a semiupright position after meals, and avoiding any increase in abdominal pressure such as may occur when the infant is placed in an infant seat after meals. Medications may be considered for infants who do not respond to conservative management or who have more severe symptoms. Medications are used to increase lower esophageal sphincter tone and improve gastric emptying. These include metoclopramide (Reglan®) and bethanechol (Urecholine®). Bethanechol should be used with caution in infants with chronic lung disease because it may induce or worsen bronchospasm. Another agent, cisapride (Propulsid®), is a prokinetic agent that increases transit time throughout the entire GI tract. As a result of reports of fatal cardiac arrhythmias or sudden death, cisapride was restricted to a limited access by gastroenterologists for use in this entity (25). Antacids, histamine H₂-receptor antagonists, or proton pump inhibitors can be used as adjunct therapy to treat or prevent secondary esophagitis.

Surgical management, most often a Nissen fundoplication, is necessary in about 10% of patients with GER. Surgery should be reserved for infants who either fail to respond to medical management or manifest recurrent pulmonary infections from suspected chronic aspiration pneumonia, chronic esophagitis, unremitting apnea, or failure to thrive despite aggressive medical management.

Intraventricular Hemorrhage

Intraventricular hemorrhage (IVH) is one of the most serious neurologic events encountered by neonates. It occurs in up to 50% of infants born weighing under 1,500 g (26). There is an inverse relationship between gestational age and the incidence of hemorrhage. With the increase in survival of infants at lower gestational ages, an increase in the number of infants with IVH may be expected as well. Follow-up imaging studies should be performed to demonstrate resolution of hemorrhage and to diagnose any anatomic sequelae. The most common complications of IVH include hemorrhagic infarction, posthemorrhagic hydrocephalus, porencephalic cyst, and ventriculomegaly without hydrocephalus (e.g., hydrocephalus ex vacuo).

In clinical practice, a common problem when an infant's head circumference crosses percentiles is distinguishing the onset of hydrocephalus from catch-up head growth. Clinically, all premature infants with and without IVH should be monitored with at least monthly measurements of head circumference and documentation of neurodevelopmental progress. If a child has a weekly increase in head circumference greater than 2 cm or demonstrates any symptoms of increased intracranial pressure or a change in neurologic status, hydrocephalus should be considered and evaluated by cranial imaging studies. In general, most ventriculomegaly following IVH occurs within 2 weeks of the initial insult, and radiographic appearance rarely changes after 3 months unless a shunt was required.

Most often, when a ventriculoperitoneal shunt is placed for progressive hydrocephalus, it continues to work without complication according to the principle of volume dependence. If complications occur, they usually are caused by mechanical malfunction or infection. Mechanical malfunctions may result from disconnections at any point along the shunt apparatus or from an obstruction either proximally, along the length of the tubing, or distally within the peritoneum. Signs of malfunction are those associated with an increase in intracranial pressure.

If symptoms suggest malfunction, ultrasonography or a computed tomographic (CT) scan is recommended to evaluate the size of the ventricles compared to baseline, as is a simple roentgenogram of the entire length of shunt tubing to determine its integrity. Pumping the reservoir, if one is present, should be performed only by a physician familiar with the procedure. The information obtained can help determine the location of a blockage but could be misinterpreted by those unfamiliar with the technique.

P.1624

An obstructed or malfunctioning shunt dictates immediate neurosurgical evaluation.

Symptoms of an infected shunt include signs of increased intraventricular pressure associated with an obstruction plus fever and irritability. Shunt infections result in ventriculitis more often than meningitis. Infection may represent colonization of the apparatus only. Diagnosis is made by performing a needle aspiration of cerebrospinal fluid (CSF) from the reservoir using aseptic technique and obtaining a Gram stain and culture. Treatment usually includes appropriate intravenous antibiotics. Removing or externalizing the shunt tubing may also be required. If it is still felt to be necessary, the shunt tubing can be replaced once the CSF remains sterile for at least 72 hours (27).

If a shunt functions properly, follow-up usually is based on the individual neurosurgeon's recommendations. A routine imaging study for baseline usually is obtained when the infant is medically stable before hospital discharge. The clinician following the infant as an outpatient should use the same imaging technique so that a comparison can be made with the baseline study for any change suggestive of an obstruction. If the brain appears normal, and no symptoms of obstruction or infection develop, a follow-up scan may be avoided.

Periventricular Leukomalacia

Periventricular leukomalacia (PVL) is caused by ischemic infarction of the white matter adjacent to the lateral ventricles. A weakening in the integrity of the white matter in this area occurs, followed by either repair or the development of cysts. The reported incidence of PVL in infants with birth weights under 1,500 g varies from 2% to 22% (28,29,30,31). Infants at risk for PVL are those whose perinatal course was complicated by severe hypoxia, ischemia, or both. Additionally, infants of early gestational age are particularly susceptible to the development of PVL because of their poorly developed cerebral vascular system, especially after sepsis, seizures, meningitis, IVH, cardiorespiratory (CR) arrest, or life-threatening apnea.

In the weeks that follow a major insult leading to PVL, phagocytosis of the necrotic material occurs with development of fluid-filled periventricular cysts. Periventricular leukomalacia and, subsequently, the presence

and size of cysts can be determined using cranial ultrasonography, T, or magnetic resonance imaging scan. Resolution of the cysts is highly variable, and some never completely resolve (29).

Beyond the neonatal period, screening for the presence of PVL should be considered in any child with cerebral palsy without an apparent cause (31). Because there are no symptoms specific for PVL, it can easily be missed during the neonatal period if routine screening is not performed.

If PVL is associated with the loss of vital areas of neural tissue as with the formation of cysts greater than 3 mm in diameter, the infant so affected is at increased risk for cerebral palsy, developmental delay, and visual or auditory impairments. If PVL is not associated with residual cysts, few if any sequelae develop. When cysts persist, an infant's motor development is most affected. Cerebral palsy, manifested as moderate to severe quadriplegia or diplegia, is reported to develop in a large proportion of children with cystic residua after PVL. The intellectual capacities of children with PVL and cyst formation are more variable. Mental retardation is more common in infants with residual cysts but ranges from mild to severe. If the cysts develop in the occipital region, visual impairment may result (31).

All infants with PVL, especially those with cysts, should be monitored closely for neurodevelopmental sequelae. Periodic cranial imaging, preferably an MRI study, will determine stability, resolution of the cysts or the degree of residual damage. Parents of infants with PVL should be counseled on the importance of periodic neurodevelopmental assessments for early detection of any sequelae and intervention when appropriate.

Seizures

Seizures during the newborn period may be subtle or overt and may occur singly or repetitively. Diagnosis usually is made while the infant still is hospitalized. Medical staff often will document motor activity or behavioral changes consistent with seizure activity that can then be confirmed by electroencephalography (EEG). Although the normal immature cortex has a relatively high seizure threshold, cortical injury enhances the brain's susceptibility to seizures. Most neonatal seizures are provoked by a significant neurologic insult such as intracranial hemorrhage, hypoxic-ischemic insult (e.g., asphyxia), cerebral infarct, metabolic disturbances, or central nervous system (CNS) infections (32).

The primary determinant of the outcome of neonatal seizures is correlated closely with the underlying cause. Infants with relatively harmless conditions such as hypocalcemia do well with appropriate treatment of the underlying disturbance. Those with an intracranial hemorrhage or an anoxic insult experience greater morbidity. Infants with seizures associated with asphyxia that was noted at younger than 24 hours of age have a poorer outcome than those with later onset of seizures. Similarly, those with more severe seizures (e.g., status epilepticus, frequent seizures) fare worse (33).

The decision to treat seizures with anticonvulsants usually is made early in the evolution of the infant's evaluation. If a transient metabolic abnormality is identified and corrected, seizure activity should cease, usually without anticonvulsant therapy. Recommendations regarding the duration of long-term anticonvulsant therapy for neonatal seizures vary. In some cases, medications may be discontinued before initial hospital discharge. Most often, however, once seizures are well controlled, a seizure-free interval of at least 3 months passes before anticonvulsants are withdrawn. Before making a decision to withdraw medications, the physician should make certain that the infant has no

P.1625

further clinical seizure activity and no epileptiform discharges on EEG. A neurologist should evaluate any infant with seizures that persist, to help in their long-term management.

Apnea and Bradycardia

Infants may continue to experience episodes of apnea or bradycardia after initial hospital discharge. Apnea of infancy is defined as "an unexplained episode of cessation of breathing for 20 seconds or longer, or a shorter respiratory pause associated with bradycardia, cyanosis, pallor, and/or marked hypotonia" (34). The incidence of apnea and bradycardia and its chronicity are inversely proportional to the gestational age of the infant and often parallel the severity of problems the infant had during the neonatal period. Although CNS immaturity is the most common cause for apnea in preterm infants, it is important to rule out medical problems that may cause apnea even after hospital discharge. If clinically indicated, the symptomatic infant with apnea should be evaluated for the possibility of underlying anemia, sepsis, meningitis or other infections, seizures, upper airway obstruction, GER, hypoxia, or bronchospasm as possible inciting factors (35).

Once it has been determined that no remediable factors exist, a decision should be made whether to monitor a child at home. The need for home memory event CR monitoring with or without medication is determined before hospital discharge based on clinical judgment or results of specialized evaluations. The use of CR monitoring, however, remains somewhat controversial. The American Academy of Pediatrics Panel on Apnea, Sudden Infant Death Syndrome, and Home Monitoring established medical indications for use of CR monitoring (36). These include the following recommendations:

- Premature infants who are at high risk of recurrent episodes of apnea, bradycardia, and hypoxemia after hospital discharge. The use of home cardiorespiratory monitoring in this population should be limited to approximately 43 weeks' postmenstrual age or after the cessation of extreme episodes, whichever comes last.
- Infants who are technology dependent (tracheostomy, continuous positive airway pressure), have unstable airways, have rare medical conditions affecting regulation of breathing, or have symptomatic chronic lung disease.

If home cardiorespiratory monitoring is prescribed, the monitor should be equipped with an event recorder. However, the AAP also recommends that parents should be advised that home cardiorespiratory monitoring has not been proven to prevent sudden unexpected deaths in infants. Pediatricians should continue to promote proven practices that decrease the risk of sudden infant death syndrome (SIDS)—supine sleep position, safe sleeping environments, and elimination of prenatal and postnatal exposure to tobacco smoke.

Alarm settings usually are placed at a low heart rate of 80 beats per minute with or without a 5 second delay and a high heart rate at 240 to 250 beats per minute with a maximum respiratory pause of 15 seconds. These may be changed depending on the infant's age or specific clinical circumstances. In most infants, resting heart rate decreases with increasing age, changing to 70 bpm at 3 months and 60 bpm at 6 months of age.

Often, preterm infants require caffeine in addition to or in lieu of home monitoring (37). Unless dosage is adjusted as the infant gains weight, the blood level of medication gradually will fall, but it rarely is necessary to recheck levels after discharge as long as apnea and/or bradycardia episodes are infrequent. If episodes continue or increase in frequency despite therapeutic xanthine levels, an evaluation for other possible causes is indicated. In most cases, the infant should be allowed to outgrow and discontinue the medication when there are no more episodes of apnea for 2 months either clinically or by monthly CR monitor downloads (37).

Once the infant is symptom-free for 4 to 6 weeks, medication most often can be safely stopped. If there are no subsequent episodes identified by the monitor, a home pneumocardiogram recording or monitor download can be performed 1 to 2 weeks after stopping the medication to determine the need for continued monitoring. If no further episodes are documented, the monitor can be safely discontinued one month after the medication has been discontinued (Fig. 59-1).

Chronic Lung Disease

Bronchopulmonary dysplasia is the most frequently diagnosed chronic lung disease in preterm infants. Usually it develops as a sequel to the acute lung injury experienced during the first few weeks of life. The definition of BPD has changed over the years. A traditional diagnosis covered lung disease resulting from respiratory distress shortly after birth that required more than 28 days of oxygen exposure with representative findings noted on chest roentgenogram (38). Because many infants with a gestational age younger than 30 weeks require oxygen for more than 28 days without developing chronic lung disease, a more restrictive definition of BPD is more appropriate: BPD in a preterm infant less than 30 weeks of gestation is now defined as lung disease for which supplemental oxygen is still required beyond 36 weeks corrected gestational age (39). Although the diagnosis of BPD is given before initial hospital discharge, some infants with mild or minimal residual lung disease may come to the primary care provider's attention with their first viral respiratory tract infection. Those with more severe disease often will be discharged with medications, nebulized bronchodilator treatments, and supplemental oxygen. Clinical manifestations are similar to those in the nursery and include tachypnea, tachycardia, retractions, rhonchi, bronchospasm, and poor air movement into the lungs bilaterally. More subtle signs of chronic respiratory distress include poor weight gain, feeding intolerance, decreased activity, and a reduced exercise tolerance. Medical management of infants with BPD often includes any combination of the following:

therapy, bronchodilator medications, steroids, and supplemental oxygen, even after initial hospital discharge. These therapies are altered depending on the infant's clinical status and are eventually withdrawn as the infant matures and improves. How early withdrawal can begin depends on both the severity of lung disease at the time of discharge and its resolution over time. Additionally, BPD may worsen after discharge so that infants who tolerated either no medication or lower doses may begin to require aggressive intervention after discharge. This occurs most often if the infant contracts a serious respiratory tract infection such as RSV pneumonia or less serious but more frequent intercurrent respiratory-related illnesses.

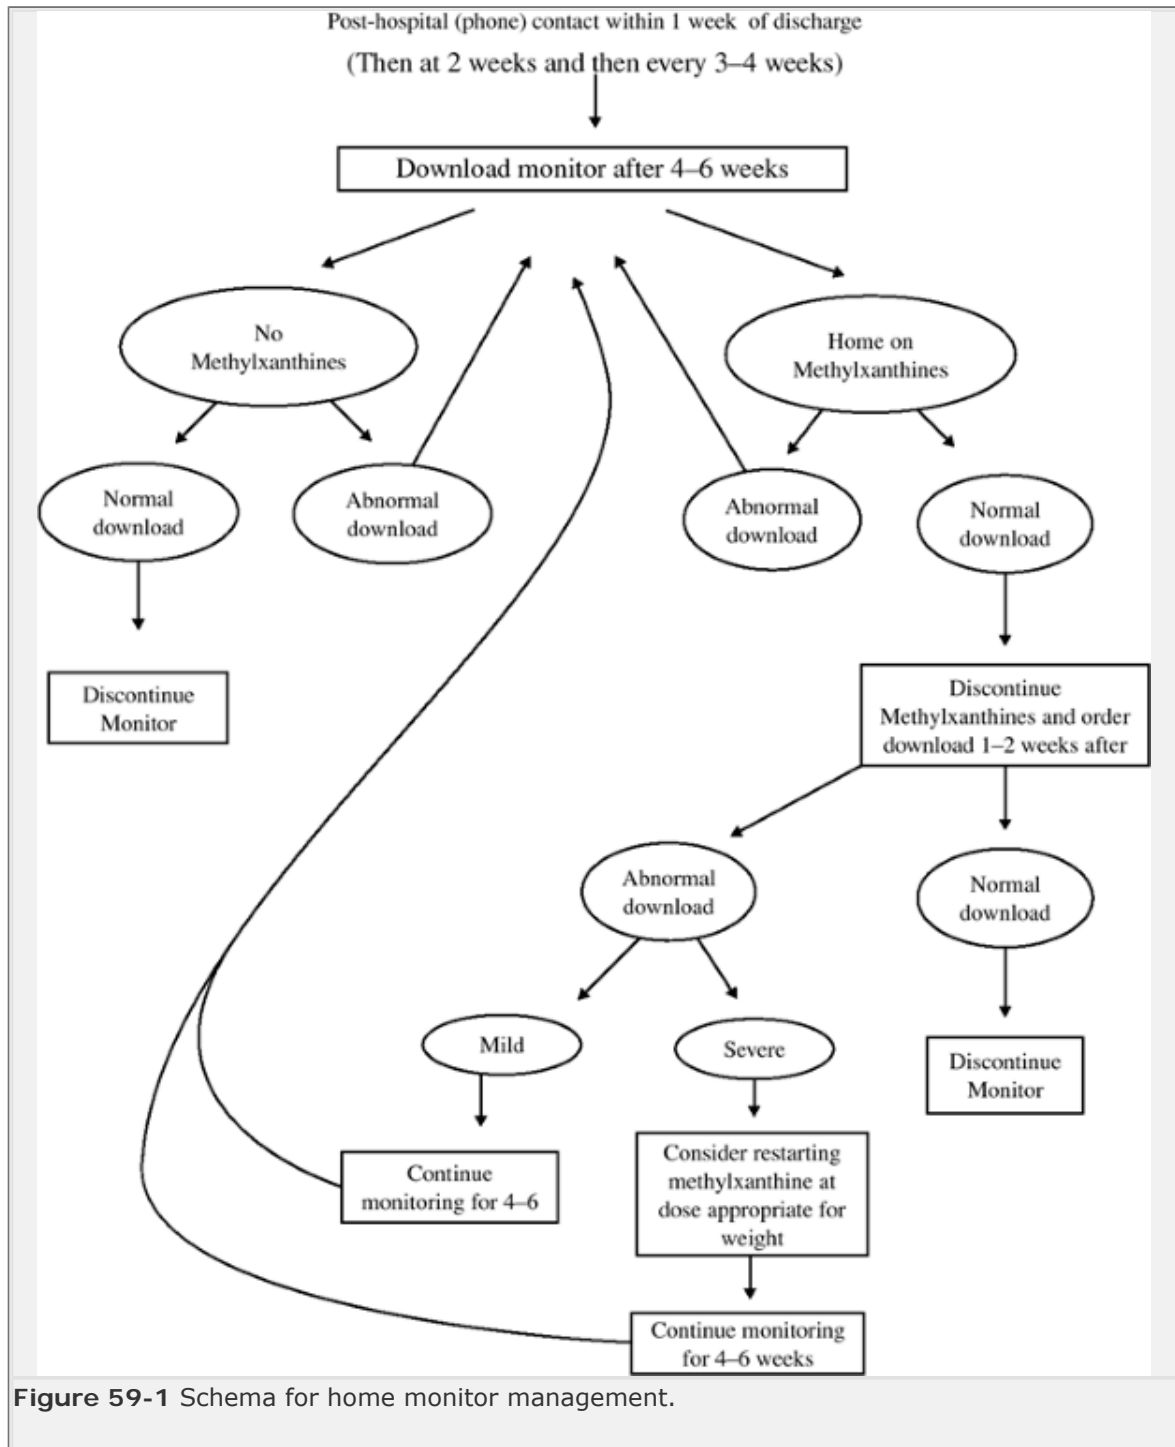

Figure 59-1 Schema for home monitor management.

Diuretics

Most often diuretic therapy supplements fluid restriction in an attempt to decrease the fluid retention typical of

BPD. Although rarely initiated after discharge, diuretic usage requires monitoring of oral intake, urine output, weight gain, and, less frequently, electrolytes. Normally, one spot-check of serum electrolytes a few weeks after

discharge is sufficient and, if normal, need not be rechecked as long as the infant remains medically stable with no significant dietary changes or increase in their diuretic dosage. Infants can outgrow their diuretic doses if there is no worsening of respiratory distress, evidence of peripheral or pulmonary edema, or clinical signs or symptoms of right ventricular strain or failure.

Bronchodilators

Many infants with BPD are discharged on maintenance bronchodilator medications. Unlike diuretics, these medications may need to be modified and continued as part of an aggressive medical regimen. Bronchodilators are used for outpatient therapy of BPD primarily to help maintain the infant's airways maximally dilated and in a bronchospasm-free state. They are used either as maintenance therapy or during intercurrent illnesses. Although the mechanisms of action of the different medications vary, all cause bronchodilation by relaxation of the smooth muscles of the small airways, allowing better oxygenation and prevention of recurrent bronchospasm. Many clinicians have been prescribing inhaled, aerosolized bronchodilators with increasing frequency because of its ease of administration and its direct effect on small airways without much in the way of systemic effect. Bronchodilators can be withdrawn if there has been adequate weight gain, medical stability, good activity level and continued developmental progress, and no exacerbation of underlying bronchospasm. Usually, weaning is not attempted until the infant is off supplemental oxygen. Bronchodilators may be needed either as maintenance therapy or intermittently for acute intercurrent illnesses that precipitate bronchospasm.

Supplemental Oxygen

The decision to continue an infant on supplemental oxygen relates to the severity of underlying lung disease. The need for supplemental oxygen that can be administered via a nasal cannula should not necessarily interfere with hospital discharge. Some of the more common indications for the use of supplemental oxygen include the following: evidence of desaturation while breathing room air; poor oral feeding because of air hunger, apnea, or bradycardia associated with hypoxia; poor growth associated with borderline hypoxia; poor exercise tolerance lethargy; and tachycardia or tachypnea that improves with the use of supplemental oxygen. If possible, it is best to determine the adequacy of oxygenation during sleep, feedings, and periods of activity. Pulse oximetry should indicate saturations of in the mid to high 90's. This level of saturation has been shown to result in a significant increase in pulmonary vasodilation, which may preclude the development of pulmonary hypertension and resultant right heart strain (41). Although many centers begin weaning infants with lower oxygen saturations, studies have shown that infants with chronic lung disease who are optimally oxygenated demonstrate better weight gain, attain corrected age-appropriate milestones more readily, and have fewer intercurrent respiratory illnesses than do infants with lower saturations (42).

Before an infant is weaned from supplemental oxygen, its medical stability must be assured, as must adequacy of weight gain, exercise tolerance, and caloric intake. It is preferable to wean a child off oxygen slowly and in a stepwise fashion (43). A period of several weeks should pass during which the infant remains medically stable, gains adequate weight, demonstrates good exercise tolerance, and maintains adequate oxygen saturations before a move to the next step is considered. If the child is sent home without a pulse oximeter, many home care services can perform intermittent oximetry in the home to assist in making management decisions. It is easier to wean an infant off oxygen if he or she is kept maximally bronchodilated with supplemental medications. During an illness, it is common to have to increase the amount of supplemental oxygen or to restart it temporarily if the child has been recently weaned.

To compensate for increased energy expenditures, the infant with BPD often requires a high caloric intake, between 120 and 150 kcal/kg per day (44). Increased caloric needs complicated by poor nutritional intake often result in poor growth. Poor nutritional intake in this population may be caused by hypoxemia, anorexia, tachypnea, exercise intolerance, oral motor dysfunction, or GER. Additionally, it often is difficult to maximize caloric intake in the face of fluid restriction and exercise intolerance related to feeding. Caloric intake can be maximized by adding supplements, concentrating formulas, or using isocaloric formulas. A list of common supplements can be found in Table 59-2.

Even when supplemental calories are provided, there are times when growth is not adequate because the infant either tires easily or refuses any additional increased oral intake. It is then that supplemental nasogastric feedings should be considered, to be given either after each bottle-feeding or continuously during the night. Each method has its own advantages and disadvantages and must be considered within the context of individual family and patient needs. It is crucial to offer sucking opportunities routinely to any child who is tube-fed to stimulate the development of the sucking reflex (45). A feeding therapist may need to begin working early with

an infant with BPD who demonstrates feeding difficulties to prevent the poor quality suck/swallow coordination frequently encountered in these children.

Intercurrent Illnesses

Bronchospasm with viral or bacterial respiratory illnesses will develop in many infants with BPD. When the infant is not already on maintenance therapy, bronchodilators can

P.1628

be initiated during acute illnesses. If the infant is on maintenance bronchodilator therapy, synergistic medications can be added during acute exacerbations and withdrawn as the acute symptoms resolve, returning to maintenance therapy.

TABLE 59-2 CALORIC SUPPLEMENTS^c

Supplement	Caloric Density	Advantages	Disadvantages
Polycose ^a	2 kcal/mL	Well tolerated	Low caloric density
Karo syrup ^a	4 kcal/mL	Well tolerated; readily available; inexpensive	May cause loose stools
Microlipids ^b	4.5 kcal/mL	Well tolerated	Limited availability; high cost
Medium-chain triglyceride oil ^b	7.6 kcal/mL	High caloric density; usually well tolerated	May cause diarrhea; does not mix well with formula
Vegetable oil ^b	9 kcal/mL	Easily available and low cost	Does not mix well with formula
Avocado (1/2 avocado/26 oz formula) (brown, Calif. Variety) (Florida variety, green)	7.4 kcal/oz 5.7 kcal/oz	High caloric density;	Season availability; expensive
Dry baby cereal	10 kcal/Tbsp	Readily available; inexpensive; may help with gastroesophageal reflux	May cause constipation
Powdered skim milk	27 kcal/Tbsp	Readily available; mixes well with formula	
Duocal	42 kcal/Tbsp	CHO and Fat mixture/well tolerated	Adding 1 tsp/8 oz. formula adds 1.75 kcal/oz

^a Often not used as a supplementation for infants with BPD, because those infants have been shown to have increased work of breathing when receiving a high-carbohydrate load, compared to those supplemented with fat.

^b Use of oil supplements is contraindicated in cases where aspiration is suspected.

^c From Bernbaum J. *Preterm Infants in Primary Care: A guide to office management*. Columbus, Ohio: 2000: Chapter 3, with permission.

Minimizing the exposure of infants with BPD to environmental irritants and communicable diseases will help decrease the frequency of intercurrent episodes of bronchospasm and allow more time for the lung to heal. Some environmental irritants include cigarette or fireplace smoke, pet fur or dander, kerosene heaters, perfumes, paint, and infectious agents. The less irritation the lung is exposed to, the quicker the recovery process will be. All infants with chronic lung disease should receive RSV prophylaxis if they fall into one of the at risk categories listed previously under immunizations.

Rehospitalization is a common occurrence in children with BPD, especially during the first year of life. Parents of these infants should be advised of this possibility before the initial hospital discharge. Every effort should be made to treat intercurrent illnesses and associated bronchospasm on an outpatient basis, but if the infant does not respond readily, hospitalization is appropriate for more aggressive treatment. If, however, the child requires an elective surgical procedure such as a hernia repair, admission should be avoided during epidemics of respiratory-related illnesses.

Managing infants with BPD is one of the greatest clinical challenges for the practicing physician. The many facets

of their care require a complete understanding of how their lung disease affects their physical well-being. Fortunately, most of their medical problems occur during the first year or two of life, and improvement can be expected in each subsequent year.

