The development of a postoperative chylothorax is a relatively infrequent complication (approximately 1%) following congenital heart surgery, but when it occurs it adds morbidity and prolongs hospitalization (322). A chylothorax may develop following thoracic duct injury, and elevated systemic venous pressures or thrombosis of the subclavian veins may exacerbate the condition (323,324). The diagnosis is confirmed by finding elevated triglyceride levels and lymphocyte counts in fluid drained from the pleural cavity (325). Treatment strategies initiate with chest tube drainage and dietary modification with a medium chain triglyceride (MCT) based formula, although many weeks may be required for drainage to stop (325). Prolonged drainage may lead to depletion of plasma proteins (albumin, coagulation factors, immunoglobulins) and lymphocytes, and consideration should be given to replacement with albumin, fresh frozen plasma, and/or intravenous immunoglobulins (IVIG) (323,326). A trial of total parenteral nutrition is warranted for infants not responding to a MCT formula (323). A small randomized animal model and several human case reports and series suggest that chylous drainage may be decreased using medications that decrease splanchnic blood and lymph flow, including somatostatin or octreotide (a synthetic somatostatin analogue) (324,327-331). Surgical options for patients with refractory chylothoraces include thoracic duct ligation, pleuroperitoneal shunt or pleurodesis (325,332,333).

Gastrointestinal Complications

Feeding problems are common in neonates following congenital heart surgery. Many of these patients never had the opportunity to learn to suck and swallow before surgery, and had prolonged periods of oral-tracheal intubation. Nasogastric feedings may be initially required, and input from a speech therapist may be useful.

NEC may occur either before or after congenital heart surgery, particularly in neonates with lesions that produce diastolic runoff, such as single ventricle patients with a systemic to pulmonary artery shunt (50). Because of bowel dysfunction related to anesthesia and narcotics, and the concern for NEC, total parenteral nutrition is commonly started on the first postoperative day in young infants until the intestinal motility returns.

Although significant gastrointestinal bleeding as a result of peptic ulcers or gastritis is rather uncommon following CPB in infants, histamine-2 antagonists are routinely administered until enteral feeding has been established.

Infectious Complications

A variety of factors predispose infants to infection following cardiac surgery. CPB generates a complex pro- and antiinflammatory response; the latter contributes to a generalized state of immunosuppression (334,335). Neonates in particular may have prolonged pre and postoperative ICU stays following cardiac surgery, during which they are exposed to a variety of indwelling catheters and tubes that predispose to infection. The risk of catheter-related blood stream infection in children increases with the number of central lines used, the duration of catheter use, and the use of ECMO (336). Guidelines for the prevention and management of catheter related infections in children have recently been published (337,338). Prophylactic antibiotics that provide coverage for gram-positive organisms (e.g., a first generation cephalosporin) are administered in the early postoperative period, generally until all of the chest tubes are removed from the patient (339).

The use of delayed sternal closure may be a risk factor for bacterial infections. In a series of children who had delayed sternal closure, the vast majority of whom were infants, the reported incidences are 1% to 7% for surgical site infection, and 0% to 4% for mediastinitis (189,190). Treatment of mediastinitis includes surgical debridement and prolonged parenteral antibiotics.

Renal Insufficiency

CPB is associated with significant fluid retention in infants, and the problem is usually exacerbated by a decline in urine output in the first 12 to 24 hours following surgery. Loop diuretics are used to improve urine output in the early postoperative period. A continuous infusion of furosemide may provide a gentler diuresis in those patients with labile hemodynamics. Spironolactone may be useful for its potassium sparing effect if the enteral route of administration is available.

Significant renal insufficiency may occur in infants with prolonged CPB times or as a result of low cardiac output in the early postoperative period (207). The development of overt renal failure requiring dialysis is associated with 40% to 60% risk of mortality (340,341). Renal perfusion pressure may be calculated by the following equation: renal perfusion pressure = mean arterial pressure—central venous pressure. In general, a renal perfusion pressure of 40 to 50 mmHg in infants is required to maintain urine output. Some surgeons electively place temporary peritoneal dialysis catheters at the time of complex cardiac surgery in infants to allow drainage of postoperative ascites and minimize external compression on the renal veins. Peritoneal dialysis may be performed if needed. Renal function usually recovers following the improvement in cardiac output (340).

Neurologic Complications

Several preoperative, intraoperative, and postoperative factors may contribute to suboptimal neurologic outcomes

P.747

following cardiac surgery in infancy. Recent reports demonstrate that preoperative neurological abnormalities may be detected on physical examination and brain MRI in some term neonates with congenital heart disease who otherwise had no known risk factors for neurologic injury (342,343).

The use of CPB may result in the embolization of gas bubbles or thrombus, which may contribute to the development of seizures, infarcts, periventricular leukomalacia, and intracranial hemorrhage (343,344). The use

of deep hypothermic circulatory arrest (DHCA) for complex neonatal arch reconstruction has been practiced since the 1960s. Data from the 1990s suggests that the use of longer periods of circulatory arrest, when compared to low flow CPB, is associated with an increased incidence of early postoperative seizures (176,345). Both early postoperative seizures and longer circulatory arrest times are associated with neurological deficits following the arterial switch and Norwood operations (346,347,348,349,350,351). In order to minimize neurologic injury related to the use of circulatory arrest, several centers have recently reported the use of regional low-flow perfusion for complex aortic arch reconstructions (4,130,352,353). Concurrently, however, there have been many advances in the pH and hematocrit strategies used in circulatory arrest that appear to minimize adverse neurologic sequelae (354,355,356). For example, the incidence of early postoperative clinical seizures following DHCA has decreased dramatically in patients from the current era (2%) as compared to the cohort reported in the 1988-1992 Boston Circulatory Arrest Study (8%) (176,344). Thus it is unclear whether neurological outcomes will be improved using regional perfusion techniques rather than DHCA.

Infants may have additional hypotensive or hypoxic episodes in the intensive care unit following surgery. These postoperative events may exacerbate neurologic insults that occurred prior to or during surgery. Infants with a longer postoperative length of stay appear to have a worse cognitive outcome when assessed at 8 years of age (357).

Early Postoperative Physiology and Management: Specific Lesions

Palliation of the Neonate with a Single Ventricle

Neonates who have cardiac anatomy unsuitable for a two ventricular repair typically have atresia or significant hypoplasia of either of the atrioventricular valves, and/or significant hypoplasia of either ventricle (358). The majority of neonates with single ventricle physiology will eventually undergo Fontan completion as toddlers. Because the Fontan circulation is characterized by passive pulmonary blood flow, this physiology is dependent on low pulmonary artery pressure, and the absence of pulmonary artery distortion, pulmonary venous obstruction, atrioventricular valve regurgitation and ventricular hypertrophy. These requirements dictate the surgical strategy in the newborn period (358). To limit ventricular hypertrophy, unobstructed systemic blood flow must exist, and if not present at birth, may be achieved using either a Norwood operation or Damus-Kaye-Stansel procedure. Pulmonary blood flow must be tightly regulated to prevent ventricular volume overload, atrioventricular valve regurgitation and pulmonary artery hypertension. This usually requires the placement of a Blalock-Taussig shunt or pulmonary artery band. Care must be taken with both of these procedures to minimize pulmonary artery distortion. Finally, pulmonary venous return must not be obstructed, as this may cause pulmonary artery hypertension. An atrial septectomy is required in some neonates, as is done during the Norwood operation.

Systemic to Pulmonary Artery Shunt

The most common type of systemic to pulmonary artery shunt operation refers to a procedure in which a Gore-Tex™ tube graft is surgically placed between the subclavian or innominate artery and the pulmonary artery, typically without the use of CPB. This operation, also known as the modified Blalock-Taussig shunt, is widely used as the operation of choice to palliate infants with single ventricle physiology and decreased pulmonary blood flow (Fig. 34-15). The operation is also used in selected infants with two-ventricular physiology and obstructed pulmonary blood flow whose complete repair will be deferred. A systemic to pulmonary artery shunt may be performed in isolation or as a part of a larger procedure, such as the Norwood operation for HLHS. In a retrospective, nonrandomized study, Odum and associates reported that performance of the modified Blalock-Taussig operation via a midline sternotomy was technically easier, and was associated with a lower rate of shunt failure when compared with a classic thoracotomy approach (359).

P.748

Another type of systemic to pulmonary artery shunt is a central shunt, which involves the placement of a Gore-Tex™ tube between the ascending aorta and pulmonary artery. A central shunt is typically placed only when anatomical issues preclude a modified Blalock-Taussig shunt. Several postoperative complications may occur following the placement of a systemic to pulmonary artery shunt. If the shunt is too large, the systemic ventricle will be subjected to volume overload and congestive heart failure may develop. In patients with single ventricle physiology, elevated pulmonary vascular resistance may exist with the large shunt that may complicate future staging operations. A small shunt will result in excessive postoperative cyanosis. The average shunt diameter is 3.5 mm for a term infant. Distortion or scarring of the pulmonary arteries may also develop at the shunt

insertion site. Thrombosis of the shunt is a dreaded postoperative complication that results in the rapid development of severe cyanosis. Most infants are started on aspirin once their chest tubes and lines have been removed. Reported neurologic complications with this shunt include Horner's syndrome, recurrent laryngeal nerve injury, and phrenic nerve injury (359).

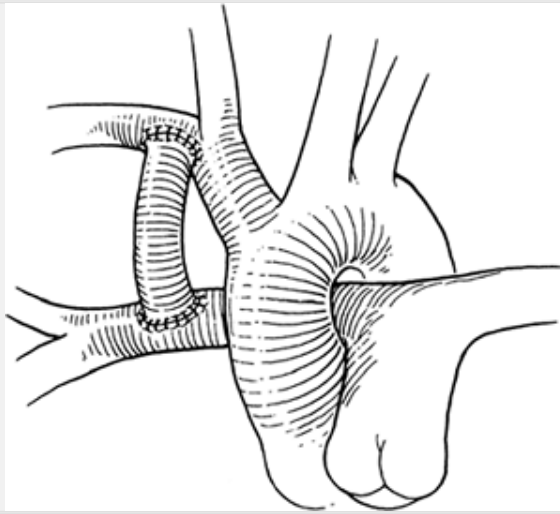

Figure 34-15 The modified Blalock-Taussig shunt operation. Reprinted from Wernovsky G, Bove EL. Single ventricle lesions. In: Chang A, Hanley FL, Wernovsky G, et al., editors. *Pediatric cardiac intensive care*. Baltimore: Williams and Wilkins, 1998:271-287, with permission.

Pulmonary Artery Band

In selected infants with single ventricular physiology and unobstructed pulmonary and systemic blood flow, or occasionally in infants with two-ventricular physiology and pulmonary overcirculation, a restrictive band is placed on the main pulmonary artery to decrease Q_p/Q_s and thus limit symptoms of congestive heart failure, the adverse effects of volume loading on the ventricle(s), and the development of pulmonary vascular obstructive disease (Fig. 34-16). CPB is not required for this procedure. It would be inappropriate to place a pulmonary artery band in an infant who has, or is likely to develop, systemic outflow tract obstruction, as the resultant "doubly obstructed" physiology will lead to the rapid development of ventricular hypertrophy. Placement of a pulmonary artery band, although conceptually simple, requires a great deal of surgical judgment. If the band is placed in an infant with high pulmonary vascular resistance, the patient's systemic oxygen saturation in the operating room may indicate a well-balanced circulation (saturation approximately 80%). However, as the pulmonary vascular resistance falls over the coming weeks, pulmonary blood flow may increase, systemic oxygen saturation will rise, and signs of congestive heart failure will develop. If the pulmonary artery band migrates distally on the main pulmonary artery, distortion of the branch pulmonary arteries may develop, which would have to be corrected before or during the bi-directional Glenn/hemi-Fontan operation. The band is removed at the time of complete surgical repair or subsequent palliation.

Damus-Kaye-Stansel Procedure

In children with single ventricular physiology and subaortic stenosis with or without distal aortic arch obstruction, a Damus-Kaye-Stansel palliation may be performed to provide unobstructed systemic blood flow. This procedure involves anastomosis of the proximal main pulmonary artery and ascending aorta, and aortic arch reconstruction if needed. The distal main pulmonary artery is over sewn and a modified Blalock-Taussig shunt is placed to provide pulmonary blood flow. The postoperative physiology and complications are similar to those seen following the Norwood operation, which are discussed in detail below.

Figure 34-16 Pulmonary artery band. Reprinted from Wernovsky G, Bove EL. Single ventricle lesions. In: Chang A, Hanley FL, Wernovsky G, et al., editors. *Pediatric cardiac intensive care*. Baltimore: Williams and Wilkins, 1998:271-287, with permission.

Bi-directional Glenn or Hemi-Fontan Operation

The bi-directional Glenn or hemi-Fontan operation involves redirection of the superior vena cava blood flow to both pulmonary arteries (Fig. 34-17). One of these two operations is commonly performed in infants with single ventricle physiology before or at approximately six months of age, in anticipation of a Fontan completion, which is typically done at 2 to 3 years of age (360). Because passive pulmonary blood flow is present following these operations, they cannot be performed when pulmonary vascular resistance is high as in the newborn period (361). The benefits of performing a bidirectional Glenn/hemi-Fontan operation as an intermediate staging procedure before Fontan completion include volume-unloading of the single ventricle, decreased atrioventricular valve regurgitation, and improved systemic oxygen saturation, and decreased

P.749

pleural effusions and mortality following the Fontan completion (360,362-364).

Figure 34-17 Bi-directional Glenn operation. Reprinted from Wernovsky G, Bove EL. Single ventricle lesions. In: Chang A, Hanley FL, Wernovsky G, et al., editors. *Pediatric cardiac intensive care*. Baltimore: Williams and Wilkins, 1998:271-287, with permission.

The bi-directional Glenn operation, also known as the bi-directional cavopulmonary shunt operation, involves an

end-to-side anastomosis between the superior vena cava and the pulmonary artery. The term "bi-directional" refers to the fact that blood from the superior vena cava perfuses both the left and right pulmonary arteries. The hemi-Fontan operation involves the end-to-side anastomosis between the superior vena cava and the pulmonary artery as described above, but in addition, the proximal superior vena cava is anastomosed to the inferior surface of the pulmonary artery, and a patch is placed at the junction of the superior vena cava and the right atrium. The functional result of this operation is the same as the bi-directional Glenn operation, but it makes the completion Fontan operation simpler if the surgeon ultimately uses a lateral tunnel type of Fontan. There may be an increase risk of sinus node dysfunction following the hemi-Fontan operation related to surgical manipulation. Surgeons that complete the Fontan using an extracardiac conduit perform the bi-directional Glenn shunt as a staging procedure. Any central pulmonary artery stenosis is addressed during the bi-directional Glenn operation.

The bi-directional Glenn operation is associated with minimal morbidity or mortality, and most infants have an unremarkable postoperative course (361,362). Superior vena cava syndrome, identified by the presence of cerebral and upper extremity venous congestion, may develop related to increased pulmonary vascular resistance, and therapies to reduce pulmonary vascular resistance should then be applied. Infants who are 2 to 3 months of age may have significant cyanosis immediately following the bi-directional Glenn/hemi-Fontan, which usually improves in 24 to 48 hours (360). The evaluation and management of the postoperative bi-directional Glenn/hemi-Fontan patient with excessive hypoxemia is discussed in detail in the previous section on cyanosis.

Fontan completion is generally performed at approximately two years of age. During this operation, the inferior vena cava blood is channeled directly to the pulmonary arteries using several different techniques, functionally bypassing the heart, and thus separating the systemic and pulmonary circulations and essentially eliminating cyanosis. Factors that have been associated with a good outcome following the Fontan operation include low pulmonary vascular resistance, undistorted pulmonary arteries and unobstructed pulmonary veins, and the absence of significant atrioventricular valve regurgitation or ventricular hypertrophy. These factors are greatly influenced by decision making in the neonatal period, as discussed earlier. As this chapter pertains to infancy, the Fontan operation will not be discussed further.

Right Ventricular Outflow Tract Obstruction

Critical Pulmonary Valve Stenosis

The initial intervention in neonates with isolated critical pulmonary valve stenosis is usually a balloon valvuloplasty, performed in the cardiac catheterization laboratory. Infants with critical pulmonary valve stenosis may have very poor right ventricular compliance following balloon valvuloplasty, perhaps related to myocardial ischemia and endocardial fibroelastosis (54). Rather than fill the right ventricle, some systemic venous blood will cross the foramen ovale to the left atrium, resulting in significant cyanosis. To ensure adequate pulmonary blood flow following the procedure, these infants may require several days of a PGE1 infusion (56,57). Occasionally a systemic to pulmonary artery shunt will be required until right ventricular compliance improves (54,59). Placement of a stent in the ductus arteriosus during cardiac catheterization is an alternative. The systemic to pulmonary artery shunt or the stented ductus arteriosus can then be coil embolized or surgically removed at a later date, once the right ventricular compliance has improved. These infants are also at risk for developing infundibular spasm ("suicide right ventricle") following balloon valvuloplasty that manifests as cyanosis and low cardiac output (365). Volume expansion and beta-blockers are the initial treatments should infundibular spasm occur.

Tetralogy of Fallot

Surgical repair of tetralogy of Fallot includes closure of the VSD(s), and reduction or elimination of obstruction to blood flow across the right ventricular outflow tract and pulmonary

P.750

arteries. Accomplishing this often involves resection of muscle bundles in the right ventricular outflow tract, a pulmonary valvotomy or leaflet resection, and patch augmentation of the proximal pulmonary arteries. In those infants with favorable anatomy, the operation may be accomplished using a transatrial-transpulmonary approach. However, right ventriculotomy with transannular patch is required in some cases to enlarge the right ventricular outflow tract. In infants with tetralogy of Fallot and pulmonary atresia, a ventriculotomy is required if a complete repair is performed using a right ventricle to pulmonary artery conduit.

Right ventricular function and compliance are abnormal following complete repair of tetralogy of Fallot. This is attributable in part to right ventricular hypertrophy that was present prior to surgery, and also to right ventricular myocardial injury related to the subpulmonic resection and VSD closure. Pulmonary regurgitation, if present, will exacerbate the right heart failure. Some surgeons leave the foramen ovale patent so that the right heart may decompress into the left atrium, thus maintaining systemic cardiac output at the expense of mild cyanosis. If the surgeon closed the atrial septum in the operating room, and significant right heart failure exists in the early postoperative period, an atrial communication may be created in the cardiac catheterization laboratory. Inotropic support of the right ventricle is commonly required immediately following surgery, and low dose dopamine and milrinone are commonly used in this regard. Strategies to maintain low pulmonary vascular resistance should be employed. JET is a common rhythm disturbance seen following tetralogy of Fallot repair (242). Following complete repair of tetralogy of Fallot, residual lesions that may complicate the postoperative course include a VSD, right ventricular outflow tract obstruction, and pulmonary artery stenosis.

Neonates with tetralogy of Fallot and significant preoperative cyanosis who have a palliative systemic to pulmonary artery shunt placed may be well saturated but develop congestive heart failure in the postoperative period. The pulmonary blood flow from the shunt plus the native flow across the right ventricular outflow tract may be excessive.

Surgical repair for tetralogy of Fallot with absent pulmonary valve syndrome includes a reduction pulmonary arterioplasty, VSD closure and placement of a valved homograft in the right ventricular outflow tract (317). Replacement of the dilated central pulmonary arteries with bifurcated valved pulmonary homograft is a surgical modification that has been associated in one report with improved survival in neonates who present with respiratory distress (366). A more recently described surgical approach includes translocation of the pulmonary artery anterior to the aorta (Lecompte maneuver) and away from the tracheobronchial tree (367). In addition to the aforementioned issues following tetralogy of Fallot repair, the postoperative course for infants with absent pulmonary valve syndrome may be significantly complicated by airway obstruction as a result of tracheobronchomalacia that persists even after plication and reduction of the aneurysmal pulmonary arteries (317,368). Case reports suggest that those with refractory tracheobronchomalacia may improve with metallic stenting of the central airways (317). Some of these infants will require a tracheostomy and long-term positive-pressure ventilation until they "outgrow" the malacia.

Pulmonary Atresia, Ventricular Septal Defect, Major Aortopulmonary Collateral Arteries

The goal of surgical intervention in infants with pulmonary atresia, a VSD and MAPCAs is to incorporate blood vessels that supply as many lung segments as possible into the repair, while eliminating any MAPCAs that represent dual blood supply to these segments. The interventional management must be individualized depending on the pulmonary artery anatomy and often involves a series of surgical procedures and transcatheter interventions with balloon dilation of the stenotic branch pulmonary arteries. Surgical options include a staged approach involving bilateral unifocalizations followed by repair using a right ventricular to pulmonary artery conduit (369). A single stage, complete repair is advocated for many of these infants in early infancy at some centers (370). In selected infants with diminutive but confluent pulmonary arteries, a transannular patch to open the right ventricular outflow tract, placement of an right ventricle to pulmonary artery conduit, or an aortopulmonary window may be used to encourage pulmonary artery growth (371). Complete repair including VSD closure is then performed at a later date provided that the pulmonary vascular bed is adequate to accept the entire right ventricular output without the development of severe pulmonary hypertension. The VSD patch may be fenestrated in selected cases to prevent the development of postoperative suprasystemic pulmonary hypertension and right ventricular failure (372).

The postoperative course for infants with pulmonary atresia, ventricular septal defect and MAPCAs is dependent on the operative strategy. Those infants undergoing complete repair including closure of the VSD and placement of a conduit from the right ventricle to the pulmonary artery are at risk for right ventricular failure, secondary to the VSD closure, right ventricular outflow tract muscle bundle resection, ventriculotomy required for conduit placement, and branch pulmonary stenosis. Often the VSD patch is fenestrated, or a foramen ovale is left patent in these patients, which leads to mild postoperative cyanosis, but serves to decompress the right heart and preserve systemic cardiac output (372). Congestive heart failure may persist in the postoperative period if all of the MAPCAs were not incorporated into the repair. Following unifocalization procedures, severe airflow limitation may occur secondary to tracheobronchial ischemia, which may originate from interruption of peribronchial arterial blood supply during mobilization of MAPCAs (321). The intermediate term prognosis is

and right ventricular failure (66). Serial cardiac catheterizations with balloon angioplasty of the pulmonary arteries are required for many patients.

Pulmonary Atresia with Intact Ventricular Septum

The postoperative course for infants with pulmonary atresia and intact ventricular septum is highly dependent upon the operation or transcatheter procedure performed. Neonates undergoing a two-ventricular repair may have poor right ventricular compliance, right to left shunting at the foramen and subsequent cyanosis, similar to that seen following repair of tetralogy of Fallot. Those with "right ventricular dependent coronary circulation" may have problems with myocardial ischemia following a systemic to pulmonary artery shunt, even though the right ventricle was not decompressed.