DISCHARGE PLANNING

Discharge of the intensive care graduate either to home or back to the referral hospital is frequently viewed as one of the most challenging tasks for the hospital staff and can be equally stressful and time-consuming for the family and the child's primary care physician. This transition can be made more smoothly and with less stress if a method is established for an organized discharge planning process (46). Discharge planning is a method whereby the needs of the patient and family are identified and a plan of care is designed and communicated to the appropriate people who will be providing care to the infant and family in the community. The process is intended to lessen the impact on the family of having to care for an infant without the support of the neonatal intensive care unit (NICU) staff on whom they have come to rely 24 hours a day. The discharge planning team usually consists of the physician caring for the infant, the patient's primary care nurse, social worker, therapist (s), and discharge planner (involved in obtaining home nursing, equipment and therapy needs, and coordinating this with insurance provider). Once a plan is determined, it must be communicated with the community agencies that will be involved in providing care. It is crucial that a primary care physician be identified well in advance of discharge not only so that they can continue to be updated on the child's progress while in the hospital but also that the discharge plan is reviewed to insure a seamless transition to home.

Preparation of the child for discharge begins with a thorough assessment of all aspects of the child's management with the goal of minimizing the disruption in the level of care being provided in the transition from hospital

P.1629

to home. One must first determine the feasibility for discharge. The following criteria should be met:

- Medical stability must be present, with minimal fluctuation in the day-to-day level of care.
- The child must tolerate a nutritional regimen that can be provided in a home setting, resulting in consistent weight gain.
- Level of care needed is practical for home.
- Parents are emotionally and technically competent in providing medical care themselves and appropriate support systems are identified when necessary.
- Funding must be available for equipment, medications, formula, and support services.
- Alternative discharge sites (chronic care facility, foster care, or relatives) should be considered for infants whose families are unable to provide the necessary care.

A thorough chart review close to the time of discharge will assist in the determination of outstanding issues. In particular, a list can be generated of pending medical test results, evaluations that are necessary before or after discharge, the types of equipment, medications, and nutritional supplements that will be needed for home care, and any unmet parental teaching needs. Additionally, a list of predischarge tests should be developed at each institution and should be reviewed before each child's discharge. Guidelines may vary from institution to institution, and the tests performed should be individualized based on the patient's history and clinical course. Tests listed in Table 59-3 can function as a guideline for the predischarge examination.

TABLE 59-3 SUGGESTED TESTS IN PREPARATION FOR DISCHARGE AFTER COMPLICATED NEONATAL COURSE^a

Test	<1,000	<1,500	>1,500 g	Other Considerations
Ophthalmologic exam	Yes	Yes	See other	1. 1500–2000 grams with an unstable clinical course or received supplemental oxygen 2. ECMO
Audiologic evaluation	Yes	Yes	Yes	Universal screening for all infants regardless of birth wt.
Thermistor/pneumogram	See other	See other	See other	Perform if clinically indicated; consider if: 1. Recent clinical A's and B's 2. Gastroesophageal reflux
Car seat evaluation	Yes	Yes	37 weeks	1. First hospital discharge 2. At risk of apnea or oxygen desaturation in car seat
CBC with reticulocyte count	See other	See other	See other	All infants approaching discharge
Drug levels	See other	See other	See other	All infants receiving medications requiring monitoring or blood levels
Rickets screening	Yes	See other	See other	1. Prolonged use of TPN 2. GI malabsorption 3. Cholestatic liver disease
Nephrocalcinosis	Yes	See other	See other	Any preterm infant receiving chronic furosemide therapy
Chest radiograph	See other	See other	See other	A recent chest radiograph should be obtained for those with chronic lung disease and a copy provided to the family to keep with infant records.

^a From Bernbaum JC. Transition Care of The Preterm Infant: Essential Elements of Neonatal Discharge. Columbus, Ohio: 1999.

When it is decided that discharge is medically feasible, all aspects of the child's care should be assessed for ways to minimize home care needs. Attempts should be made to withdraw medications that are in the subtherapeutic range based on weight or blood levels. Medications that are no longer needed should be discontinued. Once the medication needs are established, dosage should be adjusted to an amount appropriate for the infant's weight with a buffer for weight gain included. Repeat blood levels at the new dosage should be obtained when appropriate to confirm therapeutic adequacy (e.g., Phenobarbital or caffeine). Additionally, medication schedules should be streamlined to avoid middle-of-the-night doses and to decrease the frequency of administration when possible. Many pediatric medications are difficult to obtain in some communities. To minimize these difficulties, prescriptions should be written and given to the parents several days before discharge to allow time for the local pharmacy to obtain the medications. To avoid confusion, the concentration and dosage of each medication should be written. Parents should be encouraged to bring the filled prescriptions to the hospital before discharge for a final medication teaching session.

Determination of postdischarge nutritional needs should be based on the following:

P.1630

- Expected as opposed to actual rate of growth:
 - The infant's tolerance of the present feeding regimen just before discharge
 - The infant's ability to feed orally or the need for supplemental NG feedings
 - The presence of underlying illness that may increase metabolic demands, require fluid restriction,

predispose to malabsorption, or require special nutritional formulations

When possible, fluid intake should be liberalized several days before discharge to assess the child's ability to feed orally and tolerate larger volumes of formula. If possible several days before discharge, the child should be switched to a commercially available formula that can be concentrated or have supplements added when additional calories are needed to assess tolerance of the formulation and rate of growth. If a special formula or nutritional supplements are needed, arrangements must be made far enough in advance of discharge to allow for procurement of these items. The infant who is a borderline oral feeder may avoid the need for nasogastric supplementation after discharge through the use of concentrated formula or nutritional supplements.

A careful assessment of appointments that are needed after discharge can avoid fragmentation of care. A thorough chart review can identify any services that have been involved during the hospitalization, and some of these services may have suggested continued involvement immediately before or after discharge. These appointments should be set up before discharge, and attempts made to coordinate as many as possible on the same day without overstressing the child. Remind parents that some insurance policies do not cover many of the outpatient visits or they may need a referral for the visit from the infant's primary care physician. If the child requires oxygen, CPAP, or mechanical ventilation, these needs should be identified so that support can be provided during the outpatient visit.

A comprehensive discharge summary aids in providing continuity of care between the hospital and the primary care provider. The summary should include the following:

- Birth weight, gestational age, Apgar scores, and date of birth
- Significant prenatal and delivery history
- Summary of hospital course, including
 - Severity of respiratory illness
 - Type and length of ventilatory support
 - Significant neurologic insults
 - Any surgical procedures
 - Complete list of diagnoses
- Results of screening tests
- Immunizations given and dates
- List of problems remaining at the time of discharge
- Discharge medications and dosages and recent blood levels when applicable
- Relevant social history
- Need for therapeutic interventions (physical, occupational, speech/feeding, or educational services)
-

Home equipment needs

- Need for specialized nursing interventions

Careful planning and coordination of all aspects of an infant's care form the most challenging part of a successful discharge. When health care providers anticipate postdischarge needs and work in collaboration with the child's family to meet those needs, the quality of care should remain unchanged during the transition from hospital to home.

Chapter 60

Developmental Outcome

Forrest C. Bennett

More than 300,000 low-birth-weight infants (LBW; $\leq 2,500$ grams) are born each year in the United States, constituting approximately 7.5% of all live births. Of these infants, approximately 60,000 annually are of very low birth weight (VLBW; $\leq 1,500$ grams), constituting approximately 1.5% of all births. Because the estimated LBW incidence has remained relatively stable over the past 40 years and actually increased over the past 15 years (Fig. 60-1), contemporary reductions in neonatal mortality are steadily increasing the prevalence of biologically vulnerable infants and children in the overall population (1).

Although much medical, legal, ethical, and economic debate continues to occur over the effects of neonatal intensive care on the long-term developmental status of LBW survivors, most investigators are in agreement that the single clearest outcome of this technically enhanced care has been a dramatic and continuing reduction in neonatal mortality since the early 1960s, particularly for VLBW infants since the mid-1970s (Fig. 60-1) (2,3). With current standards of practice in the neonatal intensive care unit (NICU), many more LBW premature infants are surviving to be discharged home after extended hospitalizations than was the case even 5 to 10 years ago. The major factors responsible for this increased survival include the more widespread use of antenatal steroids in situations of anticipated premature birth; the technical ability to provide assisted mechanical ventilation to the smallest of LBW infants; the regionalization of perinatal-neonatal care, with greater numbers of maternal transports to and infants born in tertiary centers; and the widespread use of exogenous surfactant.

Remarkable improvements in the birth-weight-specific mortality rates accounted for 90% of the overall decline in neonatal mortality between 1960 and 1980 (4). During these two decades, decreases in the mortality rates of infants weighing between 1,500 and 2,500 grams contributed more than any other weight group because of both greater proportional decreases and higher absolute declines in mortality; however, there has been steady and statistically significant reduction in mortality rates among VLBW infants throughout the last 20 to 25 years. Mortality for infants with birth weights of 1,001 to 1,500 grams has fallen from more than 50% in 1961 to less than 10% today. Moreover, the most substantial improvement of the 1980s over the 1970s in neonatal mortality rates was in the 751 to 1,000-gram birth-weight group (5). This improvement continued between 1995 and 2000 with these infants having greater than an 85% chance of surviving today if they are admitted to an NICU (6). Finally, in the 1990s and beyond, 40% to more than 60% survival for infants between 500 and 750 grams is being accomplished even though the percent change between 1995 and 2000 was less than that for infants between 751 and 1,000 grams (6,7,8,9). The intact survival of a 380-g infant has been described (10).

Although survival continues to increase in all LBW categories, the greatest impact of neonatal intensive care technology clearly has been on the smallest, sickest, and most medically fragile infants. The success in achieving these improved survival rates for LBW premature infants raises obvious concerns about the subsequent development of such vulnerable infants. It mandates an organized neurodevelopmental follow-up approach to carefully and continuously monitor the quality of survival of the NICU graduate.

ORGANIZATION OF A HIGH-RISK INFANT FOLLOW-UP

PROGRAM

Objectives

There are a number of compelling reasons for conducting longitudinal neurodevelopmental surveillance of survivors of neonatal intensive care. There also are practical problems

P.1633

encountered in providing comprehensive follow-up services. Individual follow-up programs must clearly define their own goals and objectives and then organize their roles and activities accordingly. A community hospital's follow-up efforts likely will be determined by a different set of expectations than those of a university-affiliated tertiary care center. Furthermore, ideal follow-up care in the United States frequently is constrained by limited resources. In general, follow-up programs are designed to meet one or more of the following objectives.

Quality Control

Regular, periodic follow-up of a large proportion of survivors can provide one type of audit of an individual NICU's performance. Because intensive care nurseries differ in such critical management areas as neonatal resuscitation, modes of assisted ventilation, treatment of ventriculomegaly, and use of parenteral nutrition, and also in such neonatal outcomes as mortality and prevalence of medical complications (e.g., bronchopulmonary dysplasia [BPD], intracranial hemorrhage), units may wish to compare their neurodevelopmental morbidity with the contemporary experience of similar nurseries (11). They also may wish to monitor their major disabling morbidities from year to year to detect any significant differences that might accompany further reductions in mortality or the introduction of new intensive care procedures or treatments. It must be recognized that follow-up at 1 or 2 years of age, although providing much useful information about the prevalence of major neurosensory impairment among survivors, is of insufficient duration to identify changes over time in more subtle aspects of brain function, such as learning and behavior.

Developmental Services

Neurodevelopmental follow-up can provide important ongoing subspecialty care to at-risk children and families. Follow-up clinic personnel with a multidisciplinary approach will likely have the most experience and expertise in a given community concerning the unique developmental patterns of LBW premature infants. In general, the follow-up program should complement and serve as secondary or tertiary developmental consultants to the primary health care providers. The program will encourage and facilitate the establishment of a community-based medical home (e.g., private practitioner, public health clinic) for every medically complex survivor. Experience with biologically and environmentally vulnerable indigent populations, however, suggests that actual provision of primary health care, in addition to evaluation and case management services, may be necessary in some situations to prevent attrition and maintain contact with those children and families at greatest long-term risk (12). Although the appropriate approach to this issue of role definition is likely to vary with different populations and access to medical care in different settings, it obviously is of fundamental importance to the organization of follow-up clinics and also to the maintenance of mutual trust relationships with the primary care community.

The specific objectives of follow-up neurodevelopmental assessment activities may be grouped conveniently as follows: to provide cautious reassurance to anxious parents; to ensure early identification and intervention for persistent developmental abnormalities; and to recognize the natural history of transient developmental abnormalities and thereby avoid unnecessary, costly interventions. Maintaining an appropriate balance of diagnostic and reassurance functions is one of the greatest challenges for the contemporary high-risk follow-up program.

Developmental Training

The follow-up clinic provides a marvelous setting for interdisciplinary developmental training. It is a clinical laboratory for the observation of the gradual recovery and normalization over time of most at-risk infants and, in other cases, the gradual evolution of a wide variety of permanent neurodevelopmental dysfunctions. Thus, the at-risk population offers a longitudinal training experience that spans the normal-abnormal development continuum. In many pediatric training programs, the follow-up clinic is the sole opportunity for pediatric residents to observe the outcomes of their own intensive care efforts. It would seem virtually impossible for physicians to be informed adequately about the ethical debates and dilemmas surrounding neonatal intensive care without a first-hand follow-up experience. Likewise, other child development professionals (e.g., psychologists, physical therapists, communication disorders specialists) can use the follow-up clinic profitably as a diverse training base, particularly to broaden the range of normative development for their students. Obviously, these training objectives will apply primarily to university-affiliated tertiary care centers, with their numerous and varied trainee availability.

P.1634

Outcome Research

The university-affiliated follow-up program should be engaged actively in clinical research that contributes to the understanding of the neurodevelopmental and neurobehavioral outcomes of children who experienced neonatal intensive care. These studies may take the form of either descriptive observational reports or clinical trials of specific perinatal-neonatal interventions. For example, the University of Washington's High-Risk Infant Follow-Up Program has published studies describing the outcome of infants weighing less than 800 g at birth (13,14,15), as well as studies evaluating the utility of procedures such as electronic fetal monitoring of premature labor and delivery (16) and treatments such as high-frequency mechanical ventilation (17). Although

tremendous variability exists in the target populations, methodologies, and general scientific quality of the accumulated high-risk follow-up research, a growing consensus of valid outcome observations gradually has emerged over the last 30 years, and informative summary conclusions can be synthesized. Even though the ideal, population-based, nonrisk-controlled, longitudinal to school age study rarely is accomplished for a variety of practical reasons (e.g., cost, subject mobility, investigator discontinuity), individual follow-up investigations, carefully performed with a limited scope, continue to modify and refine overall knowledge and, in some cases, challenge assumptions.

This is not to say that broad, well-funded, collaborative follow-up efforts should not be pursued vigorously on both regional and national, and even international, levels. A recognized need for uniform population descriptions, standardized assessment protocols, common disability definitions, and adequate numbers of pooled subjects still exists. Threats to the interpretability and generalizability of small, local studies include population demographic bias, neonatal treatment differences, attrition of highest-risk (i.e., doubly vulnerable) subjects, and cross-sectional data analysis combining multiple age end points. A great deal has been learned about the short- and long-term prognoses of NICU survivors from hundreds of independent follow-up studies, but much more has yet to be clarified by enhanced research approaches (18).

Personnel

The size and complexity of the neurodevelopmental follow-up team depend on the scope of the program and size of the patient population. For example, a level II to III community hospital with primarily developmental service objectives will likely employ a smaller team, follow for a shorter period of time, and administer fewer standardized measures than a university-affiliated tertiary care center with training and research responsibilities. In either case, certain key tasks must be accomplished. Probably the most critical role in terms of maximizing follow-up compliance and minimizing attrition is that of the follow-up coordinator, usually a program nurse. This person is the liaison between the NICU and follow-up clinic. The nurse coordinator can identify and meet eligible infants and families before they leave the nursery, participate in the discharge conference and transition plans, and, in some cases, make preliminary contact with the family by means of a home visit before the initial follow-up evaluation. This liaison function is particularly important in those programs that conduct high-risk follow-up at a separate site away from the intensive care nursery and in which none of the follow-up personnel is actively involved in the NICU.

Overall program direction is typically provided by a physician or psychologist. This person ultimately is responsible both for meeting the broad programmatic objectives and also for day-to-day operations. The director of a university-affiliated follow-up program frequently must balance competing service, training, and research obligations while eclectically maintaining sufficient funding sources to ensure long-term program viability. The director certainly should be knowledgeable in terms of current follow-up literature and contemporary models of program structure and function.

Other follow-up roles of the interdisciplinary team include the following:

Medical-neurologic assessment.

This may be provided by a neonatologist, developmental pediatrician, or child neurologist. In some programs, a pediatric nurse practitioner or the nurse coordinator may provide health, nutritional, and behavioral guidance pertaining especially to such issues as feeding, sleeping, temperament, and discipline.

Developmental-intellectual-academic achievement

assessment.

This often will be performed by a physical therapist during infancy and by a clinical psychologist or psychometrist thereafter. Some tertiary centers may use a neuropsychologist at school age. In some programs, an early childhood educator or infant developmental specialist participates in early assessments.

Neuromotor assessment.

This usually will be done by a physical therapist during the first years of life when gross motor concerns are paramount, and then by an occupational therapist during the preschool and school years when fine motor concerns predominate.

Language-speech assessment.

In many follow-up programs, this responsibility is assumed by the psychologist. Some programs have the necessary personnel and funding resources to use a communication disorders specialist on a regular basis.

Family assessment.

The increasingly important task of evaluating and monitoring the home parenting environment may be performed by a social worker, clinical nurse specialist, or both. As the number of dysfunctional families in the NICU setting steadily increases because of such prevalent influences as poverty, single parenthood, and prenatal

P.1635

substance abuse, so does the requirement of follow-up programs increase for qualified psychosocial personnel.

Hearing assessment.

The adequate ability to assess hearing at any age by a clinical audiologist is imperative for tertiary follow-up programs. Both electrophysiologic and behavioral audiometric procedures should be available.

Visual assessment.

A pediatric ophthalmologist should be readily accessible for consultation to the follow-up program, particularly for extremely low-birth-weight (ELBW; $\leq 1,000$ grams birth weight) infants.

Patient Selection

Once again, the goals, objectives, personnel, and resources of an individual follow-up program will combine to determine the proportion and nature of at-risk survivors who can be served. Since it usually is impossible for a program to follow all infants receiving neonatal intensive care, somewhat arbitrary risk criteria generally are established to provide broad follow-up guidelines (19). In light of the variation and imperfection of assigned risk factors in accurately predicting neurodevelopmental outcome, a follow-up program is wise to adopt a flexible, rather than rigid, approach to the issue of eligibility. In general, a follow-up program will target the smallest and sickest NICU graduates to maximize the likely necessity of its services. Different levels of follow-up priority (e.g., high, medium, low) frequently are used to structure the selection and longitudinal

monitoring process. University-affiliated follow-up programs conducting specific clinical research will tailor patient selection according to study requirements.

TABLE 60-1 RISK FACTORS FOR MAJOR NEUROLOGIC AND COGNITIVE SEQUELAE IN SURVIVING INFANTS REQUIRING NEONATAL INTENSIVE CARE

Birth Weight (g)	Risk Factor	Category (%)
>2,500	All admissions	<5
	Respiratory distress syndrome	5
	Postasphyxia seizure	30–50
	Meningitis	30–50
	All admissions	10
1,501–2,500	Small for gestational age	<10
	Respiratory distress syndrome	<10
	Bronchopulmonary dysplasia	20–30
	Postasphyxia seizure	30–50
	Meningitis	30–50
1,000–1,500	All admissions	10–30
	Appropriate for gestational age, nonventilated	10–15
	Appropriate for gestational age, ventilated	30–50
	Small for gestational age	75–80
	Seizures, decerebrate posture	
<1,000	All admissions	10–40

Adapted from Fitzhardinge PM. Follow-up studies of the high-risk newborn. In: Avery Gb, ed. *Neonatology: pathophysiology and management of the newborn*, 2nd ed. Philadelphia: JB Lippincott, 1981:353–370, with permission

Common risk criteria for follow-up include the following factors:

- VLBW: In smaller programs with limited personnel and resources, the birth weight criterion may, by necessity, be arbitrarily lowered to 1,250, 1,200, or even 1,000 grams.
- Small for gestational age (SGA): Most programs strive to include infants whose weight or head circumference at birth was more than two standard deviations below the mean for gestational age.
- BPD: Programs will vary on the required duration of mechanic ventilation and oxygen administration.
- Neuroimaging abnormalities: This criterion typically will include such findings as severe intracranial hemorrhage (e.g., large intraventricular hemorrhage, intraparenchymal hemorrhage), severe ventriculomegaly, or extensive cystic periventricular leukomalacia.
- Prolonged seizures or other abnormal neurologic behavior: This includes those infants who continue to demonstrate an atypical neurologic examination at the time of nursery discharge.
-

Central nervous system infection: The targeted infection may have occurred during the intrauterine, intrapartum, or neonatal time period.

- Miscellaneous perinatal-neonatal events of potential neurodevelopmental significance: Most programs will prioritize infants who have experienced to a severe degree such complications as asphyxia, hyperbilirubinemia, hypoglycemia, or polycythemia. Specific threshold determinations will vary from program to program. Table 60-1

P.1636

quantifies the major neurodevelopmental risk associated with many of these follow-up inclusion criteria.

Many states use or are developing some type of comprehensive high-risk tracking or screening system to monitor the growth and development of biologically vulnerable infants (20). In some states (e.g., Iowa, North Carolina, Washington), this broadly based tracking system serves as an initial screen to identify those infants and toddlers who merit complete, tertiary developmental assessment. This coordinated approach to follow-up offers the advantages of tracking many more at-risk infants and families while also increasing the efficiency and appropriate use of the formal follow-up clinic.

Clinic Schedule

The schedule of evaluations conducted by the University of Washington's High-Risk Infant Follow-up Program is outlined in Table 60-2. This plan is illustrated as an example of a follow-up program with combined clinical service, training, and research objectives. Smaller hospital-based programs without training or research requirements often will be able to meet their clinical needs with different formats, shorter duration of follow-up, and fewer standardized assessments. Basic monitoring concepts applicable to all follow-up programs, however, include special attention to neuromotor development the first year, language and cognitive development the second and third years, school readiness skills between 4 and 5 years of age, and academic achievement during the early school years. In addition, attention to family function ideally should be an integral part of each clinic visit. With this developmental sequence of evaluations, timely identification of delays and dysfunctions as well as appropriate referral to community-based intervention services are optimized (21).

TABLE 60-2 HIGH-RISK INFANT FOLLOW-UP CLINIC SCHEDULE

Corrected Age	Test
4 months	BSID MAI Physical and neurologic examinations
8 months ^a	BSID MAI Audiologic evaluation by visual reinforcement audiometry Physical and neurologic examinations
12 months	BSID Physical and neurologic examinations
24 months	BSID Physical and neurologic examinations

36 months	Stanford-binet intelligence scale Peabody picture vocabulary test Expressive language sample Physical and neurologic examinations
4.5 years	Wechsler preschool and primary scale of intelligence Peabody developmental motor scales Physical and neurologic examinations
6 and 8 years	Wechsler intelligence scale for children Peabody individual achievement test Physical and neurologic examinations

BSID, Bayley Scales of Infant Development; MAI, Movement Assessment of Infants.

^a Scheduled selectively for those infants with possible neuromotor abnormalities at 4 months of age.

A frequent topic of debate concerns the calculation of assessment age for premature infants (22). Whereas most follow-up programs plan their clinic visit schedule and score their evaluation measures on the basis of fully corrected age (i.e., chronologic age minus the number of weeks premature), a number of others continue to use unadjusted chronologic age or even, in a few cases, one-half correction (i.e., chronologic age minus one-half the number of weeks premature). The reluctance to use full gestational age correction stems from a concern over the potential artificial inflation of developmental test scores and coincident underuse of early intervention services during the first several years of life. Although these are valid clinical concerns to consider when providing parental feedback and making referral decisions, the weight of the evidence in terms of the neuromaturation of premature infants favors the practice of gestational age correction, at least to 3 years of age, when monitoring the growth and development of NICU survivors.

Regardless of the scheduling mode used, all follow-up personnel must appreciate the imprecisions and variabilities of early developmental assessment. LBW premature infants may demonstrate improving developmental performance during the first years of life as they recover from perinatal-neonatal insults and chronic health impairments (e.g., BPD, necrotizing enterocolitis). Conversely, they also may demonstrate additional developmental dysfunction over time as more subtle disabilities become increasingly apparent and testable. In light of these patterns of development, health and developmental professionals who work with premature infants and their families must be aware of the hazards implicit in the high-risk concept. Parents may permanently regard their child as vulnerable, once so labeled, and contribute to a self-fulfilling prophecy. There can be an overzealous tendency in well-intended follow-up programs to presume the presence of abnormality rather than normality, despite the evidence of more optimistic outcome data to the contrary. In fact, most high-risk infants do not develop the conditions for which they are at increased statistical risk, and there frequently is a poor correlation between the severity of the neonatal course and specific neurodevelopmental outcomes for individual premature infants. There is a need for monitoring of this population with a keen awareness of, but not an expectation of, adverse sequelae. Documented developmental dysfunction certainly should not be ignored, but an initial follow-up posture of cautious optimism is appropriate in most cases.

NEURODEVELOPMENTAL OUTCOME OF LOW-BIRTH-WEIGHT PREMATURE INFANTS

Despite contemporary reductions in LBW morbidity compared to disability rates before the

introduction of neonatal intensive care, permanent neurodevelopmental problems are seen in many survivors. Such problems include major neurosensory impairments, cognitive and language delays, specific neuromotor deficits, neurobehavioral and socioemotional abnormalities, and school dysfunction (23).

Major Neurosensory Impairments

The major neurosensory impairments associated with prematurity are cerebral palsy, particularly of the spastic diplegia type; mental retardation (i.e., intelligence quotient [IQ] more than two standard deviations below the standardized test mean; sensorineural hearing loss; and visual impairment, primarily the consequences of retinopathy of prematurity (ROP) (24). These major developmental disabilities may occur together in the same child and occasionally are complicated by progressive hydrocephalus or a chronic seizure disorder. They usually are clinically apparent by 2 years of age and vary in severity from mild to profound. Children with one or more of these major impairments generally require special educational programming and individual therapeutic intervention throughout childhood. These conditions occur two to five times more frequently in LBW compared to normal birth weight (NBW) infants. As a group, their prevalence increases with decreasing birth weight and gestational age; the disability rate in boys consistently exceeds that in girls (25). Table 60-3 provides combined prevalence estimates and ranges by birth weight group and gestational age for these chronic neurosensory impairments. The actual numbers represent a synthesis from reporting tertiary care centers in the United States, Canada, Australia, and Western Europe.

Such major morbidity statistics may be viewed either positively or negatively, or in both ways. On the one hand, the occurrence of these major sequelae is far less than initially predicted at the beginning of the NICU era, and many more nondisabled than disabled survivors (approximately 8:1) are being added to the population (26). Conversely, epidemiologic investigations appear to document that reductions in LBW major morbidity have not paralleled or kept pace with reductions in LBW mortality and that the major impairment rate has changed little over the past 20 to 25 years. Actual increases in both the incidence and prevalence of major disabilities among the smallest and sickest survivors have been reported by some (27,28). Others, however, have reported a stable major morbidity rate for infants weighing less than 800 grams at birth (Table 60-4), a subgroup whose survival has dramatically increased during this time period (13,14,15). This encouraging observation that the overall incidence of serious neurodevelopmental deficits is remaining stable while survival continues to increase has been repeatedly corroborated even for those ELBW infants who weighed less than 750 grams at birth (9,29,32). A recent population-based study from the United Kingdom and Ireland reported a severe disability rate of almost 25% in children born at 25 or fewer weeks of gestation; nevertheless, almost 50% had no evidence of disability at a median age of 30 months (33).

TABLE 60-3 LOW-BIRTH-WEIGHT INFANTS WHO SURVIVE WITH ONE OR MORE MAJOR IMPAIRMENTS

Birth Weight (Gestational Age) (g)	Percent with Major Impairments (Range)
1,501–2,500 (32–36)	8 (5–20)
1,001–1,500 (28–31)	15 (5–30)
≤1,000 (<28)	25 (8–40)

TABLE 60-4 PREVALENCE OF MAJOR IMPAIRMENTS IN SURVIVORS WEIGHING LESS THAN 800 G AT BIRTH AT THE UNIVERSITY OF WASHINGTON

	Major Impairment (%)
1991–1995	8/74 (11)
1986–1990	17/78 (22)
1983–1985	8/38 (21)
1977–1980	3/16 (19)

Cerebral Palsy

Cerebral palsy, of varying types and severities, remains the most prevalent major developmental disability encountered in premature infants; the prevalence in VLBW infants varies between 6% and 10%, and approximately 40% of all children with cerebral palsy were born prematurely (i.e., less than 37 weeks of gestation) (34). Although both spastic (i.e., pyramidal) and athetoid (i.e., extrapyramidal) types of cerebral palsy may be encountered in NICU graduates, the spastic cerebral palsy syndromes (i.e., diplegia, hemiplegia, and quadriplegia) are the neuromuscular disorders most commonly seen in LBW infants. One specific type, spastic diplegia, in which the legs are much more affected than arms, is so strongly associated with prematurity (i.e., at least two-thirds of all children with this disorder are born before 37 weeks of gestation) that for over a century it has been referred to as “the disease of immaturity” (35). Figure 60-2 illustrates the relationship between spastic

P.1638

diplegia and gestational age. Most cases occur in a window of vulnerability in infants born between 28 and 34 weeks of gestation.

Figure 60-2 Occurrence of spastic diplegia as related to gestational age.

Despite the long consistency of the spastic diplegia-prematurity association, the exact etiologic factors involved often have been elusive and difficult to identify precisely prospectively (36). Neither the severity of perinatal-neonatal illness nor the presence or severity of intracranial hemorrhage reliably predicts spastic diplegia. Data derived primarily from studies correlating ultrasonographic, neuropathologic, and clinical information led to the conclusion that spastic diplegia is the clinical expression of periventricular leukomalacia and its variants (37). Periventricular leukomalacia appears to be caused, in large part, by hypoxic-ischemic injury to the periventricular white matter. The demonstration on serial cranial ultrasounds of initial extensive periventricular echodensities followed in days to weeks by large, bilateral cyst formation (i.e., periventricular white matter infarction) is highly predictive (80% to 85%) of permanent cerebral palsy, especially the spastic diplegia type (38,39). Many cases of symmetric cystic periventricular leukomalacia occur in infants with relatively benign clinical courses and are detected only by routine ultrasound screening. Premature infants born to mothers with prolonged rupture of membranes and/or chorioamnionitis seem to be at an increased risk in some studies (40) but not in others (41). Several investigators have implicated prenatal factors (e.g., intrauterine growth retardation) in the etiology of some cases of spastic diplegia. Hagberg (42) has postulated that the complex interaction of prenatal abnormalities (i.e., "fetal deprivation of supply") with perinatal difficulties in the birth process and the adjustment to the extrauterine environment may constitute a common pathogenetic mechanism of spastic diplegia. Accordingly, the etiology of spastic diplegia frequently is multifactorial, and all LBW infants merit close neuromotor monitoring during the first 2 years of life, regardless of the severity of their nursery course.

In contrast, development of the more severe spastic quadriplegia type of cerebral palsy, in which all four extremities are equally affected, often can be predicted better in NICU graduates on the basis of specific perinatal or neonatal events, including asphyxia, marked bilateral intraventricular hemorrhage with ventriculomegaly, prolonged neonatal seizures, and central nervous system infection. Although most premature children with spastic diplegia have average or near average mental abilities, children with spastic quadriplegia are far more likely also to have serious cognitive impairments. Spastic hemiplegia, in which only one side is affected, with the arm usually more than the leg, often is heralded by the ultrasonographic appearance of a unilateral, periventricular hemorrhagic infarction with subsequent cystic transformation that occurs in association with and presumably as a result of substantial asymmetric intraventricular hemorrhage (37).

Cerebral palsy typically presents over time in a developmental manner. Thus, very early neurologic signs and symptoms may prove to be transient in nature and not indicative of eventual cerebral palsy. Conversely, infants may initially appear asymptomatic with a relatively normal neurologic examination at the time of nursery discharge and even for several months thereafter, particularly in the cases of spastic diplegia and spastic hemiplegia, only to manifest clearly evident cerebral palsy by 1 year of age. Premature infants with evolving cerebral palsy reveal increasing neuromotor abnormalities of muscle tone, movement, posture, and reflex activity, particularly between 6 and 18 months of corrected age, in combination with increasingly delayed motor milestones.

Mental Retardation

Mental retardation, as defined by a standardized intelligence or developmental quotient consistently more than two standard deviations below the test mean for corrected age, often occurs in conjunction with one or more of the other major handicaps, especially cerebral palsy. In fact, severe mental retardation and severe cerebral palsy share associated perinatal-neonatal risk factors. Evidence suggests some increase in the prevalence of severely multihandicapped children

after increased VLBW survival (28). Mental retardation occurs in 4% to 5% of VLBW infants followed longitudinally to school age. Isolated mental retardation, without cerebral palsy, is a reported consequence of severe BPD, particularly in cases of greatly prolonged duration of mechanic ventilation and oxygen administration (43,44).

Hearing Impairment

NICU graduates are at increased risk for both sensorineural and conductive hearing loss. Although the risk of sensorineural loss sufficient to require hearing aids, special education, and nonvocal communication strategies (60 to 100 dB) usually is estimated to be 2% to 3% for VLBW infants, some investigators have reported prevalence estimates between 5% and 9% coincident with the increased survival of more vulnerable infants (45). Exposure to ototoxic drugs, infections, hypoxia/ ischemia, and hyperbilirubinemia are among the interacting and cumulative factors contributing to the risk of sensorineural loss.

P.1639

The duration and extent of hyperbilirubinemia in VLBW infants has been examined carefully. de Vries and colleagues (46) found bilirubin levels in excess of 14 mg/dL to be associated with a high risk of deafness in VLBW infants but not in healthy premature infants with a birth weight greater than 1,500 grams. Others also have emphasized the potential ototoxicity of hyperbilirubinemia in VLBW infants in combination with hypoxia, acidosis, and prolonged administration of multiple ototoxic medications such as the aminoglycoside antibiotics and furosemide. These investigators conclude that the additive effects of protracted illness plus its associated treatments, independent of specific diagnostic categories, constitute important risk factors for permanent hearing loss in this population (47).

There is ample evidence that infants of all birth weights who sustain severe persistent pulmonary hypertension of the newborn comprise a particularly high-risk subgroup for sensorineural hearing loss, with prevalence estimates ranging from 20% to 40% (48). In some cases, the loss is progressive during the first 3 years of life. The exact mechanism of insult remains unclear in this population of infants who typically experience prolonged hypoxia, severe acute and chronic lung disease, and multiple aggressive interventions. Another concern has been the potential deleterious effect of prolonged incubator noise on hearing function. Abramovich and associates (49) found no evidence for this hypothesis in VLBW infants. Many of the risk factors associated with hearing impairment also are associated with cerebral palsy, and these two disabilities often occur together in the same child.

Mild and moderate (25 to 59 dB) sensorineural hearing losses, sufficient to contribute to delayed language development but compatible with oral communication, also occur with increased frequency (6% to 8%) in LBW infants. Previously unrecognized unilateral sensorineural hearing losses, with adverse language and learning consequences, may become apparent in the older child (50). A high prevalence (20% to 30%) of chronic otitis media with middle ear effusion and fluctuating, conductive hearing loss greater than 25 dB is reported in LBW premature infants (51). Suggested mechanisms for this relationship focus on probable eustachian tube dysfunction initiated by a combination of dolichocephalic head shape, muscular hypotonia, and prolonged nasotracheal intubation.

There have been important advances in the hearing assessment of LBW infants. Two techniques in particular, electrophysiologic auditory brainstem response (ABR) audiometry and behavioral visual reinforcement audiometry, have made early, reliable detection of hearing loss in the NICU graduate clinically feasible. Centers that routinely screen high-risk, LBW infants with ABR before nursery discharge report a false-positive rate of 8% to 10% compared to follow-up testing at 4 months of age (52). Conversely, the unanticipated appearance of severe sensorineural hearing loss in high-risk survivors of neonatal intensive care after having passed an initial ABR screening test in

the newborn period has been reported (53). It also must be recognized that ABR tests only the high sound frequencies (i.e., 2,000 Hz and above) and will not detect hearing losses confined to the lower frequencies. Thus, clinicians must remember that determinations of the adequacy of hearing made only with ABR test data before nursery discharge are subject to error. Visual reinforcement audiometry is an operant conditioning technique that reliably can provide auditory thresholds for infants who are functioning at a developmental age of approximately 6 months or older. It has great utility in the high-risk follow-up clinic. A third and newer audiologic procedure, evoked otoacoustic emissions, is of use in newborn screening in conjunction with ABR (54).

Visual Impairment

The major cause of visual loss in LBW infants is retrolental fibroplasia, now included under the rubric of ROP. With controlled oxygen administration, ROP was relatively rare until the last 15 years or so, when significant numbers of extremely premature infants began to survive. The name ROP recognizes that immaturity at birth is the single largest risk factor for this disease. For all practical purposes, this is a disorder of the VLBW infant. Virtually no retinal detachment and little retinal scarring is described in larger premature infants. For the entire VLBW population, current prevalence estimates range from 20% to 25% with early-stage, regressed ROP; 5% to 10% with more advanced- stage, scarred ROP; and 2% to 4% with major visual impairments, including legal blindness and requiring special educational assistance. The distribution of visually impaired infants, however, is skewed heavily toward those weighing 1,000 grams or less at birth. In these ELBW infants, regressed ROP occurs in 40% to 50% of survivors, scarred ROP in 10% to 25%, and major visual impairments in 5% to 10%. Figure 60-3 shows the overall prevalence of ROP by birth weight. These estimates continue to apply with a greater than 80% prevalence for infants of 26 or fewer weeks' gestational age.

Alteration of normal retinal vascular development is the hallmark of ROP. Although a great deal of effort has been

P.1640

invested in clinical and animal studies of ROP, there remains an etiologic maze in which no single factor stands alone (55). It appears that the embryonic retina of the small premature infant, developing outside the uterus, is vulnerable to many sources that can disrupt orderly differentiation and vascularization. In addition to the well-known impact of hyperoxia, it seems that hypoxia, variations in arterial carbon dioxide pressure, pH, retinal oxygen consumption, light exposure, and other factors that affect retinal perfusion all may play a role. A formula for ROP could be: immaturity (always)+oxygen(often)+other factors (variably)=ROP (56). Simply stated, the smallest and sickest newborns have the most complications that potentially can impede retinal function, and they also have the most ROP.

Figure 60-3 Percentage of retinopathy of prematurity (ROP) by birth weight versus proportion of births by birth weight. (From Glass P, Avery GB, Subramanian KNS, et al. Effect of bright light in the hospital nursery on the incidence of retinopathy of prematurity. *N Engl J Med* 1985;313:401-404, with permission.)

Even regressed ROP is associated with an increased risk for refractive errors, amblyopia, and strabismus. "Myopia of prematurity," even without ROP, has been described to occur in approximately one-third of surviving ELBW infants (57). It is considered to be mostly lenticular in origin and to improve slowly, but not completely, throughout childhood, with slight visual acuity differences still apparent in early adulthood. Strabismus may represent an isolated problem or, in some cases, may be an initial indication of a generalized neuromotor problem such as cerebral palsy. Visual and hearing impairments may coexist, and prematurity is the leading cause of children with both deficits. Monitoring of eye muscle balance and alignment and visual acuity should be part of routine follow-up of the premature infant, particularly during the preschool years. Required interventions may include eye muscle surgery, antisuppression patching, or corrective lenses.

Progressive Hydrocephalus

Depending on the reporting center, between 20% and 40% of VLBW infants have neonatal ultrasonographic evidence of intracranial hemorrhage, frequently including intraventricular hemorrhage with ventriculomegaly (11). Whereas older reports indicated discouragingly high rates of posthemorrhagic hydrocephalus, subsequent reports described a much lower prevalence (2% to 4%) of progressive hydrocephalus requiring ventriculoperitoneal shunting in VLBW infants (58,59). Serial scanning with cranial ultrasonography has revealed that most cases of early ventriculomegaly either spontaneously resolve or arrest. Interventions (e.g., repeated lumbar puncture, ventricular taps) to prevent the transition from relatively asymptomatic ventriculomegaly to progressive hydrocephalus appear to be unnecessary. Surgical ventriculostomy drainage is frequently employed as a temporizing procedure in more advanced cases.

For the infant in whom posthemorrhagic progressive hydrocephalus does develop, it generally becomes clinically evident between 2 and 8 weeks of age; however, appearance during late infancy occasionally has been reported. Vigilance in measurement of the head circumference at each follow-up examination of the infant is important, and obtaining a cranial ultrasound, if head growth becomes substantially out of proportion to the other growth parameters, may be indicated. Although the initial months of life are the time when progressive hydrocephalus is most likely to develop in premature infants, it also is the period of time when the normal phenomenon of catch-up head growth in these recovering infants becomes most apparent. Thus, increase in head

circumference relative to weight and length usually is an anticipated sign rather than a pathologic one, and such awareness should guide clinical investigative decisions. When progressive hydrocephalus does occur, neurodevelopmental outcome is frequently, although not invariably, abnormal, complicated by one or more of the major disabilities (e.g., cerebral palsy, mental retardation, sensory impairments) (60).

Minor Impairments

Although major disabling sequelae are by far the easiest to quantify and report, a large and persuasive body of long-term follow-up studies clearly indicates that a broad spectrum of cognitive, behavioral, and other minor neurodevelopmental and neurobehavioral sequelae are substantially more prevalent in surviving LBW, premature infants. These morbidities become increasingly apparent in a variety of clinical manifestations with increasing age, particularly during the first 6 years of life. These early, often subtle, developmental and behavioral delays and differences are not necessarily outgrown but frequently portend future school dysfunction and may therefore become major impediments to normal academic and social progress. Collectively, these problems often are referred to as the "new morbidity" of prematurity, reflecting their more insidious nature and more intense scrutiny in recent years (24). Recent studies have documented the persistence of these differences into adolescence and young adulthood (61,62).

Specific types of developmental morbidities described in LBW cohorts include cognitive delays (i.e., lower IQ), speech and language disorders, persistent neuromotor abnormalities, including difficulties with balance and coordination, and perceptual problems. Specific areas of suboptimal behavioral style and performance include neonatal behavior, infant and toddler temperament, emotional maturity, social competence, and selective attention. As with major impairments, the overall prevalence of these minor sequelae increases with decreasing birth weight and gestational age and also is greater in male survivors. Prevalence estimates in VLBW infants vary between 15% and 25%. Accordingly, when the 15% to 20% major disability rate is combined, between 35% and 45% of VLBW survivors demonstrate a residual developmental or behavioral problem that compromises their anticipated function (63). Recent estimates for ELBW infants are in excess of 50% (64). As with major impairments, most of the minor developmental morbidities associated with LBW and prematurity also are related to the severity of perinatal-neonatal illness. That is, LBW infants who experience a prolonged hospital course with many medical complications have an increased likelihood of developing some type of developmental dysfunction. Thus, the smallest and

P.1641

sickest infants, particularly those ELBW new survivors of the 1990s, are the most vulnerable to experience these problems.

In the hundreds of outcome studies across multiple developmental and behavioral domains, a consistent finding is that, regardless of the measures used, groups of premature children are less competent and score less well than groups of full-term children (26). However, this does not mean that individual premature children will invariably be less capable than individual full-term children. Despite the large number of significant group associations in follow-up studies, individual developmental outcome remains very difficult to predict prospectively with accuracy in the NICU, and infants with apparently similar neonatal courses may develop entirely differently.

Cognitive and Perceptual Development

Consistent deficits in performance on intelligence measures repeatedly have been observed and reported in LBW premature children compared to NBW full-term children (65,66). Furthermore, these differences in cognitive development become apparent in the first years of life and then persist and increase during the preschool and early school years even when the single most

powerful predictor of IQ—socioeconomic status—is adequately controlled. In other words, significant deficits in cognitive and perceptual functions occur frequently even in middle to upper-middle social class children born prematurely, particularly compared to their full-term peers. This important and academically relevant group difference exists despite the fact that most LBW children will have measured IQs within the average range (23). Encouragingly, improvement in verbal and IQ test scores throughout early and middle childhood has recently been reported in a large cohort of VLBW infants followed over time (67).

Cognitive developmental differences between premature and full-term infants have been reported in early infancy. Rose (68) investigated the effect of increasing familiarization time on the visual recognition memory of 6- and 12- month-old premature and full-term infants. Whereas the older infants showed evidence of recognition memory after less familiarization time than the younger ones, premature infants at both ages required considerably longer familiarization times (i.e., more practice) than did full-term infants. These results suggest that there are persistent differences between premature and full-term infants throughout at least the first year of life in a very fundamental aspect of cognition, namely, visual information processing.

Because manipulative exploration of objects may be important to the infant's perception and conceptualization of objects, Ruff and colleagues (69) studied this developmental function in both premature and full-term 9-month-old infants by means of coded and scored videotapes. The videotapes were scored for behaviors such as looking, handling, mouthing, turning the object around, transferring the object from hand to hand, and banging. A high-risk subgroup of premature infants, based on neonatal complications, manipulated the objects significantly less than either the low-risk premature or full-term infants. There was a relationship between manipulative exploration at 9 months and later cognitive functioning at 24 months.

LBW cognitive deficits have been described from the earliest days of neonatal intensive care and even before. Using a sample of approximately 600 children born in two hospitals in Edinburgh, Scotland, in 1953 to 1955, Drillien (70) demonstrated that IQ scores decline with decreasing birth weight in the first 4 years of life. The percentage of children with IQ scores below 80 at 4 years was 29% for those under 4.5 pounds (2.0 kg), 13% for those between 4.5 and 5.5 pounds (2.5 kg), and 4% for those above 5.5 pounds. Wiener and colleagues (71), reporting on a sample of 417 eight- to ten-year-old LBW children who had been tested with the Wechsler Intelligence Scale for Children, found that the verbal IQ, which consists of predominantly cognitive and language items; performance IQ, which consists of predominantly motor-perceptual items; and full-scale IQ, which consists of a combination of the verbal and performance scales, all showed increasing impairment with decreasing birth weight even though all subtest means remained within the average range of intelligence. Moreover, approximately twice as large a proportion of LBW children as NBW control children fell into the borderline IQ category (70 to 84), which usually is associated with special educational needs. Visual-motor-perceptual skills, as measured independently by the Bender Gestalt Test, also varied directly with birth weight. Hunt and colleagues (72) reported the following cognitive outcome proportions in a cohort of 108 VLBW children at 8 years of age: 4.6% had a very low IQ (less than 70), 13.9% had a low IQ (70 to 84), and, for those with an IQ greater than 84, 12.0% had language disability, 12.0% had performance disability, 21.4% had visual-motor disability, and 36.1% were apparently normal.

In a Vancouver, British Columbia, study of 501 LBW and 203 NBW children born between 1958 and 1965, the IQ difference between LBW and NBW groups on the Stanford-Binet Intelligence Scale was 9 points at 30 months of age and 15 points at 48 months, even after exclusion of children with major cerebral deficit or IQ scores under 50 or significant visual problems (65). In both the Edinburgh and Vancouver studies, the poor functioning of LBW children is convincingly exacerbated in socioeconomically disadvantaged subgroups. Table 60-5 illustrates this interaction of both biologic and environmental risk factors in the determination of measured IQ of the Vancouver study children. At both 2.5 and 4 years of age, NBW, highest-social-class children earned the

highest subgroup mean IQ score, whereas LBW, lowest-social-class children earned the lowest. Both NBW and LBW groups demonstrated an IQ score continuum from the highest social class, which had the highest mean IQ, to the lowest social class, which had the lowest mean IQ, with the NBW subgroup always higher than the LBW regardless of social class; at 4 years of age, even NBW, lowest-social-class children scored higher than their LBW, highest-social-class peers.

LBW, low birth weight; IQ determined from Stanford-Binet tests.

Adapted from McBurney AK, Eaves LC. Evolution of developmental and psychological test scores. In: Dunn HG, ed.

Sequelae of low birthweight: the Vancouver Study. Philadelphia: JB Lippincott, 1986:61, with permission.

The cognitive performance of ELBW preschool children has been the subject of more recent attention. Halsey and colleagues (73) compared predominantly white, middle-class ELBW 4-year-olds with matched full-term children and also with matched LBW children (1,500 to 2,500 grams at birth) and found both comparison groups to be 2.5 times more likely to have optimal development. Comparison children had mean cognitive scores 15 to 18 points higher than ELBW children. The investigators concluded that weaker performance on all study measures (i.e., language, motor, memory, visual-motor, perceptual) exists before school entry among nondisabled ELBW children compared with their peers. Breslau and colleagues (74) confirmed these cognitive concerns for ELBW survivors in describing a gradient relationship between LBW and IQ at age 6 years. They found the largest deficit in full-scale IQ in those children born weighing 1,500 grams or less, an intermediate deficit in those born weighing 1,501 through 2,000 grams, and the least pronounced deficit in those born weighing 2,001 through 2,500 grams.

Language Development

Communication skills involving auditory and visual perception, learning and conceptualizing of a

verbal symbol system (i.e., language), and actual production of speech are critical to academic learning and social adjustment. Several investigations have focused exclusively on this important area of development in premature infants. Zarin-Ackerman and colleagues (75) noted both receptive and expressive language deficiencies at 2 years of age in a group of children born as at-risk (i.e., predominantly premature) infants compared to others born as healthy, full-term infants. They emphasized that these deficits could not be a function of social class, which is a major factor influencing language development, because this variable was controlled. In Switzerland, Largo and associates (76) compared 114 premature children to 97 healthy, full-term children throughout the first 5 years of life. Most stages of language development occurred at slightly later ages among the premature children than among those born at term. Birth weight and gestational age were negatively correlated with language development at all ages. Perinatal-neonatal complications also were significantly negatively correlated with the ages at which the stages of language development were reached, and also with final language performance at 5 years of age. There were no significant differences in socioeconomic status between the premature and full-term groups. The particular demographics of this unique study allowed the authors to conclude that biomedical factors exert a considerable effect on the early language development of premature children and that this effect is greater than previously had been recognized (76).

Several smaller studies have confirmed the existence of linguistic dysfunctions among premature children, particularly those with complicated neonatal courses (77,78). On the basis of a wide variety of measures, inferior performance has been reported consistently in receptive language or comprehension, expressive language parameters such as vocabulary and word finding, and speech qualities such as articulation and fluency.

Motor Development

Numerous studies from several continents repeatedly have documented that the neuromotor development of LBW premature infants during the first 2 years of life is different, more delayed, and generally more worrisome than that of

P.1643

healthy, full-term infants. Premature developmental scores, using such measures as the Bayley Scales of Infant Development, are consistently and significantly below those of full-term infants at 12 months of corrected age, and premature motor scores also usually are 10 to 15 points (i.e., practically one standard deviation) below premature mental scores at this age (79).

This phenomenon of transiently abnormal neuromotor signs in the first years of life was described initially by Drillien (80), in a 1972 report from Scotland, as "transient dystonia of low birth weight infants." Drillien reported that its prevalence during the first half of infancy varied inversely with birth weight, involving approximately 35% of infants weighing 1,501 to 2,000 grams at birth and 60% to 70% of infants weighing 1,500 grams or less at birth, and that its prevalence also varied directly with perinatal-neonatal complications (i.e., more frequent among sick premature infants). Transient dystonia includes such neurologic findings as increased or decreased muscle tone, diminished volitional movement, retention and accentuation of primitive reflex patterns, delayed appearance of normal infantile automatic reactions, and asymmetric neuromotor development. Because these neuromotor signs also are the very signs seen in infants in whom cerebral palsy is developing, it is not surprising that a reliable diagnosis of cerebral palsy is quite difficult in most premature infants throughout early infancy. As described by Amiel-Tison (81), however, by 8 to 10 months of corrected age, most LBW infants with transient dystonia are gradually and spontaneously normalizing on examination, whereas those relatively few infants in whom permanent cerebral palsy is developing appear increasingly abnormal. With the knowledge of this common evolution of neuromotor signs, every VLBW infant can be assigned to one of three diagnostic and prognostic groups at 12 months of age: those who were always neurologically

normal throughout infancy (25% to 30%); those who showed transient dystonia with subsequent normalization (65% to 70%); and those with cerebral palsy (5% to 10%).