Ebstein's Anomaly of the Tricuspid Valve

Neonates with Ebstein's anomaly who require early surgical intervention are at high risk for mortality as a result of pulmonary hypoplasia, pulmonary hypertension and right heart failure. Surgical options for neonates with refractory symptoms include a primary complete repair, consisting of a reduction atrioplasty, fenestrated closure of the atrial septum and tricuspid valvuloplasty (73). Another approach is to stage the patient toward Fontan palliation with a systemic to pulmonary artery shunt, over sewing of the tricuspid valve annulus and atrial septectomy (74,75). Regardless of the surgical procedure, infants recovering from surgery for Ebstein's anomaly are likely to have problems with pulmonary hypertension related in part to pulmonary hypoplasia. In addition to the usual strategies used to treat pulmonary hypertension, care should be taken to ensure that excessive positive airway pressure is not used to attempt to expand lungs, which may appear small on chest radiograph. Overdistension of the hypoplastic lungs will only lead to further increases in pulmonary vascular resistance. Residual tricuspid regurgitation and right heart failure may also complicate the postoperative course. Atrioventricular reentry tachycardia may occur at any time before or after surgery.

Left Ventricular Outflow Tract Obstruction

Critical Aortic Valve Stenosis

Following the alleviation of critical aortic valve stenosis, either by surgical valvotomy or balloon valvuloplasty, most infants will have a marked improvement in clinical status with recovery of left ventricular function. Note that the gradient across the aortic valve may be minimal immediately following intervention, but will often increase as myocardial function and cardiac output improve. Inotropic support is often required for a few days following the procedure. The PGE₁ infusion may be discontinued once left to right flow is seen at the ductal level by echocardiography. A small number of infants will do poorly in the postoperative period, as a result of inadequate size of left heart structures or extensive endocardial fibroelastosis. Such patients may require a Norwood palliation, but historically, infants who had a failed attempt at a two-ventricular repair and subsequent attempted Norwood operation have a high mortality (373).

Critical Coarctation of the Aorta

Several operative techniques are available for coarctation repair, including resection with end-to-end anastomoses, patch aortoplasty, subclavian flap aortoplasty. Resection and extended end-to-end anastomosis is a technique that also addresses aortic arch hypoplasia and appears to be associated with a low recoarctation rate (374,375). Due to a significant recoarctation rate and the potential for aneurysm formation, primary balloon angioplasty is generally not recommended in infancy at most congenital heart centers (376,377).

Following repair of an isolated critical coarctation of the aorta, accurate four extremity blood pressure measurements must be obtained to evaluate for the presence of residual aortic arch obstruction. A residual arm-leg blood pressure gradient may be secondary to an inadequate repair, hypoplasia of the aortic arch, or constriction of residual ductal tissue. If a residual coarctation exists, the timing of intervention depends upon the clinical course. Infants who have adequate left ventricular function and who are easily weaned from support may return in 2 to 3 months, after the suture lines have healed, for cardiac catheterization and possible balloon

dilation of the obstruction. Those who are unable to be weaned from the ventilator require another procedure during the same hospitalization. Infants who presented in shock may be at risk for mesenteric ischemia and enteral feedings are withheld in the early postoperative period. Infants appear to be at much lower risk for spinal cord ischemia or significant postoperative hypertension following coarctation repair when compared with older children and adults. As with any surgical intervention on the aortic arch, the phrenic and recurrent laryngeal nerves are at risk for injury during coarctation repair.

Hypoplastic Left Heart Syndrome

During the Norwood operation for HLHS, the distal pulmonary artery is over sewn, the proximal pulmonary artery and the aorta are anastomosed, and the aortic arch is reconstructed with pulmonary artery homograft material to allow for unobstructed systemic blood flow (378). An atrial septectomy is performed to allow pulmonary venous return to pass easily to the right atrium, and a modified Blalock-Taussig shunt is placed to provide pulmonary blood flow (Fig. 34-18). Thus following the Norwood operation, the single right ventricle pumps blood to the systemic circulation and coronary arteries, via the reconstructed aorta ("neoaorta"), and to the pulmonary circulation, via the systemic to pulmonary artery shunt.

Figure 34-18 Norwood operation for hypoplastic left heart syndrome. The purpose of the Norwood operation for hypoplastic left heart syndrome is to establish reliable, unobstructed outflow to the systemic circulation and to balance the systemic and pulmonary circulations. This is achieved by ligating and dividing the ductus arteriosus and detaching the central and branch pulmonary arteries from the main pulmonary artery as shown in **A**. The hypoplastic aorta is then opened from the descending aorta retrograde to the level of the aortic valve and augmented with a patch of homograft arterial wall. The augmented aorta is then connected to the cardiac end of the main pulmonary artery stump as shown in **B** and **C**. This achieves unobstructed outflow from the single right ventricle through the pulmonary valve to the aorta and systemic vascular bed. Additionally, an atrial septectomy is performed to ensure unobstructed pulmonary venous outflow, and the pulmonary circulation is supplied through the use of a right-sided modified Blalock-Taussig shunt. Reprinted from Wernovsky G, Bove EL. Single ventricle lesions. In: Chang A, Hanley FL, Wernovsky G, et al., editors. *Pediatric cardiac intensive care*. Baltimore: Williams and Wilkins, 1998:271-287, with permission.

A variety of problems may arise following the Norwood operation that often are poorly tolerated as a result of the limited physiologic reserve possessed by these infants. Excessive pulmonary blood flow with inadequate systemic perfusion, similar to that seen in a typical preoperative neonate with HLHS, may be seen but is less common than in prior years due the smaller diameter Blalock-Taussig shunts that are currently used. Others may have problems with myocardial dysfunction, pulmonary hypertension, or the systemic to pulmonary artery shunt.

Ideally, the circulations will be balanced following the Norwood operation such that the Qp/Qs ratio will be approximately 1:1. Pulmonary blood flow will be determined by the pulmonary vascular resistance and the resistance provided by the systemic to pulmonary artery shunt, assuming an unrestrictive, surgically created ASD and unobstructed pulmonary venous blood flow. Systemic blood flow will be determined by the systemic vascular resistance and if present, any residual aortic arch obstruction. The ratio of systemic and pulmonary

blood flow may be calculated by the following modified Fick equation: $Q_p/Q_s = (SaO_2 - SvO_2) / (PvO_2 - PaO_2)$, in which SaO_2 = aortic saturation; SvO_2 = mixed venous saturation (estimated by the superior vena cava oxygen saturation); PvO_2 = pulmonary venous oxygen saturation (assumed to be >95% if not directly measured); and PaO_2 > pulmonary artery oxygen saturation (assumed to equal the aortic saturation). Estimating Q_p/Q_s using only the arterial PaO_2 or SaO_2 may be misleading without knowledge of SvO_2 , estimated by the superior vena cava oxygen saturation, and PvO_2 (Fig. 34-19) (191,379-383). One study documented pulmonary venous desaturation in 11/12 infants following the Norwood operation at some point in the early postoperative period, despite the absence of radiographic abnormalities on chest radiograph (191). Many centers monitor SvO_2 following the Norwood operation, but few monitor PvO_2 . Caution must be used when using saturation data for clinical decision-making following the Norwood operation. The CXR must be carefully examined to ensure that the tips of the catheters from which blood gas samples are drawn are in the proper location. The oximetry data cannot be used in isolation and the entire clinical picture must be considered.

Signs of low cardiac output following the Norwood palliation may be attributed to pulmonary overcirculation, myocardial dysfunction, or a combination of the two. An imbalance between the systemic and pulmonary blood flows, particularly a high Q_p/Q_s , has been implicated as a major factor in the high early postoperative mortality following the Norwood operation. Such infants will have high SaO_2 , low SvO_2 , and other clinical and laboratory evidence for low cardiac output. Investigators have thus spent

P.753

considerable effort to study the cardiovascular physiology following the Norwood operation, and several interventions are available that may serve to better "balance" the pulmonary and systemic circulations. In an experimental animal model of postoperative single ventricle physiology with a systemic to pulmonary shunt, addition of carbon dioxide ($PiCO_2$) to the inspired gas resulted in increase pulmonary vascular resistance, even when systemic pH was controlled by administration of tromethamine buffer (Tham) (85). Other investigators have reported the ability to manipulate pulmonary vascular resistance, Q_p/Q_s , and oxygen delivery in single ventricle animal models by varying the inspired concentrations of oxygen or providing inhaled carbon dioxide or NO (380,384).

Figure 34-19 Regression analysis of SaO_2 against true Q_p/Q_s following the Norwood operation. SaO_2 is a poor predictor of Q_p/Q_s ($R^2 = 0.08$, $p < 0.05$). Variability in Q_p/Q_s is most pronounced at SaO_2 values in range of 65% to 85%, usual target range for patients after Norwood palliation. Reprinted from Taeed R, Schwartz SM, Pearl JM, et al. Unrecognized pulmonary venous desaturation early after Norwood palliation confounds Q_p/Q_s assessment and compromises oxygen delivery. *Circulation* 2001; 103:2699-2704, with permission.

The findings from preoperative studies in neonates and postoperative animal models that have evaluated the use of sub-ambient oxygen or inspired carbon dioxide to alter pulmonary vascular resistance should not be extrapolated to neonates recovering from the Norwood operation. Doing so would not account for several important variables, including the fixed resistance provided by the relatively small (3.5 to 4 mm) systemic to pulmonary shunts used in most Norwood operations in the current era as compared to the 6 mm shunts used in some animal models (4,380,385). Although early reports suggest that an imbalance of systemic to pulmonary blood flow may be life threatening to infants following the Norwood operation, several recent postoperative

studies suggest that supplemental oxygen or alkalosis do not have deleterious effects on the hemodynamics of most patients with Norwood physiology, presumably as a result of the fixed resistance provided by the systemic to pulmonary shunt (94,191,382,383,386,387). With the above considerations in mind, an infant recovering from the Norwood operation with signs of isolated pulmonary overcirculation (i.e., high calculated Qp/Qs, pulmonary edema on chest radiograph) should have measures taken to lower systemic vascular resistance and increase pulmonary vascular resistance. Residual aortic arch obstruction must also be excluded in this situation, as such an obstruction will limit systemic blood flow and direct more blood through the shunt.

Several recent reports suggest that myocardial dysfunction may be the dominant hemodynamic disturbance in those infants with low cardiac output following the Norwood operation (201,383,388). Tricuspid valve regurgitation may also contribute to low cardiac output. Isolated myocardial dysfunction is present when the Qp/Qs is calculated to be approximately 1:1, and the SvO₂ is low. An anaerobic threshold is reached when the SvO₂ falls below 30% following the Norwood operation, and efforts to maintain SvO₂ above this value have been associated with very low early mortality (389). Inotropic support and afterload reduction will be beneficial for such patients. A study examining the effect of various inotropic agents in an animal model of single ventricle physiology found that low-dose dopamine and epinephrine had favorable effects on Qp/Qs, and epinephrine improved oxygen delivery, whereas dobutamine increased Qp/Qs and decreased oxygen delivery (390).

The use of phenoxybenzamine, an alpha-adrenergic blocker, may address both the problems of pulmonary overcirculation and myocardial dysfunction following the Norwood operation. In a prospective, nonrandomized study, Tweddell and associates report favorable hemodynamic effects of administering phenoxybenzamine to neonates undergoing the Norwood palliation. Phenoxybenzamine produced lower systemic vascular resistance, resulting in a Qp/Qs that approached unity, and a higher SvO₂ (Fig. 34-20 and 34.21)

P.754

(382). In a retrospective study, Tweddell et al found several variables in addition to the use of phenoxybenzamine that may be associated with improved survival following the Norwood operation, including the use of a modified operative technique designed to avoid kinking of the ascending aorta, use of modified ultrafiltration and aprotinin, and postoperative continuous monitoring of SvO₂ (4). Phenoxybenzamine has a long half-life, which makes some clinicians reluctant to use the drug.

Figure 34-20 Superior vena cava saturation (SvO₂) during the first 48 hours after the Norwood procedure. The SvO₂ was significantly higher in the phenoxybenzamine group than in the control group during hours 1 to 10 and hour 25 ($p < 0.05$, RM ANOVA). Reprinted from Tweddell JS, Hoffman GM, Fedderly RT, et al. Phenoxybenzamine improves systemic oxygen delivery after the Norwood procedure. *Ann Thorac Surg* 1999;67:161-167, with permission from The Society of Thoracic Surgeons.

Figure 34-21 Pulmonary to systemic flow ratio (Qp/Qs) during the first 48 hours after the Norwood procedure. The Qp/Qs was significantly higher in the control group than in the phenoxymethamine group during hours 1 to 10, 30 to 32, and 36 ($p < 0.05$, RM ANOVA). Reprinted from Tweddell JS, Hoffman GM, Fedderly RT, et al. Phenoxymethamine improves systemic oxygen delivery after the Norwood procedure. *Ann Thorac Surg* 1999;67:161-167, with permission from The Society of Thoracic Surgeons.

Excessive desaturation may occur following the Norwood operation, and the differential diagnosis and management strategies are discussed previously in the postoperative cyanosis section. One particular cause for cyanosis following the Norwood operation is inadequate surgical resection of the atrial septum. The septum primum is often displaced posteriorly and to the left. If it is not completely resected, pulmonary venous obstruction may occur.

Recent interest has developed in a surgical variant of the Norwood operation, commonly known as the "Sano modification" (391). In this operation, a right ventricular to pulmonary artery conduit instead of a systemic to pulmonary artery shunt is used to provide pulmonary blood flow, which may improve myocardial function by increasing diastolic blood pressure and thus coronary perfusion pressure (352,392). The postoperative physiology following the Sano modification is somewhat different from the standard Norwood operation and deserves comment. Due to the absence of diastolic runoff through a Blalock-Taussig shunt, infants with "Sano physiology" do not have pulmonary overcirculation (or a large Qp/Qs) and thus, in contrast to patients with typical "Norwood physiology," usually will not benefit from aggressive afterload reduction. In fact, excessive systemic vasodilation may be harmful by creating inadequate pulmonary blood flow and severe cyanosis, similar to the physiology of a patient with unrepaired tetralogy of Fallot. Early, nonrandomized reports suggest that the Sano modification may improve early survival following stage I palliation of HLHS (391,393). Risks related to this modification center upon the effects of performing a ventriculotomy in an infant with a single right ventricle, and include myocardial dysfunction, arrhythmias, and false aneurysm formation. A multicenter, randomized, clinical trial is planned to compare outcomes following the Sano modification with the standard Norwood operation.

Interrupted Aortic Arch

Complete repair, including VSD closure and reconstruction of the aortic arch, is the preferred operation for newborns with IAA (101). If significant subaortic stenosis is present, a Norwood-type operation may be used to stage the patient for a later biventricular repair (394). Following IAA repair, one must ensure that a residual VSD, sub-aortic obstruction, or aortic arch obstruction does not exist (101,395). Patients with respiratory compromise may have compression of the left mainstem bronchus by the reconstructed aortic arch. Complications related to DiGeorge syndrome, such as hypocalcemia and infection, may also occur.

Mixing Lesions

Transposition of the Great Arteries

In neonates with TGA and no significant outflow tract obstruction, the arterial switch operation is performed and the VSD, if present, is closed (1). The arterial switch operation involves transecting the aorta and pulmonary arteries above the semilunar valves, and anastomosing the aorta to the neo-aortic root, such that the left ventricle ejects into the systemic circulation (1). The pulmonary artery is brought anterior to the aorta such that its branches drape over the aorta (Lecompte maneuver), and the pulmonary artery is anastomosed such that it receives blood from the right ventricular outflow tract. The coronary arteries are mobilized with a button of tissue around the ostia and reimplanted into the neo-aorta. The VSD (if present) is closed (Fig. 34-22). If significant right ventricular outflow tract obstruction is present in TGA, a Damus-Kaye-Stansel procedure may be performed as an initial palliation, or as a part of the complete repair including closure of the VSD and placement of a right ventricle to pulmonary artery conduit. If significant left ventricular outflow tract obstruction exists, the classic surgical repair is the Rastelli procedure, which involves using a baffle to close the VSD to the aorta and placement a right ventricle to pulmonary artery conduit (396). Other options that do not require a conduit include the Nikaidoh operation (aortic root translocation into the surgically enlarged left ventricular outflow tract, VSD closure, and right ventricular outflow tract reconstruction) or the Réparation à l'Etage ventriculaire ("REV procedure;" involving infundibular resection to enlarge the VSD,

P.755

baffle closure of the VSD directing left ventricular flow to the aorta, the Lecompte maneuver, and right ventricular to pulmonary artery connection using a patch) (397,398).

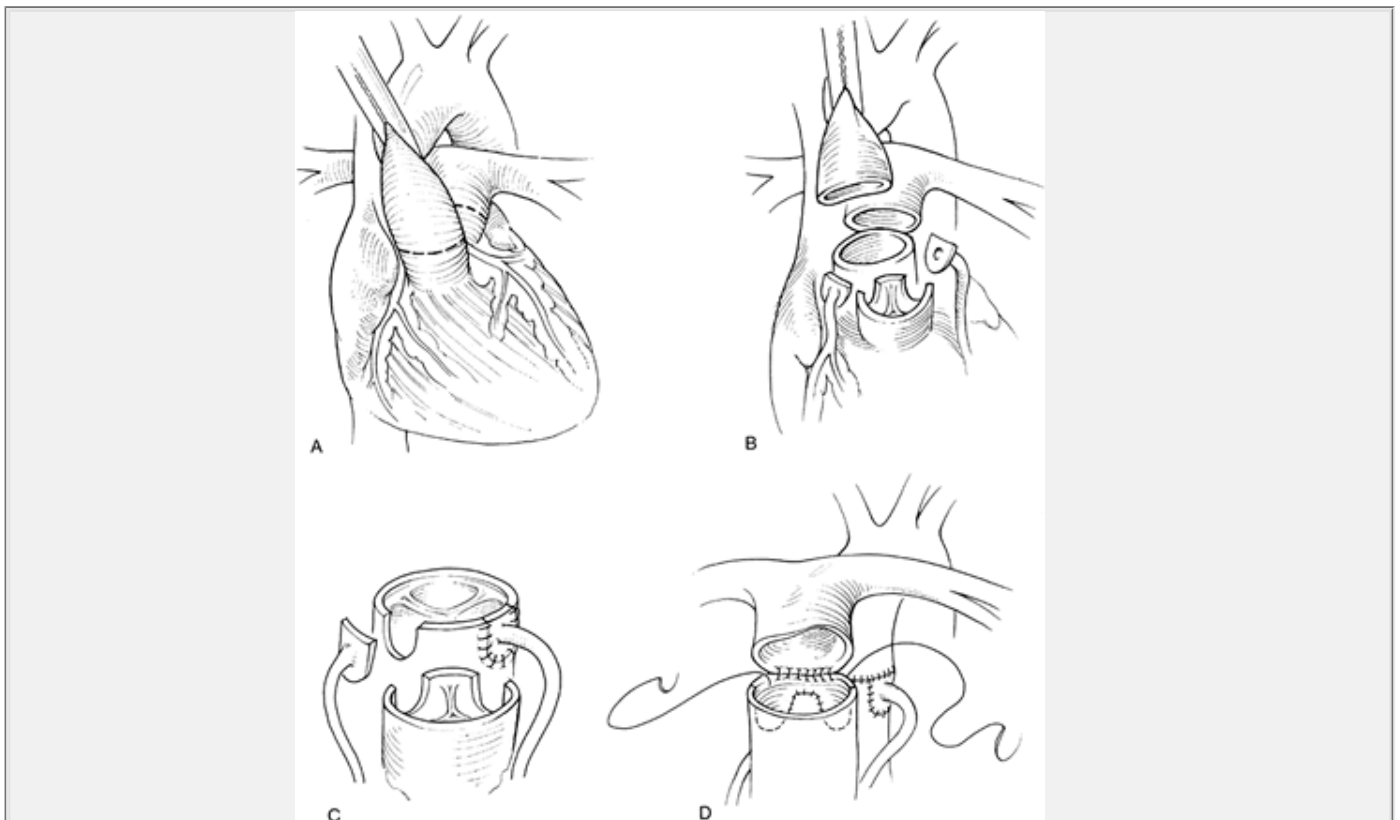

Figure 34-22 Arterial switch operation for transposition of the great arteries (TGA). **A.** The external anatomy is shown. The procedure is performed using cardiopulmonary bypass and either moderate or deep hypothermia with or without circulatory arrest. The broken lines show the sites of transection of the two great vessels. The aorta and main pulmonary arteries have been surgically transected and the coronary ostia have been removed from the native aortic root. The coronary buttons are in the process of being transferred to the native aortic root. The coronary transfer has been completed and the neo-aortic root has been anastomosed to the ascending aorta. The coronary explantation sites on the neopulmonary root have been repaired with a patch and the neopulmonary artery is in the process of anastomosis to the distal pulmonary artery. Note, the distal pulmonary artery has been moved anterior to the ascending aorta as described by Lecompte. The procedure also involves closing the atrial septal defect and dividing the patent ductus arteriosus. Reprinted from Wernovsky G, Jonas RA. Other conotruncal lesions. In: Chang A, Hanley FL, Wernovsky G, et al., editors. *Pediatric cardiac intensive care*. Baltimore: Williams and Wilkins, 1998:289-301, with permission.

The expected mortality for the arterial switch operation is very low (399), and many infants will have an unremarkable postoperative course. A period of early low cardiac output has been documented in approximately

25% of these patients (140). Problems with coronary ischemia may occur if there is kinking or stenosis of a coronary artery following reimplantation into the neo-aorta. Volume overload in the immediate postoperative period can cause cardiac distension that stretches the newly implanted coronary arteries, resulting in myocardial ischemia and/or infarction. Coronary insufficiency may manifest as low cardiac output with ischemic electrocardiographic changes or ventricular arrhythmias. Significant obstruction of the aortic or pulmonary anastomosis is unusual in the early postoperative period. Residual VSDs and ventricular outflow obstruction can be problematic in complex cases.

Infants with TGA and intact ventricular septum who are referred after 1 to 2 months of age for the arterial switch operation often require placement of a pulmonary artery band to "prepare" the left ventricle before the arterial switch operation (400). A systemic to pulmonary artery

P.756

shunt is also placed at the time of the pulmonary artery band to ensure adequate pulmonary blood flow. These patients are often critically ill following this operation with biventricular failure (right ventricular failure as a result of the acute volume overload created by the shunt and left ventricular failure related to the acute increase in afterload from the pulmonary artery band) and low cardiac output (400,401). Inotropic support and measures to decrease pulmonary overcirculation are often required for several days until the hemodynamics stabilize. Once the left ventricle is prepared, the patient is returned to the operating room, in which the systemic to pulmonary artery shunt and pulmonary band are removed and the arterial switch operation is performed.

Tricuspid Atresia

The postoperative course following palliation for tricuspid atresia depends upon the operation performed. Infants who require surgery in early infancy will have either a systemic to pulmonary artery shunt or a pulmonary artery band, and the complications associated with these procedures were described earlier. Infants with tricuspid atresia and TGA often require a Damus-Kaye-Stansel procedure, and the postoperative problems are similar to those seen following the Norwood operation as described above. A bi-directional Glenn or hemi-Fontan operation is then performed at around six months of life, and the postoperative course for these operations is also discussed earlier in the chapter.