Coolman and colleagues (82) and others have extended these observations to 24 months of age, albeit most neuromotor changes occur in the first year of life. They found that some infants with transient dystonia retained subtle, persistent neuromotor differences that would not be labeled as cerebral palsy but that represented qualitative deviations from the norm. Longitudinal studies indicate that infants who have experienced transient dystonia are far more likely to have language, learning, and behavioral problems (i.e., minimal brain dysfunction) in later childhood than are infants who never demonstrated these abnormalities (83,84). This would indicate that although transient dystonia largely resolves, these neuromotor signs in early infancy may be predictive markers for later manifestations of central nervous system disorganization.

Differences in the motor development of premature infants throughout the preschool years have been reported. Burns and Bullock (85) found premature children at 5 years of age to be significantly different from their full-term peers in terms of tremulous involuntary hand movements, less competent gross motor ability, and difficulties in postural control and balance. Crowe and associates (86) described ELBW infants as a group to have significantly inferior skills in all motor functions at 4 years of age. Symptomatic intracranial hemorrhage was associated with poorer motor performance.

Neurobehavioral Development

As LBW premature survivors are assessed more critically and at older ages, a variety of potential behavioral dysfunctions throughout infancy and childhood become evident. Numerous studies have compared the neonatal neurobehavioral performance of LBW infants to that of NBW infants. These studies typically compare premature infants at their corrected age and also tend to use premature infants with relatively uncomplicated neonatal courses. Nevertheless, despite these sampling features that might obscure group differences, premature infants consistently perform less optimally than healthy, full-term infants on these early measures.

Ferrari and colleagues (87) compared low-risk premature infants to healthy, full-term infants using the Brazelton Neonatal Behavioral Assessment Scale. They found the premature infants to be significantly inferior in sensory orientation, regulation of behavioral state (i.e., quiet-active status), and autonomic regulation. Additionally, the clustering of neurobehavioral items was more heterogeneous among premature infants. The authors concluded that prematurity itself is associated with a behavioral repertoire that is different, more variable, and on the average less competent than that of full-term infants (87). Friedman and colleagues (88), also comparing low-risk premature infants and healthy, full-term infants, found that the premature infants fussed and cried more, were less soothable, and tended to change behavioral state more frequently. They suggested that these neonatal neurobehavioral differences are potential contributors to suboptimal interaction between premature infants and their caregivers. Aylward and colleagues (89), in a report from the National Institutes of Health (NIH) Collaborative Study on Antenatal Steroid Therapy, reported significant effects of both gestational age and severity of perinatal-neonatal illness on the neurobehavioral responses of premature infants. Specifically, at 40 weeks of corrected age, premature infants born at younger gestational ages and with greater medical complications demonstrated altered behavior in terms of diminished spontaneous activity and vigor, inability to maintain and modulate responses, and poorer visual orientation capabilities.

A number of studies using a wide variety of electrophysiologic techniques have supported the results of these clinical behavioral investigations. Compared to full-term infants, premature infants have shown delayed maturation of both cortical and brainstem auditory-evoked potentials, more variable and labile behavioral state organization as measured by time-lapse videosomnography, and decreased

resting heart rate variability and vagal tone (i.e., an indirect measure of overall autonomic nervous system activity) (90,91,92,93). Several of these functions, particularly state organization and autonomic regulation, have been related positively to longer-term developmental outcome (94,95).

Several studies have explored the related behavioral areas of temperament, social interaction and competence, and emotional expression and affect. Most of these studies have examined mother-infant interactions, and there is an overall consensus of findings that indicates an imbalance in LBW premature dyads compared to NBW full-term dyads, with LBW infants typically less responsive and low in communicative signaling behavior, and their mothers compensating for this relative inactivity by displaying high levels of stimulating and engaging activity. Investigations of LBW infants with complicated perinatal-neonatal courses have indicated that these infants exhibit high levels of gaze aversion, avoidance of interaction, and low levels of vocalizing and playing (96,97,98). Field (99) has reported these interactional differences in depth and succinctly summarizes the problem: "High-risk infants and their parents 'have less fun' than normal infants and their parents during their early interactions together." In a study comparing premature-mother dyads with full-term-mother dyads at approximately 4 months of corrected age, Field found the premature infants to be less alert and attentive, less responsive, less interested in game playing, less contingent, less smiling and content, and more affectively negative and irritable than the matched full-term infants. Correspondingly, the mothers of premature infants exhibited fewer happy expressions than the mothers of full-terms but were more vocal as they attempted to elicit social and communicative responses from their infants.

Crnic and associates (100) and Malatesta and colleagues (101) have replicated and extended these observations throughout the entire first year of life; LBW/NBW differences in expressive behavior and affect were persistent and continued to affect maternal behavior. Malatesta and colleagues emphasized that in their primarily middle to upper-middle social class sample, these differences were seen even in the absence of confounding neonatal medical complications. They speculate that the observed LBW/NBW differences probably are even more pronounced with less advantaged, more stressed, or sicker premature infants. Of long-term importance and concern is the increasing evidence of continuity between early interactional disturbances and later behavioral dysfunctions.

School Function

Finally, as increasing numbers of studies have followed LBW premature infants into the school years, the full spectrum of these children's learning and behavioral performance is emerging and becoming clearer. Although prevalence estimates of school problems vary between reports, almost all investigators agree that LBW survivors have a distinctly increased risk for school dysfunction in some form (24). A disturbing four-fold greater likelihood than NBW children of not graduating from high school by age 19 has been reported (102). The most recent reports have focused on school-age ELBW children and consistently describe the most problematic school function of all. Again, these new survivors, although relatively small in overall number, are disproportionately represented in regard to academic and social failure. There also is general agreement that although this substantial risk exists independently of socioeconomic status, the combination and interaction of biologic and environmental risks produces an especially worrisome doubly vulnerable milieu and a highly appropriate target population for early developmental intervention efforts because of the documented importance of psychosocial variables in the ultimate prognosis for LBW premature infants (103).

Dunn and colleagues (104), in one of the most extensive longitudinal follow-up studies published, reported minimal cerebral dysfunction (i.e., minor developmental and behavioral abnormalities) to be the single most prevalent (20%) disabling syndrome at school age in a population of more than

300 LBW premature children. Further-more, the authors stress the difficulty in adequately predicting or identifying such dysfunctions before school entry at the age of 5 years (104). This important group of sequelae consequently is liable to be missed when the outcome of NICU graduates is assessed before that age. Figure 60-4 illustrates this diagnostic evolution and increase in developmental-behavioral problems over time.

As in other studies, this study found a disproportionate number of boys compared to girls who experienced school dysfunction and required remedial assistance. This investigation was continued into adolescence (105). Although several of the LBW children with earlier problems no longer were demonstrating all of them, an almost equal number of previously unrecognized children had manifested academic and social problems, thus resulting in a relatively stable number of such problems over time. Additionally, whereas behaviors such as overactivity, temper tantrums, and perseveration had greatly subsided, symptoms of neuropsychiatric disturbance, including distractibility, irritability, unhappiness, low frustration tolerance, fears, disobedience, poor motivation, and sleep difficulties, persisted or increased.

Other studies have confirmed these observations in VLBW children at 8 to 15 years of age and have documented, in such areas as verbal expression, academic achievement, social competence, and emotional maturity, continued problems that cannot be attributed primarily to social class or differences in the quality of parenting (106,107). Nickel and colleagues (108) evaluated the school performances at a mean age of 10 years of 25 ELBW children who were cared for at a time (1960-1972) when only very premature infants who had little or no neonatal illness survived. Despite an overall mean IQ of 90 (range 50 to 141), 16 (64%) of these children had been or currently were in special educational programs. Only seven (28%) were rated by their teachers to be achieving at or above grade level. Arithmetic reasoning, mathematics achievement, reading comprehension, balance, fine motor coordination, and perceptual function were specific and common weaknesses for these children.

Klein and associates (109) compared 65 nine-year-old children born in Cleveland, Ohio, in 1976,

who were VLBW and free of neurologic impairment, to 65 NBW children who had been matched for age, gender, race, and social class on measures of IQ, visual-motor and fine motor abilities, and academic achievement. The following were the major findings:

- The VLBW children scored significantly lower than the NBW children on tests that measured general intelligence, even though both group means were within the average range.
- The VLBW children scored significantly lower than the NBW children on tests that measured academic achievement.
- The VLBW children had particular deficits in mathematics achievement.
- The VLBW children had particular deficits on tests that involved visual or spatial skills.
- These results were independent of social class.

In a similarly controlled and longitudinal New York City study, Ross and colleagues (110) showed that a much higher proportion of 8-year-old VLBW children required special educational interventions (48%) than either NBW children (15%) or the New York State public elementary school population (10%). VLBW children scored significantly lower than NBW children on tests of IQ, verbal ability, academic achievement, and auditory memory. There was an interaction of prematurity and social class on IQ, verbal tests, academic achievement, and attention, with premature children of lower socioeconomic status scoring lowest on these measures. Rickards and associates (61) compared the academic and social function of VLBW and NBW children at 14 years of age. VLBW children continued to perform at a significantly lower level on tests of intelligence, arithmetic, visual processing, visual memory, and overall problem solving. In addition, significantly more VLBW children were rated by teachers as socially rejected and by their parents as having learning problems at school.

A number of more recent reports emphasize the school problems of ELBW children. From an analysis by birth-weight subgroups, Klebanov and colleagues (111) indicated that as birth weight decreases, the prevalence of grade failure, placement in special classes, and classification as impaired increases, even when maternal education and neonatal length of stay are controlled for. The ELBW children scored lower than all other birth-weight groups on math and reading achievement tests. Even among children with IQ scores above 85, ELBW children still obtained lower math scores than the other children. Even with optimal socioeconomic environments, approximately one of every two ELBW children requires special educational services (112). In a Scottish population-based sample of 8-year-old children, ELBW children placed heavy demands on regular schools, with 52% requiring learning support compared with 16% of NBW comparison children (113). Hack and colleagues (64) have delineated school-age outcomes in ELBW children with birth weights under 750 grams (Fig. 60-5). Compared with VLBW children weighing 750 to 1,499 grams at birth and also with NBW children, these markedly ELBW children were inferior in cognitive ability, psychomotor skills, and academic achievement. They had poorer social skills and adaptive behavior and more behavioral and attention problems. In all assessed areas, the functioning of VLBW children was intermediate between that of ELBW and NBW children. Saigal et al. (114) recently reported that ELBW teens aged 12 to 16 years, who were born in Ontario, Canada, scored 13 to 18 points lower on cognitive and academic achievement tests than an NBW comparison group. more than half (58%) of ELBW teens were receiving special educational

assistance and/or had repeated a grade compared with 13% of NBW teens. Even apparently normal ELBW teens were having significantly more school difficulties

than NBW teens. ELBW teens who weighed less than 750 grams at birth fared worst in all areas.

Although data on the prevalence of behavior problems in older LBW children are somewhat sparse, it is likely that the prevalence is substantially higher than in NBW children. For example, Escalona (115) found that 30% of a primarily disadvantaged premature sample exhibited major behavior problems before the age of 4 years. The most comprehensive investigation of long-term behavioral function in this population comes from the same Cleveland, Ohio cohort described in terms of academic achievement (109). Breslau and colleagues (116) compared 65 nine-year-old VLBW children to 65 NBW children, matched for age, gender, race, social class, and school, on parents' ratings on the Child Behavior Checklist and teachers' ratings on the Teacher's Report Form. Results from parents and teachers converged on key findings. The major findings were the following:

The VLBW boys manifested significantly more behavioral disturbances and poorer social competence than NBW boys.

The excess in behavior problems in VLBW boys spanned a wide range of behavioral domains, including both internalizing (e.g., depressive-anxious) and externalizing (e.g., hyperactive, aggressive, conduct problems) syndromes.

The effect of VLBW on behavior problems and social adjustment in boys was not a function of IQ.

These results were independent of social class.

Although VLBW girls did not differ significantly from NBW girls, suggestive trends in the same direction as the boys may indicate that there is an increased risk for behavior problems in both genders but that these sequelae become evident at an earlier age in boys than in girls.

As in other neurodevelopmental and neurobehavioral domains, Klebanov and colleagues (117) found that ELBW children had lower attention, language skills, overall social competence, scholastic competence, and athletic ability than all other birth-weight groups (very low, low, and normal) as measured by classroom teachers, even when neonatal length of stay, child's gender and ethnicity, and maternal education were controlled for. The classroom behavior of ELBW children was rated by teachers as poor, even for children who had not failed a grade. More recently Hille and associates (118) reported that, in spite of cultural differences, ELBW children in the Netherlands, Germany, Canada, and the United States had very similar difficulties in thought, social interactions, and attention compared with NBW children. They tended to have trouble making friends, be immature, be impulsive, and have trouble with concentration leading to the diagnosis of attention deficit hyperactivity disorder. The investigators concluded that biologic mechanisms are major contributors to the behavior problems of ELBW children.

A number of recent studies have attempted to quantify "quality of life" outcomes. Direct measures of self-reported health status and overall functionality scores indicated that, as a group, ELBW adolescents suffer from a greater burden of morbidity and rate their health-related quality of life as significantly lower than NBW adolescents (119). Nevertheless, the vast majority of ELBW respondents view their quality of life as quite satisfactory and are difficult to distinguish from controls. Likewise, interviews of parents of ELBW teens revealed that they were fully aware that their children were more disabled than their age-matched peers but still believed that their children's quality of life was fairly high (120). Msall and Tremont (121) conclude that the measurement of long-term functional outcomes including higher education attainment, independent living, and job success will elucidate the full risks and resiliencies of low birth weight/prematurity and is the ultimate challenge of future studies.

SPECIFIC PERINATAL-NEONATAL COMPLICATIONS IN HIGH-RISK INFANTS

Intrauterine Growth Retardation

The SGA infant has a higher mortality rate, higher incidence of perinatal-neonatal complications, and higher prevalence of chronic neurologic impairments than the appropriate-for-gestational-age (AGA) infant of similar gestational age (122). The diagnosis of SGA is useful in identifying a high-risk population needing careful follow-up; however, the population of SGA infants is a heterogeneous one with multiple etiologies. Intrauterine growth pattern, associated congenital anomalies, mortality rate, risk of perinatal-neonatal complications, and long-term outcome reflect the nature of the insult and the timing as well. Drillien and colleagues (83) have stressed the need to differentiate early-pregnancy-onset SGA infants, many of whom demonstrate intrinsic defects such as congenital anomalies, from late-pregnancy-onset SGA infants, who may have antenatal histories of placental insufficiency or maternal chronic illness. Long-term developmental prognosis, in terms of major and minor impairments and school function, is significantly worse for early-pregnancy-onset SGA infants.

Most SGA outcome studies also distinguish between full-term and premature SGA infants because of marked differences in mortality and morbidity rates, both of which are significantly higher for premature SGA infants. For both groups of SGA infants, great variability among outcome studies is the norm, again reflecting the inevitable heterogeneity of the SGA diagnosis. Many studies report few major neurologic disabilities in full-term SGA infants followed from birth. In 96 full-term SGA infants followed to the age of 5 years, Fitzhardinge and Stevens (123) reported only a 1% prevalence of cerebral palsy and 6% prevalence of seizures. In a cerebral-palsied population in Sweden, full-term SGA infants had a somewhat higher risk for cerebral palsy than full-term AGA infants but a much lower risk than premature AGA and premature SGA infants (42). Most full-term

whether tested during the preschool or school years, even though the mean IQ of the SGA population usually has been somewhat lower than that of control groups (124). Fitzhardinge and Stevens, however, found that, despite average intelligence, 50% of the SGA boys and 36% of the SGA girls were doing poorly in school. One-third of the SGA children with IQs above 100 were failing consistently at school. A history of perinatal asphyxia was an important contributing risk factor. Other studies provide good evidence of an increased prevalence of speech and language problems, minor neurologic findings, and attention deficits in this subgroup (125).

More recently, several long-term studies have added further information to our understanding of this important risk group. Hollo and associates (126), reporting on a Finnish cohort, confirmed multiple academic deficiencies at age 10 years. Of particular interest, a 26-year follow-up of the 1970 British Birth Cohort found that adults who were born SGA had significant reductions in academic achievement and professional attainment compared with adults who were NBW (127). However, there were no long-term social or emotional consequences of being SGA; these adults were as likely to be employed, married, and satisfied with life.

Relatively few studies evaluate the outcome of premature SGA infants, and the results are contradictory. The prevalence of reported impairments varies from nearly 50% to as low as 10%. Commey and Fitzhardinge (128) found that 15% of premature SGA infants had cerebral palsy at the age of 2 years, twice the prevalence encountered in premature AGA infants. In the Swedish cerebral palsy study, premature SGA infants had the highest risk for cerebral palsy, 15 times greater than full-term AGA infants and significantly more than full-term SGA and premature AGA infants (42). Commey and Fitzhardinge found a high prevalence of subnormal intelligence in premature SGA infants tested at the age of 2 years. Drillien (129) reported that, in all birth-weight subgroups, fewer premature SGA infants were average cognitively, and more had borderline intelligence or mental retardation, especially those born to parents of low socioeconomic status.

There is little specific information about school function in this subgroup, but premature SGA infants certainly must be presumed to be at substantial risk in this area as well. A recent report compared the cognitive and neurologic outcomes of 129 premature SGA infants with 300 premature AGA infants through 6 years of age (130). The SGA infants had significantly poorer cognitive scores at each assessment age than AGA infants of similar gestational ages. Normal neurologic status was more likely at all assessments for the AGA than for SGA infants of comparable gestational age. Nevertheless, there was a significant effect of SGA on cognitive outcome at school age independent of neurologic status.

Asphyxia

Hypoxic-ischemic brain injury is the single most important neurologic problem occurring in the perinatal period (131). This variety of brain injury accounts for many, although not the majority, of the severe, nonprogressive neurologic deficits seen in children. This is particularly the case for full-term infants but also is of etiologic significance for premature infants. The neurodevelopmental deficits of concern are principally the triad of cerebral palsy, mental retardation, and epilepsy, often occurring together in varying degrees. In addition, more subtle developmental and behavioral dysfunctions in the areas of language, fine motor coordination, socioemotional competence, attention, and school learning are increasingly recognized in the relatively few studies designed to investigate these long-term sequelae. The common denominator of this form of brain injury is deprivation of the supply of oxygen to the central nervous system. The developing brain can be deprived of oxygen by two major pathogenetic mechanisms—hypoxemia (i.e., diminished amount of oxygen in the blood supply) or ischemia (i.e., diminished amount of blood perfusing the tissue). These two overlapping mechanisms typically coexist clinically, are virtually impossible to

isolate and delineate precisely in the individual infant, and together constitute the basis of the syndrome of asphyxia (132).

As noted by Paneth and Stark (133), the fundamental problem in assessing the exact relationship between asphyxia and subsequent neurodevelopmental outcome has been the difficulty in assessing the degree of asphyxia. Various techniques have been used to identify the asphyxiated infant, including the time to initiate spontaneous respiration (less than 1 minute), the time that positive-pressure ventilation was required to sustain the infant (less than 1 minute), and the use of the neonatal scoring system developed by Apgar (134). This scoring system originally was created to identify infants who were physiologically depressed at birth and who required resuscitative efforts. It has been shown to have limited utility in premature infants (135). Although Apgar did not design the scoring system to be used as a tool to predict long-term neurologic status, it has been used by many for correlation with ultimate outcome because of the paucity of alternative asphyxial markers. Fetal scalp blood and umbilic cord blood sampling for pH and other acid-base parameters have been recommended as potentially providing more objective perinatal data.

Although the Apgar scoring system is not perfect, it continues to be the standard by which almost all neonates are evaluated immediately after birth, and, as such, was the perinatal measure used in the NIH National Collaborative Perinatal Project between 1959 and 1966. This multisite prospective study of more than 50,000 pregnant woman and their children remains the largest single resource for investigating the associations between perinatal asphyxia and neurodevelopmental outcome, particularly cerebral palsy. Several main conclusions emerged (136):

Cerebral palsy does not develop in most (95%) asphyxiated full-term infants with an Apgar score less than or equal to 3 at 5 minutes.

P.1648

As the duration of severe asphyxia increases from 5 to 20 minutes, the likelihood of neonatal death or permanent cerebral palsy also increases in parallel fashion; approximately 60% cerebral palsy prevalence exists in full-term survivors with Apgar scores of less than or equal to 3 at 20 minutes.

The more premature the infant, the greater the incidence (i.e., approximately 30% at 28 weeks of gestational age), severity, and mortality associated with perinatal asphyxia.

Most infants in whom cerebral palsy develops were not asphyxiated at birth.

Although perinatal asphyxia certainly is an important cause of severe psychomotor retardation, especially during the intrapartum period, its relative contribution to these adverse outcomes has, in the past, frequently been overstated. It is estimated that between 10% and 20% of all cases of cerebral palsy are attributable to intrapartum asphyxia. Many of these cases are complicated by mental retardation of variable severity. Freeman and Nelson (137) correctly emphasize the four necessary criteria to link causally intrapartum asphyxia and neurodevelopmental disability in full-term infants:

- Intrapartum abnormalities (e.g., nonreassuring fetal heart rate patterns, passage of meconium, hemorrhage)
-

Depression at birth (e.g., low Apgar scores, need for resuscitation)

- Neonatal hypoxic ischemic encephalopathy (e.g., seizures in the first 48 hours, hypotonia and lethargy, metabolic acidosis, apnea)
- Anticipated outcomes (e.g., cerebral palsy with associated deficits, not severe mental retardation or epilepsy by themselves)

Outcome studies in full-term infants have identified the neonatal factors most predictive of neurodevelopmental disability after an episode of intrapartum asphyxia. The key predictors include failure to establish spontaneous respiration by 5 minutes, onset of seizures within the first 12 hours and refractory to treatment, prolonged deep encephalopathy (i.e., Sarnat stage 3) (138), failure of the electroencephalogram to normalize by 5 to 7 days, and inability to establish adequate oral feedings by 1 week of age (139). Fitzhardinge and colleagues (140) described the predictive utility of the computed tomography scan between 1 and 2 weeks after birth. The most ominous findings were diffuse hypodensities throughout both the white and gray matter and extensive intraparenchymal or intraventricular hemorrhage. Byrne and associates (141) reported that 8 months of age appears to be the earliest time at which magnetic resonance imaging findings (e.g., delayed myelination, acquired structural abnormalities) correlate well with later adverse neurodevelopmental outcome in this population. Finally, Robertson and colleagues (142) compared 145 asphyxiated full-term children who had experienced neonatal encephalopathy with a similar number of nonasphyxiated peer children at 8 years of age. The prevalence of major impairment, which included cerebral palsy, mental retardation, epilepsy, cortical blindness, and severe hearing loss, was 16%. Intellectual, visual-motor integration, and receptive vocabulary scores, as well as reading, spelling, and arithmetic grade levels for those children with moderate or severe encephalopathy were significantly below those in the mild encephalopathy or peer comparison groups. Thus, children who survive moderate or severe neonatal asphyxial encephalopathy are at increased risk for both major neurosensory impairment and reduced school performance.

Appendices

Appendix A: The Healthcare Matrix

A. The Healthcare Matrix is a response to the challenge of linking all six competencies with the realities of medical education. It is a framework that accurately projects the complexity of an “episode of care” yet uncovers the interaction between quality outcomes (*IOM Aims for Improvement*) and the skills, knowledge and attitudes (*ACGME Core Competencies*) necessary to affect those outcomes. The first row, “Patient Care,” is evaluated against the six IOM Aims. If care fails to meet (or in some instances exceeds) these Aims, the learner drills down through the remaining four competencies to analyze deficiencies or to learn why the system worked well. Finally, suboptimal performance is synthesized into the implementation of improvement strategies (practice-based learning and improvement). The intent is to create a new organizational culture by imbedding the Matrix in the daily work of the residents. This new culture acknowledges that residents are learning *in* and *about* the system of care. The Matrix provides a common framework for evaluating patient care across all disciplines and for all specialties (Reference: Joint Commission on Accreditation of Hospitals, *Journal of Quality and Safety*, February 2005).

P.1654

APPENDIX A: HEALTHCARE MATRIX: CARE OF PATIENT(S) WITH....

	IOM [†]	SAFE ¹	TIMELY ²	EFFECTIVE ³	EFFICIENT ⁴	EQUITABLE ⁵	PATIENT-CENTERED ⁶
ACGME*	Assessment of Care						
I. PATIENT CARE ⁷ (Overall Assessment) Yes/No							
II. A MEDICAL KNOWLEDGE ⁸ (What must I know)							
II. B INTERPERSONAL AND COMMUNICATION SKILLS ⁹ (What must I say)							
II. C PROFESSIONALISM ¹⁰ (How must I act)							
II. D SYSTEM-BASED PRACTICE ¹¹ (On whom do I depend and who depends on me)							
Improvement							
III. PRACTICE-BASED LEARNING AND IMPROVEMENT ¹² (How must we improve)							
Information Technology							

© 2004 Bingham, Quinn Vanderbilt University. All rights reserved.

¹ Safe: Avoiding injuries to patients from the care that is intended to help them.

² Timely: reducing waits and sometimes harmful delays for both those who receive and those who give care.

³ Effective: providing services based on scientific knowledge to all who could benefit and refraining from providing services to those not likely to benefit (avoiding underuse and overuse, respectively).

⁴ Efficient: avoiding waste, including waste of equipment, supplies, ideas, and energy.

⁵ Equitable: providing care that does not vary in quality because of personal characteristics such as gender, ethnicity, geographic location, and socioeconomic status.

⁶ Patient-Centered: providing care that is respectful of and responsive to individual patient preferences, needs and values and ensuring that patient values guide all clinical decisions.

⁷ Patient care that is compassionate, appropriate, and effective for the treatment of health problems and the promotion of health.

⁸ Medical Knowledge about established and evolving biomedical, clinical, and cognate sciences (e.g. epidemiological and social-behavioral) and the application of this knowledge to patient care.

⁹ Interpersonal and communication skills that result in effective information exchange and teaming with patients, their families and other health professionals.

¹⁰ Professionalism, as manifested through a commitment to carrying out professional responsibilities, adherence to ethical principles, and sensitivity to a diverse patient population.

¹¹ System-based practice, as manifested by actions that demonstrate an awareness of and responsiveness to the larger context and system of health care and the ability to effectively call on system resources to provide care that is of optimal value.

¹² Practice-based learning and improvement that involves investigation and evaluation of their own patient care, appraisal and assimilation of scientific evidence, and improvement in patient care.

Appendix B: Hemoglobin–Oxygen Dissociation Curves

APPENDIX B: OXYGEN DISSOCIATION CURVES OF FETAL AND ADULT HEMOGLOBINS AT A pH OF 7.4 AND TEMPERATURE OF 37°C

Cyanosis is observed at 5 g unsaturated hemoglobin, which corresponds to different arterial tensions in the adult and the infant.

From Klaus MH, Fanaroff AA. Care of the high risk neonate. Philadelphia: WB Saunders, 1973.

Appendix C: Breast Milk in the NICU

APPENDIX C-1: GALACTOGOGUES: AUGMENTING MATERNAL MILK SUPPLY^a

Galactogogues are medications or other substances believed to assist initiation or maintenance of maternal milk production. Low milk supply is one of the most common reasons given for discontinuing breastfeeding so both mothers and physicians have sought help for this problem. Common indications for galactogogues are adoptive nursing, relactation, and improving a faltering milk supply. Before using any medication to increase the supply, attention should be directed to improving the supply by evaluation of frequency and thoroughness of milk removal. The mother should be given information on any medication and be followed up by the prescribing physician. Short-term use of these medications may have been studied but long-term use has not. Below is a brief table of galactogogues. Modified from the Academy of Breast Feeding Medicine, clinical protocol #9. More information may be obtained at <http://www.bfmed.org>.

Medications	Mechanism of Action	Side Effects in Mother	Effects in Infant	Dose
Metoclopramide	dopamine antagonist ; ↑prolactin	restlessness , fatigue, headache, depression, confusion, anxiety. Acute dystonic reactions rare.	none noted	30–45 mg/day in 3 or 4 divided doses for 7–14d then taper over 5–7d
Domperidone *	dopamine antagonist	dry mouth, headache, abdominal cramps	none noted	10–20 mg 3–4 times/day for 3–8 wks
Human growth hormone**			none noted	0.1 IU/kg/day subcutaneousl y for 7d
Thyrotrophin-releasing*** hormone	releases prolactin from pituitary		none noted	1 spray qid.

Herbal remedies

Fenugreek		odor of sweat & urine, lower blood glucose	none noted	1-4 capsules 3-4 times/day
Goat's rue		none noted	lethargy in 2 infants	1 tsp dried leaves in 8 oz water as tea tid
Milk thistle		none noted	none noted	1 tsp crushed seeds in 8 oz water as tea tid

- * Not available in US except from compounding pharmacists
- ** Expensive, usefulness appears limited
- *** Long-term use not evaluated. Not commonly used.

P.1657

APPENDIX C-2: HUMAN MILK FOR THE HOSPITALIZED ILL BABY^a

Below are the important points about assisting mothers with supplying human milk for their hospitalized infant.

- A. **Expression (collection) of human milk in the hospital:** Use a pumping kit suitable for double breast pumping, instruct the mother in the correct use of the pump and hygiene. Use a single-use clean hard-plastic milk storage container for collection. Medications the mother is taking should be noted and contraindicated medications discussed with mother's physician for a change to allow mother to continue to safely breastfeed. Signs and symptoms of infections should be monitored and treated as necessary. Extremely few maternal illnesses require stopping breastfeeding.
- B. **Handling human milk:** Hospital staff should follow Standard Precautions when handling expressed human milk.

- C. **Labeling human milk:** Label with a human milk label, a patient name and ID, and date/time milk expressed and date/time thawed if previously frozen. Place in a bin labeled with the patient's name in refrigerator and/or freezer dedicated for that purpose. Milk intended for use within a 24–48 hour period should be refrigerated. Milk containing supplements or additives can be refrigerated for 24 hours. Human milk can be stored in a self-contained freezer in a refrigerator, i.e., separate door, at $>0^{\circ}$ Celsius for 3 months; or in a deep freezer ($\leq 0^{\circ}$ Celsius) for 6 months.
- E. **Transportation of human milk:** Use an insulated container with a freezer gel pack.
- F. **Identifying human milk:** Verify correct patient label by two RNs before use or addition of additives.
- G. **Thawing frozen milk:** Check expiration date and use oldest first. Thaw in patient's own basin with lukewarm water and label with time and date. Do not allow water to touch lid. Do not microwave. Swirl container to distribute milk components.

^a Modified from The Academy of Breastfeeding Medicine clinical protocol number #10. <http://www.bfmed.org>

APPENDIX C-3: PROCESS OF OBTAINING DONOR HUMAN MILK FOR THE HOSPITALIZED PATIENT

Donor human milk may be important for the treatment of various medical conditions.

- A. Consent for use of donor human milk is obtained by using a standard hospital consent form.
- B. The patient's insurance company must be informed that donor human milk has been prescribed. Hospital Purchasing is contacted to obtain a PO number that is used when ordering the milk.
- C. Donor milk is obtained from a milk bank belonging to the Human Milk Banking Association of North America (HMBANA) <http://www.hmbana.org>.
- D. A prescription for a week's worth of milk is sent/faxed to the Milk Bank, along with any required documentation. Donor milk is usually shipped on a weekly basis. Donor milk specifically from mothers of premature infants can be ordered and will be shipped when available.
- E. Donor milk is shipped to hospital receiving area and should be labeled with the patient's name following Milk Banks' request. Any milk that has completely defrosted must be used in the next 24 hours or discarded. If milk arrives defrosted, notify the sending Donor Milk Bank.

APPENDIX C-4: *TRANSITIONING THE BREASTFEEDING/BREASTMILK-FED PREMATURE INFANT FROM THE NEONATAL INTENSIVE CARE UNIT TO HOME*^a

This protocol addresses the care of premature infants <37 weeks gestation and <2500 grams at birth, who are being transitioned from the hospital to home. Most slow growth in these babies, with the exception of the extremely low birth weight infant is a function of absolute intake rather than milk composition such that every effort to ensure optimal milk volume should be exhausted prior to switching feedings to formula.

General support of mothers of prematures wishing to breastfeed includes encouraging kangaroo care early, expression of milk soon after delivery and continuing every 3 hours. Mothers should understand that early feeding attempts are gradual, and not expected to result in full feedings. Sustained suckling with swallowing for five minutes is an indicator that the infant may be ready to transition from nasogastric tube to breastfeeding. Trained breastfeeding personnel should help evaluate the breastfeeding on a regular basis.

I. Pre-discharge: Discharge Planning

- The clinician should work with the mother to devise a feeding plan well before the actual date of discharge. The plan may include a combination of breastmilk (directly from the breast and/or expressed) or breast milk and formula.
- The following aspects of the current feeding plan should be assessed: type of feeding, amount of feeding, P.1658 method of feeding, adequacy of growth and adequacy of nutrition.
 - Optimal nutrition includes: entire intake orally, normal growth, and normal biochemical indices. (Table 1)
 - Sub-optimal nutrition includes ANY of the following: intake is <160 cc/kg/day, cannot consume all feedings orally, growth is inadequate, and/or biochemical indices are abnormal.
- For infants with optimal nutritional assessment: change diet to unfortified human milk ad libitum, by breastfeeding and/or alternative feeding methods, one week before anticipated discharge. Add iron, 2 mg/kg/day and a complete multivitamin preparation. Monitor milk intake and growth (weight and length) during this week. If intake and growth are adequate, continue this diet after discharge.
- For infants with sub-optimal assessment: change diet to unfortified human milk, plus a minimum of 2 to 3 feedings of enriched post-discharge formula prepared per manufacturer instructions (~22 kcal/oz) at least one week before anticipated discharge. The mother should continue pumping or expressing milk at least three times/day. Assess adequacy of breastfeeding and address problems with latch, milk volume, frequency of feeds, maternal satisfaction, and consider a feeding device such as a shield or feeding tube device. If intake and growth are adequate during this week after switching, add iron and multivitamin preparation (1/2 to full dose depending upon how much formula is fed).

II. Post-Discharge Assessment

- Nutrition should be monitored one week after discharge with growth assessment and biochemical indices of status. Reassess nutritional status as optimal or sub-optimal. If optimal re-evaluate in one month. If sub-optimal assessment, consider the issues with the adequacy of breastfeeding such as latch, volume, frequency etc.

APPENDIX C-5: BIOCHEMICAL^a AND GROWTH MONITORING FOR PREMATURE INFANTS IN THE POST-DISCHARGE PERIOD^b

Parameter	Action Values
Growth	
Weight gain	<20 g/day
Length increase	<0.5 cm/wk
Head circumference increase	<0.5 cm/wk
Biochemical Markers	
Phosphorus	<4.5 mg/dL
Alkaline phosphatase	>450 IU/L
Blood Urea Nitrogen	<5 mg/dL

^a It is recognized that biochemical monitoring is not feasible in all settings; presence or absence of clinical rickets then becomes a substitute parameter.

^b Modified from Hall RA. Nutritional follow-up of the breastfeeding premature infant after hospital discharge. *Pediatr Clin North Amer* 2001;48:453-460 and Schanler RJ. Nutrition support of the low birth weight infant. IN: Walker WA, Watkins JB, Duggan CP (eds): *Nutrition in Pediatrics*, 3rd edition, BC Decker Inc, Hamilton, ON, Canada, 2003;392-412.

Appendix E: Jaundice

Appendix E. The following “Frequently Asked Questions” (FAQs) are from the American Academy of Pediatrics (AAP). Feel free to excerpt these FAQs or use them in their entirety for distribution to your families. Please attribute these FAQs to the American Academy of Pediatrics.

Congratulations on the birth of your new baby!

To make sure your baby's first week is safe and healthy, it is important that:

Your baby is checked for jaundice in the hospital.

If you are breastfeeding, you get the help you need to make sure it is going well.

Your baby is seen by a doctor or nurse at 3 to 5 days of age.

Q: What is jaundice?

[View Answer](#)

A: Jaundice is the yellow color seen in the skin of many newborns. It happens when a chemical called bilirubin builds up in the baby's blood. Jaundice can occur in babies of any race or color.

Q: Why is jaundice common in newborns?

[View Answer](#)

A: Everyone's blood contains bilirubin, which is removed by the liver. Before birth, the mother's liver does this for the baby. Most babies develop jaundice in the first few days after birth because it takes a few days for the baby's liver to get better at removing bilirubin.

Q: How can I tell if my baby is jaundiced?[View Answer](#)

A: The skin of a baby with jaundice usually appears yellow. The best way to see jaundice is in good light, such as daylight or under fluorescent lights. Jaundice usually appears first in the face and then moves to the chest, abdomen, arms, and legs as the bilirubin level increases. The whites of the eyes may also be yellow. Jaundice may be harder to see in babies with darker skin color.

Q: Can jaundice hurt my baby?[View Answer](#)

A: Most infants have mild jaundice that is harmless, but in unusual situations the bilirubin level can get very high and might cause brain damage. This is why newborns should be checked carefully for jaundice and treated to prevent a high bilirubin level.

Q: How should my baby be checked for jaundice?[View Answer](#)

A: If your baby looks jaundiced in the first few days after birth, your baby's doctor or nurse may use a skin test or blood test to check your baby's bilirubin level. A bilirubin level is always needed if jaundice develops before the baby is 24 hours old. Whether a test is needed after that depends on the baby's age, the amount of jaundice, and whether the baby has other factors that make jaundice more likely or harder to see.

Q: Does breastfeeding affect jaundice?[View Answer](#)

A: Jaundice is more common in babies who are breastfed than babies who are formula-fed, but this occurs mainly in infants who are not nursing well. If you are breastfeeding, you should nurse your baby at least 8 to 12 times a day for the first few days. This will help you produce enough milk and will help to keep the baby's bilirubin level down. If you are having trouble breastfeeding, ask your baby's doctor or nurse or a lactation specialist for help. Breast milk is the ideal food for your baby.

Q: When should my newborn get checked after leaving the hospital?[View Answer](#)

A: It is important for your baby to be seen by a nurse or doctor when the baby is between 3 and 5 days old, because this is usually when a baby's bilirubin level is highest. The timing of this visit may vary depending on your baby's age when released from the hospital and other factors.

Q: Which babies require more attention for jaundice?[View Answer](#)

A: Some babies have a greater risk for high levels of bilirubin and may need to be seen sooner after discharge from the hospital. Ask your doctor about an early follow-up visit if your baby has any of the following:

- A high bilirubin level before leaving the hospital
- Early birth (more than 2 weeks before the due date)
- Jaundice in the first 24 hours after birth
- Breastfeeding that is not going well
- A lot of bruising or bleeding under the scalp related to labor and delivery

- A parent or brother or sister who had high bilirubin and received light therapy

Q: When should I call my baby's doctor?

[View Answer](#)

A: Call your baby's doctor if:

- Your baby's skin turns more yellow.
- Your baby's abdomen, arms, or legs are yellow.
- The whites of your baby's eyes are yellow.
- Your baby is jaundiced and is hard to wake, fussy, or not nursing or taking formula well.

P.1671

Q: How is harmful jaundice prevented?

[View Answer](#)

A: Most jaundice requires no treatment. When treatment is necessary, placing your baby under special lights while he or she is undressed will lower the bilirubin level. Depending on your baby's bilirubin level, this can be done in the hospital or at home. Jaundice is treated at levels that are much lower than those at which brain damage is a concern. Treatment can prevent the harmful effects of jaundice.

Putting your baby in sunlight is not recommended as a safe way of treating jaundice. Exposing your baby to sunlight might help lower the bilirubin level, but this will only work if the baby is completely undressed. This cannot be done safely inside your home because your baby will get cold, and newborns should never be put in direct sunlight outside because they might get sunburned.

Q: When does jaundice go away?

[View Answer](#)

A: In breastfed infants, jaundice often lasts for more than 2 to 3 weeks. In formula-fed infants, most jaundice goes away by 2 weeks. If your baby is jaundiced for more than 3 weeks, see your baby's doctor.

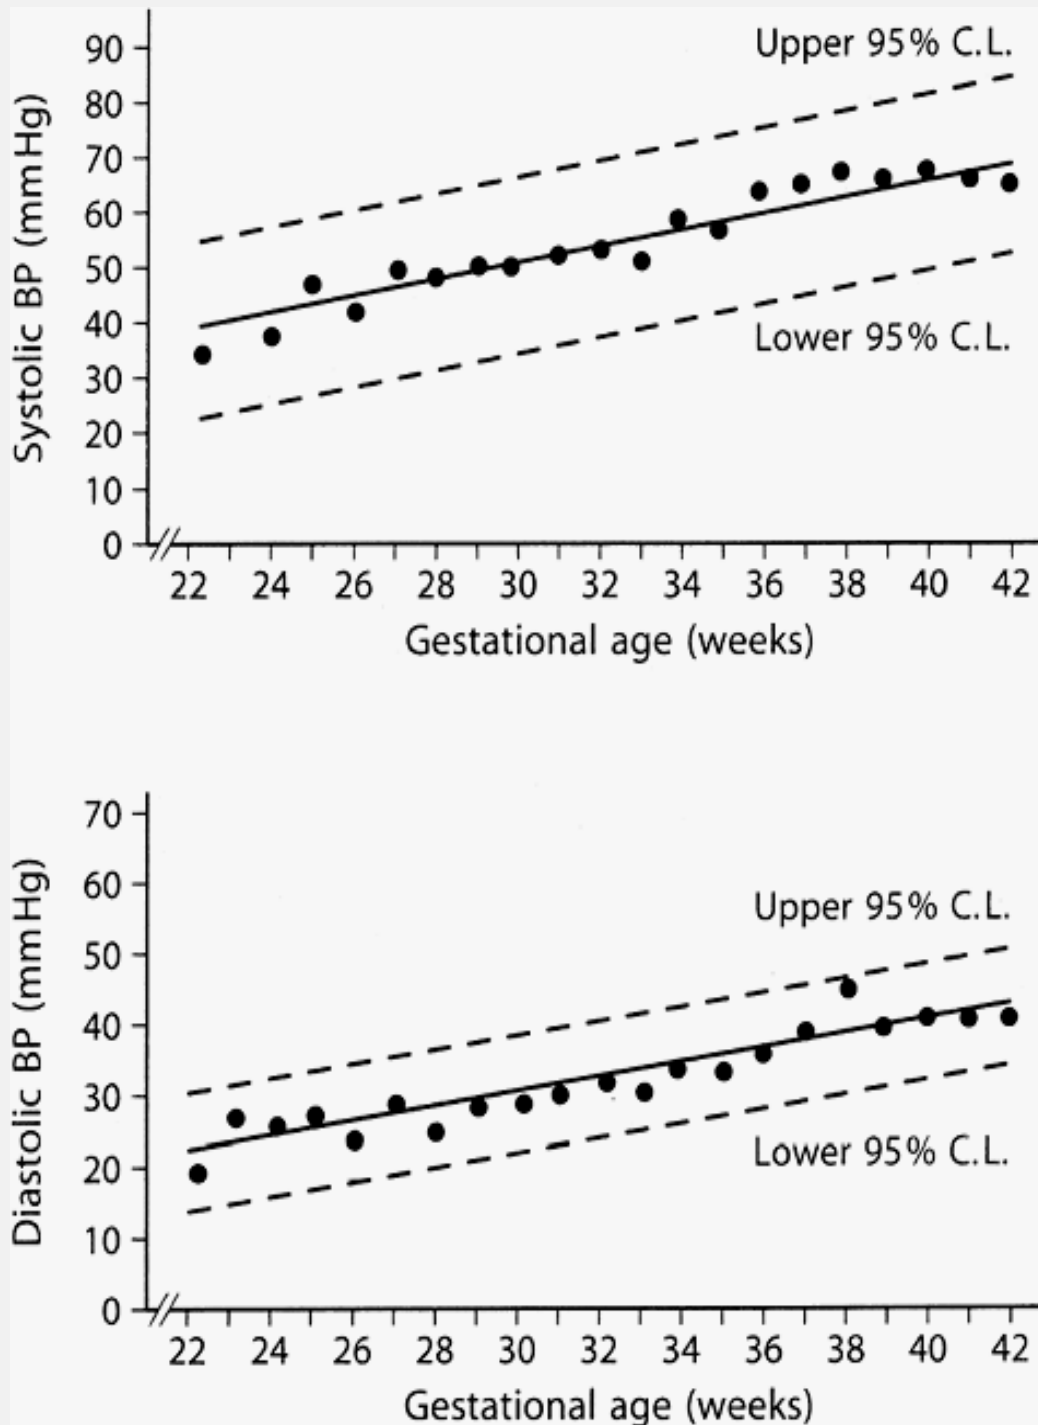

The information contained in this publication should not be used as a substitute for the medical care and advice of your pediatrician. There may be variations in treatment that your pediatrician may recommend based on individual facts and circumstances.

APPENDIX F-6: DIAGNOSTIC STUDIES FOR EVALUATION OF HYPERTENSIVE INFANTS

Generally Useful	Useful in Selected Infants
BUN, Creatinine	Abdominal/pelvic ultrasound
Calcium	Aldosterone
CBC & platelet count	Aortography
Chest x-ray	Cortisol (morning)
Electrolytes	Echocardiogram
Plasma renin	Nuclear scan (DTPA/MAG-3)
Renal Ultrasound with Doppler	Renal angiography
Urinalysis (+/- culture)	Thyroid studies
	Urine VMA/HVA
	VCUG

Abbreviations used: BUN, blood urea nitrogen; CBC, complete blood count; DTPA, diethylenetriaminepentaacetic acid; HVA, homovanillic acid; MAG, mercaptoacetyl triglycine; VMA, vanillylmandelic acid; VCUG, voiding cystourethrogram.

Appendix G: Renal and Urinary Tract Anomalies

APPENDIX G-1: ASSOCIATIONS BETWEEN RENAL-URINARY TRACT ANOMALIES AND OTHER STRUCTURAL DEFECTS

Diagnosis (Mode of Genetic Transmission)	Frequency of Anomalies	Renal Anomalies	Urologic Anomalies	Other Associations
--	------------------------	-----------------	--------------------	--------------------

Hereditary associations

Acrorenal syndrome, or radial ray aplasia and renal anomalies (AD)*	100%	Agenesis, ectopia		Absence of radius and thumb
Acrorenocular syndrome (AD/sporadic)	100%	Malrotation, ectopia	VUR, bladder diverticula	Thumb hypoplasia preaxial polydactyly, coloboma, ptosis
Acrorenomandibular syndrome (AR)†	Frequent	Agenesis, ectopia		Split hand/split foot, cataracts ear and genital anomalies
Adams-Oliver syndrome (AD)	Occasional		Duplicated collecting system	Aplasia cutis congenita, terminal transverse defects of limbs
Alport syndrome (AD, but fully expressed only in males; X-linked)	Frequent	Nephritis; recurrent hematuria		Deafness cataracts, myopia lenticonus
Antley-Bixler syndrome (AR?)	Occasional	Displaced kidney, accessory renal artery		Craniosynostosis, choanal atresia, radiohumeral synostosis
Arthrogryposis multiplex congenita	100%	Glycosuria, polyuria, nephrocalcinosis		Arthrogryposis multiplex congenita, rarefaction of

with renal and hepatic abnormalities (AR/X-linked?)		hypercalciuria, hyperphosphaturia		motor neurons in anterior horn, cholestasis, all reported patients died before 4 months of age
Baller-Gerold syndrome, or Craniosynostosis-radial aplasia syndrome (AR)	Occasional	Pelvic kidney		MR (50%), growth deficiency, craniosynostosis, radial aplasia, CHD
Branchiootoureteral syndrome (AD)	50%	Bifid renal pelvis	Bifid ureters	Preauricular pit/tag, bilateral hearing loss
Campomelic dysplasia (AR)	30%	Usually hydronephrosis, MKD		Bowed tibiae, hypoplastic scapulae, flat facies growth deficiency, CNS disorganization, most die of respiratory failure as neonates or in infancy
Carpenter syndrome (AR)	Occasional		Ureteral dilatation	Acrocephaly, polydactyly—syndactyly of feet, lateral displacement of inner canthi, hypogenitalism
CHILD syndrome (X-linked?, lethal in hemizygotic male)	Occasional	Unilateral agenesis		Unilateral hypomelia, ichthyosis, CHD, mild SGA
COFS syndrome (AR)	Occasional	Agenesis		Neurogenic arthrogryposis, microcephaly, microphthalmia/cataract/blepharophimosis,

				large ear pinnae, prominent nasal bridge, no growth, usually die before 5 years of age
Cohen syndrome (AR)	Occasional		UPJ obstruction	Hypotonia, obesity, prominent incisors, moderate MR
Deal syndrome (AR)	100%	Fanconi syndrome		Ichthyosis, jaundice, musculoskeletal deformities, diarrhea, failure to thrive, death in infancy
Digitorenocerebral syndrome (AR)	Frequent	Agensis, hypoplasia, dysplasia		Facial dysmorphism, seizures, malformed fingers and toes
EEC syndrome (AD, variable penetrance)	Occasional	Agensis, hydronephrosis medullary dysplasia	Ureterocele	Ectrodactyly, ectodermal dysplasia, cleft lip/palate, defective lacrimal duct
Fanconi-pancytopenia syndrome (AR)	Frequent	Hypoplastic/malformed	Hypospadias, ureter duplication	Radial hypoplasia, hyperpigmentation, pancytopenia, short stature, microcephaly, MR
FG syndrome (X-linked R)	Occasional		Dilation	Prominent forehead, hypotonia, MR, imperforate anus
Fraser or cryptophthalmos	Frequent	Agensis or hypoplasia		Cryptophthalmos, ear anomalies, genital anomaly,

syndrome (AR)				laryngeal stenosis/atresia, anal atresia, CHD
Frontometaphyseal dysplasia (X-linked, severe in male)	Occasional		Obstruction	Coarse facies, prominent supraorbital ridges, joint limitations, splayed metaphyses
Hereditary renal aplasia (AD, 50%–90% penetrance) Jarcho-Levin syndrome, or spondylothoracic dysplasia (AR)	50%–90%	Unilateral or bilateral agenesis		Potter (oligohydramnios) sequence if bilateral agenesis, uterine anomaly
	Occasional	Hydronephrosis	Urethral atresia Ureteral obstruction, bilobate bladder	Prominent occiput, short neck, most die in infancy due to lung hypoplasia, short thorax, diminished ribs, vertebral defects, most Puerto Rican origin
Johanson-Blizzard syndrome (AR)	Frequent	Caliectasis, hydronephrosis		Hypoplasia alae nasi, hypothyroidism, deafness
LEOPARD syndrome; or multiple lentigines syndrome (AD)	Occasional	Agenesis or hypoplasia		Lentigines, hypertelorism, deafness, pulmonary stenosis, obstructive cardiomyopathy, mild growth failure, variable expression in individual patient
Lethal multiple pterygium syndrome (AR)	Occasional	Hydronephrosis	Megaureter	SGA, hypertelorism, epicanthal folds, joint contractures, pterygia, early death due to lung hypoplasia

Levy-Hollister syndrome, or lacrimo-auriculo-dento-digital syndrome (AD)	Occasional	Agenesis, nephrosclerosis		Nasolacrimal duct obstruction, ear anomalies, hearing loss, variable anomalies of upper limbs
Melnick-Fraser syndrome, or branchio-oto-renal syndrome (AD)	Frequent	Dysplasia, hypoplasia, agenesis, ectopia		Hearing loss, preauricular pits, anomalous pinna, branchial fistula
Melnick-Needles syndrome (AD?; lethal in male or X-linked)	Occasional	Hydronephrosis	Ureteral stenosis	Prominent eyes, bowing of long bones, ribbonlike ribs
Menke's Kinky Hair syndrome (X-linked R)	Occasional		Bladder diverticula	Sparse, brittle hair, short stature wormian bones
Neu-Laxova syndrome (AR)	Occasional	Agenesis		Microcephaly, lissencephaly, exophthalmos, syndactyly and edema, polyhydramnios, short umbilical cord, early death
Opitz-Frias syndrome, G syndrome; or hypertelorism-hypospadias syndrome (AD)	Occasional	Renal defect	Hypospadias, cryptorchidism, bifid scrotum	Hypertelorism, swallowing difficulties
Perlman syndrome (AR?)		Nephromegaly, nephroblastomatosis	Cryptorchidism, hypospadias	Macrosomia, visceromegaly, polyhydramnios, diaphragmatic hernia, interrupted aortic arch, polysplenia