Total Anomalous Pulmonary Venous Return

In infants with supracardiac and infracardiac total anomalous pulmonary venous return, the pulmonary venous confluence is anastomosed to the back of the left atrium using circulatory arrest, the primitive vertical vein is ligated, and the ASD is closed. If the pulmonary veins drain to the coronary sinus, surgical intervention involves unroofing of the coronary sinus, and closure of the ASD.

Following repair of TAPVR, infants may be predisposed to pulmonary hypertensive crises or persistent pulmonary vein obstruction, in part related to abnormal muscularity of the pulmonary arteries and veins which develops in utero (106,402,403). Pulmonary edema and poor lung compliance may be seen in infants whose pulmonary veins were obstructed preoperatively. The left atrium may be small and poorly compliant, and rapid volume infusions may exacerbate pulmonary edema and pulmonary hypertension in this setting. Deep sedation and the judicious use of positive end-expiratory pressure (PEEP) are indicated in the early postoperative period to facilitate gas exchange. The pulmonary hypertension seen in some infants following repair of TAPVR is very responsive to INO (270).

Truncus Arteriosus

Surgical repair of truncus arteriosus involves VSD closure, removal of the pulmonary arteries from the arterial trunk, and placement of a conduit from the right ventricle to the pulmonary arteries. If present, surgical attention is also given to the IAA and/or truncal valve insufficiency (404). Care must be taken to identify the origin and course of the coronary arteries so that they are not injured during the operation.

Following repair of truncus arteriosus, infants are at risk for developing right ventricular failure related to pulmonary hypertension, the VSD closure, and the ventriculotomy required for the right ventricle to pulmonary artery conduit. Pulmonary hypertension may be problematic, particularly in patients referred for surgery beyond the neonatal period. Surgeons may leave an atrial communication to decompress the right heart, at the expense of mild postoperative cyanosis. The truncal valve functions as the aortic valve following surgical repair. The severity of preoperative truncal valve stenosis usually is decreased in the postoperative period as the volume

overload has been eliminated. Severe truncal valve insufficiency will be poorly tolerated in the postoperative period and may require a surgical valvuloplasty or replacement (109,404). The left ventricle is exposed to increased afterload following surgery as a result of the elimination of the low vascular resistance pulmonary circulation, and the effects of CPB, which may create temporary left ventricular failure. A residual VSD will add a volume load to the left ventricle and contribute to pulmonary hypertension. A state of low cardiac output may exist related to one or more of the above problems. If an IAA was repaired, care must be taken to ensure that residual arch obstruction does not exist and exacerbate myocardial dysfunction and truncal valve insufficiency.

Left to Right Shunts

Atrial Septal Defect

Secundum ASDs may be surgically closed primarily or with a pericardial or Gore-Tex™ patch. Primum ASDs typically require patch closure, and the commonly associated cleft in the mitral valve is usually sutured closed. Sinus venosus ASDs are typically associated with anomalous pulmonary venous drainage of the right pulmonary veins, which must be redirected to the left atrium.

Most patients may be extubated in the operating room or soon after returning to the intensive care unit following ASD closure (405). Atrial arrhythmias may occur following any ASD closure. There is an increase incidence of sinus node dysfunction following sinus venosus ASD repair that is usually transient, however, temporary atrial pacing may be required (406).

Ventricular Septal Defect

The surgical approach to a VSD depends on its location. Perimembranous and inlet VSDs are approached through the right atrium. Tricuspid valve detachment may be required for adequate exposure of the defect (407). Conal VSDs are approached through the pulmonary artery

P.757

(408). Muscular VSDs may be approached through the atrium, although apical defects often require a small ventriculotomy (409). Selected infants with large VSDs who are not thought to be candidates for primary repair because of patient size, the presence of multiple VSDs with anticipated difficult surgical exposure, or noncardiac co-morbidities may be palliated with a pulmonary artery band.

The postoperative course following repair of large, isolated VSDs may be complicated by pulmonary hypertension, although this is quite uncommon in the current era as a result of earlier repair. The incidence of a significant residual VSD, which also will cause pulmonary hypertension, is minimized with the routine use of transesophageal echocardiography. Patch dehiscence is a rare complication of VSD closure that may occur once the infant leaves the operating room and thus will be not detected by the transesophageal echocardiogram. Data that would suggest a significant residual VSD include elevated left atrial and pulmonary artery pressures, a step-up of greater than 10% in oxygen saturation from the superior vena cava or right atrium to the pulmonary artery, the presence of low cardiac output syndrome, persistent cardiomegaly and increased pulmonary vascular markings on chest radiograph, and difficulty weaning from the ventilator. JET or surgical heart block may occur following repair of a VSD. Right bundle branch block commonly occurs but does not appear to be of long-term significance.

Atrioventricular Canal Defect

Incomplete and transitional atrioventricular canal defects typically are repaired with a patch closure of the ASD and, commonly, suture closure of the cleft in the mitral valve. The postoperative course is similar to that seen following ASD closure as described above.

Complete atrioventricular septal defect repair may be accomplished using a one or two patch technique to close the primum atrial and inlet ventricular septal defects, dependent on patient anatomy and surgical preference (410). The common atrioventricular valve is divided to create separate tricuspid and mitral valves. All of the postoperative concerns following VSD closure as discussed above also apply to the infant following atrioventricular canal repair. These include pulmonary hypertension, residual VSDs, and arrhythmias (specifically, JET and complete heart block). Additionally, mitral valve regurgitation may occur, causing ventricular volume overload, congestive heart failure, and pulmonary hypertension (411). Mitral regurgitation may be suspected by auscultation and the identification of large ventricular waves on the left atrial line tracing,

and further quantified by echocardiography. Afterload reduction should be initiated when significant mitral regurgitation is identified, and volume overload should be avoided. Mitral stenosis is less common, but will cause elevated left atrial pressures and large atrial waves on the left atrial pressure tracing.

Patent Ductus Arteriosus

PDAs may be ligated surgically via a thoracotomy or using a video-assisted thoracoscopic technique (VATS). Specific complications that are uncommonly encountered are related to the injury of nearby structures, including the recurrent laryngeal and phrenic nerves. Coils and occluding devices may be used to close PDAs in the cardiac catheterization laboratory. Hemolysis or obstructions by the coil of the aorta or the proximal left pulmonary artery are rare complications following transcatheter occlusion of a PDA.

Aortopulmonary Window

Although several surgical techniques have been used in the past for aortopulmonary windows, currently the transaortic patch repair is favored by many centers (119). Any associated cardiac lesions are repaired at the same operation. Postoperative problems that may be encountered include pulmonary hypertension and residual left to right shunting. A related and somewhat rare lesion in which one pulmonary artery arises from the ascending aorta and the other from the right ventricle deserves special consideration. Preoperatively, the pulmonary artery that arises from the ascending aorta is exposed to systemic pressures, and the other pulmonary artery receives the entire cardiac output from the right ventricle. This unique combination of high pressure to one pulmonary vascular bed and high flow to the other predisposes these infants to having significant problems with pulmonary hypertension in the immediate postoperative period.

Heart Transplantation

The classical surgical technique used in heart transplantation involves a bi-atrial anastomosis, and connection of the great vessels at the level of the ascending aorta and main pulmonary artery. Many surgeons are now performing a bicaval anastomosis, which eliminates suture lines in the right atrium, includes the donor sinus node in the transplantation, and may reduce the incidence of atrial arrhythmias (412).

Several unique issues must be considered during the early postoperative period following heart transplantation. The characteristics of the donor heart may impact on the postoperative course. The circumstances leading to brain death of the donor, the amount of inotropic support required prior to the organ harvest, and the duration of total ischemic time all impact on myocardial function following transplantation. The size of the donor heart in relation to the recipient is also important. For example, a larger donor heart may be useful to overcome pulmonary hypertension in the recipient but may make sternal closure difficult. The condition of the recipient going into the transplant will certainly impact the postoperative course. For example, inadequate nutrition, pulmonary hypertension or renal insufficiency may have been present before surgery and will influence postoperative management.

P.758

Immunosuppression is required to prevent rejection and is based on a triple drug regimen including corticosteroids, a calcineurin inhibitor (cyclosporine or tacrolimus) and an antiproliferative agent (azathioprine or mycophenolate mofetil) (413). This strategy suppresses the immune system at multiple different levels while minimizing the toxicity of individual drugs. The use of induction immunotherapy, which refers to the administration of anti-T cell antibodies, may be considered immediately following transplant in patients at high risk for rejection or renal insufficiency (414,415). Induction immunotherapy may allow for dose reduction or delayed introduction of calcineurin inhibitors, allowing time for recovery of renal function. The risk of rejection is highest immediately following transplantation, and thus intense immunosuppression is initiated and then tapered over time. Serial echocardiograms and myocardial biopsies are needed for close surveillance. Signs and symptoms of severe rejection include tachycardia, hypotension, tachypnea, poor perfusion and arrhythmias. Treatment of rejection centers on the augmentation of immune suppression and supportive care until recovery of myocardial function occurs.

Severe pulmonary hypertension may lead to right ventricular failure, and aggressive measures may be required to lower the pulmonary vascular resistance and support the right ventricular systolic function. In patients who are known to be at risk for postoperative hypertension, it may be advantageous to transplant a slightly oversized donor heart. If the donor heart is too large, however, the sternum may need to be left open for

several days.

Systemic hypertension is common following heart transplantation related in part to fluid retention, and the side effects of corticosteroids and cyclosporine. Treatment is based on the severity of hypertension and the availability of the enteral route of delivering medications. Intravenous vasodilators and oral antihypertensive agents, such as calcium channel blockers and angiotensin-converting enzyme inhibitors, are commonly used. Seizures may also occur, sometimes related to severe hypertension or cyclosporine toxicity.

The risk of infection following heart transplantation is increased due to a variety of factors. Many infants have prolonged preoperative ICU stays, prolonged exposure to central venous catheters, and malnutrition. Immunosuppression is intense in the early postoperative period. Thus vigilance for infection is high immediately following surgery. In addition to standard surgical antibiotic prophylaxis against gram-positive organisms, additional prophylactic drugs are commonly prescribed to minimize the incidence of infection against cytomegalovirus, herpes viruses and *Pneumocystis carinii* pneumonia.

CONCLUSION

Neonates and infants with critical congenital heart disease present a tremendous challenge to all medical personnel who are involved in their care. The general pathophysiology, presentations, and management strategies describe above serve as a starting point to guide physicians toward providing state of the art care. Subtle variations in cardiac anatomy and physiology exist within each type of heart defect, and the importance of developing individualized medical management and interventional plans for each patient cannot be overstated. Optimal outcomes are achieved when problems are anticipated and addressed in a timely fashion (proactive, not reactive management). Frequent reevaluation of response to treatment is essential. Detailed communication across all subspecialties is equally important to achieve optimal outcomes. Perioperative care for infants with congenital heart disease continues to evolve, as new medications, treatment strategies, and surgical and interventional techniques are reported on a routine basis. Fetal heart surgery and transcatheter interventional procedures are still in the developmental stages but are likely to play an expanding role in this patient population, and this trend will certainly present a new set of challenges in the years to come (92,416-418).

Chapter 35

JAUNDICE

M. Jeffrey Maisels M.B., B.Ch.

Introduction

Jaundice is the most common and one of the most vexing problems that can occur in the newborn. As Hansen points out in an elegant historical review (1), “neonatal jaundice must have been noticed by caregivers throughout the centuries%...,” but the first documented scientific description of neonatal jaundice occurred in the latter part of the eighteenth century when Baumes was awarded a prize from the University of Paris for his description of the clinical course of jaundice in 10 infants (1). Although most jaundiced infants are otherwise perfectly healthy, they make us anxious because bilirubin is potentially toxic to the central nervous system.

Jaundice occurs when the liver cannot clear a sufficient amount of bilirubin from the plasma. When the problem is excessive bilirubin formation or limited uptake and conjugation, unconjugated (i.e., indirect-reacting) bilirubin appears in the blood. When bilirubin glucuronide excretion is impaired (i.e., cholestasis), conjugated monoglucuronide and diglucuronide (i.e., direct-reacting) bilirubin accumulate in plasma and, because of their solubility, also appear in the urine. There is also a fourth bilirubin fraction (unconjugated, monoglucuronide, and diglucuronide are the first three) known as σ -bilirubin, which is formed nonenzymatically from conjugated bilirubin and reacts directly with the diazo reagent (2).

In most jaundiced neonates, only unconjugated bilirubin is found in the blood, and the accumulated bilirubin is distributed by the circulation throughout the body and produces clinical jaundice. It generally is assumed that to cross intact cell membrane barriers the bilirubin must be free, or dissociated, from its albumin binding.

Formation, Structure, and Properties of Bilirubin

Detailed reviews of the chemistry and metabolism of bilirubin are found elsewhere ([3,4,5,6,7](#)).

Bilirubin is the end product of the catabolism of iron protoporphyrin or heme, of which the major source is circulating hemoglobin ([8](#)). The formation of bilirubin from hemoglobin involves removal of the iron and protein moieties, followed by an oxidative process catalyzed by the enzyme microsomal heme oxygenase, an enzyme found in the reticuloendothelial system as well as many other tissues ([9](#)). The α -methane bridge of the heme porphyrin ring is opened and carbon monoxide (CO) and biliverdin are formed ([Fig. 35-1](#)). One molecule of CO and biliverdin (and, subsequently, bilirubin) is formed for each molecule of heme degraded ([4](#)).

[Figure 35-2](#) shows a linear representation of bilirubin. Although conventionally illustrated as in [Figs. 35-1](#) and [35-2](#), it is likely that the prevalent structure of bilirubin in plasma has the ridge-tile conformation shown in [Fig. 35-3](#), because it is consistent with the biologic properties of bilirubin. In this conformation, the bilirubin polar groups of the molecule are involved in intramolecular hydrogen bonding that restricts solvation and renders the pigment nearly insoluble in water at pH 7.4 but soluble in nonpolar solvents such as chloroform ([10](#)). Under these circumstances, bilirubin behaves like other lipophilic substances (e.g., dioxin, polychlorinated biphenyls)—it is difficult to excrete but crosses biologic membranes, such as the placenta, blood-brain barrier, and hepatocyte plasma membrane, easily ([10,11](#)). The addition of methanol or ethanol interferes with hydrogen bonding and results in an immediate diazo reaction, the basis for measurement of indirect-reacting bilirubin by the van den Bergh test.

Fetal Bilirubin Metabolism

Bilirubin can be detected in normal amniotic fluid after about 12 weeks of gestation, but it disappears by 36 to 37 weeks' gestation. The ability of human fetal liver to remove bilirubin from the circulation and to conjugate it is severely limited. Between 17 and 30 weeks of gestation, uridine diphosphoglucuronosyl transferase (UDPGT) activity in fetal liver is only 0.1% of adult values, but it increases tenfold to 1% of adult values between 30 and 40 weeks' gestation. After birth, activity increases exponentially, reaching adult levels by 6 to 14 weeks' gestation (Fig. 35-4). This increase is independent of gestation (Table 35-1) (12,13).

The major route of fetal bilirubin excretion is across the placenta. Because virtually all the fetal plasma bilirubin is

P.769

unconjugated, it is readily transferred across the placenta to the maternal circulation, where it is excreted by the maternal liver. Thus, the newborn rarely is born jaundiced, except in the presence of severe hemolytic disease, when there may be accumulation of unconjugated bilirubin in the fetus. Conjugated bilirubin is not transferred across the placenta, and it also may accumulate in the fetal plasma and other tissues.

Figure 35-1 Biosynthesis of bilirubin. (From Lightner DA, McDonagh AF. Molecular mechanisms of phototherapy for neonatal jaundice. *Acc Chem Res* 1984;17:417-424, with permission.)

Maternal Hyperbilirubinemia and Its Effect on the Fetus

Obstetricians and pediatricians occasionally are confronted with a pregnant mother who has hyperbilirubinemia as a result of hemolytic anemia or liver disease. Reported cases in the literature provide evidence for transfer of unconjugated bilirubin from the mother to her fetus, but no clear guidelines for management (14,15,16).

Figure 35-2 The chemical structure of bilirubin. (From McDonagh AF, Lightner DA. "Like a shrivelled blood orange"—bilirubin, jaundice and phototherapy. *Pediatrics* 1985;75:443-455, with permission.)

It is possible that prolonged exposure of the fetus to a modest degree of unconjugated hyperbilirubinemia *in utero* could lead to neurologic damage (16).

Neonatal Bilirubin Metabolism

Bilirubin Production

The normal destruction of circulating erythrocytes accounts for about 75% of the daily bilirubin production in the newborn. Senescent erythrocytes are removed and destroyed in the reticuloendothelial system, where the heme is catabolized and converted to bilirubin (Fig. 35-5). The catabolism of 1 g of hemoglobin yields 35 mg of bilirubin.

A significant contribution (25% or more) to the daily production of bilirubin in the neonate comes from sources other than effete erythrocytes (see Fig. 35-5). This bilirubin consists of two major components:

- A nonerythropoietic component resulting from the turnover of nonhemoglobin heme protein and free heme, primarily in the liver.

P.770

- An erythropoietic component arising primarily from ineffective erythropoiesis and the destruction of immature erythrocyte precursors, either in the bone marrow or soon after release into the circulation.

Figure 35-3 Preferred conformation of bilirubin. Chemical structure (**left**); bent paper clip analogy (**middle**); space-filling molecular model (**right**). Each representation is asymmetric and has a nonsuperimposable mirror image, like a D- or L-amino acid. Only one of the two possible mirror-image forms is shown in each representation. (From McDonagh AF, Lightner DA. "Like a shrivelled blood orange" —bilirubin, jaundice and phototherapy. *Pediatrics* 1985;75:443-455 with permission.)

Figure 35-4 Developmental pattern of human hepatic uridine diphosphoglucuronosyl transferase (UDPGT) activity. Samples were obtained from the livers of fetuses after elective abortions, at autopsy from premature and full-term newborns who survived fewer than 7 days, and from liver biopsies of infants, children, and adults undergoing laparotomy. Each point represents the activity of the liver homogenate of a single patient, but results for patients older than 18 weeks of age are shown as a mean \pm SD. (From Kawade N, Onishi S. The prenatal and postnatal development of UDP-glucuronyl transferase activity toward bilirubin and the effect of premature birth on this activity in the human liver. *Biochem J* 1981;196:257-260, with permission.)

Transport and Hepatic Uptake of Bilirubin

Once bilirubin leaves the reticuloendothelial system, it is transported in the plasma and bound reversibly to albumin. Unconjugated bilirubin is bound tightly to albumin at a primary (high-affinity) binding site as well as a secondary (low-affinity) site. Because binding affinity at the primary binding site is 10^7 to 10^8 L/mol (17), the concentrations of free or unbound bilirubin in plasma are very low, even in the presence of significant hyperbilirubinemia. (The magnitude of the affinity constant was recently questioned (18).) At pH 7.4, the solubility of bilirubin is very low (about 4 nmol/L [0.24 mg/dL]).

TABLE 35-1 FETAL BILIRUBIN METABOLISM

Bilirubin detected in amniotic fluid at 12 weeks of gestation
 Unconjugated bilirubin excreted across placenta
 UDPGT activity at term \sim 1% of adult
 UDPGT activity reaches adult levels by 6–14 weeks

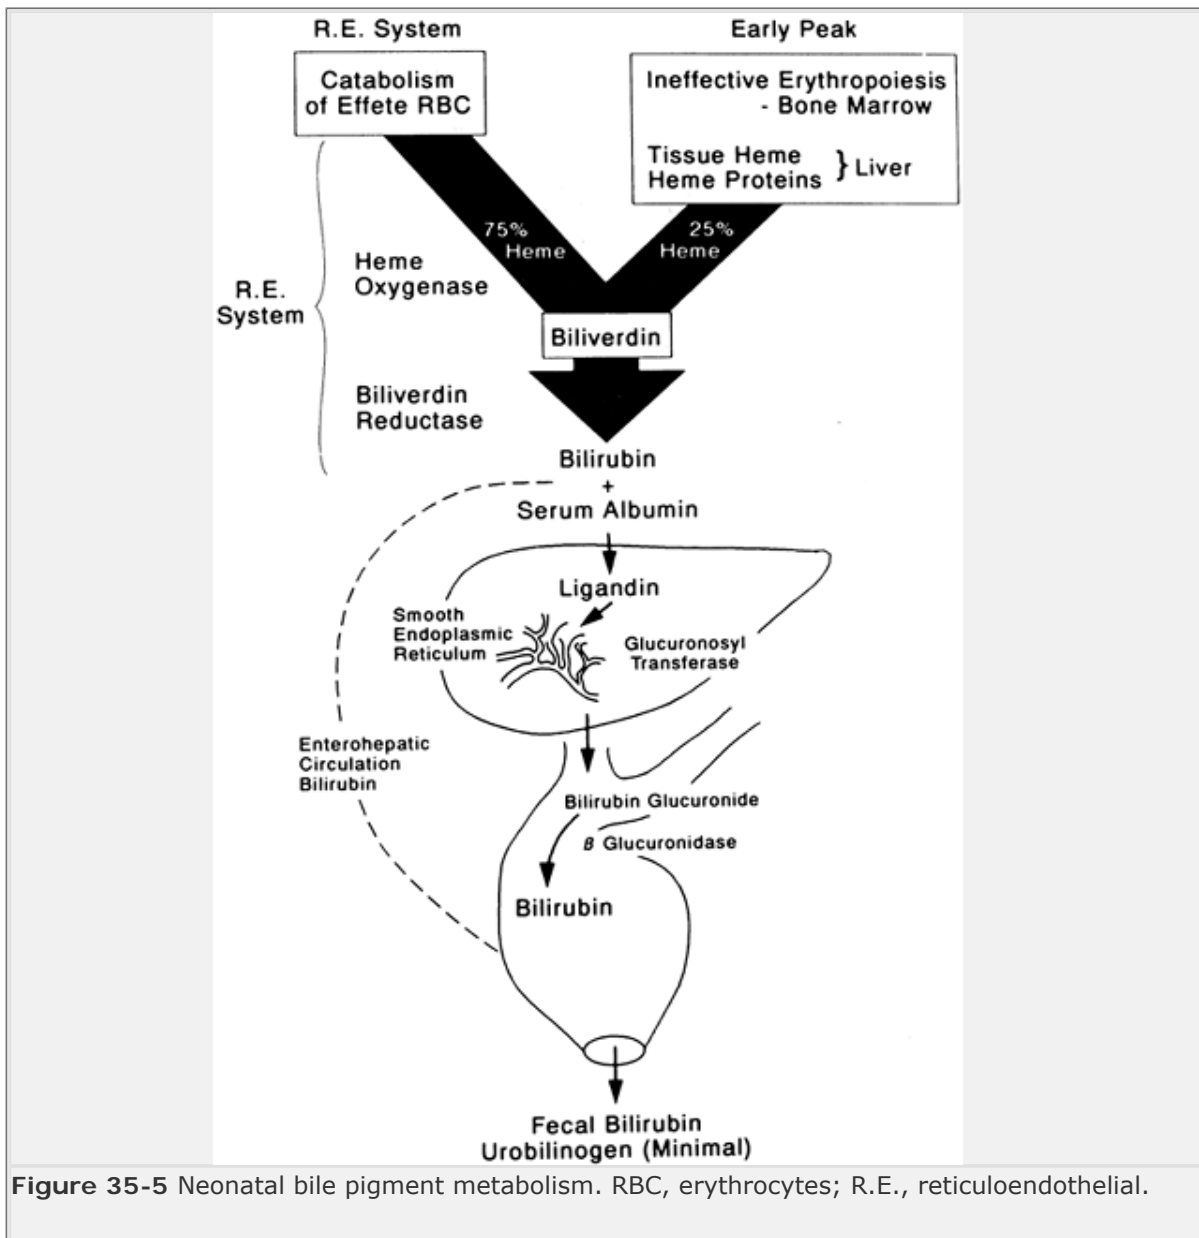

Figure 35-5 Neonatal bile pigment metabolism. RBC, erythrocytes; R.E., reticuloendothelial.

The parenchymal cells of the liver have a selective and highly efficient capacity for removing unconjugated bilirubin from the plasma. When the bilirubin-albumin complex reaches the plasma membrane of the hepatocyte, a proportion of the bilirubin, but not the albumin, is transferred across the cell membrane into the hepatocyte, a process that potentially involves four different transport proteins (3). In the hepatocyte, bilirubin is bound principally to ligandin and possibly other cytosolic-binding proteins (Fig. 35-6) (3). A network of intracellular microsomal membranes may also play an important role in the transfer of bilirubin within the cell and to the endoplasmic reticulum (3,5).

Conjugation and Excretion of Bilirubin

Because of its hydrogen-bonded conformation (see Formation, Structure, and Properties of Bilirubin above), unconjugated (i.e., indirect-reacting)

P.771

bilirubin is nonpolar and insoluble in aqueous solutions at pH 7.4 and must be converted to its water-soluble conjugate (i.e., direct-reacting bilirubin) before it can be excreted (see Fig. 35-6). This is achieved when bilirubin is combined enzymatically with a sugar, glucuronic acid, producing bilirubin monoglucuronide and diglucuronide pigments that are more water soluble and sufficiently polar to be excreted into the bile or filtered through the kidney.

Figure 35-6 Bilirubin transport and conjugation in the hepatocyte. Two mechanisms have been proposed for uptake of bilirubin from the extracellular environment: by means of an albumin receptor or directly. In either case, carrier protein may be involved in transmembrane passage (**upper box**). Transport into the endoplasmic reticulum is facilitated by complexing to ligandin, but direct membrane-to-membrane transfer also may occur. Cytosolic bilirubin is in equilibrium with endoplasmic reticulum bilirubin. The hypothesis of conjugation of insoluble bilirubin to polar glucuronides (**lower box**). Conjugated bilirubin may enter the bile canaliculi by either vesicular transport or carrier-mediated transport. (From Gollan JL, Knapp AB. Bilirubin metabolism and congenital jaundice. *Hosp Pract (Off Ed)* 1985;Feb 15:83-106, with permission.)

The presence of elevated bilirubin concentrations *in utero* prematurely induces bilirubin uridine diphosphoglucuronate glucuronosyltransferase (UGT) activity, which suggests that bilirubin plays an important role in the initiation of its own conjugation after birth (19).

Structure and Function of the Uridine Diphosphoglucuronate Glucuronosyltransferase 1A1 Gene

The process of conjugation is catalyzed by a specific hepatic enzyme isoform (1A1) belonging to the UGT family of enzymes. These enzymes metabolize endogenous compounds and various food chemicals in most tissues.

Although the UGT1 family contains several isoforms, only the A1 isoform (UGT1A1) participates in the conjugation of bilirubin (20). The glucuronosyltransferase enzyme is synthesized in the hepatocyte and its structure is determined by the UGT1A1 gene (Fig. 35-7 and Table 35-2).

The gene encoding the UGT1 enzyme is located on chromosome 2 at 2q37 (21) and consists of 4 common exons and 13 variable exons (see Fig. 35-7) (22,23). The gene also has a noncoding promoter area (see Fig. 35-7B), which is an upstream regulatory region controlling gene expression. The UGT promoter contains a TATAA box, which is a DNA deoxyribonucleic acid (DNA) sequence of thymine (T) and adenine (A). Mutations in the 1A1 exon or its promoter will affect bilirubin conjugation. Examples of this effect are seen in Gilbert syndrome and the Crigler-Najjar syndromes (see *Pathologic Causes of Jaundice: Decreased Bilirubin Clearance* below). Variations in the promoter sequence can also cause indirect-reacting hyperbilirubinemia.

TABLE 35-2 THE UGT 1A1 GENE

Encodes the UGT1 enzyme
 Located on chromosome 2
 Consists of 4 common exons (2–5) and 13 variable exons (A1–A13)
 Noncoding promoter area controls gene expression
 UGT promoter contains TATAA box
 Mutations in 1A1 exon or promoter affect bilirubin conjugation (e.g., Gilbert and Crigler-Najjar syndromes)

Figure 35-7 The human UGT1 gene locus. **A:** Schematic of the genomic structure of the UGT1 gene complex. **B:** Exploded view of exon 1A1 and common exons 2 to 5 of the gene complex that have been identified as sites for genetic mutations associated with absent or decreased UGT activity that cause deficiencies of bilirubin conjugation. (From Clarke DJ, Moghrabi N, Monaghan G, et al. Genetic defects of the UDP-glucuronosyltransferase-1 (UGT1) gene that cause familial nonhaemolytic unconjugated hyperbilirubinemias. *Clinica Chim Acta* 1997;266:63-74, with permission.)

Transfer of Bilirubin into Bile and Intestinal Transport

After conjugation, bilirubin is excreted rapidly into the bile canaliculi by the liver cell, a process that requires metabolic work for the active transport of bilirubin across a large concentration gradient (see Fig. 35-6) (5). Inter-ference with this process is probably responsible for the hyperbilirubinemia associated with hepatocellular disorders such as hepatitis.

Once in the small intestine, conjugated bilirubin is not reabsorbed. In the healthy adult, it is largely reduced by

the action of colonic bacteria to a series of colorless tetra-pyrroles, collectively known as urobilinogen, and an insignificant amount is hydrolyzed to unconjugated bilirubin and reabsorbed by way of the enterohepatic circulation. In the newborn, however, this enterohepatic circulation of bilirubin is significant and important (see Jaundice in the Healthy Newborn: Physiologic Jaundice below). In addition, in conditions involving high plasma bilirubin levels and poor hepatic excretion, there is a gradient for unconjugated bilirubin from the plasma to the intestinal lumen, and significant amounts of unconjugated bilirubin may be cleared by diffusion across the intestinal wall (24). Figure 35-5 summarizes bile pigment metabolism in the newborn.

Physiologic Mechanisms of Neonatal Jaundice

At any time in the infant's first few days after birth, the serum bilirubin level reflects a combination of the effects of bilirubin production, conjugation, and enterohepatic circulation. Using measurements of blood carboxyhemoglobin (COHb) corrected for ambient CO (COHbc) as an index of bilirubin production and high-performance liquid chromatography (HPLC) measurements of conjugated bilirubin, Kaplan and associates (25) demonstrated that an imbalance between bilirubin production and conjugation is fundamental in the pathogenesis of neonatal bilirubinemia. Several processes account for the bilirubinemia that occurs in virtually all newborns (Table 35-3).

Increased Bilirubin Load on the Liver Cell

Bilirubin Production

CO is produced in equimolar quantities with bilirubin and measurements of CO production show that the normal

P.773

newborn produces an average of 8 to 10 mg/kg (13.7 to 17.1 $\mu\text{mol}/\text{kg}$) of bilirubin per day (26,27). This is more than twice the rate of normal daily bilirubin production in the adult and is explained by the fact that the neonate has a higher circulating erythrocyte volume, a shorter mean erythrocyte lifespan, and a larger early labeled bilirubin peak (see Table 35-3). Bilirubin production decreases with increasing postnatal age but is still about twice the adult rate by age 2 weeks (26).

TABLE 35-3 PHYSIOLOGIC MECHANISMS OF NEONATAL JAUNDICE

Increased bilirubin load on liver cell

- Increased erythrocyte volume
- Decreased erythrocyte survival
- Increased early labeled bilirubin
- Increased enterohepatic circulation of bilirubin

Decreased hepatic uptake of bilirubin from plasma

- Decreased ligandin

Decreased bilirubin conjugation

- Decreased uridine diphosphoglucuronosyl transferase activity

Defective bilirubin excretion

- Excretion impaired but not rate limiting

Enterohepatic Circulation

The newborn reabsorbs much larger quantities of unconjugated bilirubin by way of the enterohepatic circulation, than does the adult. Infants have fewer bacteria in the small and large bowel and greater activity of the deconjugating enzyme β -glucuronidase.([28](#)) As a result, conjugated bilirubin, which is not reabsorbed, is not converted to urobilinogen but is hydrolyzed to unconjugated bilirubin, which is reabsorbed, thus increasing the bilirubin load on an already stressed liver (see [Fig. 35-5](#)). Studies in newborn humans ([29](#)), monkeys ([30](#)), and Gunn rats ([31](#)) suggest that the enterohepatic circulation of bilirubin is a significant contributor to physiologic jaundice. In the first few days after birth, caloric intake is low, which contributes to an increase in the enterohepatic circulation ([32,33](#)).

Decreased Clearance of Bilirubin from the Plasma Uptake

Ligandin, the predominant bilirubin-binding protein in the human liver cell, is deficient in the liver of newborn monkeys. It reaches adult levels in the monkey by 5 days of age, coinciding with a fall in bilirubin levels, and administration of phenobarbital increases the concentration of ligandin ([34](#)). Although this suggests that impaired uptake may contribute to the pathogenesis of physiologic jaundice, uptake does not appear to be rate limiting.

Conjugation

Deficient UGT1A1 activity, with resultant impairment of bilirubin conjugation, has long been considered a major cause of physiologic jaundice. In human infants, the early postnatal increase in serum bilirubin appears to play an important role in the initiation of bilirubin conjugation. ([19](#)) In the first 10 days after birth, UGT1A1 activity in full-term and premature neonates usually is less than 1% of adult values (see [Fig. 35-4](#)) ([12,13](#)). Thereafter, the activity increases at an exponential rate, reaching adult values by 6 to 14 weeks of age ([13](#)). The postnatal increase in UGT1A1 activity is independent of the infant's gestation.

Excretion

The absence of an elevated serum level of conjugated bilirubin in physiologic jaundice suggests that, under normal circumstances, the neonatal liver cell is capable of excreting the bilirubin that it has just conjugated. Nevertheless, the ability of the newborn liver to excrete conjugated bilirubin and other anions (e.g., drugs, hormones) is more limited than that of the older child or adult and may become rate limiting when the bilirubin load is significantly increased. Thus, when intrauterine hyperbilirubinemia occurs, usually as a result of isoimmunization, it is not uncommon to find an elevated serum level of conjugated bilirubin ([19](#)).

Physiologic Jaundice

Because at some point during the first week of life almost every newborn has a total serum bilirubin (TSB) level that exceeds 1 mg/dL (17 μ mol/L, the upper limit of normal for an adult), and two-thirds or more of newborns will appear clinically jaundiced, this type of transient hyperbilirubinemia has been called *physiologic jaundice*. This jaundice results from the interaction of a number of factors (see [Table 35-3](#)). The term *physiologic jaundice* generally is applied to newborns whose TSB level falls within the normal range, but because of the significant differences in TSB levels in different populations, it can be difficult to define what is normal or abnormal, physiologic or nonphysiologic. Additionally, defining the term “normal” is, in itself, a difficult task, and depends on whether one chooses a gaussian, percentile, diagnostic, risk factor, or therapeutic definition of the term ([35](#)).

In premature newborns, the term *physiologic jaundice* is of little value. If untreated, low-birth-weight infants have exaggerated and prolonged hyperbilirubinemia. Although this may be considered “physiologic” because it occurs in all preterm infants, in very-low-birth-weight infants, TSB levels well within the “physiologic range” are considered potentially hazardous and are treated with phototherapy. Thus, the natural history of hyperbilirubinemia in the very-low-birth-weight infant is never observed, and defining certain bilirubin levels as “physiologic” in this population is misleading and potentially dangerous. Using a diagnostic definition of normal ([35](#)), a TSB level of 10 mg/dL (171 μ mol/L) on day 4 in a 750-g neonate would be considered completely “physiologic,” and no investigation need be done to identify a cause for this jaundice. Nevertheless, almost all neonatologists would *treat* this infant with phototherapy, implying that this value exceeds the therapeutic definition of normal (i.e., treatment is much more likely to do good than harm). Thus, in today's neonatal intensive care population, the term *physiologic jaundice* has no meaning and no utility and should be abandoned.

Bilirubin Toxicity

Kernicterus

Pathology

The first description of kernicterus (or brain jaundice) in newborns was provided by Hervieux in 1847 (1) and in

P.774

1875, Orth (36) observed bilirubin pigment at autopsy in the brains of infants who were severely jaundiced. Schmorl (37) subsequently described two forms of "brain icterus," the first "characterized by a diffuse yellow coloration of the entire brain substance," and a second form in which "the jaundiced coloration appears to be completely circumscribed and...limited to the so-called 'kern' or nuclear region of the brain."

Topography

Full-term infants who die of kernicterus demonstrate bilirubin staining in a characteristic distribution (Table 35-4), although a variety of patterns have been described, grossly and microscopically (38). Kernicteric premature infants and Gunn rats with inherited UGT deficiency display a similar topography of neuronal damage (see Table 35-4) (39). Those regions most commonly affected are the basal ganglia, particularly the subthalamic nucleus and the globus pallidus; the hippocampus; the geniculate bodies; various brainstem nuclei, including the inferior colliculus, oculomotor, vestibular, cochlear, and inferior olivary nuclei; and the cerebellum, especially the dentate nucleus and the vermis (39,40). Ahdab-Barmada has provided a detailed review of the neuropathology of kernicterus, and its anatomic, cytologic, and histologic characteristics (41).

Gross Anatomy

Yellow staining of the brain occurs when it is exposed to elevated levels of bilirubin. Table 35-5 lists the three patterns of bilirubin staining of the brain seen in the newborn (41).

Histology and Cytology

Table 35-6 summarizes the neuropathologic findings of kernicterus. There can be some confusion regarding the diagnosis of kernicterus in the presence of yellow discoloration of the central nervous system. Ahdab-Barmada emphasizes that the diagnosis of kernicterus should only be applied to the incorporation of bilirubin pigment into gangliosides or phospholipids of mature neurons with subsequent damage to the neuron, depending on the amount of pigment trapped within the cell (41). The unique topographic pattern of nuclear involvement is described above (see Topography) and the combination of the bright yellow-orange staining of these brain nuclei, together with evidence of neuronal damage and degeneration within the nuclei, is necessary before a diagnosis of kernicterus can be made (41).

TABLE 35-5 PATTERNS OF BILIRUBIN STAINING OF THE BRAIN IN HYPERBILIRUBINEMIA

Diffuse yellow staining of areas that normally lack a blood-brain barrier, e.g., leptomeninges, ependyma, choroid plexus, cerebrospinal fluid.

Diffuse yellow staining of brain tissues in areas where blood-brain barrier integrity has been compromised (as can occur following hypoxic ischemic encephalopathy, periventricular leukomalacia, ischemic cerebral infarct).

Yellow staining of specific neuronal groups (kernicterus).

Autopsies on jaundiced infants reveal bilirubin staining of the aorta, pleural fluid, and ascitic fluid, or a generalized yellow cast throughout the viscera. The staining usually is not considered a sign of tissue damage unless other cytologic changes are found (38). Bilirubin staining also can be found in necrotic tissue anywhere in the body and has been described in the gastrointestinal tract, lungs (hyaline membranes) (42), kidney, adrenals, and gonads. In infants with hemolytic disease, bile plugs commonly are found in the canaliculi between the hepatocytes, especially in the periportal areas. The kidneys may show bilirubin-stained tubular casts, bilirubin crystals in the small vessels or in edematous interstitium, and renal tubular necrosis. The bilirubin infarcts (i.e., patches of yellow staining in the renal medulla) are probably the result of focal areas of acute

tubular necrosis that have been stained by bilirubin (38).

Neuronal necrosis is the dominant histopathologic feature after 7 to 10 days of postnatal life (see Table 35-6). For the most part, its distribution corresponds with the distribution of bilirubin staining, although there are some exceptions to this rule. For example, intense staining develops in the olivary and dentate nuclei, but there is little neuronal necrosis in these regions. The important areas of neuronal injury (as opposed to staining) include the basal ganglia, brainstem oculomotor nuclei, and brainstem auditory (cochlear) nuclei (40). The involvement of these regions explains some of the clinical sequelae of bilirubin encephalopathy (see Clinical Features of Bilirubin Encephalopathy below).

Clinical and Pathologic Correlations

Originally a pathologic diagnosis and later a well-defined acute and chronic neurologic syndrome, kernicterus or bilirubin encephalopathy appears to be a less-well-circumscribed entity that includes nuclear bilirubin staining of very-low-birth-weight infants who died of other causes and, possibly, a subtle chronic encephalopathy in which extrapyramidal motor disturbances and sensorineural hearing deficit are not the predominant features.

Most, but not all, full-term infants seen today with the pathologic changes described manifest the clinical symptomatology of this disorder, including very high serum bilirubin levels (commonly higher than 30 mg/dL [513 μmol/L]). Exceptions have been described. Perlman and associates (43) recently reported kernicterus at autopsy in two very sick near-term infants with maximum TSB levels of 5.2 and 14.4 mg/dL (89 to 246 μmol/L).

Yellow staining of the brain also has been observed in premature infants who manifested none of the clinical signs of kernicterus during life and in whom TSB levels remained low (44,45). Turkel and colleagues (46) identified 32 infants with kernicterus at autopsy and compared them with 32 control infants of similar gestational ages without kernicterus. In the kernicteric infants, although the gross pattern of staining followed that of classic kernicterus, the typical histologic changes characteristic of kernicterus were found in only three patients. These authors suggest that the bilirubin staining they observed probably was not the same clinicopathologic entity as the kernicterus of posticteric encephalopathy. Instead of the neuronal degeneration typically seen, they found spongy change and gliosis, which both imply nonspecific damage to the brain. This suggests that prior diffuse injury may predispose the brain to bilirubin deposition at relatively low levels of serum bilirubin.

Ahdab-Barmada and Moossy (39) found kernicterus in 97 autopsies of neonates (95 younger than 36 weeks of gestation)

P.776

The neuropathology in these infants was strikingly similar to that of classic kernicterus in the full-term neonate and in the Gunn rat (see Table 35-4). In the National Institute of Child Health and Human Development (NICHD) cooperative phototherapy study, four low-birth-weight infants had autopsy-proven kernicterus (47). The neuropathologic findings in these infants were those of classic kernicterus. As Table 35-7 shows, the neuropathology of kernicterus is different from that of hypoxic ischemic encephalopathy. Even though hypoxic ischemic insults may predispose the brain to bilirubin deposition in some low-birth-weight infants, in others the typical histologic features of kernicterus will be found.

TABLE 35-7 COMPARATIVE NEUROPATHOLOGY OF KERNICTERUS AND ANOXIC-ISCHEMIC ENCEPHALOPATHY IN THE PREMATURE NEONATE

Topography of Lesions ^a	Kernicterus	Anoxic-Ischemic Encephalopathy
Cerebral cortex	Absent	Present
Periventricular white matter	Absent	Present
Corpus striatum	Globus pallidus	Putamen and caudate nuclei

Pathophysiology of Bilirubin Toxicity

The pathogenesis of kernicterus is highly complex and the risk of developing kernicterus is related to a multiplicity of factors (48), which are discussed below. The cellular and molecular mechanisms of bilirubin toxicity were reviewed by Hansen (49,50) and Volpe (Fig. 35-8) (51).

Bilirubin Chemistry and Neurotoxicity

As discussed in Formation, Structure, and Properties of Bilirubin above, the polar groups of the bilirubin molecule, in its most stable conformation, are involved in intramolecular hydrogen bonding that restricts solvation and renders the pigment nearly insoluble in water at pH 7.4. When doubly ionized in alkaline medium, the molecule is much more soluble. The low water solubility of bilirubin and its tendency to aggregate and precipitate at physiologic pH, particularly acid pH, have long been thought to be key factors in its toxicity. Thus, when the concentration of bilirubin acid exceeds its solubility, bilirubin may gradually aggregate and precipitate from solution (17). Bilirubin crystals have been found in the brain cells of infants who died from kernicterus, and bilirubin concentrations of 2 mg/dL (34 μ mol/L) have been observed in kernicteric brains (52). It is likely that even higher local concentrations of pigment exist in the brain in kernicterus and may occur when aggregates precipitate within brain cells (53,54). Wennberg (55) suggested that formation of reversible complexes between bilirubin monoanion and membranes is also important in the development of bilirubin encephalopathy.

Although it is known that bilirubin uncouples oxidative phosphorylation and inhibits cellular respiration and protein phosphorylation, there is no agreement that these are the key mechanisms of bilirubin toxicity *in vivo* (see Fig. 35-8). Bilirubin also inhibits mitochondrial enzymes, interferes with DNA and protein synthesis (56), and alters cerebral glucose metabolism (49,57). Unconjugated bilirubin will initiate a mitochondrial pathway of apoptosis in developing brain neurons (58) and it inhibits the function of *Nmethyl*-aspartate-receptor ion channels (59). Bilirubin also binds to lysine sites on albumin and ligandin, proteins that are essential for bilirubin transport and metabolism (49). Consequently, lysine binding may have a role in the pathogenesis of bilirubin toxicity.

It is not known why bilirubin is deposited preferentially in the basal ganglia, but it is possible that regional differences in uptake, tissue binding, metabolism, or cellular

P.777

clearance play a role (49). It is also possible that there are regional differences in blood flow or blood brain barrier permeability.