Polycystic Kidney Disease Adult-AD, infantile-AR	100%	Polycystic kidneys		Cysts in liver and other organs
Rutledge syndrome (AR?)	100%	Oligopapillary renal hypoplasia	Urethral anomalies	Joint contractures, cerebellar hypoplasia, tongue cysts, short limbs, eye and ear anomalies, CHD, gallbladder agenesis
Saethre-Chotzen syndrome (AD)	Occasional	Renal anomaly		Craniosynostosis, brachycephaly, maxillary hypoplasia, abnormal ear, syndactyly
Schinz-Giedion syndrome (AR)	Frequent	Hydronephrosis	Hydroureter, hypospadias	Severe growth failure, profound MR, midface retraction, cardiac and skeletal anomalies
TAR syndrome (AR)	Occasional	Ectopia, dysplasia	Hypospadias	Thrombocytopenia, granulocytosis, eosinophilia, anemia, radial absence or hypoplasia with thumbs present, CHD
Townes syndrome (AD)	Frequent	Hypoplasia	Ureterovesical reflux, urethral valves	Thumb, ear, and anal anomalies
Weyers oligodactyly syndrome (AR)	Frequent	Bilateral hydronephrosis		Deficient ulnar and fibular rays, oligodactyly

Chromosomal anomalies

Chromosomal anomalies			
4p—syndrome	Occasional	Agenesis	Hypertelorism, broad or beaked nose, microcephaly, cranial asymmetry, low-set ears, dimple, CHD, severe MR, seizures
5p—syndrome, or cri du chat syndrome	Occasional	Agenesis	SGA, slow growth, catlike cry, MR, hypotonia, CHD, microcephaly, downslanting palpebral fissures, hypertelorism, round face, epicanthal folds, strabismus, low set ears
9p—syndrome	Occasional	Hydronephrosis	Craniostenosis, trigonocephaly, upslanting palpebral fissures, hypoplastic supraorbital ridges
13q—syndrome	Occasional	Agenesis or hypoplasia, PKD, hydronephrosis	Microcephaly, high nasal bridge, MR, CHD, hypertelorism, coloboma, microphthalmia, retinoblastoma
18q—syndrome	Occasional	Horseshoe kidney	Poor growth, microcephaly, hypotonia, midfacial hypoplasia, abnormal ears, cleft palate, thumb hypoplasia

Cat-eye syndrome ^a	Frequent	Horseshoe kidney, agenesis, hydronephrosis		Coloboma of the iris, downslanting palpebral fissures, anal atresia
Klinefelter's syndrome, or XXY, XXXY	Frequent		Testes small, undescended	Delayed puberty
Partial trisomy 10q syndrome	Frequent			Ptosis, short palpebral fissures, campodactyly, marked MR
Penta X syndrome, or XXXXX syndrome	Occasional	Dysplasia		Microcephaly, growth deficiency, upward slanting palpebral fissures, low nasal bridge, short neck, small hands, clinodactyly of fifth fingers, PDA
Triploidy syndrome	Frequent	Cystic kidney, hydronephrosis, dysplasia		Large placenta and hydatiform changes; poor growth; brain, facies, and cardiac anomalies; syndactyly
Trisomy 4p syndrome	Occasional	Atresia, horseshoe kidney, hypoplasia, hydronephrosis	VUR	Microcephaly, severe MR, hypertonia in infancy, seizures, SGA, bulbous nose, prominent forehead, clinodactyly
Trisomy 8 syndrome, or mosaic syndrome	Occasional	Hydronephrosis, horseshoe kidney, agenesis	Bifid pelvis	Prominent forehead and ears, deep-set eyes, hypertelorism, micrognathia, MR, CHD, vertebral anomalies,

				campodactyly
Trisomy 9 mosaic syndrome	Frequent			Joint contractures; heart, CNS, and ear anomalies
Trisomy 9p syndrome	Occasional	Malformations		SGA, macrocephaly, hypertelorism, downslanting palpebral fissures, distal phalangeal hypoplasia, skeletal anomalies
Trisomy 13 syndrome	Occasional	PKD, glomerular cysts, duplication	Ureter duplication, hydroureter	Holoprosencephaly, occipital scalp defect, polydactyly, microphthalmia, narrow hyperconvex fingernails
Trisomy 18 syndrome	Frequent	Horseshoe kidney, ectopic, PKD, hypoplasia or agenesis, duplication	Ureter duplication	Polyhydramnios, single UA, poor growth, prominent occiput, clenched hand
Trisomy 20p syndrome	Occasional	Malformations		Blepharophimosis, brachycephaly, large ears, MR, cubitus valgus, vertebral defects, CHD
Turner syndrome, or XO syndrome	60%	Horseshoe kidney, hypertension	Double or cleft pelvis	Short broad chest, widely spaced nipples, lymphedema, webbed neck, cubitus valgus
Sporadic associations				

Aniridia-Wilms tumor association ^b	50%	Bilateral Wilms tumor		Microcephaly, growth deficiency, MR, prominent lips, cataracts, ptosis, nystagmus, ambiguous genitalia
Beckwith-Wiedemann syndrome, or exomphalos-“ macroglossia-gigantism syndrome	Frequent	Large kidneys, medullary dysplasia, Wilms tumor	Hypospadias	Omphalocele, macroglossia, gigantism, ear creases, polyhydramnios, prematurity, hypoglycemia, polycythemia, apnea
Caudal dysplasia sequence, or caudal regression sequence	Occasional	Agensis	Neurogenic bladder	Abnormal vertebrae and lower limbs, neurologic defects, R/O maternal diabetes, imperforate anus
CHARGE association	5%	Agensis, hypoplasia, hydronephrosis, heterotopic kidneys		Coloboma (iris, retina, anophthalmos), CHD, choanal atresia, growth retardation (postnatal), mental deficiency, genital hypoplasia (in males), ear anomalies, deafness
Goldenhar syndrome, facioauriculovertebral spectrum, first and second branchial arch syndrome	Occasional	Renal anomalies		Hemifacial microsomia, hemivertebrae, occasional abnormal ears and eyes, deafness, CHD, MR, SGA
Klippel-Feil syndrome	Frequent	Renal anomalies		Short neck, abnormal cervical vertebrae, deafness, CHD

Klippel Trenauny syndrome	Occasional		Hemangiomas of urinary tract	Multiple arterio venous fistulae, limb overgrowth
Laterality sequences Ivemark syndrome, or bilateral right-sidedness	Frequent	Renal anomalies		Situs inversus, asplenia, CHD and vessel anomalies,
Bilateral left-sidedness	Occasional	Renal anomalies		Situs inversus, CHD, polysplenia
Meningomyelocele, spina bifida and occult spinal dysraphism sequence	Frequent	Hydronephrosis, UTI, renal failure, horseshoe kidney, hypoplasia, agenesis, ectopia, duplication	Neurogenic bladder	Neurologic defect, hydrocephalus
Megacystis-microcolon-intestinal hypoperistalsis syndrome	100%	Hydronephrosis	Massive bladder distention (100%), VUR	Neonatal bowel obstruction, hypoperistalsis, microcolon, frequently early death
Mullerian aplasia, Rokitansky sequence, or Rokitansky-Kustner-Hauser syndrome	30%–50%	Unilateral renal aplasia, hypoplasia, ectopia	Ureter duplication	Vaginal atresia, rudimentary uterus
MURCS association	>50%	Agenesis or ectopia (88%)		Absence of vagina, hypoplasia of uterus, abnormal cervico-thoracic vertebrae
Monozygote twinning	Occasional		Exstrophy of the	Sacroccygeal teratoma,

			cloaca	sirenomelia, VATER, holoprosencephaly, anencephaly
Pallister-Hall syndrome	Frequent	Dysplasia		Hypothalamic hamartoblastoma, hypopituitarism, imperforate anus, polydactyly
Poland anomaly	Occasional	Renal anomaly		Variable unilateral features: absence of pectoralis muscle, upper limb hypoplasia, syndactyly
Potter sequence, or oligohydramnios sequence	100%	Hypoplasia, aplasia, agenesis, PKD, dysplasia	Urethral valves	Amnion nodosum, oligohydramnios, lung hypoplasia, limb malposition, facies compression
Prune-belly syndrome, or early urethral obstruction sequence	100%	Dysplasia, hypoplasia, horseshoe kidney, hydronephrosis	Urethral valves, persistent urachus, bladder agenesis, ectopic ureter	Prune belly, cryptorchidism, abnormal genitalia, Potter GI malformation (anal, hepatobiliary, mesentery, esophageal, pancreas), talipes equinovarus, scoliosis, thorax deformities, cardiac anomalies, iliac vessel compression
Rubinstein-Taybi syndrome	Frequent	Duplication	Ureter duplication	Broad thumbs and toes, hypoplastic maxilla, MR, slanted palpebral fissures
Sirenomelia sequence	Frequent	Agenesis, dysplasia	Bladder	Fusion of lower limbs, single

			agenesis	UA, absence of genitalia except gonads, absence of sacrum and rectum, imperforate anus
Thanatophoric dysplasia	Occasional	Horseshoe kidney, hydronephrosis		Short limbs, flat vertebrae, large cranium, low nasal bridge, severe SGA, hypotonia, polyhydramnios, lung hypoplasia, early death
Tracheal agenesis association ^c	50%	Agenesis, hydronephrosis, dysplasia	Duplication	Laryngeal/tracheal atresia, GI anomalies (e.g., duodenal atresia), CHD, limb reduction defect (i.e., radial hypoplasia)
VATER/VACTERL association	50%–74%	Agenesis, hydronephrosis, cystic dysplasia	Duplication, urethral atresia	TEF, vertebral and anal atresia, CHD, limb anomalies (i.e., radial dysplasia)
Renal cystic disease^d				
Alagille syndrome, or arteriohepatic dysplasia (AD)	Occasional	Cystic tubular dilatations, CRF, tubulointerstitial disease		Facies: deep-set eyes, prominent forehead, cholestasis, PPS, butterfly vertebrae
Apart syndrome, or acrocephalosyndactyly (AD; fresh mutation common)	Occasional	MKD, hydronephrosis		Craniosynostosis, midfacial hypoplasia, syndactyly, broad distal phalanx (i.e., thumb and big toe), occasional CHD, GI tract and lung anomalies

Congenital nephrotic syndrome, Finnish type (AR)	100%	CNF, tubular cystic dilatations		Polyhydramnios, elevated a-fetoprotein in amniotic fluid
Cystic hamartomata of lung and kidney	100%	Multilocular cysts		Hamartomatous pulmonary cysts
Dandy-Walker malformation	Occasional	MKD		Congenital hepatic fibrosis
Ehler-Danlos syndrome (AD, AR, X-linked)	Occasional	RTA		Skin and joint hyperextensibility, poor wound healing
Elejalde syndrome (AR)		Cystic dysplasia		Short-limb dwarfism, acrocephaly, polysyndactyly, subcutaneous hypertrophy, cholestasis, pancreatic dysplasia
Ellis-van Creveld syndrome, or chondroectodermal dysplasia (AR)	Occasional	Ageneis, cystic/ medullary dysplasia	Epispadias	Short distal extremities, polydactyly, nail hypoplasia CHD (50%), SGA and short eventual stature, cholestasis
Familial juvenile nephronophthisis with hepatic fibrosis (AR)	Frequent	Glomerular cysts		Congenital hepatic fibrosis
Familial renal-retinal dystrophy (AR)	Common	Nephronophthisis-medullary cystic kidney		Pigmentary retinal dystrophy

		disease		
Femoral hypoplasia-unusual facies syndrome		PKD, agenesis	Abnormal collecting system	Femoral hypoplasia, short nose, cleft palate
Fryns syndrome (AR)	50%	MKD, cortical cysts		Facial dysmorphism, microretrognathia, diaphragm defects, lung hypoplasia, neonatal death, bicornuate uterus or scrotum anomaly, distal limb hypoplasia
Glutaric aciduria syndrome, type II, or multiple acyl-coA dehydrogenase deficiency (AR)	Frequent	Cystic dysplasia, ultrastructural anomaly of glomerular basement membrane		Cerebral dysplasia, macrocephaly, facial dysmorphism, fatty liver, genital defects, hypoglycemia, metabolic acidosis
Ivemark syndrome, or renal-hepatic-pancreatic dysplasia (AR)	Frequent	Glomerular cysts, cystic dysplasia		Hepatic and pancreatic dysplasia, occasional splenic anomalies, may be associated with homogenous syndrome (Bernstein)
Jeune asphyxiating thoracic dystrophy (AR)	Frequent	Glomerular sclerosis, tubular cysts, renal failure		Small chest, lung hypoplasia, short limbs, cholestasis
Lowe syndrome, or oculocerebrorenal syndrome (X-linked)	100% (male)	Fanconi syndrome, CRF		Cataracts, mental deficiency, hypotonia

Meckel-Gruber syndrome, or dysencephalia splanchnocystica (AR)	100%	MKD, PKD, dysplasia, hypoplasia		Encephalocele, holoprosencephaly, polydactyly, Potter sequence, cholestasis
Nail-patella syndrome, or hereditary osteonychodystrophy	Frequent	Proteinuria, hematuria, casts, CRF, PKD	Ureter duplication	Nail dysplasia, patella hypoplasia, iliac spurs
Orofacial digital syndrome, type 1 (D, lethal in male)	Frequent	Glomerular cysts		Oral frenula and clefts, hypoplasia of alae nasi, digital asymmetry
Roberts-SC phocomelia syndrome, hypomelia-hypotrichosis-facial hemangioma syndrome, or pseudothalidomide (AR)	Occasional	MKD, horseshoe kidney		Hypomelia, midfacial defect, cleft palate and lip, severe growth deficiency, cholestasis
Short-rib polydactyly, type I (Saldino-Noonan type)	Frequent	MKD, hypoplastic		Short-limb dwarfism, severe lung hypoplasia, early death, short ribs, with or without polydactyly,
Short rib-polydactyly syndrome, type II (Majewski type) (AR)	Frequent	Glomerular cysts, focal dilatation of distal tubules		CHD, imperforate anus Short-limb dwarfism, severe lung hypoplasia, early death, short ribs, with or without polydactyly, CHD, ambiguous genitalia
Smith-Lemli-Opitz	Occasional	MKD		MR, growth retardation,

syndrome (AR)				microcephaly, micrognathia, anteverted nostrils, ptosis of eyelids, syndactyly of second-third toes, ambiguous genitalia
Tuberous sclerosis (AD)	50%—80%	Glomerular and tubular cysts (rarely neonatal), angiomyolipomas, CRF		Seizures, skin lesions, tumors
Von Hippel-Lindau syndrome (AD)	Occasional	PKD		Retinal angioma, cerebellar hemangioblastoma
Zellweger syndrome, or cerebrohepatorenal syndrome (AR)	100%	Glomerular cysts, albuminuria		Hypotonia, abnormal brain, seizures, flat facies, peroxisomal deficiency, cholestasis
Metabolic diseases				
Hyperoxaluria type I, or oxalosis (AR)	100%	Nephrocalcinosis/lithiasis, CRF		Anorexia, failure to thrive, vomiting, dehydration and fever, liver failure, acidosis
Galactose-1-phosphate uridyl transferase deficiency, or galactosemia (AR)	Frequent	Fanconi syndrome		Hypoglycemia, anorexia, liver failure, sepsis, cataracts, MR
Hereditary fructose intolerance, fructose-1-	Frequent	Fanconi syndrome		Hypoglycemia, anorexia, liver failure, failure to thrive

phosphate aldolase deficiency (AR)				
Tyrosinemia type I, tyrosinosis, or hepatorenal tyrosinemia (AR)	Frequent	Fanconi syndrome		Growth failure, cabbagelike odor, vomiting, diarrhea, metabolic acidosis, liver failure, edema, fever
Glycogenosis with Fanconi syndrome, or Fanconi-Bickel syndrome (AR)	100%	Fanconi syndrome		Fever, vomiting, growth failure, rickets, hypoglycemia, hepatomegaly
Cystinosis (AR)	100%	Fanconi syndrome		Light skin and hair, failure to thrive, anorexia, fussiness, episodes of acidosis, dehydration and fever, rickets
Teratogens				
Fetal alcohol syndrome	18%	Renal agenesis, hypoplasia, hydronephrosis	Ureteral duplication	SGA, microcephaly, facial dysmorphism, MR
Fetal hydantoin syndrome	Occasional	Various malformations		Poor growth; microcephaly; cranio facial dysmorphism; brain, limb, and GI anomalies; CHD
Thalidomide embryopathy	Occasional	Various malformations		Phocomelia; polydactyly; syndactyly; hydrocephalus; facial capillary hemangioma;

				CHD; ear, eye, and GI anomalies
Fetal trimethadione syndrome	Occasional	Various malformations		Poor growth, craniofacial anomalies, CHD
Angiotensin converting enzyme inhibitors	Frequent(?)	Nephron dysgenesis		Hypocalvaria
Congenital infections				
Congenital syphilis	Occasional	Nephrotic syndrome		Snuffles, meningitis, bone changes
Congenital toxoplasmosis	Rare	Nephrotic syndrome		Microcephaly, deafness, chorioretinitis, SGA
Renal failure^e				
Bardet-Biedl syndrome, or Laurence-Moon-Biedl syndrome (AR)	Frequent	Dysplasia, nephrosclerosis, interstitial scarring, cyst, HTN	Hydroureter	Retinitis pigmentosa, obesity, polydactyly
Drash syndrome, or nephropathy associated with gonadal dysgenesis and Wilms tumor	100%	Glomerulonephritis, interstitial changes, nephrotic syndrome, hematuria, HTN, ESRD, often Wilms tumor		Ambiguous genitalia (often male pseudohermaphroditism)

Fabry syndrome, or angiokeratoma corporis diffusum (X-linked)	Frequent	Proteinuria, hematuria, casts, leukocyturia		Dark nodular angiectases, corneal opacities, seizures, CNS symptoms
Russell-Silver syndrome (AD)	Sporadic	Wilms syndrome	Posterior urethral valves, hypospadias	Small stature, skeletal asymmetry, small fifth finger, small triangular facies
Williams syndrome	Occasional	Hypertension	Bladder diverticula	Decreased growth, hypercalcemia, subaortic stenosis, prominent lips, hoarse voice

* AD-autosomal dominant

† AR-autosomal recessive

This table has been made by selecting well-defined associations, described in at least three patients, in whom renal manifestations may develop before 1 year of age.

^a Extra chromosome corresponding to segments of chromosome 22.

^b May have partial deletion of chromosome 1 p.

^c Overlaps with VATER association.

^d See also trisomy 13 and 18, VATER, cocaine, and other subheadings (i.e., renal dysplasia).

^e See also other headings.

AD, autosomal dominant; AR, autosomal recessive; CHD, congenital heart disease; CHARGE, coloboma, heart disease, atresia of the choanae, retarded mental development and growth, genital hypoplasia, ear anomalies; CHILD, congenital hemidysplasia with ichthyosiform erythroderma and limb defects; COFS, cerebrooculofacioskeletal; CNS; central nervous system; CRF, chronic renal failure; D, dominant; EEC, ectrodactyly-ectodermal dysplasia-clefting; EKG, electrocardiogram; ESRD, end-stage renal disease; GI, gastrointestinal; HTN, hypertension; LEOPARD, lentigenes, EKG anomalies, ocular anomalies, pulmonary stenosis, abnormal genitalia, retardation of growth, and deafness; MKD, multicystic kidney disease; MR, mental retardation; MURCS, Mullerian duct, renal, cervical somite; PDA, patent ductus arteriosus; PKD, polycystic kidney disease; PPS, peripheral pulmonic stenosis; R, recessive; R/0, rule out; RTA, renal tubular acidosis; SGA, small for gestational age; TAR, radial aplasia-thrombocytopenia; TEF, tracheoesophageal fistula; UA, umbilical artery; UPJ, ureteropelvic junction; UTI, urinary tract infection; VACTERL, vertebrae, anus, cardiac, tracheoesophageal, renal, limb; VATER, vertebrae, anus, tracheoesophageal, renal; VUR, vesicoureteral reflux.

APPENDIX G-2: RELATIONSHIP BETWEEN SINGLE SIGNS AND RENAL-URINARY TRACT MALFORMATIONS

Table. No caption available.

Sign	Criteria for Entry into the Study	Method used to Detect Renal-Urinary Tract Malformations	Type of Malformations	Minimum Incidence^a of Patients with Renal-Urinary Tract Anomalies	Incidence of Patients with Renal-Urinary Tract Anomalies Who had no Evidence of Other Malformations at Birth^b
Abnormal Vertebrae					
Kohler 1982 (1)	Abnormal vertebrae or vertebrae	IVU	Agensis, ectopic, horseshoe kidney, duplication	8/46 (17%)	NA
Macewen 1972 (2)	Congenital scoliosis, without suspicion of neurogenic bladder	IVU	Agensis, duplication, ectopia, obstruction, VUR, horseshoe kidney	42/231 (18%)	NA
Anorectal Anomalies					
Munn 1983 (3)	Imperforation or atresia	IVU	Agensis, duplication, VUR, hypospadias, UPJ obstruction, neurogenic bladder	20/28 (71%)	NA

Hoekstra 1983 (4) ^c	Congenital anomalies	Autopsy; IVU excess in 3/126	VUR, agenesis, hypoplasia, ectopia, PKD UPJ obstruction, horseshoe kidney, hypospadias	95/150 (63%)	NA
Khuri 1981 (5) ^d	Imperforate anus and hypospadias	IVU	NA (part of study on hypospadias)	6/13 (46%)	NA
Congenital Diaphragmatic Hernia					
Siebert 1990 (6)	Autopsy	Autopsy	Agenesis, dysplasia or hypoplasia, UPJ/ureterovesical obstruction	16/27 (59%)	4/16 (25%)
Cunniff 1990 (7)	Chart review	Surgery or autopsy	Agenesis, hydronephrosis , cysts, ectopic or duplicated ureter	5/103 (5%)	0%
Hypospadias					
Khuri 1981 (5)	Hypospadias	IVU in 460/1076	Agenesis, UPJ obstruction, VUR, Wilms, PKD, ectopic kidney, horseshoe kidney	48/1076 (4%)	15/48 (31%) ^e
Shelton	Asymptomatic	IVU, VCUG	Agenesis,	27/102	0%

1985 (8)	hypospadias		duplication, pelvic kidney, VUR	(27%)	
Pulmonary Hypoplasia					
Page 1982 (9)	Neonatal autopsy	Autopsy	Agenesis, dysgenesis, dysplasia, PKD	16/77 (21%)	NA
Single Umbilical Artery					
Bourke (10)	Isolated single UA, examination of umbilical cord	US with VCUG if persistently abnormal	VUR, megaureter, agenesis, dilation of collecting system	8/112 (7%)	8/112 (7%)
Spontaneous Air Leak Syndrome					
Bashour 1977 (11)	Symptomatic pneumothorax	IVU	hypoplasia or agenesis, PKD, dysplasia, urethral valves, Potter facies (n=3)	12/47 (26%)	3/12 (25%)
Supernumerary Nipples					
Mehes 1983 (12)	Hospitalized	Clinical examination and IVU	Hydronephrosis, megaureter, duplication	9/37 (24%)	NA

Mimouni 1983 (13)	Neonatal (Israel)	Physical examination US (11/42)		0/43 (0%)	0%
Varsano 1984 (14)	ER/pediatric clinic (Israel)	IVU	PKD, hydronephrosis (UPJ obstruction), duplicated ureter, ureteral prolapse	6/26 (23%)	6/6 (100%) ^g
Robertson 1986 (15)	Neonatal (African- Americans)	US		0/32 (0%)	0%
Hersh 1987 (16)	Genetic/developmental clinic; 10 controls (United States, mostly Caucasian)	US or IVU	MKD, agenesis, Hydronephrosis, horseshoe kidney	7/65 (11%)	2/7 (29%) ^h
Urbani 1996 (17)	Adult subjects	US, urinalysis	ADPKD, unilateral renal agenesis MKD, familial cysts, UPJ stenosis	NA	NA

^aHypospadias excluded.

^b Except for minor anomalies such as pes equinovarus.

^c Eighty-one of 150 patients in the study had no congenital abnormalities of the other organs (54%).

^d Among patients with first-degree hypospadias, the incidence of upper urinary tract malformations was 1.3%.

^e Also 3 patients with undescended testes.

^f One patient had epilepsy; two patients had pyloric stenosis.

^g One patient had Niemann-Pick disease.

^h Three patients had anomalies.

ER, emergency room; IVU, intravenous urography; MKD, multicystic kidney dysplasia; NA, not available; PKD, polycystic kidney disease; UA, umbilical artery, UPJ/UV, ureteropelvic junction-ureterovesical; US, ultrasound; VUR, vesicoureteral reflex.