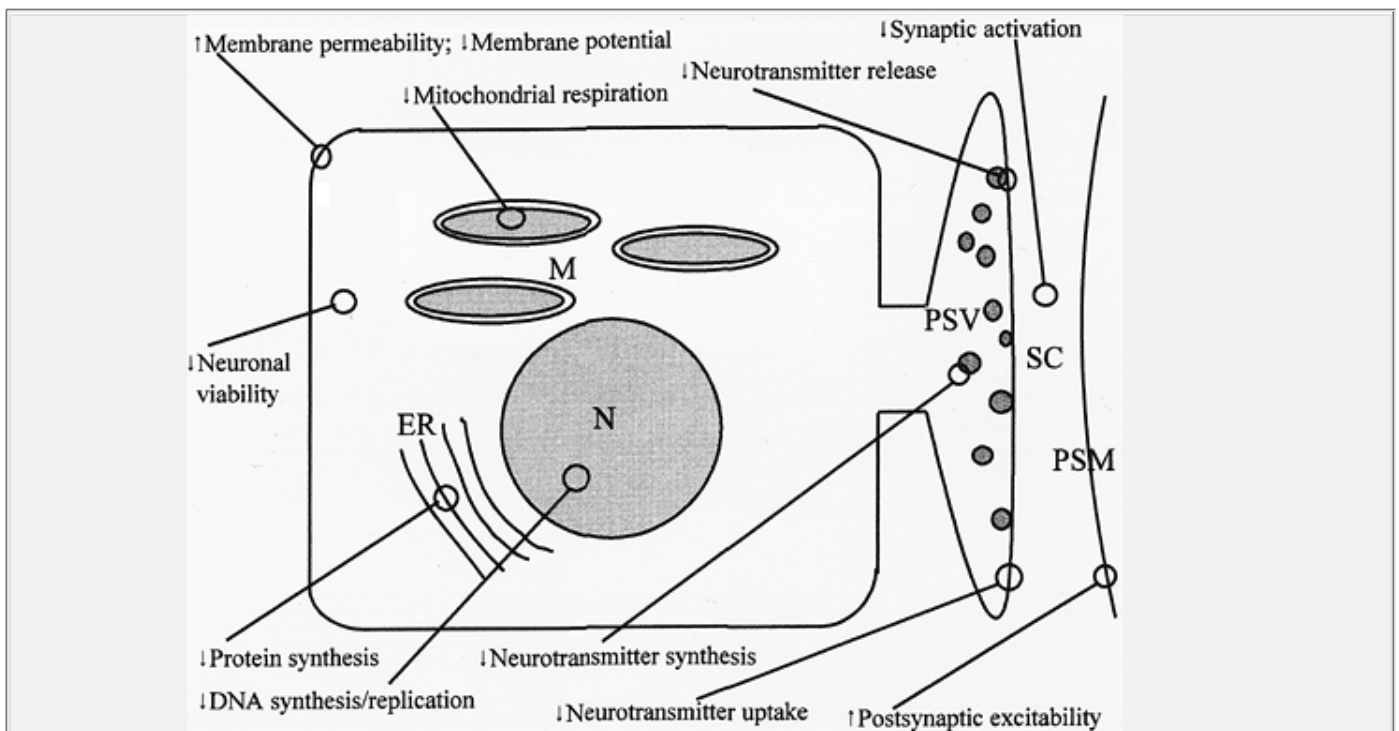

Figure 35-8 Effects of bilirubin on neurons and neuronal metabolic processes. Bilirubin affects a large number of cellular functions and processes, both *in vivo* and *in vitro*. It decreases neuronal viability; increases membrane permeability and decreases membrane potential; uncouples oxidative phosphorylation; inhibits neurotransmitter release, synthesis, and uptake; inhibits synaptic activation; increases postsynaptic excitability; decreases protein synthesis; and decreases synthesis and replication of DNA. Other bilirubin-affected functions not indicated in the illustration are inhibition of enzyme function and protein phosphorylation. ER, endoplasmic reticulum; M, mitochondria; N, nucleus; PSM, postsynaptic membrane; PSV, presynaptic vesicles; SC, synaptic cleft. (From Hansen TWR. The pathophysiology of bilirubin toxicity. In: Maisels MJ, Watchko JF, eds. *Neonatal jaundice*. London: Harwood Academic, 2000:89-104, with permission.)

Albumin Binding and the Concept of Free Bilirubin

Bilirubin is transported in the plasma as a dianion bound tightly, but reversibly, to serum albumin and the portion that is unbound or loosely bound (sometimes termed *free bilirubin*) can more readily leave the intravascular space and cross the intact blood brain barrier (60). Albumin has a primary, high-affinity binding site at which the association constant, derived from the equilibrium concentrations of bound and free bilirubin, is about 10^7 to 10^8 moles⁻¹ (17). Because of this high binding affinity, equilibrium concentrations of unbound or free bilirubin in plasma are very low. It has been widely accepted that bilirubin toxicity occurs when free bilirubin enters the brain and binds to cell membranes (61) and that the presence of albumin mitigates the *in vivo* and *in vitro* toxic effects of bilirubin (61,62).

The relationship between free bilirubin levels, kernicterus, and developmental outcome is discussed below in the section on the clinical sequelae of hyperbilirubinemia (see Clinical Sequelae of Hyperbilirubinemia: Bilirubin Binding Capacity, Kernicterus, and Developmental Outcome) Drugs that decrease albumin binding of bilirubin, such as sulfisoxazole, increase the risk of kernicterus (63, 64). These observations are consistent with the hypothesis that bilirubin is able to move freely across the blood-brain barrier, bind to tissues, and damage the cells of the central nervous system.

Ostrow and colleagues have questioned the significance of some published data from *in vitro* models of bilirubin cellular toxicity because of the high concentrations of unconjugated bilirubin that were used (18,65,66,67). They suggest that bilirubin toxicity might occur at free bilirubin levels that are significantly lower than those previously documented and that precipitation of unconjugated bilirubin in, or on, cells may not be required to produce neurotoxicity (67). These issues cannot be resolved until clinical studies are performed on infants who have had appropriate measurements of free bilirubin as newborns (68) and are then followed into childhood.

Measurement of Free Bilirubin

Although several techniques exist for measuring or estimating free or loosely bound bilirubin and the binding

capacity and affinity of bilirubin for albumin (17), changes in free bilirubin concentrations can be transient because there is rapid equilibration and redistribution of bilirubin between the plasma (i.e., albumin) and the tissues. Even under experimental conditions that lead to a significant increase in brain bilirubin content, the differences in free

bilirubin concentrations in the serum between control and study animals is small (69) and Brodersen has expressed doubt that the accurate measurement of free bilirubin is possible or clinically useful (17). Nevertheless, there is some evidence to suggest that estimates of unbound bilirubin can provide clinically relevant information regarding changes in auditory brainstem responses (ABRs) (70,71) and in frank kernicterus (72).

There is an extensive literature dealing with bilirubin-binding tests, but no test is currently in general use in the United States in clinical decision making, although a relatively simple semiautomated application of the peroxidase oxidation test is in use in Japan (73) and has been approved in the United States by the Food and Drug Administration (FDA) (74). However, the peroxidase method employs a 40-fold dilution of the sample that can alter intrinsic bilirubin binding (68). Ahlfors developed a test that combines the peroxidase technique with a diazo method for measuring conjugated and unconjugated bilirubin (68). This method uses minimal dilution and should provide more reliable data on free bilirubin levels (68).

Because one molecule of albumin is capable of binding one molecule of bilirubin tightly at the primary binding site, a bilirubin-albumin molar ratio of 1 represents about 8.5 mg of bilirubin per gram of albumin. Thus, a well, full-term infant with a serum albumin concentration of 3 to 3.5 g/dL should be able to bind about 25 to 28 mg/dL of bilirubin (428 to 479 $\mu\text{mol/L}$) if no other endogenous or exogenous ligands compete for the same site. The albumin-binding capacity of sick low-birth-weight infants is much less than that of full-term infants, and their serum albumin levels often are lower so they are able to bind effectively much less bilirubin. Ahlfors has suggested a range of bilirubin-to-albumin ratios (in mg/g) that can be used as a guide in the process of deciding whether or not to perform an exchange transfusion in term and preterm infants at different levels of risk (75), an approach that has been endorsed by the American Academy of Pediatrics (AAP) (76) (see *Treatment* below). It should be noted, however, that there is significant variability in bilirubin-albumin binding among infants (77), which can affect the validity of the bilirubin-to-albumin ratio. Because binding improves with increasing birth weight, Ahlfors suggests a level of 1.3 $\mu\text{g/dL}$ per kg as a level of free bilirubin at which exchange transfusion should be considered (72), although we have no data relating such free bilirubin levels to long-term outcome. These data are urgently needed.

Factors Affecting the Binding of Bilirubin to Serum Albumin

This subject has been reviewed in detail (17); however, a few of the factors are discussed here.

Fatty Acids

Free fatty acids in plasma may compete with bilirubin for its binding to albumin, but significant interference with bilirubin binding probably does not occur until molar ratios of free fatty acids-to-albumin (F:A) exceed 4:1 (17).

The infusion of 1 g/kg of intralipid over a 15-hour period in infants of less than 30 weeks of gestation produced an F:A ratio of less than 3 and minimal increases in unbound bilirubin concentrations (78). With doses of 2 to 3 g/kg, however, higher ratios were found. Intravenous fat, given as a continuous infusion of 2 g/kg per day for 7 days to infants of 32 weeks or less of gestation (mean birth weight 1,200 g) produced F:A ratios of only 0.1 to 1.8. (79)

pH

The binding of bilirubin to albumin is thought to be unaffected by changes in the serum pH (80,81). Nevertheless, the correction of neonatal acidosis in 11 sick newborns appeared to decrease the serum free bilirubin concentration as measured by a peroxidase technique (82). The role of pH, on the other hand, may be pivotal in determining the binding of bilirubin to cells and partitioning to extravascular tissue and, therefore, its deposition in the central nervous system (55,60).

Drugs

The effect of numerous drugs on bilirubin-albumin binding has been tested *in vitro* using different methods. The measured effect varies with the method used; some systems require much greater concentrations of the drug than others to demonstrate an increase in unbound bilirubin. *In vivo*, of course, the effect of drugs and their potential for inducing kernicterus depends, not simply on their ability to displace bilirubin from albumin, but also on their route and mode of administration. Thus, a displacing drug is likely to be more dangerous when administered intravenously as a bolus than as an infusion. Robertson and colleagues (83) reviewed the bilirubin-displacing effect of drugs used in neonatology (Table 35-8). They arbitrarily chose to consider an increase in the free bilirubin concentration of 5% as potentially dangerous, and they consider a drug to be a potential displacer if it occupies 5% or more of the available albumin. Knowledge of the usual peak serum bilirubin concentrations and the percentage of albumin-bound drug also can be used to calculate the concentration of bound drug. If the bound drug concentration is less than 15 $\mu\text{mol/L}$, it is unlikely that this drug will cause significant displacement of bilirubin (83).

Robertson and colleagues (83) calculated a maximal displacement factor, σ , from the K_D value, using the following equation:

$$\delta = K_D d + 1$$

where d is the concentration of free drug in the patient's plasma, and K_D is the displacement constant, which represents the competitive effect of the drug with bilirubin for albumin binding. If K_D is 0, then $\sigma=1$, and the drug does not displace bilirubin. If $\sigma=1.2$, there has been a 20% increase of free bilirubin concentration after drug administration. Although an arbitrary value of 1.2 has been suggested as the upper permissible limit for bilirubin displacement,

P.779

P.780

it is recommended that, as much as possible, drugs with the lowest σ values be selected. Table 35-8 lists the effects of drugs used in neonatology on bilirubin-albumin binding. The free drug concentration is calculated from the serum concentration and the percentage of bound drug as taken from existing data in the literature.

TABLE 35-8 EFFECT OF DRUGS USED IN NEONATOLOGY ON BILIRUBIN-ALBUMIN BINDING	
Agent	δ
Anticonvulsants	
Diazepam	1.00
Phenobarbital	1.04
Phenytoin	1.02
Valproate	1.09

Tolazoline	1.00
Tromethamine	1.00
Testing not required: bicarbonate, cimetidine, dextran, enalapril, flumecinol, heparin, ketamine, metoclopramide, naloxone, nicardipine, prostaglandin E ₁	
Neuromuscular junction agents	
Pancuronium	1.01
Testing not required: atracurium besylate, neostigmine, tubocurarine, vecuronium	
Sedative and analgesic agents	
Chloral hydrate	1.00
Paraldehyde	1.00
Pentobarbital	1.03
Thiopental	1.04
Testing not required: alfentanil, chlorpromazine, fentanyl, meperidine, midazolam, morphine	
Stimulants	
Aminophylline	1.24
Doxapram	1.00
Sympathetic and parasympathetic agents	
Edrophonium chloride	1.00
Testing not required: atropine, dobutamine, dopamine, epinephrine, isoproterenol, propranolol	

Drugs are listed according to the category of their use. The symbol represents the maximal displacement factor. If $\delta = 1.2$, there is a 20% increase in free bilirubin concentration following drug administration. Drugs listed as not requiring testing have low protein binding or low mean peak serum concentrations. A question mark indicates that the drug requires testing but that the peroxidase technique is not applicable.

From Robertson A, Carp W, Broderson R. Bilirubin displacing effect of drugs used in neonatology. *Acta Paediatr Scand* 1991;80:1119-1127, with permission.

Other drugs used (or with potential for use) in the neonatal intensive care unit (NICU) have also been tested. Aminoglycosides have minimal binding to albumin and should have no displacing effect. This has been confirmed for gentamicin (84). The use of ibuprofen has been suggested as an alternative to indomethacin to close the ductus arteriosus in premature newborns. Although indomethacin has some effect on bilirubin-albumin binding, it does so only at plasma levels far greater than those that occur clinically (85). Using the peroxidase-diazo method (68), Ahlfors found a significant increase in the unbound bilirubin concentration at serum ibuprofen levels of 100 $\mu\text{g/mL}$ or greater. This effect was similar to that found with sulfisoxazole. On the first day of life, serum bilirubin levels are very low, but ibuprofen has a long half-life and, over the next few days, could displace bilirubin from its albumin binding and distribute it to the extravascular spaces and cause "low bilirubin" kernicterus. Using a different technique, others have also found significant displacement of bilirubin by ibuprofen (86). Following a dose of 10 mg/kg, plasma ibuprofen levels range from 181 $\mu\text{g/mL}$ on day 1 to 33 $\mu\text{g/mL}$ on day 3 (87,88). These data argue against the use of ibuprofen in the sick, low-birth-weight infant who is already at a greater risk for developing kernicterus.

Benzyl alcohol has been used as a bacteriostatic agent in multidose bottles. A significant association was found between the use of benzyl alcohol and the development of kernicterus and intraventricular hemorrhage (89). Benzyl alcohol is a membrane fluidizer (55) and might act by increasing the permeability of the blood-brain barrier (90). On the other hand, benzoate, a metabolite of benzyl alcohol, is a powerful displacer of bilirubin and leads to an increase in unbound bilirubin levels (91).

Robertson and associates (92) also evaluated the effect of drug combinations on bilirubin-albumin binding. This is important because drug combinations are commonly administered to sick neonates, and the data show that the bilirubin-displacing effect of these combinations cannot be predicted from each drug's effect. For example, the administration of aminophylline with vancomycin increased the displacing effect when compared with either drug alone, but the overall effect was still minimal. In the absence of published data, drugs should be selected that have a low affinity for albumin and that have therapeutic concentrations much lower than the usual concentration of albumin (about 2.8 g/dL in a very-low-birth-weight newborn). Simultaneous treatment with several drugs should be limited as much as possible (92). Finally, as discussed in Blood-Brain and Blood-Cerebrospinal Fluid Barriers below, drugs that do not affect albumin binding of bilirubin may nevertheless affect brain uptake of bilirubin by inhibiting P-glycoprotein (P-gp) function (93).

Other Competing Anions

It is possible that certain unidentified anions interfere with the albumin binding of bilirubin. Evidence for this is suggested by the failure of exchange transfusion to alter significantly the albumin binding of infants' serum, even though the exchange transfusion removes bilirubin, replaces much of the infant's serum albumin with bilirubin-free albumin, and lowers the free bilirubin level (94). Anions that interfere with albumin binding might be present in the extravascular compartment and might not be removed by exchange transfusion.

Clinical Status of the Infant

A relation may exist between bilirubin-binding capacity and the clinical condition and gestational age of the infant. In some studies, very premature and sick infants were able to bind less bilirubin per mole of albumin than were more mature infants (95,96). However, no relation was found between bilirubin-binding ability and gestational age in other studies (97,98).

Finally, while a great deal of attention has focused on the effects of drugs on bilirubin binding and metabolism, relatively little attention has been given to the effects of bilirubin on the pharmacokinetics, efficacy, and toxicities of commonly used drugs.

Bilirubin and the Brain

Under normal circumstances, there is thought to be a constant movement of bilirubin in and out of the brain. Experimentally, however, it is difficult to induce kernicterus or electrical central nervous system changes in healthy animals by infusion of bilirubin, regardless of how much is infused. This may be related to the practical difficulty of preparing homogenous infusates with high bilirubin concentrations, as well as the efficient mechanisms for clearance of bilirubin in experimental animals (99,100). Gross staining of the brain and electrophysiologic changes, however, occur readily in asphyxiated animals and in those subjected to perturbations of the blood-brain barrier or of bilirubin-albumin binding (99,101,102,103,104,105,106).

Genetic factors may be involved in determining the susceptibility of patients to bilirubin-induced neurotoxicity. For example, in different strains of Gunn rats exposed to similar bilirubin and albumin concentrations, there were significant differences in susceptibility to kernicterus and mortality, suggesting that genetic or other factors may be important in determining individual susceptibility to bilirubin toxicity (107).

Blood-Brain and Blood-Cerebrospinal Fluid Barriers

The blood-brain barrier (BBB) is the barrier that exists between the brain capillary endothelium and the brain parenchyma; it limits the entry of certain substances into the central nervous system (CNS) (Fig. 35-9). The choroid plexus is the barrier between the blood and the cerebrospinal

P.781

fluid (CSF) (67). The BBB consists of a continuous lining of endothelial cells connected by tight junctions that restrict intercellular diffusion. The BBB normally excludes most water-soluble substances, proteins, and macromolecules, but is permeable to low-molecular-weight lipid-soluble substances that are not highly protein bound. Large molecules, such as albumin, are excluded from the brain but may enter when the BBB is made permeable by the infusion of a hypertonic solution (62, 101,106). The endothelial cells of the choroid plexus lack tight junctions and are fenestrated, allowing some proteins and their bound ligands to enter the CSF (67).

Although the total protein concentration of CSF in the newborn is only approximately 2% of the plasma protein concentration, the ratios of TSB to protein are similar in CSF and plasma, suggesting that the steep

concentration gradient from plasma to CSF is the result of the much lower concentration of bilirubin binding protein in the CSF (67).

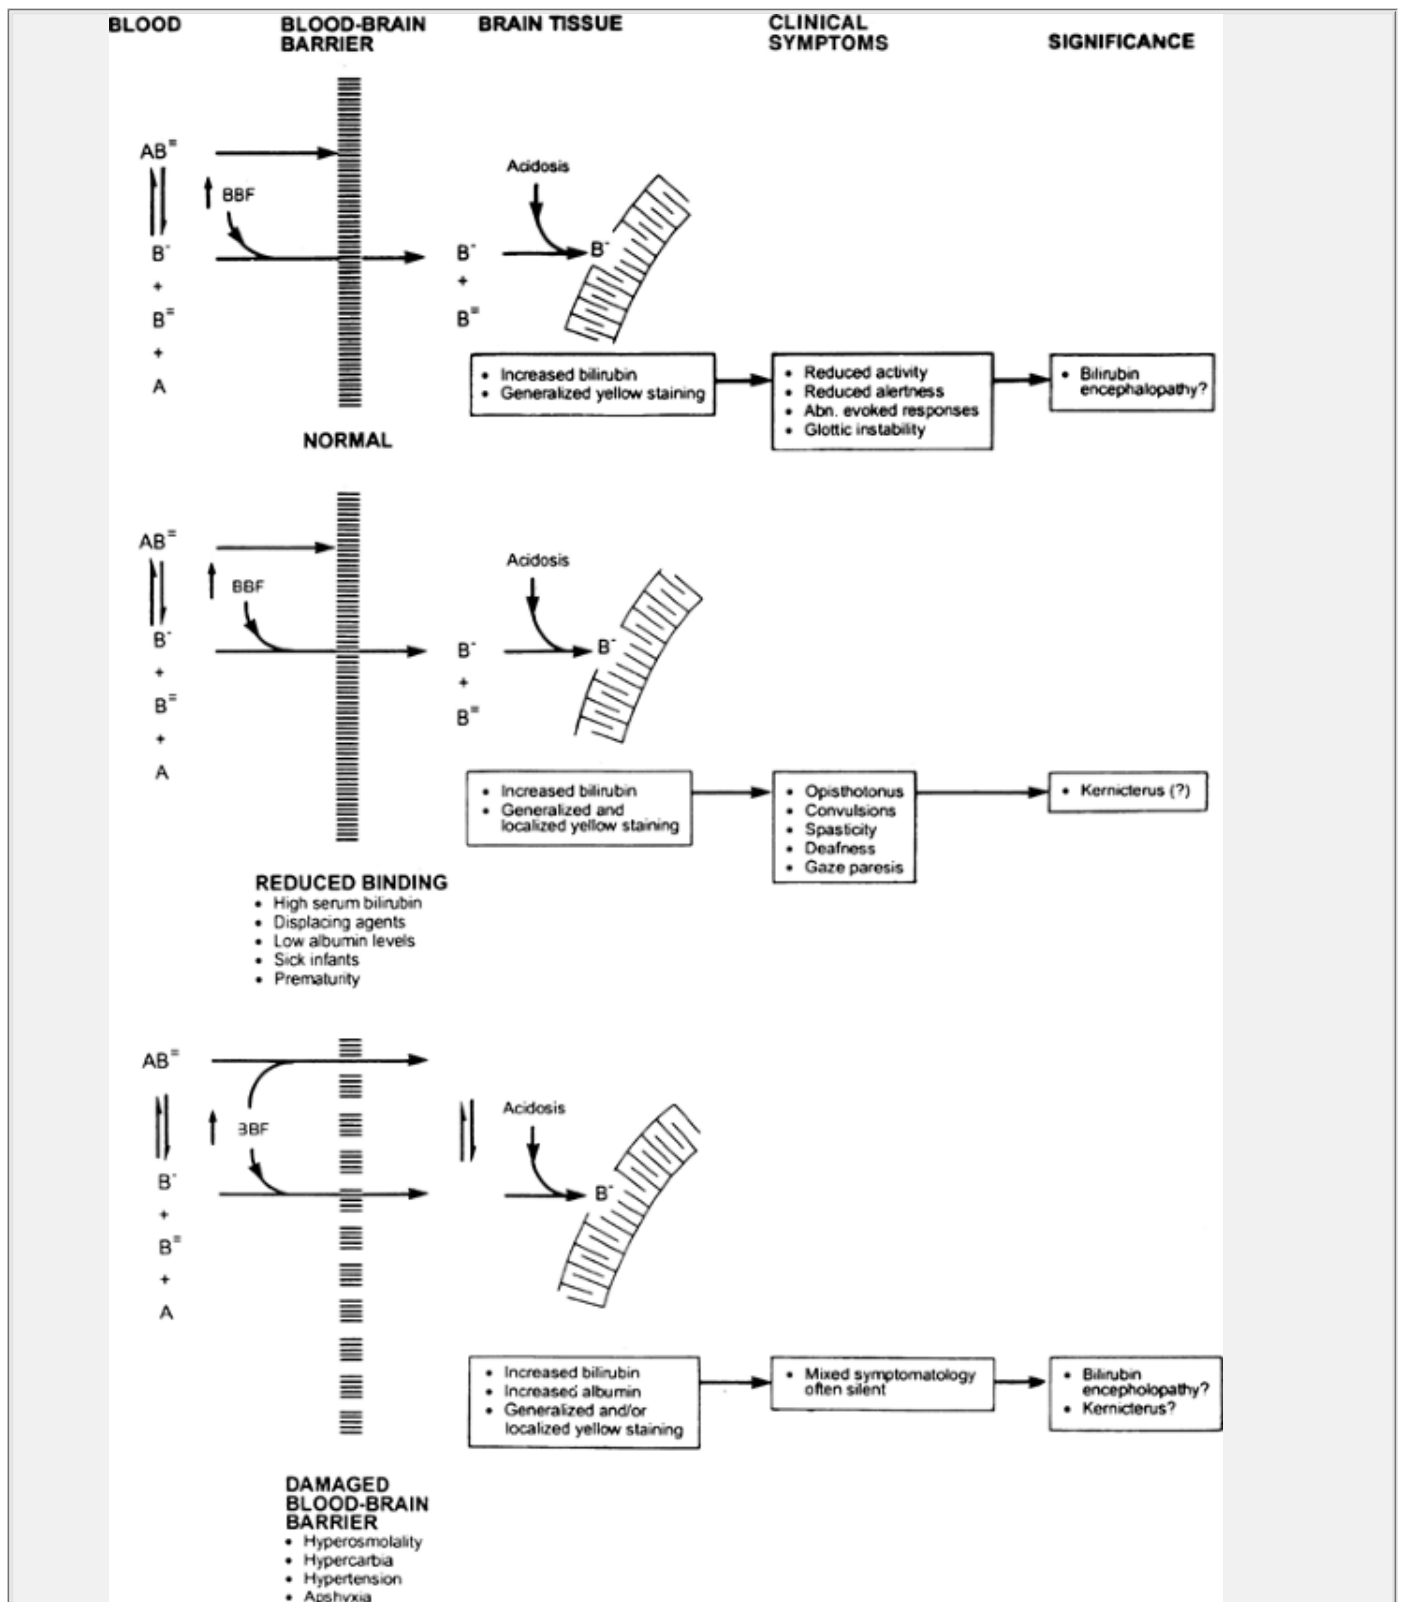

Figure 35-9 Possible mechanisms for bilirubin entry into the brain and for binding to neuronal cell membranes. The different factors affecting this process are indicated. A, albumin; AB, albumin-bilirubin complex; B^- , bilirubin monoanion; B^- , bilirubin dianion; BBF, brain-blood flow. (From Bratlid D. How bilirubin gets into the brain. *Clin Perinatol* 1990;17:449-465, with permission.)

Opening of the BBB allows albumin-bound bilirubin to bathe the neurons. The partitioning of sufficient bilirubin from albumin to neuronal membranes will produce changes in the electroencephalogram.(62). Disruption of the BBB and increased delivery of bilirubin to the brain may be important in the pathogenesis of bilirubin toxicity.

Protection of Cells from Neurotoxicity and Limiting Bilirubin Access to the Brain.

Certain factors—including intracellular binding of unconjugated bilirubin to cytosolic proteins (67,108), neuronal apoptosis inhibitor proteins (NAIPs), and bilirubin oxidation in brain cells (50)—may protect cells of the central nervous system during exposure to elevated concentrations of unconjugated bilirubin. Other factors play a role in limiting bilirubin access to the brain. adenosine triphosphate binding cassette (ABC) transporters are proteins that use adenosine triphosphate (ATP) to translocate substrates across biologic membranes (109) and they play a role in limiting the accumulation of organic anions and other small molecules in the CNS and CSF (67). These are multidrug resistance-associated proteins (MRPs) and multidrug resistance P-glycoproteins (MDR/P-gps). P-gp is a member of the ABC family of membrane transporters and is encoded for by a family of genes known as the multidrug resistance (MDR) genes (MDR1 and MDR2 in humans; *mdr1a*, *mdr1b*, and *mdr2* in rodents) (67,109,110). P-gp is an ATP-dependent plasma membrane efflux pump expressed in brain capillary endothelial cells and astrocytes of the blood-brain barrier. It limits the passage of lipophilic substrates and, possibly, bilirubin, into the brain (110). Following a high-load bilirubin infusion, P-gp-deficient mice have higher brain bilirubin content than do controls (110). Drugs that inhibit P-gp function increase brain uptake of bilirubin under the same experimental conditions (93). P-gp and other transporters could have an important influence on the deposition of bilirubin in the cells of the CNS (109), but their specific role has yet to be defined.

Lipid Solubility

Lipid-soluble substances that are not protein bound and gases, such as carbon dioxide and oxygen, cross the BBB easily, by simple diffusion, whereas water-soluble substances, proteins, and polar compounds (i.e., ions) do not.

Factors Affecting Blood-Brain Barrier Permeability

Anoxia, hypercarbia, and hyperosmolality open the BBB and increase the deposition of bilirubin and albumin in the brain, producing neurophysiologic and biochemical changes as well as changes in brain physiology and energy metabolism (see Fig. 35-9) (49,60,111). Thus, opening of the BBB is likely to be one important mechanism in the pathogenesis of kernicterus, although other mechanisms undoubtedly exist. For example, during hypercarbia, the increased bilirubin that is deposited in the brain is predominantly in the unbound form, although some is also albumin bound (69,104). The regional deposition of bilirubin in the brain of piglets occurs in areas where hypercarbia produces the greatest increase in regional blood flow (104). Respiratory acidosis increases bilirubin deposition in the brain but metabolic acidosis does not (103,104).

Effect of Maturity on Blood-Brain Barrier Permeability

Is the BBB of the neonate more permeable to bilirubin and albumin than in older children or adults? The immature brain demonstrates greater passive permeability between the blood and central nervous system for lipid-insoluble molecules (112). Studies in newborn piglets show that the BBB is more permeable to bilirubin in 2-day-old than in 2-week-old piglets, whereas the permeability to albumin does not change (113). Other studies have found that albumin transfer into the brain of newborn Gunn rats decreases with age (114).

Mechanisms by Which Bilirubin Enters the Brain

Bratlid (60) has provided a simplified scheme, not involving membrane transporters for bilirubin entry into the brain, its binding to neuronal cell membranes, and the potential clinical signs that may follow (see Fig. 35-9). Under normal circumstances, bilirubin can enter the brain unaccompanied by albumin. Clinical confirmation of this fact is provided by the observation that even modest elevations of serum bilirubin can sometimes produce clinical and electrophysiologic alterations in healthy full-term infants as demonstrated by changes in behavior (115), characteristics of the cry (116), and changes in the brainstem auditory evoked response (BAER) (117). These symptoms disappear as the bilirubin level decreases (117,118).

The probability of toxic levels of bilirubin entering the brain increases when the serum level of unbound pigment increases, as depicted in the center panel of Fig. 35-9. Finally, if the BBB is disrupted, both albumin and bilirubin can enter the brain; but even in the presence of a damaged BBB, more bilirubin than albumin, on a molar basis, seems to be deposited (69,101,102,103). In all of these situations, acidosis would increase deposition of

bilirubin in brain cells.

Oxidation of Bilirubin in the Brain

There is some evidence that mitochondria in the brain and other tissues contain a bilirubin oxidase that converts bilirubin to biliverdin and other nontoxic products (119, 120). The specificity and clinical relevance of this putative enzyme remains to be established.

Clinical Features of Bilirubin Encephalopathy

Terminology

Although originally a pathologic diagnosis characterized by bilirubin staining of the brainstem nuclei and cerebellum, the term *kernicterus* has come to be used interchangeably with both the acute and chronic findings of bilirubin encephalopathy. Bilirubin encephalopathy describes the

P.783

clinical central nervous system findings caused by bilirubin toxicity to the basal ganglia and various brainstem nuclei. To avoid confusion and encourage greater consistency in the literature, the AAP recommends (76) that the term *acute bilirubin encephalopathy* be used to describe the acute manifestations of bilirubin toxicity seen in the first weeks after birth and that the term *kernicterus* be reserved for the chronic and permanent clinical sequelae of bilirubin toxicity. This is the terminology that is used in this chapter. Recently, Johnson and associates suggested the use of the term *bilirubin-induced neurologic dysfunction* (BIND) (121) to describe the changes associated with acute bilirubin encephalopathy; they also proposed a scoring system to quantify the severity of the clinical manifestations.

Acute Bilirubin Encephalopathy

In classic acute bilirubin encephalopathy, markedly jaundiced infants progress through three fairly distinct clinical phases (Table 35-9) (51,122,123,124). In the early phase, the infant becomes lethargic and hypotonic, and sucks poorly. The intermediate phase is characterized by moderate stupor, irritability, and hypertonia. The infant may develop a fever and a high-pitched cry (51), which might alternate with drowsiness and hypertonia. The hypertonia involves the extensor muscle groups, and most infants exhibit backward arching of the neck (retrocollis) and trunk (opisthotonos) (Fig. 35-10). The fever may be caused by diencephalic involvement. The advanced phase is characterized by pronounced retrocollis-opisthotonos, shrill cry, refusal to feed, apnea, fever, deep stupor to coma, and sometimes seizures and death (51,123,124).

Figure 35-10 This infant presented at age 30 days with a serum bilirubin level of 30 mg/dL (513 μ mol/L) secondary to the Crigler-Najjar syndrome type I. He demonstrates retrocollis and opisthotonos, signs of the intermediate to advanced stage of acute bilirubin encephalopathy.

TABLE 35-9 MAJOR CLINICAL FEATURES OF ACUTE BILIRUBIN ENCEPHALOPATHY

Initial phase

- Slight stupor (“lethargic,” “sleepy”)
- Slight hypotonia, paucity of movement
- Poor sucking; slightly high-pitched cry

Intermediate phase

- Moderate stupor—irritable
- Tone variable—usually increased; some with retrocollis-opisthotonos
- Minimal feeding; high-pitched cry

Advanced phase

- Deep stupor to coma
- Tone usually increased; some with retrocollis-opisthotonos
- No feeding; shrill cry

From Volpe JJ. Neurology of the newborn. 4th ed. Philadelphia: WB Saunders, 2001, with permission.

Subsequently, usually after 1 week, hypertonia subsides and is replaced by hypotonia. Infants who manifest hypertonia during the second phase almost always develop the clinical features of chronic bilirubin encephalopathy (122,123) although an emergent exchange transfusion might, in some cases, reverse the CNS changes (125). Van Praagh (123) found that those who were consistently neurologically normal during the first week of life never developed the features of chronic encephalopathy, but other investigators found later evidence of brain

damage in some infants in whom no, or equivocal, manifestations of kernicterus were apparent in the newborn (Table 35-10) (122,126,127).

Clinical Features	Percent (%) of Cases
No definite neurologic signs	15
Equivocal neurologic signs	20–30
Definite neurologic signs	55–65

Diagnosis of kernicterus in the neonatal period. *Pediatrics* 1961;28:870–876; and Byers RK, Paine RS, Crothers V. Extrapyrarnidal cerebral palsy with hearing loss following erythroblastosis. *Pediatrics* 1955;15:248.

P.784

Kernicterus (Chronic Bilirubin Encephalopathy)

Temporal Evolution

There is a typical temporal evolution of chronic bilirubin encephalopathy after neonatal erythroblastosis fetalis (128). In the first year, infants typically feed poorly, develop a high-pitched cry, and are hypotonic, but have increased deep tendon reflexes, a persistent tonic neck reflex, and motor delay. There is a delay in acquisition of motor skills, although most infants walk alone by 5 years of age. The other typical features of chronic bilirubin encephalopathy usually are not apparent before 1 year of age and often not for several years (51). These children generally are hypotonic at rest for the first 6 or 7 years. By the time they reach their teens, hypertonia has replaced hypotonia (129).

Clinical Features

The classic sequelae of posticteric encephalopathy constitute a tetrad consisting of extrapyramidal disturbances, auditory abnormalities, gaze palsies, and dental dysplasia (Table 35-11) (129).

Extrapyramidal Disturbances

Athetosis (i.e., involuntary, sinuous, writhing movements) may develop as early as

18 months of age, but may be delayed until as late as 8 or 9 years of age (128). If sufficiently severe, athetosis may prevent useful limb function. These movements are described as "uncontrollable, purposeless, involuntary, and incoordinate. They may be rapid and jerky (choreiform), slow and worm-like (orthodox athetosis), or so slowed by hypertonicity that the patient may assume momentarily fixed attitudes with stiffness of the extremities (dystonia)" (129). Occasionally, extrapyramidal rigidity may predominate, rather than involuntary motion. In the opinion of Perlstein (129), "the absence of athetosis or of other forms of extrapyramidal dyskinesia, makes the diagnosis of post-icteric encephalopathy dubious, if not untenable." Severely affected children also may have dysarthria, facial grimacing, drooling, and difficulty chewing and swallowing.

TABLE 35-11 MAJOR CLINICAL FEATURES OF CHRONIC POSTKERNICTERIC BILIRUBIN ENCEPHALOPATHY

Extrapyramidal abnormalities, especially athetosis

Gaze abnormalities, especially of upward gaze

Auditory disturbance, especially sensorineural hearing loss

Intellectual deficits, but minority in mentally retarded range

From Volpe JJ. Neurology of the newborn. 4th ed. Philadelphia: WB Saunders, 2001, with permission.

Auditory Abnormalities

Some degree of hearing loss is often found in children with kernicterus. Pathologic studies and studies of BAERs indicate that injury to the brainstem, specifically to the cochlear nuclei, is the principal cause of hearing loss, although occasional studies suggest possible involvement of the peripheral auditory system as well (39,73,117,130). It is noteworthy that in some frequently quoted studies, virtually all of the infants who developed severe hearing loss had received prophylactic streptomycin (an ototoxic antibiotic) prior to exchange transfusion (126,131).

Hearing loss is generally most severe in the high frequencies, and an association between moderate hyperbilirubinemia and subsequent sensorineural hearing loss has been described in low-birth-weight infants (see Clinical Sequelae of Hyperbilirubinemia below).

Auditory neuropathy, or auditory dyssynchrony is a recently described entity that is functionally defined as abnormal or absent BAER with normal inner ear function

as tested by cochlear microphonic responses or otoacoustic emissions (132). The inner ear or cochlea is normal but the ascending auditory pathway in the nerve or brainstem is abnormal (132). Shapiro has diagnosed auditory neuropathy in ten children with classical kernicterus (132).

Gaze Abnormalities

There may be limitation of upward gaze and other gaze abnormalities although full vertical eye movements during the doll's-eye maneuver are attained in most affected children. This suggests that the lesion is above the level of the oculomotor nuclei (51). Some patients have paralytic gaze palsies. Supranuclear palsies can be explained by bilirubin deposition and neuronal injury in the rostral midbrain, and nuclear palsies can be explained by damage to the oculomotor nuclei (39).

Dental Dysplasia

Approximately 75% of kernicterus children with posticteric encephalopathy have some degree of dental enamel hypoplasia. A smaller percentage have green discoloration of the teeth (129).

Magnetic Resonance Imaging

The diagnosis of acute bilirubin encephalopathy and kernicterus can now be confirmed by magnetic resonance

P.785

imaging (MRI) (133,134,135,136 and 137). The most characteristic image is a bilateral, symmetric, high-intensity signal in the globus pallidus seen on both T₁- and T₂-weighted images (Fig. 35-11), although it should be noted that similar findings in the globus pallidi have been described in mitochondrial disorders and in pyruvate dehydrogenase deficiency (138). High signal intensity also has been seen in the hippocampus and the thalamus (133). We do not yet know the natural history or time course of the MRI changes of kernicterus, how early these changes will occur, and whether or not they are seen in every case. They have been seen in an 8-day-old infant as well as in a 12-year-old child with a history of severe neonatal jaundice (133,134).

Figure 35-11 Magnetic resonance imaging scan of a 21-month-old male infant who had erythroblastosis fetalis and presented with extreme hyperbilirubinemia and clinical signs of kernicterus at age 54 hours. Note the symmetric, abnormally high-intensity signal from the area of the globus pallidus on both sides (*arrows*). (From Grobler JM, Mercer MJ. Kernicterus associated with elevated predominantly direct-reacting bilirubin. *S Afr Med J* 1997;87:146, with permission.)

Clinical Sequelae of Hyperbilirubinemia

Although there is no doubt about the relationship between elevated TSB levels and brain damage, the ability of a single peak bilirubin level to predict long-term neurodevelopmental outcomes is poor (139,140). In addition, our conclusions regarding hyperbilirubinemia and neurodevelopmental outcomes are limited by the quality of the published data. In many case reports of kernicterus, analyzed in detail by Ip and associates (139,140), it is impossible to know if the putative peak TSB levels (measured in some cases more than 7 days after birth) were true peak levels, and many cohort studies have significant problems with blinding of the examiners and dropouts (139,140,141). For a detailed analysis of the published literature from 1966 to 2001 dealing with these issues, see the evidence reports of Ip and associates (139,140).

Hsia and colleagues (142) and Mollison and Cutbush (143) first established the link between bilirubin levels and brain damage in the early 1950s, when they demonstrated that the risk of kernicterus in infants with Rh hemolytic disease increased dramatically with rising bilirubin levels and that exchange transfusion could markedly reduce the risk. Subsequent studies suggested that, in untreated infants with hemolytic disease, the incidence of kernicterus was much higher than the incidence in markedly jaundiced infants without hemolytic disease (144,145). For many years, there has been considerable disagreement about how jaundice in infants without hemolytic disease should be treated (144,145,146,147,148,149). Some investigators have described clinical and pathologic kernicterus in premature infants who did not have hemolytic disease and whose TSB levels were well below 20 mg/dL (342 $\mu\text{mol/L}$) (150,151). In some small, sick infants, yellow staining of the brain was seen at autopsy, with TSB levels less than 10 mg/dL (171 $\mu\text{mol/L}$) (151). In addition, the finding that gross bilirubin staining of the brain can occur in the absence of the typical microscopic neuronal damage described with kernicterus called into question the meaning of yellow staining of the brain in some very-low-birth-weight infants (46). Unlike the classic form of fatal kernicterus, these very-low-birth-weight infants, although they may have had kernicterus, died of other causes.

Starting in 1967 and continuing into the late 1970s, reports from the Collaborative Perinatal Project (CPP), a study of 53,000 pregnant women and their offspring, linked moderate elevations of neonatal serum bilirubin to lower developmental scores, lower IQ scores, and increased risk of neurologic abnormalities (152). These findings occurred at TSB levels previously presumed to be safe and suggested that acute bilirubin encephalopathy or classic kernicterus was only the most obvious and extreme manifestation of a spectrum of bilirubin toxicity. At the other end of the spectrum might lie more subtle forms of neurotoxicity that occur

at much lower bilirubin levels and in the absence of any obvious abnormal clinical findings in the neonatal period; there are some data to support this view (140).

The following section deals with the clinical sequelae of hyperbilirubinemia in different groups of infants.

Rh Hemolytic Disease of the Newborn

In the only controlled clinical trial conducted on the treatment of hemolytic disease of the newborn, Mollison and Walker (153) demonstrated beyond reasonable doubt that exchange transfusion in these infants improved their chance of survival and decreased the risk of fatal kernicterus. The results of these studies, combined with subsequent uncontrolled observations, established exchange transfusion as the standard treatment for preventing

P.786

kernicterus in infants with erythroblastosis fetalis and showed that kernicterus was unlikely to occur if TSB levels were kept below 20 mg/dL (342 μ mol/L), an observation that has been amply confirmed by subsequent experience with the treatment of hemolytic disease (142,143). It is interesting to recall, however, that these studies were performed on infants born in the late 1940s and early 1950s. These infants were commonly asphyxiated and seriously ill, and many were delivered prematurely to prevent stillbirth. Streptomycin, an ototoxic drug was frequently administered to those who received exchange transfusions.

Hsia and associates (142) reported that the incidence of kernicterus in their infants was 8% for those with TSB levels of 19 to 24 mg/dL (325 to 410 μ mol/L), 33% for TSB levels of 25 to 29 mg/dL (428 to 496 μ mol/L), and 73% for those with bilirubin levels higher than 30 mg/dL (513 μ mol/L). Later experience with Rh hemolytic disease was far more encouraging. Johnston and associates (126) studied 129 infants born between 1957 and 1958, all of whom had *indirect-reacting* serum bilirubin levels higher than 20 mg/dL (342 μ mol/L). Ninety-two infants with Rh hemolytic disease were followed to age 5 to 6 years and evaluated with detailed psychometric, neurologic, and audiologic evaluations. One of 92 infants had a minimal sensorineural hearing loss (and a normal IQ) and 1 infant had mild athetosis, moderate sensorineural hearing loss, and a normal IQ. Thus, the risk of bilirubin encephalopathy in infants with Rh disease born from 1957 to 1958 with indirect-reacting bilirubin levels higher than 20 mg/dL (342 μ mol/L) was 2 of 92 or approximately 2% (126).

In a study of full-term Turkish infants (154), those who had Coombs-positive ABO incompatibility or Rh immunization had a greater risk (vs. infants without hemolytic disease) of neurologic abnormalities and lower IQ scores when their indirect-reacting bilirubin levels exceeded 20 mg/dL (342 μ mol/L). These data reinforce the belief that hemolysis is an important risk factor in bilirubin-dependent brain damage. The risk of neurologic abnormalities also was associated

with the duration of indirect-reacting hyperbilirubinemia higher than 20 mg/dL (342 $\mu\text{mol/L}$). In those exposed to these bilirubin levels for less than 6 hours, the incidence of neurologic abnormalities was 2.3%. This increased to 18.7% if the exposure lasted 6 to 11 hours and to 26% with 12 or more hours of exposure (154). These data support earlier observations suggesting that the duration of hyperbilirubinemia is related to the risk of long-term neurodevelopmental outcome (155). It is difficult to define the risk of abnormal outcomes in infants with hemolysis from causes such as red cell membrane defects and glucose-6-phosphate dehydrogenase (G6PD) deficiency, although the risk of bilirubin encephalopathy in G6PD deficiency appears to be similar to that of Rh hemolytic disease (156).

Full-Term and Near-Term Infants Without Hemolysis

Two issues in neonatal medicine that consistently generate controversy are the relationship between hyperbilirubinemia and adverse developmental outcome in nonhemolyzing newborns and the indications for treating these infants. These issues are addressed in multiple studies and the reader is referred to extensive reviews for details of the individual studies (124,139,140,144,152). When carefully analyzed, the data tend to demonstrate that, in otherwise healthy neonates without hemolytic disease, TSB levels that do not exceed approximately 25 mg/dL (428 $\mu\text{mol/L}$) are very unlikely to place these infants at risk of adverse neurodevelopmental consequences. Specifically, in many large studies there has been no convincing demonstration of any adverse effect of such serum bilirubin levels on IQs, definite neurologic abnormalities, or sensorineural hearing loss (124,139,140,144,152).