APPENDIX G-3: CLASSIFICATION OF CYSTIC KIDNEY DISEASE

Genetic Diseases

- AR polycystic kidney disease: associated with congenital hepatic fibrosis
- AD polycystic kidney disease: associated with central nervous system aneurysms
 - Type I – chromosome 16
 - Type II – chromosome 4
- Juvenile nephronophthisis—medullary cystic disease complex
 - Juvenile nephronophthisis with hepatic fibrosis (AR)
 - Medullary cystic disease complex (AD)
- Glomerulocystic kidney disease:
 - AD glomerulocystic kidney disease
 - Familial hypoplastic glomerulocystic kidney disease
- Malformation syndromes
 - Multicystic kidney disease
 - Apert syndrome, or acrocephalosyndactyly (AD, new mutation common)
 - Elejalde syndrome (AR)
 - Ellis-van Creveld syndrome, or chondroectodermal dysplasia (AR)
 - Fryns syndrome (AR)
 - Joubert syndrome (AR)
 - Meckel-Gruber syndrome, or dysencephalia splanchnocystica (AR)
 - Roberts phocomelia, hypomelia—hypotrichosis—facial hemangioma syndrome or pseudothalidomide syndrome (AR)
 - Short rib-polydactyly syndrome, Saldino-Noonan type (AR)
 - Smith-Lemli-Optiz syndrome (AR)
 - Glomerulocystic disease
 - Short rib-polydactyly syndrome, Majewski type (AR)
 - Tuberous sclerosis (AD): glomerular and tubular cysts
 - Zellweger cerebrohepatorenal syndrome (AR)
 - Ivemark syndrome, or renal-hepatic-pancreatic dysplasia (AR): cystic dysplasia
 - Orofacial digital syndrome, type 1 (X-linked D, lethal in males)
 - Nephronophthisis-medullary cystic disease
 - Familial renal-retinal dystrophy (AR)
- Other
 - Von Hippel-Lindau syndrome (AD)
 - Jeune syndrome, or asphyxiating thoracic dystrophy (AR)
 - Alagille syndrome, or arteriohepatic dysplasia (AD)
 - Trisomy 13
 - Trisomy 18
 - Ehlers-Danlos syndrome (AD, AR, X-linked)
 - Glutaric aciduria syndrome, type II, or multiple acyl-coA dehydrogenase deficiency (AR)
 - Lowe syndrome, or oculo-cerebro-renal syndrome (X-linked)

Nail-patella syndrome, or hereditary osteonychodystrophy (AD)
Congenital hypernephronic nephromegaly with tubular dysgenesis syndrome (AR)
Congenital nephritic syndrome, Finnish type, or infantile microcystic disease (AR)

Sporadic and Acquired Diseases

Multicystic kidney disease, or multicystic dysplasia
Dandy-Walker malformation
Sporadic glomerulocystic kidney disease
Nephron dysgenesis: glomerular or tubular immaturity
Brachymesomelia-renal syndrome (only one case described)
Femoral hypoplasia-unusual facies syndrome
Multilocular cystic nephroma, or cystadenoma
Simple cyst (benign)
Medullary sponge kidney (<5% inherited; no renal failure)
Cystic hamartoma of lung and kidney (multilocular cysts)
Acquired renal cystic disease in chronic hemodialysis patients
Caliceal diverticulum, or pyelogenic cyst
AD, autosomal dominant; AR, autosomal recessive; D, dominant.

Appendix H: Drug Formulary

1. MEDICATIONS IN BREAST MILK

APPENDIX H-1a: CYTOTOXIC DRUGS THAT MAY INTERFERE WITH CELLULAR METABOLISM OF NURSING INFANT

Drug	Reason for Concern, Reported Sign or, Symptom in Infant, or Effect on Lactation
Cyclophosphamide	Possible immune suppression; unknown effect on growth or association with carcinogenesis neutropenia
Cyclosporine	Possible immune suppression; unknown effect on growth or association with carcinogenesis
Doxorubicin*	Possible immune suppression; unknown effect on growth or association with carcinogenesis

Methotrexate

Possible immune suppression; unknown effect on growth or association with carcinogenesis; neutropenia

* Drug is concentrated in human milk

APPENDIX H-1b: DRUGS OF ABUSE FOR WHICH ADVERSE EFFECTS ON THE INFANT DURING BREAST-FEEDING HAVE BEEN REPORTED*

Drug	Reported Effect or Reason for Concern
Amphetaminet	Irritability, poor sleeping pattern
Cocaine	Cocaine Intoxication: irritability, vomiting, diarrhea, tremulousness, seizures
Heroin	Tremors, restlessness, vomiting, poor feeding
Marijuana	Only 1 report in literature; no effect mentioned; very long half-life of some components
Phencyclidine	Potent hallucinogen

* The Committee on Drugs strongly believes that nursing mothers should not ingest drugs of abuse, because they are hazardous to the nursing infant and to the health of the mother

† Drug is concentrated in Human milk

APPENDIX H-1c: RADIOACTIVE COMPOUNDS THAT REQUIRE TEMPORARY CESSATION OF BREASTFEEDING*

Compound	Recommended Time for Cessation of Breastfeeding
Copper 64 (^{65}Cu)	Radioactivity in milk present at 50 h
Gallium 67 (^{67}Ga)	Radioactivity in milk present for 2 wk
Indium 111 (^{111}In)	Very small amount present at 20 h
Iodine 123 (^{123}I)	Radioactivity in milk present up to 36 h
Iodine 125 (^{125}I)	Radioactivity in milk present for 12 d
Iodine 131 (^{131}I)	Radioactivity in milk present 2–14 d, depending on study
Iodine 131	If used for treatment of thyroid cancer, high radioactivity may prolong exposure to infant
Radioactive Sodium	Radioactivity in milk present at 96 h
Technetium 99m ($^{99\text{m}}\text{Tc}$), $^{99\text{m}}\text{Tc}$ Macroaggregates, $^{99\text{m}}\text{TcO}_4$	Radioactivity in milk present at 15 h to 3 d

* Consult nuclear medicine physician before performing diagnostic study so that radionuclide that has the shortest excretion time in breast milk can be used. Before study, the mother should pump her breast and store enough milk in the freezer for feeding the infant; after the study, the mother should pump her breast to maintain milk production but discard all milk for the required time that radioactivity is present in milk. Milk samples can be screened by radiology departments for radioactivity before resumption of nursing.

APPENDIX H-1d: DRUGS FOR WHICH THE EFFECT ON NURSING INFANTS IS UNKNOWN BUT MAY BE OF CONCERN

Drug	Reported or Possible Effect
Anti-anxiety	
Alprazolam	None
Diazepam	None
Lorazepam	None
Midazolam	None
Perphenazine	None
Prazepam†	None
Quazepam	None
Temazepam	None
Antidepressants	
Amitriptyline	None
Amoxapine	None
Bupropion	None
Clomipramine	None

Desipramine	None
Dothiepin	None
Doxepin	None
Fluoxetine	Colic, irritability, feeding and sleep disorders, slow weight gain
Fluvoxamine	
Imipramine	None
Nortriptyline	None
Paroxetine	None
Sertraline†	None
Trazadone	None
Antipsychotic	
Chlorpromazine	Galactorrhea in mother; drowsiness and lethargy in infant; decline in developmental scores
Chlorprothixene	None
Clozapine†	None
Haloperidol	Decline in developmental scores
Mesoridazine	None

Trifluoperazine	None
OTHERS	
Amiodarone	Possible hypothyroidism
Chloramphenicol	Possible idiosyncratic bone marrow suppression
Clofazimine	Potential for transfer of high percentage of maternal dose; possible increase in skin pigmentation
Lamotrigine	Potential therapeutic serum concentrations in infant
Metoclopramide†	None described; dopaminergic blocking agent
Metronidazole	In vitro mutagen; may discontinue breastfeeding for 12–24 h to allow excretion of dose when single- therapy given to mother
Tinidazole	See Metronidazole

* Psychotropic drugs, the compounds listed under anti-anxiety, antidepressant, and antipsychotic categories, are of special concern when given to nursing mothers for long periods. Although there are very few case reports of adverse effects in breastfeeding infants, these drugs do appear in human milk, and thus, could conceivably alter short-term and long-term central nervous system functions.⁵⁶ See discussion in text of psychotropic drug

† Drug is concentrated in human milk relative to simultaneous maternal plasma concentrations

APPENDIX H-1e: DRUGS THAT HAVE BEEN ASSOCIATED WITH SIGNIFICANT EFFECTS ON NURSING INFANTS AND SHOULD BE GIVEN TO NURSING MOTHERS WITH CAUTION*

Drug	Reason for Concern
Acebutolol	Hypotension; bradycardia; tachypnea
5-Aminosalicylic Acid	Diarrhea (1 case)
Atenolol	Cyanosis; bradycardia
Bromocriptine	Suppresses lactation; may be hazardous to the mother
Aspirin (salicylates)	Metabolic acidosis (1 case)
Clemastine	Drowsiness, irritability, refusal to feed, high-pitched cry, neck stiffness (1 case)
Ergotamine	Vomiting, diarrhea, convulsions (doses used in migraine medications)
Lithium	1/3 to 1/2 therapeutic blood concentrations in infants
Phenindione	Anticoagulant; increased prothrombin and partial Thromboplastin time in one infant; not used in U.S.
Phenobarbital	Sedation; infantile spasms after weaning from milk containing Phenobarbital, methemoglobinemia (1 case)
Primidone	Sedation, feeding problems
Sulfasalazine	Bloody diarrhea (1 case) (salicylazosulfapyridine)

* Blood concentration in the infant may be of critical importance. Modified from American Academy of Pediatrics, Committee on Drugs. Transfer of drugs and other chemicals into human milk. *Pediatrics* 2001;108:776-789

2. PHARMACOPOEIA

APPENDIX H-2: PHARMACOPOEIA

Drug	Dose/kg	Route and Frequency	Comments
Abelcet	See Amphotericin B lipid complex		
Acetazolamide	Diuretic: 5 mg	PO, IV, qd	May cause acidosis, hypokalemia, and GI irritation
	Hydrocephalus: 5 mg (increase each day by 25 mg/kg/day up to a max of 100 mg/kg/day)	q6h	
Acyclovir	neonatal HSV 20 mg	IV; over 1 h Term, normal renal function q8h <30 wk or mod. decrease renal function: q12h dec renal function and dec u/o (Cr > 1.2): q24h	Treat for 14–21 d Adequate hydration required to avoid crystalline nephropathy
Adenosine	0.05 mg	IVP Titrate dose in increments of 0.05 mg/kg every 2 min to a max of 0.25 mg/kg or until termination of PSVT	Push over 1–2 seconds flush with NS Higher doses may be needed for peripheral administration vs, central administration

Albumin 5%	0.5–1 g (1 g/20 mL)	IV over 30–60 min	Contains 0.13–0.16 mEq of sodium per ml Avoid circulatory overload
Albuterol	0.05–0.25 mg per dose	Inhalation for bronchodilation q2h to q6h	Tachycardia, arrhythmias, tremor, hypokalemia, and irritable behavior have been reported
Amikacin	<1.2 kg (0–4 wks) 7.5 mg	IM, IV, over 30 min q24h	Therapeutic levels: Pk = 20–30 mcg/ml Tr = 5–10 mcg/ml
	1.2–2 kg (0–7 days) 7.5 mg	q12h	Dose adjustment required in renal dysfunction
	>7 days 7.5 mg	q8–12h	Risk of ototoxicity increases when given concurrently with loop diuretics
	>2 kg (0–7days) 10 mg >7 days 10 mg	q12 q8h	
Aminophylline	loading dose 6 mg	IV once	Therapeutic level Bronchospasm: 10–20 mcg/ml Neonatal apnea: 6–13 mcg/ml
	maintenance dose	Infuse over 20–30 min IV q8h give first	Signs of toxicity include

	<1000 g 2 mg/kg/dose	maintenance dose 8 h after the loading dose	irritability, GI upset and arrhythmias. When switching to theophylline, remember that aminophylline is 80% theophylline
	>1000 g 2.5-3 mg/kg/dose	q8h	
Ammonium chloride	Metabolic alkalosis 1-2 mEq	PO, IV × 1	GI Irritation-administer oral doses after meals Hyperventilation Pain at injection site if infused too rapidly Maximum concentration for injection is 0.4 mEq/ml Maximum infusion rate is 1 mEq/kg/h
	Urinary acidification 0.25-0.37 mEq	PO, IV q6h	
Amoxicillin	10-15 mg	PO q12h	See comments for Ampicillin
Amphotericin B	Test dose for infants and children: 0.1 mg (maximum total dose: 1 mg) test dose is optional in neonates	IV once infuse over 1 h	Total dose for treatment: Disseminated infection: 25-30 mg/kg Catheter-associated infection: 10-15 mg/kg Not to exceed 1.5 mg/kg/day Max concentration: 0.1 mg/ml

	Initial dose: 0.5 mg	On the first day of treatment, subtract the test dose from the initial dose and give the remainder over 3 h if there is no adverse reaction	Max dextrose concentration: 20% Incompatible with saline solution and TPN Monitor electrolytes, renal and hematological status
	Maintenance dose: 0.5–1 mg (increase dose in increments of 0.25 mg/kg/d)	IV qd over 2–4 h	Avoid additional nephrotoxic drugs
Amphotericin B Lipid complex	2.5–5 mg (increase dose daily in 1 mg/kg increments)	Infuse over 2 h	Use higher doses for meningitis, osteoarthritis, cryptococcal infections, and aspergillosis Mix to a 1–2 mg/ml dilution with D5W only Do not mix with saline or any other drug Flush line with D5W
Ampicillin	Sepsis: 25 mg	Infusion 15–30 min IV, IM ≤7 d: ≤2 kg: q12h ≤7 d: ≥2 kg: q8h >7 d: <1.2 kg: q12h >7 d: 1.2–2 kg q8h >7 d: >2 kg q6h	May cause rash, interstitial nephritis, hemolytic anemia, and pseudomembranous colitis Lengthen interval in renal dysfunction Not to exceed 100 mg/min infusion
	Meningitis: 50 mg	≤7 d: ≤2 kg: q12h ≤7 d: >2 kg: q8h >7 d: <1.2 kg q12h >7 d: 1.2–2 kg q8h >7 d: >2 kg q6h	

Atracurium	Initial dose 0.3–0.5 mg	IV; once	
	Maintenance dose: 0.3–0.4 mg	As needed to maintain paralysis	Hypertension associated with histamine release Ventilatory rate may need to be adjusted to compensate for loss of spontaneous ventilation Aminoglycoside antibiotics prolong duration of action Preservative Free now available Elimination not substantially altered by renal or hepatic dysfunction
Atropine	Bradycardia: 0.02 mg	IV over 1 min; min single dose 0.1 mg, max single dose 0.5 mg May repeat every 5 min to a max total dose of 1 mg or 0.04 mg/kg	Infants with down syndrome have both increased sensitivity to cardiac effects and mydriasis May cause hyperthermia, urinary retention, tachycardia, and elevated WBC count
	Bronchospasm: 0.03–0.05 mg	Via inhalation q8h–q6h; min single dose 0.25 mg, max single dose 1 mg	Antidote: physostigmine
Bumetanide	0.01–0.05 mg	IV, IM, PO qod–qd	Push IV doses over 1–2 min 40 times more potent than furosemide Monitor serum electrolytes Ototoxic

Caffeine base	Loading dose 5-10 mg Maintenance daily dose 2.5 mg-5 mg	IV, PO once Infuse over 30 min qd Administer first maintenance dose 24 h after the loading dose	Therapeutic levels: 5-20 mcg/ml Do Not skip scheduled doses when giving a bolus Toxicity (CV, neurological and GI) rarely occurs at levels <50 mcg/ml
Calcium chloride 10% (27 mg elemental calcium/ml)	Hypocalcemia: 10-20 mg elemental Ca	IV PO q6h	
	Cardiac arrest: 5 mg elemental Ca	IV slow push over 10 min max rate 1 mg/kg/min	Use IV solution with extreme caution severe necrosis occurs in extravasation Monitor serum Ca levels Use with caution in digitalized patients
Calcium Glubionate (Neo-Calglucon) (23 mg elemental calcium/ml)	Hypocalcemia: 10-20 mg elemental Ca	PO q6h	Give prior to feeds for best absorption High osmotic load: large doses may cause diarrhea Dilute 1:1 with sterile water to have osmolarity Monitor serum Ca level
Calcium Gluconate 10% (9.4 mg elemental calcium/ml)	Hypocalcemia: 10-20 mg elemental Ca	IV, PO q6-q12h	
	Cardiac arrest: 10 mg elemental Ca	IV may repeat every 10 min	May cause bradycardia and potentiation of digitalis Extravasation causes necrosis of

			<p>subcutaneous tissues Do not use scalp veins Precipitates with Na Bicarb and phosphate salts Monitor serum Ca levels</p>
Captopril	0.05–0.1 mg; may titrate up to 0.5 mg/kg/dose	PO q6h–q24h	<p>Give 1 h prior to feeds Adjust dose in renal dysfunction Monitor blood pressure; severe hypotension may occur in patients who are sodium or volume depleted May cause rash, proteinuria, neutropenia</p>
Cefazolin	20 mg	<p>IV, IM ≤7 d: q12h >7 d, ≤2 kg: q12h >7 d >2 kg: q8h</p>	<p>First generation cephalosporin Adjust dose and or interval in renal dysfunction May cause rash and elevated liver enzymes</p>
Cefotaxime	50 mg	<p>IV, IM <1.2 kg, <7 d: q12h ≥1.2 kg, >7 d: q8h</p>	<p>Third generation cephalosporin Good CNS penetration Adjust dose and/or interval in renal dysfunction</p>
Ceftazidime	50 mg	<p>IV, IM <1.2 kg 0–4 wk: q12h ≥1.2 kg ≤7d: q12h ≥1.2 kg >7d: q8h</p>	<p>Third generation cephalosporin Adjust dose and/or interval in renal dysfunction Rash, false positive Coomb's test</p>

Ceftriaxone	50 mg	IV, IM	Third generation cephalosporin
	50–75 mg	<p>≤7 d: q24h</p> <p>>7 d ≤2 kg: q24h</p> <p>>7 d >2 kg: qd or may divide into two daily doses</p>	No adjustment in renal dysfunction
	Meningitis: LD 75–100 mg		Painful IM injection. The use of lidocaine for reconstitution of ceftriaxone doses for very small babies is not recommended due to possible lidocaine-related cardiac adverse effects
	MD 50 mg	<p>IV × 1</p> <p>IV q12–24hr begin maintenance dose 12–24 h after loading dose</p>	Not recommended for use in neonates with hyperbilirubinemia
Cefuroxime	25–50 mg	IV, IM q12h	<p>Second generation cephalosporin</p> <p>Adjust dose in renal dysfunction</p> <p>May cause transient elevation in BUN/Cr, pseudomembranous colitis and rash</p>
Chloral Hydrate	Sedative: 25–40 mg	PO, PR q6–8h prn	<p>May cause paradoxical excitement and accumulation of toxic metabolites</p> <p>Use with caution in hepatic and/or renal failure</p> <p>May cause GI distress and indirect hyperbilirubinemia</p>

	Hypnotic: 25–50 mg	PO, PR once	
Chloramphenicol	25 mg	IV, PO >2 kg ≤7 d: qd ≤2 kg >7 d: qd >2 kg >7 d: q12h	Therapeutic levels: 10–25 mcg/ml “Gray baby”: syndrome with levels >50 mcg/ml May cause bone marrow depression Increases phenytoin blood levels
Chlorothiazide	10–20 mg Max 375 mg/day	PO q12h	Use with caution in liver and severe renal failure May cause fluid and electrolyte imbalance, hyperbilirubinemia, and hyperglycemia
	1–4 mg	IV q12h	
Cholestyramine	80 mg of the active resin	PO; tid with feeds	May cause constipation, diarrhea, malabsorption of fat soluble vitamins, and metabolic acidosis Alters absorption of drugs when given concurrently. Give oral meds 1 h prior to or 4–6 h after cholestyramine
Cimetidine	5–10 mg/kg/day in neonates	IV, IM, PO q8–12h	May cause diarrhea, rash, neutropenia, and gynecomastia Increases blood levels of theophylline, phenytoin, and other drugs Decrease dose in renal dysfunction

	10–20 mg/kg/day in infants	IV, IM, PO q6–12h	
Cisapride	0.15–0.3 mg	PO, tid-qid 15–30 min prior to feeds	available only by limited access protocol
Clindamycin	5 mg	<7 d: <2 kg: q12h IV, IM ≤7 d: ≤2 kg; q12h ≤7 d: >2 kg: q8h <7 d: 1.2–2 kg: q8h >7 d: >2 kg: q6h	Not indicated for meningitis GI disturbance Pseudomembranous colitis (rare in children)
Cromolyn	20 mg /dose	Inhalation q6–q8h	Bronchospasm, cough, nasal congestion, and pharyngeal irritation have been reported
Dexamethasone	Anti-inflammatory: 0.025–0.05 mg Airway edema: 0.25 mg	IV, IM, PO q6–q12h IV, IM, PO For extubation: Give first dose 4 h prior to extubation. Then repeat q8h × 3 doses. Max 1 mg/kg/day. A longer duration of therapy may be needed with more severe cases.	May increase risk of infection May cause hypertension, salt retention, adrenal suppression, hyperglycemia, and leukocytosis Consider steroid coverage for periods of stress after therapy for BPD, and in intercurrent illness (see BPD section) Give hydrocortisone stress doses for surgery up to six months after stopping taper See hydrocortisone for stress dosing guidelines All calculations must use the same body weight

	BPD	IV, IM, PO (numerous tapers have proposed) Day Daily dose 1-2 0.2-0.3 mg/kg 3-4 0.1-0.15 mg/kg 5-6 0.05 mg/ kg divided q12h with max exposure of 7-10 days	Recent AAP statement recommends use in VLBW only for the most serious chronic lung disease due to long-term neurologic sequelae associated with therapy.
Diazepam	Status epilepticus: 0.1-0.5 mg	Slow IV push (over 3 min) every 15-30 min for two to three doses; may repeat in 4 h to a max of 2 mg per 24 hr	Not a first line agent for neonates Lorazepam is a better choice for maintenance therapy May cause hypotension and respiratory depression Displacement of bilirubin by sodium benzoate may occur
	Sedation: 0.04-0.3 mg	IV q2-4h prn Maximum of 0.6 mg/kg within 8 h period	
Diazoxide	Hypertension 1-3 mg	IV push every 5-15 min until blood pressure is controlled, then q4-24h	May cause hyperglycemia, ketoacidosis, GI irritation, salt and water retention, hypotension
	Hypoglycemia 2-5 mg	PO q8-q12h	Use only if refractory to glucose infusion
Digoxin	Total digitalizing dose (TDD) oral	Give 1/2 of the TDD initially, then 1/4 of the TDD q8h-q24h x 2 doses	May cause bradycardia, PVC's, vomiting, poor feeding, and

	Premie: 20–30 mcg Term: 25–35 mcg 1–24 mo: 35–60 mcg		arrhythmias Check ECG trace during digitalization and periodically
	Oral maintenance (25% of TDD) Premie: 5–7.5 mcg Term 6–10 mcg 1–24 mo: 10–15 mcg	q12h	Adjust dose per clinical response and renal function Bioavailability of elixir is 70–85% of the injectable preparation
	TDD injectable: Premie: 15–25 mcg Term 20–30 mcg 1–24 mo: 30–50 mcg	IV, IM follow same guidelines as for oral administration	
	Injectable maintenance dose (25% of TDD) Premie: 4–6 mcg Term: 5–8 mcg 1–24 mo: 7.5–12 mcg	IV, IM q12h	
Dobutamine	1–20 mcg/kg/min; max dose: 40 mcg/min	IV infusion	Titrate according to patient's response Use same precautions as with dopamine
Dopamine	1–5 mcg/kg/min	IV infusion, mostly dopaminergic effect and some beta-adrenergic;	Monitor blood and pulse pressures Observe for pulmonary hypertension

	5–15 mcg/min	Mostly beta-adrenergic; some dopaminergic effect at lower end of this range; some alpha-adrenergic at higher end of dosage range	Tissue necrosis may occur with extravasation May cause ectopic beats
	>20 mcg/min; max dose 50 mcg/min	Mostly alpha-adrenergic effect	
Doxapram	Loading dose 2.5–3 mg	IV infusion over 1 h	Maintain therapeutic caffeine or theophylline levels while on doxapram Taper drug to avoid rebound apneic episodes Increases oxygen consumption and may cause hypertension, tachycardia, and seizures
	Maintenance dose 1–2.5 mg/kg/h	Continuous IV infusion; start at 1 mg/kg/h and titrate up to minimum effective dose Max dose 2.5 mg/kg/hr Maximum concentration; 2 mg/ml	
Edrophonium	Myasthenia gravis test: Neonates: 0.1 mg (single dose, not per kg) Infants: 0.04 mg/kg/dose ×1 (max of 1 mg for body weight) <34 kg and 2 mg ≥34 kg	IV once If no IV access available, may give IM or SC	Keep atropine and resuscitation equipment available Antidote: Atropine 0.01–0.04 mg/kg/dose

Enalapril (PO)	0.05–0.1 mg	PO qd titrate to max of 0.5 mg/kg	Adjust dose in renal impairment: CrCl 10–50 ml/min: give 75% of dose
Enalaprilat (IV)	5–10 mcg	IV q8–24 h administer over 5 min	CrCl < 10 ml/min: give 50% of dose May cause hypoglycemia, hyperkalemia, neutropenia, anemia, and deterioration of renal function
Epinephrine 1:10,000	0.1–0.3 ml	IV, Intratracheal Every 3–5 min as needed	IV drip used for hypotension refractory to dopamine and dobutamine Higher end of dosage range used for cardiac resuscitation; intracardiac route should be last resort Dilute intratracheal doses to 1–2 ml with saline soln
	0.1–1 mcg/kg/min	Continuous IV infusion; titrate up as needed	
Epinephrine (racemic) 2.25% solution	0.25 ml total dose	Inhalation via nebulizer over 15 min q4h prn Dilute with NS to total volume of 2.5–3 ml	May cause tachycardia and arrhythmias
Epoetin	see	Erythropoietin	

Erythromycin	anti-infective: 10 mg	IV, PO ≤7 d: q12h >7 d <1.2 kg: q12h >7 d ≥1.2 kg: q8h	Decreases clearance of theophylline, digoxin, carbamazepine, and others
	Prokinetic agent: 3 mg then 5 mg	IV × 1 infuse over 60 min Po q6h	Causes GI distress
Erythropoietin	Anemia of prematurity: 50–100 units or 200 units	SC three times weekly	Must give iron supplementation
		Titrate dose up based on clinical response IV/SC qd/qod for 2–6 wk	
Exosurf	(see Surfactant)		
Fentanyl	1–3 mcg 0.5–2 mcg/kg/h	IV, IM q2–q4h prn pain Continuous IV infusion; titrate up	Causes muscle rigidity, respiratory depression and dependence; causes less CV effect than morphine
Ferrous sulfate	Iron deficiency anemia: 2–3 mg elemental Fe/kg/day	PO q12–24h (max dose: 15 mg/day)	Do not give concurrently with antacids, milk, or cereal Cimetidine decreases absorption of Iron May cause GI irritation; colors stools black