No studies have looked specifically at infants who are 35 to 37 weeks of gestation, although the data analyzed by Ip and associates includes infants of 34 weeks and older (139,140). In the very large CPP, the study population included all infants with birth weights $\geq 2,500$ g (145,152, 157). Presumably some of these infants were in the 34- to 37-weeks' gestational age category. There are insufficient followup data on infants who had TSB levels of 25 to 30 mg/dL (292 to 513 $\mu\text{mol/L}$) to draw firm conclusions about this group. Nevertheless, a 21-month followup of 26 Coombs-negative, healthy, term infants with TSB levels of 26.2 to 46.3 mg/dL (446 to 788 $\mu\text{mol/L}$) revealed no neurodevelopmental abnormalities and no hearing loss (158). Newman identified 11 infants out of 111,009 infants born between 1995 and 1998 with TSB levels ≥ 30 mg/dL (513 $\mu\text{mol/L}$); 5 were 35 to 37 weeks' gestation and 5 were 38 to 39 weeks' gestation. They were followed for 1.5 to 5 years and none had neurologic or developmental problems (159).

When they combined both abnormal and suspicious neurologic examination results, Newman and Klebanoff (160), in their analysis of the CPP, did

demonstrate a significant increase in abnormalities associated with increasing bilirubin levels. The "suspicious" abnormalities included nonspecific gait abnormalities, awkwardness, an equivocal Babinski reflex, abnormal cremasteric reflex, abnormal abdominal reflex, failure of stereognosis, questionable hypotonia, and gaze abnormalities. The most frequent abnormal findings were awkwardness and abnormal cremasteric reflexes. When the abnormal and suspiciously abnormal children were combined, the risk of abnormalities increased from 14.9% for those whose TSB levels were less than 10.0 mg/dL (171 μ mol/L) to 22.4% for those whose TSB levels exceeded 20 mg/dL (340 μ mol/L). Because 41,324 infants were enrolled in this study, these differences were statistically highly significant, but this finding should be kept in perspective. Even if the relationship between these findings is causal, we have no evidence that the use of a bilirubin-lowering intervention, such as phototherapy, at these low bilirubin levels would affect the outcome. Finally, as Newman and Klebanoff (160) point out, even if bilirubin levels had been prevented from exceeding 10 mg/dL (171 μ mol/L) in every infant, the expected rate of abnormal or suspicious neurologic examination results would only decline from 15.13% to 14.85%.

P.787

Less-reassuring information is provided by a study of a group of Israeli army draftees ($n = 1,948$) in which their preinduction psychological and physical examinations at age 17 years were matched with their newborn bilirubin levels. Seidman and associates (161) found an association between the risk of an IQ below 85 and a TSB level higher than 20 mg/dL (342 μ mol/L) in full-term boys (but not with girls) with a negative Coombs test ($p = 0.01$). On the other hand, no association was found between bilirubin levels and mean IQ score, the risk of physical or neurologic abnormality, or hearing loss. In a subsequent analysis of a similar population, Seidman and colleagues (162) found no increase in the risk of an IQ less than 85 with TSB levels higher than 20 mg/dL (342 μ mol/L).

Two studies raised concerns regarding "soft signs" of neurologic dysfunction in infants exposed to moderate levels of bilirubin (163,164). In a study performed in the Netherlands, the investigators prospectively evaluated 20 jaundiced infants whose TSB levels ranged from 13.6 to 26 mg/dL (233 to 444 μ mol/L) and compared them with a control group of 20, healthy, nonjaundiced infants matched for sex and gestational age (164). At age 1 year, 5 of 8 (63%) infants with TSB levels between 19.6 and 26 mg/dL (335 and 444 μ mol/L) demonstrated minor abnormalities in muscle tone and posture compared with 0 of 20 control infants ($p < 0.001$). In a German study, children at 7 years of age whose neonatal TSB levels had exceeded 20 mg/dL (342 μ mol/L) scored significantly worse on a scale designed to measure choreiform and athetoid movements. In that study 8 of 16 (50%) children in the hyperbilirubinemia group versus 3 of 18 (17%) in the control group had abnormal scores (data not found in the original paper but kindly provided by the authors) (141,163). The sample sizes in both the Dutch and

German studies were small, but the effect sizes were large. Nevertheless, the outcome measurements are subjective and the blinding was not rigorous.

In a much earlier study, Johnson and Boggs followed 83 infants for 4 years and found abnormal neurologic examinations in 14 of 68 (21%) children whose indirect-reacting bilirubin levels were ≥ 15 mg/dL (257 $\mu\text{mol/L}$) versus 0 of 15 in those with TSB levels less than 15 mg/dL (155) (1 tail $p = 0.047$). Of the 14 children, 11 had "minimal cerebral dysfunction" and 3 had other abnormal signs, including fine and gross motor delay, athetoid movements, and mild mental retardation (it is not stated how many of the 3 infants had some or all of these findings). In that study, however, 53% of the infants had hemolytic disease and 33% were premature, and there is no mention of whether or not the followup evaluations were performed in a blinded fashion (155).

Comorbid Factors and Outcome

In term and near-term infants, there appears to be an increase in the likelihood of neurologic damage if hyperbilirubinemia is accompanied by other risk factors (43,139,140). The risk factors commonly listed include isoimmune hemolytic disease, prematurity, G6PD deficiency, asphyxia, sepsis, acidosis, and hypoalbuminemia (Table 35-12) (139,140).

In the CPP population, Naeye found that infants who were exposed to chorioamnionitis prior to delivery had a higher incidence of low IQ scores and neurologic abnormalities at age 7 years in relationship to increasing bilirubin levels than did those infants who were not exposed to chorioamnionitis (165).

It is long been believed that infants with hemolytic disease are at a greater risk for bilirubin-related brain damage than are those infants who do not have hemolysis. This applies to Rh and ABO hemolytic disease, as well as to G6PD deficiency. Notwithstanding the general agreement on this subject, the data supporting this conclusion are not very strong, nor is there any documented mechanism that explains why a serum bilirubin level of 20 mg/dL in an infant with hemolytic disease should be more dangerous than the same level in an infant without hemolysis. For example, there is no evidence of any difference in the binding of bilirubin to albumin in infants with hemolytic disease as compared with those who are not hemolyzing. Nevertheless, the consensus among experts is that infants who have hemolytic disease should be treated more aggressively than those who do not.

Bilirubin Binding Capacity, Kernicterus, and Developmental Outcome

Because bilirubin that is "free" or loosely bound to albumin is more likely to cross the blood-brain barrier (see Bilirubin Chemistry and Neurotoxicity and Blood-Brain

and Blood-Cerebrospinal Fluid Barriers above), our ability to predict the risk of bilirubin encephalopathy might be improved by measurement of unbound bilirubin or the reserve albumin binding capacity. A reduced albumin-binding capacity has been associated with abnormal developmental outcome in some studies (155,166) but not in others (167), although such associations have been found between free bilirubin levels and abnormalities in the BAER (70,71,73,168). Elevated free bilirubin concentrations have also been found in preterm infants with kernicterus (44,72,77,169). Currently there are no bilirubin-binding tests in routine clinical use in the United States, although a semiautomated peroxidase method has been used in Japan (71,73) and a modification of this technique developed in the United States (68). Nevertheless, there are no long-term studies of the developmental outcome of infants in whom binding measurements have been obtained with this technique.

Duration of Hyperbilirubinemia

A relationship has been described between neurologic and psychometric abnormalities and the duration of exposure to TSB levels higher than 15 mg/dL (154,155,166). Many

P.788

P.789

of the infants in these studies were either premature or had hemolytic disease. In a Turkish study, exposure to TSB levels greater than 20 mg/dL (342 μ mol/L) for less than 6 hours was associated with a 2.3% incidence of neurologic abnormalities. This increased to 18.7% if exposure lasted 6 to 11 hours, and to 26% with 12 or more hours of exposure (154). In the large NICHHD collaborative phototherapy trial, a 6-year followup of 224 control infants who did not receive phototherapy and who had birth weights of less than 2,000 g showed no association between IQ and duration of exposure to bilirubin (170).

TABLE 35-12 SUMMARY OF 88 CASE REPORTS OF TERM AND NEAR-TERM (GESTATIONAL AGE \geq 34 WEEKS) INFANTS WITH COMORBID FACTORS WHO HAD CLINICAL SIGNS OF ACUTE OR CHRONIC BILIRUBIN ENCEPHALPATHY OR KERNICTERUS DIAGNOSED AT AUTOPSY

Comorbidity	Diagnosis of Kernicterus				Autopsy	Total(N)	Mean Peak TSB \pm SD (Range), mg/dL	Mean BW \pm SD ^a (Range), g	Gender
	Acute Phase Without Followup	Acute Phase but Normal Followup	Chronic Sequelae						
ABO incompatibility	6	0	12	1 ^b	19	31.6 \pm 8.2 (19.0–51.0)	3,118 \pm 680 (2,270–4,313)	6 females, 11 males, 2 unknown,	
Rh incompatibility	3	2	27	1	33	32.1 \pm 7.1 (17.7–46.0)	3,063 \pm 387 (2,300–3,969)	5 females, 4 males, 24 unknown	
G6PD deficiency	10	0	1	2	13	31.8 \pm 8.5 (23.0–50.0)	3,353 \pm 437 (2,700–4,100)	2 males, 11 unknown	
Sepsis or infections	3	1	4	5	13	31.8 \pm 9.9 (14.5–47.8)	3,368 \pm 586 (2,580–4,360)	7 females, 4 males, 2 unknown	
Multiple conditions	3	0	4	3	10	29.1 \pm 16.1 (4.0–49.2)	2,913 \pm 750 (1,780–3,686)	3 females, 4 males, 3 unknown	
Total	25	3	48	12	88	31.6 \pm 9.0 (4.0–51.0)	3,155 \pm 534 (1,780–4,360)	20 females, 25 males, 42 unknown	

BW, birth weight; G6PD, glucose-6-phosphate dehydrogenase; TSB, total serum bilirubin.

^a Contain some missing data.

^b This infant had acute phase of kernicterus and chronic kernicterus sequelae and then died at the age of 19 months.

From Ip S, Chung M, Kulig J, et al. An evidence-based review of important issues concerning neonatal hyperbilirubinemia. Pediatrics 2004;114:e130–e153, with permission.

An 18-year followup of 55 boys with a history of neonatal hyperbilirubinemia (greater than 15 mg/dL [257 μ mol/L]) was performed in Norway at the time of military draft physical examinations (171). Compared with the total cohort of Norwegian conscripts, there were no significant differences revealed on physical examination or tests of vision, hearing, or IQ. However, seven boys who had a history of positive Coombs tests and bilirubin in excess of 15 mg/dL (257 μ mol/L) for more than 5 days had significantly lower IQ scores than the national average.

Hearing Loss and Audiometric Evoked Responses

The BAER test is an accurate and noninvasive means of assessing the functional status of the auditory nerve and the brainstem auditory pathway. Figure 35-12 shows the BAER tracing of a normal full-term infant. The three positive waveforms labeled in the figure are those most easily identified in the neonate (118). The latency for wave I represents the peripheral conduction time. Latency of waves III and V and the interpeak latency of waves I to III, III to V, and I to V all represent measurements of central conduction time. The interpeak latency I to V is referred to as the brainstem conduction time. Reports also include amplitudes of the waveforms. These may decrease or be lost in response to various insults.

Figure 35-12 A typical tracing of brainstem auditory evoked response has various components. Wave I reflects the response of the peripheral auditory nerve; wave III reflects the superior olive; waves IV to V reflect the inferior colliculus with peak and trough shown. Wave I peak to waves IV to V trough (i.e., interpeak latency) reflects brainstem conduction time. (From Vohr BR. New approaches to assessing the risks of hyperbilirubinemia. *Clin Perinatol* 1990;17:293-306, with permission.)

Several studies have documented a relationship between TSB levels and the BAER (118,132,172), and the acute changes seen in the BAER can be reversed by lowering the TSB level with phototherapy or exchange transfusion (118). Abnormalities of the BAER are more closely related to unbound bilirubin levels than to TSB level (70,71,73,168), but there are no studies relating abnormalities in the BAER to long-term outcome.

Despite evidence for bilirubin damage to the auditory pathway in full-term and preterm infants with classical kernicterus, there is virtually no evidence for a risk of hearing loss related to hyperbilirubinemia in full-term infants who do not have hemolytic disease (152,161,170,173). In

a study of almost 17,000 children who received complete hearing and speech evaluations at 8 years of age, the incidence of sensorineural hearing loss in those who had TSB levels 20 mg/dL (342 μ mol/L) or higher was 2.2%, and it was also 2.2% in those whose TSB levels were less than 20 mg/dL (342 μ mol/L) (152). In the NICHHD phototherapy study, the incidence of sensorineural hearing loss in children followed to age 6 years was identical in the phototherapy and control groups (1.8% vs. 1.9%) (167). Remarkably, in a followup of 36 children with the Crigler-Najjar syndrome, none had evidence of sensorineural hearing loss (173).

Nevertheless, deficits in central hearing, speech, and language can occur in the absence of pure-tone hearing loss (174) and these may be manifestations of *auditory neuropathy* or *dyssynchrony* (132). This recently described entity is defined as abnormal or absent BAER with normal inner ear function as tested by cochlear microphonic responses or otoacoustic emissions (132) and has been diagnosed in children with kernicterus (132).

Cry Analysis

An abnormal cry is a sign of neurologic distress and is associated with acute bilirubin encephalopathy (40). Modest degrees of hyperbilirubinemia also affect the infant's cry (116,118).

Infant Behavior

Investigators have used the Brazelton Neonatal Behavioral Assessment Scale to evaluate the effect of hyperbilirubinemia on infant behavior. Most studies show some effect, although several are confounded by the use of phototherapy (118,140). Jaundiced infants score lower than controls in habituation, orientation, motor performance, regulation of state, and autonomic stability (118).

Premature Infants and Low-Bilirubin Kernicterus

Kernicterus and Developmental Outcome

It is generally believed that premature infants are at greater risk of developing kernicterus or bilirubin encephalopathy

P.790

than are full-term newborns exposed to similar bilirubin levels.

Watchko and Oski (150) provided a detailed historical review of kernicterus in preterm infants from the 1950s, which has been updated (151). Reports during the years 1950 to 1965 suggested that kernicterus or the clinical sequelae of hyperbilirubinemia were unlikely to develop if exchange transfusions were used to maintain TSB levels below 18 to 22 mg/dL (308 to 376 μ mol/L) (150). However, most of the infants in these studies were larger (1,250 to 2,500 g) and more mature (28 to 36 weeks of gestation) than the extremely low-birth-weight infants currently seen in NICUs.

Between 1958 and 1972, a group of studies reported the occurrence of kernicterus at TSB levels well below 20 mg/dL (342 μ mol/L) (150). In general, these infants were significantly more premature and of much lower birth weight than those previously observed with kernicterus. Some were exposed to sulfisoxazole, which previously was shown in a controlled trial to be a powerful displacer of bilirubin from its binding to albumin (63,175). As a result of these findings, exchange transfusion in preterm infants was recommended at TSB levels of less than 20 mg/dL (342 μ mol/L). Publication of data from the CPP that suggested an association between impaired psychomotor performance and TSB levels higher than 10 to 14 mg/dL (171 to 239 μ mol/L) in low-birth-weight infants provided additional support for these recommendations (165,176).

In the NICHHD cooperative phototherapy study (1974 to 1976), infants were randomly assigned to a control group that received no phototherapy or to a group that received phototherapy at predetermined TSB levels. The criteria for exchange transfusion for all infants mandated exchange transfusions at low levels of serum bilirubin (10 mg/dL [171 μ mol/L]) in high-risk newborns with birth weights less than 1,250 g (177). Kernicterus was found in 4 of 76 autopsied infants whose birth weights ranged from 760 to 1,270 g (47). Their peak TSB levels ranged from 6.5 to 14.2 mg/dL (111 to 243 μ mol/L). All were asphyxiated or had hyaline membrane disease, and all had some degree of periventricular-intraventricular hemorrhage (PIVH). Two had periventricular leukomalacia (PVL) (47).

Surviving infants in the study were followed and evaluated at 6 years of age with the Wechsler Verbal and Performance IQ test. No differences were found between the control and phototherapy groups in the incidence of definite and suspect cerebral palsy, clumsy or abnormal movements, hypotonia, or an IQ lower than 70. There were no differences between the two groups in growth, speech, hearing loss, or evidence of hyperactivity (170).

Scheidt and colleagues (167) also published a 6-year followup of 224 control children from the NICHHD study whose birth weights were lower than 2,000 g. None of these infants received phototherapy, but bilirubin levels were maintained below specified levels by the use of exchange transfusion. No relation was found between serum bilirubin levels and the incidence of cerebral palsy, nor was there any association between maximal bilirubin level and IQ. IQ was not associated with mean bilirubin level, time and duration of exposure to bilirubin, or measures of bilirubin-albumin binding (167).

Two studies reviewed the risk factors previously suggested to predict the development of kernicterus. They were unable to identify any risk factor or group of factors that was associated with the development of kernicterus in the premature neonate, including birth weight less than 1,500 g, hypothermia, asphyxia, acidosis, hypoalbuminemia, sepsis, meningitis, drug therapy, and TSB levels (178,179).

It is likely that there are some risk factors for the development of kernicterus that are unknown. An excellent example of this possibility was the report from one NICU of an abrupt decrease in kernicterus at autopsy in premature infants. The incidence of kernicterus fell from 31% to 0% when the practice of flushing intravenous catheters with bacteriostatic saline that contained benzyl alcohol was stopped (89). In an earlier study from the same NICU, the incidence of kernicterus diagnosed postmortem among neonates of 25 to 32 weeks of gestation was a remarkably high 25% (39). Benzyl alcohol is an agent that increases membrane fluidity and may facilitate the passage of bilirubin into the brain (55). At the same institution, Watchko and Claasen (160) found only three cases of kernicterus in 72 autopsies performed from 1984 through 1991 on newborns of less than 34 weeks of gestation who lived at least 48 hours. In the 69 newborns who did not have kernicterus, the peak TSB level ranged from 6.3 to 20.6 mg/dL (108 to 352 μ mol/L), and 56% had peak TSB values higher than those suggested for exchange transfusion by the NICHHD phototherapy study guidelines (160). This sustained decrease in the incidence of kernicterus confirms the experience in most nurseries that kernicterus in premature newborns is now rare, although it has not disappeared completely.

Sugama and associates documented the surprising observation of the presence of hypotonia and (in one infant) choreoathetosis together with the classical MRI findings of kernicterus in two preterm infants at 31 and 34 weeks gestation (136). Neither of these infants was acutely ill and their TSB levels were 13.1 mg/dL (224 μ mol/L) and 14.7 mg/dL (251 μ mol/L), respectively (136). Govaert and associates reported MRI findings in five preterm and three term infants with kernicterus. The TSB levels in the term infants ranged from 37.0 to 44.6 mg/dL (632 to 763 μ mol/L), but in the preterm infants (25 to 29 weeks' gestation) peak TSB levels ranged from 8.7 to 11.9 mg/dL (148 to 204 μ mol/L). Serum albumin levels in these preterm infants were strikingly

low (1.4 to 2.1 g/dL).

Several recent studies have failed to document an association between maximal TSB levels and developmental outcomes in very-low-birth-weight infants (180,181,182,183). van de Bor and colleagues (184) found a relation between maximal TSB concentrations in the neonatal period and cerebral palsy (not of the type characteristically found with kernicterus) at a corrected age of 2 years. No relation was found between maximal TSB concentrations and hearing defects. However, in a followup of the same population at 5 years, no significant difference was found in mean maximal TSB concentrations between children with and without

P.791

handicaps (180) although there was an association between TSB levels and handicap in children who had suffered a grade I intracranial hemorrhage. This effect was not seen in the more severe hemorrhages, but the number of infants with severe hemorrhages was small.

Although these data are reassuring, few of the infants in the reported studies had markedly elevated bilirubin levels (180,181,182,183). Most recently, however, peak TSB levels were associated with an increased risk of death, hearing loss and neurodevelopmental impairment in extremely low-birth-weight (ELBW) infants born between 1994 and 1997 (185). Although these associations were statistically significant, the effect sizes were very small. The data in all of these observational studies must be treated with caution because of the multifactorial nature of the causes of adverse neurologic sequelae, the possibility of compounding effects of variables on outcomes, and the difficulty inherent in fully controlling for these variables in such studies.

Some studies suggest an association between hyperbilirubinemia and cystic PVL in low-birth-weight infants (186,187,188), but others have not found this association (183). Despite the associations described (all from multiple significance testing with the resultant possibility of spurious conclusions), it is unlikely that hyperbilirubinemia is causally related to cystic PVL. PVL is primarily an ischemic lesion, most likely caused by hypoperfusion of the periventricular white matter. Bilirubin normally is not deposited in the periventricular region and primarily is toxic to neurons and not the glial elements that predominate in the periventricular white matter.

Significant associations between peak TSB levels and hearing loss have been documented in low-birth-weight (LBW) infants (189,190,191) and confirmed recently in a population of ELBW infants (185).

Because of the known role of bilirubin as a powerful antioxidant and the fact that more than 90% of ELBW infants receive phototherapy, the NICHD neonatal research network has initiated a prospective randomized trial to compare aggressive with conservative phototherapy in a population of ELBW infants (192) (see section on Treatment). The results of this study should provide important information about the association between low TSB levels and developmental outcomes in ELBW infants, as well as the risks and benefits of phototherapy in this highly vulnerable population.

Thus, although kernicterus is currently a very rare event in premature infants hospitalized in NICUs, it is still occurring. Data from the NICHD trial that is in progress at the time of this writing should be of immense help in guiding our management of the jaundiced ELBW infant (192).

Until further information is available, there seems good reason to believe that the very-low-birth-weight (VLBW) infant's brain is more susceptible to damage from a number of sources and, given that preterm infants have lower serum albumin levels and less-effective albumin binding and are much more likely to be sick than are full-term infants, it makes sense to take a more aggressive approach to maintaining low bilirubin levels in this population (137,185).

Hyperbilirubinemia and Pulmonary Hemorrhage

Studies from the late 1940s and early 1950s suggested an association between pulmonary hemorrhage and kernicterus (90,193,194). All of the infants described died of severe erythroblastosis fetalis. We know that these infants were profoundly anemic, had marked hypoalbuminemia, thrombocytopenia, and disturbances of coagulation, and occasionally were hydropic. It is not surprising that some of these infants developed hemorrhagic pulmonary edema. In an autopsy series of low-birth-weight infants with kernicterus, pulmonary hemorrhage was not found more frequently in the kernicteric infants when compared with those who did not have kernicterus (63). In animal studies, the infusion of bilirubin led to circulatory collapse and anoxia and an increased incidence of hemorrhage, including pulmonary hemorrhages (100). On the other hand, kernicteric Gunn rats showed a significantly lower prevalence of pulmonary hemorrhage when compared with nonkernicteric animals, although the kernicteric group had significantly higher bilirubin levels (195).