	With Erythropoietin: 3-6 mg elemental Fe Premature supplement: 1 mg	PO q12-q8h Max 15 mg/kg/day PO q12h or give formula with Fe	
Fluconazole	5-6 mg	PO/IV Infuse over 1-2h <29 wks gestation 0-14 days: q72h	Monitor renal and liver functions; Renal dosing CrCl 21-50 ml/min 50% of dose CrCl 11-20 ml/min 25% of dose
	5-6 mg 3-6 mg	>14 days: q48h 30-36 wks gestation 0-14 days: q48h	
	6 mg	>14 days: qd	
Flucytosine	25-50 mg	PO q12-24h	May cause GI irritation, bone marrow depression, elevated liver enzymes, elevated BUN, and creatinine Used in combination with amphotericin B or fluconazole
Furosemide	1-2 mg 2-4 mg	IV, IM q12h- q24h PO q12h-q24h	Causes sodium and potassium depletion: dehydration Additive ototoxicity with aminoglycosid
Gentamicin	3 mg 2.5 mg	<1.2 kg <30 days: qd <1.2 kg >30 days: q12h	Monitor renal function Ototoxicity is related to length of therapy

	2.5 mg	≥1.2 kg 0-14 days:q12h	Therapeutic range: Peak 5-12 mcg/ml
	2.5 mg	≥1.2 kg >14 days: q8h	Trough <2 mcg/ml
Gentian violet	1% topical solution	Dilute to 0.5% solution 3-4 drops under the tongue or apply to lesions after feedings bid-tid	Stains skin and clothing; apply with cotton tip applicator Do not apply to face
Glucagon	Hypoglycemia or insulin shock: 0.03-0.3 mg Max dose 1 mg/dose	IV push, SC, IM Every 30 min prn	1 unit = 1 mg May cause rebound hypoglycemia
Heparin	For maintenance of central catheters: 0.5-2 units/ mL of IV fluid	IV	See protamine sulfate for treatment of overdose Monitor clotting time; titrate dose to achieve 1.5-2.5 times normal physiologic values
	Anticoagulation: bolus 50 units/kg	IV Once	
	Maintenance: 10-25 units/kg/h	IV continuous infusion titrate up based on APTT/PTT	

	Intermittent dosing: 50–100 units/kg/dose	IV q4h	Not preferred						
Hydralazine	Parenteral Initial: 0.1–0.8 titrate up not, to exceed 2 mg/kg/dose	IV, IM q4–q6h	Adjust dose in renal impairment: CrCl 10–50 ml/min: give q8h CrCl 10 ml/min; give q12–q24h						
	Oral Initial 0.2–0.3 mg titrate up, Max daily dose 5 mg/kg	PO, NG q8–q12h	May cause tachycardia and sodium and water retention						
Hydrocortisone	Congenital adrenal hyperplasia 20–35 mg/m ² /d Maintenance: 12.5– 37.5 mg/m ² /d	PO divided as follows: 1/4 dose in morning and at noon, 1/2 dose at night	Increases chance of infection May cause hypertension, salt and water retention, adrenal suppression, and hyperglycemia						
	Shock: Initial 35–50 mg/kg Maintenance: 12.5–37.5 mg/kg	IV Once IV q6h ×48–72 h	Approximate weight to body surface area conversion table: <table border="1" data-bbox="1592 1038 2141 1425"> <thead> <tr> <th>Weight kg</th> <th>M²</th> </tr> </thead> <tbody> <tr> <td>0.5</td> <td>0.5</td> </tr> <tr> <td>1</td> <td>0.1</td> </tr> </tbody> </table>	Weight kg	M ²	0.5	0.5	1	0.1
	Weight kg	M ²

Extended treatment
0.2 mg

IV qd × 5 days following standard
three dose regimen may decrease
recurrence of PDA

Prevention of IVH:
0.1 mg/kg

q24h for three doses, beginning at
6-12 h of age

Insulin	Hyperglycemia: Initial: 0.1 unit	IV Once over 15–20 min	Monitor blood glucose and titrate dose accordingly: may cause rebound hyperglycemia if discontinued abruptly
	Maintenance: 0.02–0.1 unit/kg/h	IV, continuous infusion	Use only human regular insulin for IV infusions
	Intermittent: 0.1–0.2 units	SC, q6–q12h	
	Hyperkalemia: 0.3 units/g of glucose	IV with dextrose: 500 mg/kg/dose	
Iron	See Ferrous sulfate		
Isoniazid	5–10 mg	PO, IM q12–24h	May cause vitamin B6 (pyridoxine) depletion; monitor liver function
Kayexalate (sodium polystyrene)	1 g	PO, PR q6h prn	Hyperosmotic; monitor serum electrolytes
Labetalol	Bolus: 0.25 mg	IV over 2 min Dose can be doubled and repeated every 10 min until desired clinical	Absolute contraindication: CHF, heart block, sinus tachycardia

		response or total dose of 4 mg/kg is reached	
	Maintenance: 0.25–1 mg	IV q4h	May cause bradycardia, edema, and bronchospasm
	1.5–2 mg 0.25–1.5 mg/kg/h	PO q12h Continuous IV infusion Max conc 1 mg/ml	
Levothyroxine	5–8 mcg	IV push over 30–60 sec; q24h	Monitor serum T4 and TSH levels Do not mix with any other IV fluids; mix immediately prior to administration
	8–14 mcg Alternate dose: 25–50 mcg total	PO q24h PO q24h	Increases effects of oral anticoagulants
Lidocaine	0.5–1 mg 10–50 mcg/kg/min	IV every 5–10 min × 2 doses Continuous IV infusion Max conc 8 mg/ml	May cause bradycardia and hypotension; decrease dose in CHF; contraindicated in severe heart block Therapeutic levels 1.5–5 mcg/ml
Lorazepam	Status epilepticus: 0.05 mg Sedation: 0.05–0.1 mg	IV may repeat every 15–20 min × 2 doses IV q4–8h	Contains benzyl alcohol; may cause respiratory depression, hypotension, and bradycardia

		Max dose 2 mg	Do not give intraarterially Administer over 2–5 min
Magnesium sulfate	Hypomagnesemia: 0.2–0.4 mEq	Infuse over 2–4 h IV 2–3 doses q8–12h	Monitor serum levels May cause hypotension and respiratory depression Max concentration 1.6 mEq/ml
Mannitol	0.25–1 g (15%–20% solution)	IV once over 2–6 h	Always use a 5 micron filter
	Oliguria test dose: 0.2 g	IV over 3–5 min	May cause rebound edema and circulatory overload
Methylene blue	1–2 mg	IV slow push over 5 min (1% soln)	Methylene blue is a reducing agent; it may decrease hemoglobin O2 capacity
Metoclopramide	0.1–0.2 mg	May repeat in 1 h IV, IM, PO q6h	Dilute to 0.2 mg/ml and infuse over 15–30 min
	Renal dose adjustment: <table border="1" data-bbox="510 1241 853 1390"> <tr> <td>C/Cr</td> <td>% of dose</td> </tr> </table>		C/Cr
C/Cr	% of dose		

	<table border="1"> <tr> <td>20-50</td> <td>75</td> </tr> <tr> <td><40</td> <td>50</td> </tr> <tr> <td><10</td> <td>25-50</td> </tr> </table>	20-50	75	<40	50	<10	25-50		
20-50	75								
<40	50								
<10	25-50								
Metolazone	0.2 mg	PO 12-q24h	May cause metabolic alkalosis and hyperuricemia; monitor serum electrolytes						
Metronidazole	7.5 mg	IV, PO 0-4 wk <1.2 kg q48h ≤7 d 1.2-2 kg q24h ≤7 d 2 kg q12h	Penetrates effectively into CSF; may cause leukopenia, rash, phlebitis, and seizures						
	15 mg	>7 d 1.2-2 kg q12h >7 d 2 >kg q12h							
Midazolam	0.03-0.1 mg 0.05 mg/h	IV, IM, q2-4h prn Continuous IV infusion; titrate up based on clinical response	May cause respiratory depression, hypotension, and dependence						
Morphine	0.05-0.1 mg	IV, IM, SC q2-q4h prn	May cause respiratory and CNS						

	10–20 mcg/kg/h	Continuous IV infusion: titrate up based on clinical response	depression, hypotension, and dependence Nalxone reverses acute overdose Use preservative free formulation
Nafcillin	25 mg	IV, IM <1.2 kg <1 mo: q12h 1.2–2 kg ≤7 d: q12h >2 kg ≤7 d: q8h 1.2–2 kg >7 d: q8h >2 kg >7 d: q6h	Consider changing dosing interval in patients with hepatic dysfunction Cases of granulocytopenia or agranulocytosis have been reported
Naloxone	Maternal opiate exposure 0.1mg	IV, IM, SC endotracheally every 2–3 min prn	For ET administration dilute to 1–2 ml with NS
	Reversal of opiate analgesia 0.01 mg		Max conc for IV infusion: 4 mcg/ml; undiluted drug may be pushed over 30 sec May precipitate withdrawal symptoms in patients with physical dependence
Neo-calglucon	See Calcium glubionate		
Neomycin	12.5–25 mg	PO q6h	May cause nephrotoxicity and ototoxicity

Neostigmine	Myasthenia gravis test: 0.025–0.04 mg Treatment: 0.01– 0.04 mg 0.25–0.3 mg	IM Once IV, IM, SC q2–q4h prn PO q3–q4h prn	May cause cholinergic crisis Antidote: atropine 0.01–0.4 mg/kg
Nitroprusside	Initial	IV continuous infusion	Monitor for cyanide toxicity
	0.3–0.5 mcg/kg/min Maintenance: 3–4 mcg/kg/min Max 8–10 mcg/min		May cause hypotension and tachyphylaxis Protect from light
Nystatin	100,000–200,000 units total dose	PO q6h Apply 1/2 of the dose to each side of the mouth for oral thrush	Poor oral absorption
Octreotide	1–10 mcg	IV, SC q12–q24h	Start treatment using lower end of dosage range Causes growth hormone suppression
Oxacillin	25 mg	IV, IM ≤ 2 kg <7 d q12h ≤2 kg >7 d q8h >2 kg ≤7 d q8h >2 kg >7 d q6h	Contraindicated in patients allergic to penicillins May cause thrombophlebitis and clostridium difficile colitis Monitor liver function
Palivizumab	See Synagis		

Pancuronium	0.04–0.1 mg	IV q1–4h prn movement	Short half-life; titrate dose based on clinical response Aminoglycosides increase the action of pancuronium
Paregoric	Initial dose: 0.2–0.3 ml total dose subsequent doses: increase by 0.05 ml up to max of 0.7 ml total dose	PO q3–4h	Monitor for CNS depression Give with feeds to minimize GI irritation; same adverse effects as morphine
Penicillin-G K	Congenital syphilis: 50,000 units	IV, IM ≤7 d: q12h >7 d: q8	May cause hypersensitivity reactions, thrombophlebitis, and acute interstitial nephritis
	Meningitis: group B strep: 75,000–100,000 units	IV, IM ≤2 kg ≤7 d: q12h ≤2 kg >7 d: q8h	
	Other infections: 25,000–50,000 units	>2 kg <7 d q8h >2 kg >7 d: q6h	
Phenobarbital	Loading dose: 20 mg	IV, IM once	Monitor levels weekly or as clinically indicated Induces the metabolism of other drugs, may cause respiratory and CNS depression at higher doses Therapeutic levels: seizures: 20–40 mcg/ml hyperbilirubinemia: 15 mcg/ml

	Maintenance dose: 3-4 mg/kg/day	IV, IM, PO qd	
Phenytoin	Loading dose: 20 mg	IV once	Rapid infusion may precipitate cardiovascular collapse; do not exceed 0.5 mg/kg/min infusion
	Maintenance dose: 2-4 mg	IV, PO q12h Some patients may need q8h intervals	Toxicity may lead to seizures and CNS depression Therapeutic range: 15-20 mcg/ml
Phytonadione (vitamin K1)	Neonatal hemorrhagic disease: Prophylaxis: 0.5-1 mg total dose	IM, SC once within 1 hour of birth; may repeat 6-8 h later	IV route should be used only when other routes are not available; infuse at a max rate of 1 mg/min; severe reactions resembling anaphylaxis may occur with IV administration
	Treatment: 1-2 mg total dose	IV, SC once	
Piperacillin	50 mg	IV ≤7 d q8h >7 d q6h	Used in combination with aminoglycosides Eosinophilia, hyperbilirubinemia, elevations in ALT, AST, BUN, and serum creatinine have been observed

Prednisolone	Antiinflammatory: 0.5–1 mg	PO q12h	May cause hypertension, GI irritation, and adrenal suppression								
Propranolol	0.01–0.1 mg maximum 0.25 mg	IV push over 10 min q6–q8h dose: 1 mg PO q6–q8h titrate up to maximum of 5 mg/kg/day	May cause hypotension, bronchospasm, and heart block								
Prostaglandin E₁	0.05–0.4 mcg/kg/min	IV continuous infusion; use lowest effective dose	May cause apnea, fever, hypotension, and cutaneous vasodilation								
Protamine	Dose of protamine in mg to neutralize 100 units of heparin	<table border="1"> <thead> <tr> <th>Protamine</th> <th>Time elapsed</th> </tr> </thead> <tbody> <tr> <td>1–1.5</td> <td>immediate</td> </tr> <tr> <td>0.5–0.75</td> <td>30–60 min</td> </tr> <tr> <td>0.25–0.375</td> <td>>2 h</td> </tr> </tbody> </table>	Protamine	Time elapsed	1–1.5	immediate	0.5–0.75	30–60 min	0.25–0.375	>2 h	May cause hypotension and bradycardia Max conc: 10 mg/ml
Protamine	Time elapsed										
1–1.5	immediate										
0.5–0.75	30–60 min										
0.25–0.375	>2 h										
Pyridoxine (vitamin B₆)	Deficiency: 5–25 mg × 3 weeks then 1.5– 2.5 mg	PO, IV, IM Q24h	Decreases serum levels of phenobarbital, phenytoin, and folic acid; may cause hypersensitivity reactions, respiratory distress, and burning								

			at site of injection
	pyridoxine dependent seizure: 50–100 mg total dose	PO, IV, IM Q24h	
Pyrimethamine	Toxoplasmosis: LD: 2 mg/kg/day	PO q12h for 2 days	Supplementation with folic acid is recommended May cause glossitis, seizures, and rash Given with sulfadiazine
		PO; qd for 2–6 months, then 3× per week to complete 12 months treatment	
Ranitidine	0.75–1.5 mg	IV, IM q6–q8h max 6 mg/kg/d	Renal dosing: CrCl < 50 ml/min oral give q24h IV, IM: give q18–q24h Monitor serum creatinine
	1.25–2.5 mg	PO q12h	
RSV immune globulin	750 mg (15 ml)	IV, monthly during RSV season Administration guidelines: 1.5 ml/kg/h × 15 min	Not recommended for use in patients with cyanotic heart disease. Some patients may develop respiratory distress due to excessive fluid

		3 ml/kg/h × 15 min 6 ml/kg/h until finished	Live vaccines should be delayed for 9 mo after administration
Spironolactone	0.5–1.5 mg	PO q8–q12h	Avoid in hyperkalemia; may cause rash, vomiting, and diarrhea; contraindicated in renal failure
Surfactant	Curosurf (poractant alfa) initial: 2.5 ml subsequent: 1.25 ml	One dose as soon as RDS diagnosis is confirmed intratracheally. Subsequent dose × 2 q12h after first dose if baby is still ventilator dependent.	Adverse effects include pulmonary hemorrhage, apnea, and mucous plugging Adjust ventilatory parameters to prevent hyperoxia and hypocarbia May open ductus
Surfactant	Infasurf (calfactant) 3 ml	Endotracheal: one dose q12h up to a total of 3 doses	Adverse effects include pulmonary hemorrhage, apnea, and mucous plugging Adjust ventilatory parameters to prevent hyperoxia and hypocarbia May open ductus
Surfactant	Survanta (beractant) 4 ml	Endotracheal rescue treatment: one dose as soon as RDS diagnosis is confirmed. May repeat q6h to a total of four doses Prophylaxis: First dose given as soon as possible after birth; may give a total of four doses during first 48 hours of life, no more frequently than 6 h apart	Adverse effects include pulmonary hemorrhage, apnea, and mucous plugging Adjust ventilatory parameters to prevent hyperoxia and hypocarbia May open ductus

Survanta	See Surfactant		
Synagis	15 mg	IM; monthly during RSV season	Typically RSV season begins in November and last through April Inject in the anterolateral aspect of the thigh. Gluteal injections may damage the sciatic nerve
Tham Ticarcillin ± Clavulanic acid (Timentin)	See Tromethamine 75 mg	IV, IM ≤2 kg 0-7 d q12h ≤2 kg > 7 d q8h >2 kg 0-7 d q8h >2 kg > 7 d q6h	May cause hypersensitivity reactions, phlebitis, pseudomembranous colitis, hypernatremia, and inhibition of platelet aggregation
Tobramycin	3 mg 2.5 mg 2.5 mg 2.5 mg	<2 kg < 30 days qd <1.2 kg > 30 days q12h ≥2 kg 0-14 days q12h ≥1.2 kg > 14 days q8h	Monitor renal function Therapeutic range: Peak 5-10 mcg/ml Trough <2 mcg/ml
Tromethamine	3 ml	IV slow infusion Max rate: 1ml/h	1 ml = 0.3 mEq; 1mM = 1 Meq Infuse preferably in large blood vessel; may cause hypoglycemia, hyperkalemia, apnea, and fluid overload
Vancomycin	15 mg	IV infused over 90-120 min <1.2 kg q24h	Therapeutic range: Peak 20-40 mcg/ml Trough <10 mcg/ml

	15 mg 15 mg	≤7 days 1.2-2 kg: q12h ≤7 days >2 kg: q12h	May cause renal and ototoxicity, redman syndrome may occur with rapid infusion; some patients may require 2 h infusion
	15 mg 15 mg	>7 days > 1.2-2 kg: q8-12h >2 kg: q8h	
Vasopressin (aqueous)	Diabetes insipidus 2.5-10 units total dose	IM, SC q12-q16h	May cause bronchoconstriction, diarrhea and electrolyte imbalance
Vecuronium	0.03-0.15 mg 0.05-0.1 mg/kg/h	IV q1-2 h prn movement IV continuous infusion Max concentration:1 mg/ml	Neuromuscular effects may be prolonged after continuous infusion and when aminoglycosides are administered concurrently May need to adjust for renal dysfunction
Vitamin K₁	See phytonadione		

Dosages in this table are single dose per kilogram. Frequency is suggested in the third column but may vary with maturity and rate of metabolism. In most cases, the most conservative dosage is given.

ACTH, adrenocorticotrophic hormone; AV, atrioventricular; BP, blood pressure; BUN, blood urea nitrogen; CNS, central nervous system; CSF, cerebrospinal fluid; ECG, electrocardiogram; ET, endotracheal; GI, gastrointestinal; IT, intrathecal; NS, normal saline; PO, by mouth; PR, per rectum; prn, as needed; PVC, premature ventricular contraction; SC, subcutaneous; TDD, total digitalizing dose; TSH, thyroid stimulating hormone; WBC, leukocyte.

Reviewed and updated by Diana Joachim, Pharm D and Kelsey Briggs, Pharm D, West Virginia University Hospitals, Morgantown, WV.

Appendix J: Technical Procedures

1. PLACEMENT OF UMBILICAL CATHETERS

APPENDIX J-1A: THE LENGTH OF CATHETER INSERTED INTO THE UMBILICAL ARTERY IN ORDER TO REACH THE BIFURCATION OF THE AORTA, THE DIAPHRAGM, OR THE AORTIC VALVES VERSUS THE TOTAL BODY LENGTH OF AN INFANT

From Dunn PM. *Arch Dis Child* 1966;41:71

APPENDIX J-1B: THE LENGTH OF CATHETER INSERTED INTO THE UMBILICAL VEIN IN ORDER TO REACH THE DIAPHRAGM (X) AND THE LEFT ATRIUM (O) VERSUS THE SHOULDER—UMBILICUS LENGTH OF AN INFANT

From Dunn PM. *Arch Dis Child* 1966;41:71

APPENDIX J-1C: ESTIMATES OF INSERTIONAL LENGTH OF UMBILICAL CATHETERS BASED ON BIRTH WEIGHT, WITH 95% CONFIDENCE INTERVALS

Umbilical artery catheter tip inserted between T6 and T10; umbilical vein catheter tip inserted above diaphragm in inferior vena cava near the right atrium. Modified estimating equations using birth weight (BW) are as follows: umbilical artery length = $2.5 \times BW + 9.7$ (top) and umbilical vein length = $1.5 \times BW + 5.6$ (bottom), where BW is measured in kilograms and lengths in centimeters.

From Shukla H, Ferrara A. *Am J Dis Child* 1986;140:786.

2. DETERMINING ENDOTRACHEAL TUBE SIZE

APPENDIX J-2: ENDOTRACHEAL TUBE SIZE

Infant weight (g)	Tube Diameter	
	Inside	Outside
<1000	2.5 mm	12 Fr
1000-1500	3 mm	14 Fr
1500-2200	3.5 mm	16 Fr
2200+	4 mm	18 Fr

Color Plate

A

B

C

D

E

Cyanosis. A. Generalized cyanosis due to total anomalous pulmonary venous return with an oxygen saturation level of 80%. **B.** Perioral cyanosis. The mucous membranes and area over the chest remain pink in the presence of mild cyanosis above the lips. Petechiae make the forehead area appear blue. **C.** Lips appear blue from normal pigment deposition in vermillion border but the mucous membranes are pink. **D.** Acrocyanosis in the first half hour of life in a 32-week infant. **E.** Cyanosis localized to the abdominal wall. The blue color is caused by meconium peritonitis after an intrauterine bowel perforation. If peritoneal meconium is of long enough standing, a flat plat of the abdomen would show calcifications.

Figure 5-3 This image of an infant with ROP demonstrates the wide-field imaging capability of the RetCamII. (See black and white figure)

Figure 13-3 Surgical isolation of the fetal trachea prior to placement of hemoclips in a tracheal occlusion procedure for congenital diaphragmatic hernia. (See black and white figure)

Figure 13-5 Sacrococcygeal teratoma in a fetus. (See black and white figure)

Figure 33-15 A: Echocardiographic apical four-chamber view in systole. Color Doppler analysis of the right heart demonstrates a jet of tricuspid regurgitation depicted by the blue flow jet (white arrow). (See black and white figure)

Figure 33-39 Echocardiogram 4 chamber view with color Doppler analysis demonstrates an apical muscular ventricular septal defect. (LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; VSD, ventricular septal defect.) (See black and white figure)

Figure 33-40 Echocardiogram 4 subcostal view with color Doppler analysis demonstrates an secundum atrial septal defect. (ASD, ventricular septal defect; LA, left atrium; RA, right atrium.) (See black and white figure)

Figure 34-1 Critical pulmonary valve stenosis. **B.** Application of color Doppler during ventricular systole demonstrates a turbulent flow jet originating at the pulmonary valve leaflets and extending into the main pulmonary artery. (See black and white figure)

Figure 34-2 Tetralogy of Fallot with absent pulmonary valve. **B.** Application of color Doppler during ventricular diastole revealing free regurgitation from the main pulmonary artery into the right ventricular outflow tract. MPA, main pulmonary artery; PV, pulmonary valve; RVOT, right ventricular outflow tract. (See black and white figure)

Figure 34-3 Ebstein's anomaly of the tricuspid valve. **B.** During ventricular diastole, color Doppler demonstrating free retrograde flow across the tricuspid valve annulus. ARV, atrialized right ventricle; LA, left atrium; LV, left ventricle; RA, right atrium; TV, tricuspid valve. (See black and white figure)

Figure 34-12 Restrictive atrial septum in a newborn with transposition of the great arteries. **A.** Two-dimensional echocardiogram with color Doppler from the subcostal window demonstrating a tiny patent foramen ovale with left to right flow across the atrial septum. **B.** Following successful balloon atrial septostomy, a wide communication now exists between the left and right atria. LA, left atrium; PFO, patent foramen ovale; RA, right atrium. (See black and white figure)

Figure 53-1 Congenital acute monocytic leukemia with skin nodules. (See black and white figure)

Figure 54-1 When the corneal diameter exceeds 11 mm in a neonate, a differential diagnosis must be considered. (See black and white figure)

neonatal jaundice [795](#)

Well being

evaluation of [260-264](#)

Werner's syndrome [1445](#)

West Nile virus 1314-1315 (includes [Lymphocytic Choriomeningitis Virus](#) and [West Nile Virus](#))

Weyers oligodactyly syndrome [1677](#)

WHIM syndrome [1206](#)

WHIM (warts, hypogammaglobulinemia, infections, myelokathexis) syndrome [1207](#)

White blood cell counts [1705](#)

White-out lungs [1288](#)

White spots [1497](#)

Williams-Beuren syndrome [636](#)

Williams syndrome [141](#) [1682](#)

associated with congenital heart disease [717](#)

cardiac disease [635](#)

hypercalcemia [864](#)

Wilms tumor [1451-1452](#)

Wiskott-Aldrich syndrome [1206](#) [1207](#)

Withdrawal reflex
examination [348](#)

Withdrawing [13-14](#)

Withholding [13-14](#)

Wnt-4 [915](#)

Wolfe syndrome [637](#)

Wolffian duct [1067](#)

Wolff-Parkinson-White syndrome

atrioventricular reciprocating tachycardia [702-703](#)

following congenital heart surgery [741](#)

Wolf-Hirschhorn syndrome

associated with congenital heart disease [717](#)

Wolf-Parkinson-White syndrome 638 (includes [Etiology](#) and [Fetal Cardiology](#))

Wolman disease

with liver disease [960](#)

Wrist

physical examination [1428](#)

X

Xanax

fetal effects [242](#)

Xanthinuria [1028](#)

Xeroderma pigmentosum [1445](#)

X-linked hypophosphatemia [1036](#)

X-linked recessive inheritance severe combined immunodeficiency syndrome (X-SCID) [197-198](#)

Y

Yellow orange lesions [1503-1504](#)

Yolk sac tumors [1453-1454](#)

Z

4Z, 15E bilirubin isomer [831](#) [831](#)

Zalcitabine [1319](#)

pregnancy [1320](#)

teratogenic potential [1319](#)

Zellweger syndrome [637](#) [974](#) [975](#) [1681](#)

abnormal eye findings [976–977](#)

with liver disease [960](#)

Zidovudine [1319](#) [1321](#) [1322](#)

active transport [153](#)

placental transport [153](#)

pregnancy [1320](#)

Zinc

absorption [942](#)

maternal nutrition [205–206](#)