The Clinical Approach to the Jaundiced Newborn

Epidemiology of Neonatal Hyperbilirubinemia

An important first step in the diagnosis and management of any jaundiced newborn is an understanding of the factors that normally affect neonatal bilirubin levels (Table 35-13). Some of these factors have been identified only in large epidemiologic studies and their clinical relevance is questionable, but there are some (designated by asterisks in Table 35-13) that repeatedly have an important influence on TSB levels.

Genetic, Ethnic, and Familial Influences

East Asian and Native American infants have mean maximal TSB concentrations that are significantly higher than those of white infants (196,197,198,199,200 and 201). Increased bilirubin production appears to be one factor contributing to the hyperbilirubinemia in these infants (200). In a Hispanic (primarily Mexican) population, 31% of infants had TSB levels greater than 15 mg/dL (202) compared with 3% to 10% of infants in other populations (203,204). Black infants in the United States and Great Britain have lower TSB levels than white infants (197,198,205,206). Neonatal jaundice runs in families (207,208). In a study of 3,301 infants, Khoury and associates (207) found that if a previous sibling had a TSB level higher than 12 mg/dL (205 μ mol/L) or higher than 15 mg/dL (257 μ mol/L), the risk of similar TSB levels in subsequent siblings was 3.1 and 12.5 times greater, respectively, than in siblings of infants who did not have that degree of jaundice.

TABLE 35-13 EPIDEMIOLOGY OF NEONATAL JAUNDICE

Associated Factors	Effect on Neonatal Serum Bilirubin Levels		
	Increase	Decrease	No Effect
Race	East Asian*	African American*	
	Native American		
	Greek		
	Hispanic (Mexican)*		
Genetic or familial	Previous sibling with jaundice*		
Maternal	Primipara (?)	Smoking	
	Maternal age \geq 25 years		
	Diabetes (if infant macrosomic)		
	Hypertension		
	Oral contraceptive use at time of conception		
	First-trimester bleeding		
	Decreased plasma zinc level		

Drugs administered to mother	Oxytocin Diazepam Epidural anesthesia Promethazine	Phenobarbital Meperidine Reserpine Aspirin Chloral hydrate Heroin	β -Adrenergic agents
Labor and delivery	Premature rupture of membranes	Phenytoin Antipyrine Alcohol	Fetal distress Low Apgar scores
Infant	Forceps delivery Vacuum extraction* Breech delivery Decreasing gestation* Male gender* Delayed cord clamping Elevated cord blood bilirubin level Jaundice observed before discharge Predischarge TSB level in higher risk zones (Fig. 35.20) Cephalhematoma or bruising* Delayed meconium passage Breast-feeding* Caloric deprivation* Larger weight loss after birth* Low serum zinc and magnesium	Gestation \geq 41 weeks* Formula feeding*	
Drugs administered to infant	Chloral hydrate		
Other	Pancuronium Altitude Short hospital stay after birth*		
* Most relevant clinical factors.			

Maternal Factors

Smoking

Some studies suggest that infants of mothers who smoke during pregnancy have lower serum bilirubin levels than infants of nonsmokers (197,209), but others have not found this (210,211).

These data are confounded by the fact that women who smoke are much less likely to breast-feed, and the likelihood of breast-feeding is inversely related to the number of cigarettes smoked per day (212).

Diabetes

Macrosomic infants of insulin-dependent diabetic mothers are more likely to become jaundiced than are control

P.793

infants (213). This most likely is the result of an increase in bilirubin production, which is directly related to the degree of macrosomia in these infants (214). These infants have high erythropoietin levels and evidence of increased erythropoiesis, so that ineffective erythropoiesis and polycythemia probably are responsible for the increased bilirubin production (215,216). In addition, diabetic mothers have three times more β -glucuronidase in their breast milk than nondiabetic mothers (216). This enzyme enhances the enterohepatic reabsorption of bilirubin (see Breast-Feeding and Jaundice below).

Events During Labor and Delivery

Induction and Augmentation of Labor by Oxytocin.

Multiple studies and several controlled trials have shown an association between the use of oxytocin to induce or augment labor and an increased incidence of neonatal hyperbilirubinemia, although the mechanism for this is unclear (217,218).

Anesthesia and Analgesia.

Several studies associate epidural anesthesia, specifically, bupivacaine, with neonatal jaundice (211,219,220). These agents readily cross the placenta and produce measurable levels in the new born (221).

Other Drugs.

Tocolytics did not affect neonatal carboxyhemoglobin levels or the need for phototherapy (222,223).

The administration of narcotic agents, barbiturates, aspirin, chloral hydrate, reserpine, and phenytoin sodium to mothers was associated with lower TSB concentrations in their infants, whereas the use of diazepam increased TSB levels by less than 1 mg/dL (224). Antipyrine administered to the mother before delivery decreased TSB levels, and infants of heroin-addicted mothers have lower TSB levels (225). Phenobarbital, if given in sufficient doses to the mother, significantly lowers TSB levels during the first week (217,226).

Delivery Mode.

Vaginally delivered term newborns have higher TSB levels than those delivered by cesarean section (227), although this was not found in a controlled trial involving low-birth-weight infants (228). When compared with forceps delivery, the use of vacuum extraction does not increase the number of babies who require phototherapy, although more clinical jaundice is seen with vacuum extraction (229,230).

Placental Transfusion and Hyperviscosity.

Although a high hematocrit often is considered a risk factor for neonatal jaundice, controlled trials of an intervention for infants with symptomatic hyperviscosity using partial exchange transfusions showed no differences in the incidence of hyperbilirubinemia in the treated and control groups (231,232,233). In one study, infants were held 30 cm below the introitus after delivery. If cord clamping was delayed, the mean TSB level at age 72 hours was 7.7 mg/dL (132 μ mol/L) compared with 3.2 mg/dL (55 μ mol/L) in the early clamped group (234).

Cord Blood Bilirubin Levels.

More than 50 years ago, Davidson and associates (235) found an association between bilirubin levels in cord blood and later neonatal bilirubin concentrations. This observation has been confirmed in infants with and without hemolytic disease (236,237,238).

Neonatal Factors

Birth Weight and Gestation

Low birth weight and decreasing gestational age are strongly correlated with an increased risk of hyperbilirubinemia (197,206,211,239,240 and 241). So-called "near-term" infants of 35 to 38 weeks' gestation are at significantly greater risk of hyperbilirubinemia than are full-term infants (206,211,239,241). Compared with infants at 40 weeks' gestation, infants of 36 to 38 weeks of gestation are 7 to 8 times, and those who are less than 36 weeks are 13 times, more likely to be readmitted to the hospital with severe hyperbilirubinemia (241).

Gender

As a group, male infants consistently have higher bilirubin levels than females (206,211,240,241 and 242).

Caloric Intake and Weight Loss

Decreased caloric intake is associated with an increase in serum bilirubin in animals and humans (32). The primary mechanism responsible for this appears to be an increase in the enterohepatic circulation of bilirubin (32,33). A significant association also exists between hyperbilirubinemia and weight loss in the first few days after birth (211, 240,241 and 242).

Type of Diet

Infants fed a casein-hydrolysate formula had significantly lower TSB levels from days 10 through 18 than did those infants fed standard casein or whey-predominant formulas (243). The cumulative stool output of the infants fed the casein-hydrolysate was lower than that of the infants fed the other formulas, suggesting that factors other than stool output and its effect on the enterohepatic circulation must explain these observations.

Breast-Feeding and Jaundice

Multiple studies over the last 25 years have found a strong association between breast-feeding and an increased incidence of neonatal hyperbilirubinemia (Figs. 35-13 and 35-14) (244).

Although occasional studies have not found this (245,246), a pooled analysis of 12 studies of more than 8,000 newborns showed that breast-fed infants were three times more likely to develop TSB levels of 12 mg/dL (205 μ mol) or higher and six times more likely to develop levels of 15 mg/dL (257 μ mol) or higher than formula-fed infants (Fig. 35-14) (247). Ninety percent or more of

P.794

infants readmitted to hospital in the first 2 weeks of life because of severe hyperbilirubinemia are fully or partially breast-fed (239,241,248,249). In a northern California population, exclusively breast-fed infants were six times more likely than formula-fed infants to develop a TSB greater than 25 mg/dL (428 μ mol/L) (206). Of 61 term and near-term infants with kernicterus, 59 were breast-fed (124) (the 2 formula-fed infants were G6PD deficient).

There is some debate about the studies listed above and the data illustrated in Fig. 35-13 (250). Some studies show no differences in TSB levels between formula-fed and breast-fed infants in the first few days after birth. Bertini and associates (246) studied infants in their well baby nursery. Formula supplementation was given to breast-fed infants if a weight loss was considered to be excessive ($\geq 4\%$ after 24 hours, $\geq 8\%$ after 48 hours, or $\geq 10\%$ after 72 hours). The investigators found a positive correlation between TSB levels greater than 12.9 mg/dL (221 μ mol/L), weight loss after birth, and breast-feeding requiring supplementation with formula. Breast-feeding, *per se* was not associated with hyperbilirubinemia. They concluded that infants who are successfully breast-fed and therefore lose little weight, are not more likely to be jaundiced than formula-fed infants, whereas those who required formula supplementation because of excess weight loss were more likely to be jaundiced. This supports an important role for caloric intake in the development of jaundice and has led some experts to categorize jaundice associated with breast-feeding in the first days after birth as "starvation jaundice" or "breast-nonfeeding jaundice" (250). The implication is that if breast-fed infants were nursed effectively from birth, they would not be more

jaundiced than formula-fed infants and there is evidence to support this view (246,251,252).

Figure 35-14 Pooled analysis of 12 studies showing the percent of newborns with serum bilirubin levels ≥ 12 mg/dL (205 μ mol/L) in breast-fed and formula-fed newborns and, in 6 of the 12 studies, the percent of newborns with serum bilirubin levels ≥ 15 mg/dL (256 μ mol/L) (From Schneider AP. Breast milk jaundice in the newborn. A real entity. *JAMA* 1986;255:3270-3274, with permission.)

P.795

Jaundice associated with breast-feeding in the first 2 to 4 days of age has been called "the breast-feeding jaundice syndrome" or "breast-feeding-associated jaundice," and that which appears later (onset at 4 to 7 days of age and prolonged jaundice) has been called the "breast milk jaundice syndrome" (253). There is considerable overlap between these two entities, and evidence to support two distinct syndromes is meager, although calorie deprivation appears to play a major role in the early type of jaundice. In addition to having higher TSB levels in the first 3 to 5 days (see Fig. 35-13) (254), as a group, breast-fed infants have TSB levels that are higher than formula-fed infants for at least 3 to 6 weeks (243,255,256). These are the same infants who have high bilirubin levels in the first week of life, and it is hard to believe that those who are still jaundiced at age 2 to 3 weeks represent a distinct group.

Prolonged indirect-reacting hyperbilirubinemia (beyond 2 to 3 weeks) occurs in 20% to 30% of all breast-feeding infants and, in some infants, may persist for up to 3 months (257). TSB levels were measured at age 28 to 33 days in 282 healthy, breast-fed Turkish infants that were 37 weeks' gestation or older. The TSB was greater than 5 mg/dL (85 μ mol/L) in 20.2% and greater than 10 mg/dL (171 μ mol/L) in 6% of the infants. (258) Recent evidence suggests that in some infants mutations of the UGT1A1 gene (Gilbert syndrome) play a role in the pathogenesis of this hyperbilirubinemia (259,260).

Pathogenesis of Jaundice Associated with Breast-Feeding.

Factors that play a role in the pathophysiology of jaundice associated with breast-feeding are reviewed in detail elsewhere (28,244,253) and are listed in Table 35-14. The primary mechanism for jaundice in the breast-fed infant appears to be an increase in the enterohepatic circulation of

bilirubin. Some authors suggest an additional role for inhibitory substances in breast milk, but the data regarding their contribution are conflicting (244).

Intestinal Reabsorption of Bilirubin. Intestinal reabsorption of bilirubin (the enterohepatic circulation) appears to be the most important mechanism responsible for the jaundice associated with breast-feeding (244). Breast-fed infants take in fewer calories than formula-fed infants in the first days after birth and a relationship between decreased caloric intake and an increase in the enterohepatic circulation of bilirubin has been shown (32,33). Breast-fed infants produce lower-weight individual stools, their cumulative stool output (by weight) is lower (243), and their stools contain less bilirubin than those of formula-fed infants (28,261). An increase in stool excretion in the first 21 days is associated with lower TSB levels and in the first 3 weeks, infants fed human milk pass significantly less stool than do infants who are fed casein-predominant formulas (243). Infants fed casein-hydrolysate formulas pass less stool, cumulatively, than those given whey- or casein-predominant formulas (243).

TABLE 35-14 PATHOGENESIS OF JAUNDICE ASSOCIATED WITH BREAST-FEEDING

Increased enterohepatic circulation of bilirubin
Decreased caloric intake
Less cumulative stool output and stools contain less bilirubin (compared with formula-fed infants)
Increased intestinal fat absorption
Less formation of urobilin in gastrointestinal tract
Increased activity of β -glucuronidase in breast milk
Mutations of the UGT1A1 gene (Gilbert syndrome)—prolonged breast milk jaundice

The relationship between fecal bilirubin excretion and TSB levels may be related to the fecal excretion of unabsorbed fat (262). Unconjugated bilirubin apparently associates with unabsorbed fat in the intestinal lumen. When Gunn rats were fed orlistat, a substance that inhibits lipase, they excreted more fat in their stools and their TSB levels were significantly lower (31). This suggests that a substance that increases fecal excretion of fat will decrease the enterohepatic absorption of unconjugated bilirubin and facilitate bilirubin excretion in the gut. Breast-fed infants have higher fat absorption than formula-fed infants (possibly related to the presence of bile salt-stimulated lipase in human milk [263]). It is possible that hyperbilirubinemia could be prevented or mitigated by the administration of orlistat to newborns (31,262). All of these findings support a major role for the enterohepatic circulation in the jaundice associated with breast-feeding.

Urobilinogen Formation.

In adults, bilirubin in the gut is reduced rapidly by the action of colonic bacteria to urobilinogen. At birth, the fetal gut is sterile, and although there is an increase in the bacterial content of the gut after delivery, the neonatal intestinal flora do not convert conjugated bilirubin to urobilin. This leaves bilirubin in the bowel and allows it to be deconjugated and thus available for reabsorption. Formula-fed infants excrete urobilin in their stools earlier than breast-fed infants do, perhaps as a consequence of the effect of formula feeding on the intestinal flora (264). Thus, the effect of breast milk on intestinal flora, by slowing the formation of urobilin, further enhances the possibility of intestinal reabsorption of bilirubin.

β-Glucuronidase.

β -Glucuronidase is an enzyme that cleaves the ester linkage of bilirubin glucuronide, producing unconjugated bilirubin, which can then be reabsorbed through the gut. Significant concentrations of β -glucuronidase are found in the neonatal intestine, and its activity is higher in human milk than in infant formulas (244).

Gourley and Arend (265) found a positive relation between TSB levels and breast milk β -glucuronidase activity in the first 3 to 4 days after birth, but other researchers have not been able to confirm these findings (257,266).

P.796

Meconium Passage

Because the enterohepatic circulation of bilirubin is an important contributor to neonatal hyperbilirubinemia, increasing the rate of bilirubin evacuation from the bowel should decrease the incidence of neonatal jaundice. Two randomized studies showed that the early passage of meconium (stimulated by a rectal thermometer or a suppository) reduced peak TSB levels by about 1 mg/dL (17 μ mol) when compared with control groups (267,268).

Phenolic Detergents

The use of phenolic detergents to disinfect incubators and other nursery surfaces was associated with an epidemic of neonatal hyperbilirubinemia in two hospitals (269,270). These detergents should not be used in the nursery.

Altitude

Infants born 3,100 m above sea level are four times more likely to have a bilirubin level above 12 mg/dL (205 μ mol/L) than are those born at sea level (271). Both short- and long-term exposure to high altitudes increases TSB levels in adults. The possible mechanisms for these observations include an increase in bilirubin load because of high hematocrits and impaired conjugation and excretion of bilirubin (272,273,274).

Drugs Administered to the Infant

The use of pancuronium and chloral hydrate in the neonate are associated with an increased risk of hyperbilirubinemia (275,276,277). Chloral hydrate is metabolized to trichloroacetic acid and the toxic trichloroethanol, both of which accumulate in the tissues of compromised infants. The administration of chloral hydrate is associated with both indirect-reacting and direct-reacting hyperbilirubinemia (276).

Free-Radical Production

Bilirubin appears to have an important physiologic function as an antioxidant and may play a role in the prevention of oxidative membrane damage *in vivo* (see Physiologic Role of Bilirubin below) (278). Infants with circulatory failure, sepsis, aspiration syndromes, and asphyxia—conditions believed to enhance free-radical production—had a significantly lower daily rise in mean TSB levels than control infants (279). These findings are consistent with the hypothesis that bilirubin is a free-radical scavenger and is consumed as an antioxidant.

Jaundice in the Healthy Newborn

Cord Bilirubin Levels

Mean bilirubin levels in cord blood range from 1.4 to 1.9 mg/dL (24 to 32 $\mu\text{mol/L}$) (235,280,281), and elevated cord bilirubin levels are associated with an increased risk of hyperbilirubinemia (235,237,280,281).

Normal Serum Bilirubin Levels and the Natural History of Neonatal Jaundice

It is difficult to agree on what represents a "normal bilirubin level" in the term and near-term infant. TSB levels vary considerably, depending on the racial composition of the population, the incidence of breast-feeding, and other genetic and epidemiologic factors (see Table 35-13 and Fig. 35-15). An additional important factor is the large variation found in the laboratory measurements of serum bilirubin, a problem that has been recognized for four decades and currently is unresolved (282,283,284) (see Laboratory Measurements of Bilirubin below).

Reference to Fig. 35-15 gives some idea of the range of mean bilirubin values found in different populations and the natural history of neonatal jaundice. Since the advent of exchange transfusion and, more recently, phototherapy, it has been impossible to obtain a true picture of the natural history of neonatal bilirubinemia because we treat some infants with rising TSB levels in the first 72 to 96 hours so that what we see is, ultimately, a "damped" picture. Recognizing these limitations, however, some recent studies have helped to clarify the picture (285,286).

An important change in the United States population has been the dramatic increase in breast-feeding at hospital discharge, from 30% in the 1960s to 65% in 2001 (287). In some hospitals, 85% or more of mothers are nursing their

P.797

infants on discharge from the hospital. Data from the CPP conducted from 1955 to 1961 (when 30% or fewer mothers breast-fed their infants) and more recent studies (254) found that approximately 95% of all infants had a TSB concentration that did not exceed 12.9 mg/dL (215 $\mu\text{mol/L}$), and this (95th percentile) became the accepted upper limit of "physiologic jaundice" (205).

Figure 35-15 Mean total daily bilirubin concentrations in normal full-term and near-term infants. [black down-pointing triangle], Fifty healthy Japanese newborn infants, 37 to 42 weeks of gestation, all breast-fed. Excludes Rh and ABO incompatibility (292). ^, One hundred seventy-six term breast-fed Canadian infants. Excludes Rh hemolytic disease, but includes nine ABO incompatible infants with positive Coombs tests. Seventeen infants received phototherapy. ^, One hundred sixty-four Canadian term formula-fed infants, seven ABO incompatible with positive Coombs tests, and three who received phototherapy (280). ◇, One thousand eighty-seven term Israeli infants, 78% fully or partially breast-fed (Siedman D, personal communication, 1998) ^, Fifty-six Nigerian term appropriate for gestational age infants. Excludes ABO or Rh incompatibility and G6PD deficiency. Infants were "largely breast-fed" (291). (◇), Twenty-nine full-term American infants, all formula-fed, approximately 50% African American and 50% white (30).

More recent data suggest that these values no longer define normal TSB levels in the newborn population (203,288,289). We now see more jaundiced babies, and the TSB levels found in the normal population are significantly higher than previously reported. Three recent studies provide consistent information regarding the upper limits of TSB levels found in the normal population. In a study of 2,840 infants, all of whom had at least one TSB level measured after discharge from hospital, the 95th percentile was a level of 17.5 mg/dL (300 μmol/L) (289). This population was 43% white, 41% black, and 4% Asian; 59% of infants were fully or partially breast-fed. In 11 Kaiser Permanente Northern California Hospitals, the 95th percentile was a TSB level of 17.5 mg/dL (298 μmol/L) (203). In a multicenter study of infants 36 weeks or older in nurseries in the United States, Hong Kong, Japan, and Israel, 2 SD above the mean for the peak TSB levels at 96 ± 6.5 hours was 17 mg/dL (291 μmol/L), and the 95th percentile was 15.5 mg/dL (265 μmol/L) (290). The consistency of these data suggests that we can now accept that the upper limit of "normal" in diverse populations is a TSB level of about 17 to 18 mg/dL (291 to 308 μmol/L). This implies that a 4- to 5-day-old breast-fed infant whose TSB level is 15 to 16 mg/dL (291 μmol/L) does not require any laboratory investigation to find out *why* the infant is jaundiced, although followup is necessary to ensure that the bilirubin levels do not become excessive (289). Data from studies of predominantly breast-fed infants suggest that the normal mean peak TSB level is approximately 8 to 9 mg/dL (137 to 154 μmol/L) (240,280,290,291). In the international, multicenter study, the mean TSB level at 96± 6.5 hours was 9.3 mg/dL (290).

In the Japanese population (292) and in other populations of predominantly breast-fed infants, it is clear that the TSB levels are substantially higher, reach their peak later, and remain elevated for much longer than in formula-fed infants. No significant decline in TSB is seen in any of these

populations until after the fifth day (see Fig. 35-15).

Figure 35-16 shows "idealized" smoothed curves based on the data from a number of studies that provide a guide to the expected course of bilirubin levels in a primarily breast-fed (60% to 70%) western population (203,235,240, 242,280,289,290). Recognizing all of the limitations to these data already discussed, Fig. 35-16 should be useful for plotting the course of jaundice in an infant and using the velocity of the increase in TSB to make decisions about evaluation, follow-up, and potential intervention.

Bhutani and associates developed a nomogram that defines predischarge risk zones for the subsequent development of hyperbilirubinemia (289) (see Preventing Extreme Hyperbilirubinemia and Kernicterus below). Because of sampling bias, however, this nomogram probably does not describe the natural history of bilirubinemia in the newborn (293), although it is a very useful tool for predicting the risk of subsequent hyperbilirubinemia (289) and is recommended by the AAP for this purpose.

Figure 35-16 Smoothed curves from studies in diverse populations illustrating the expected velocity of total serum bilirubin (TSB) levels and approximate values for the 50th and 95th percentiles. Data for cord blood values come from the studies of Davidson and associates (235) and Saigal and associates (280), values in the first 12 hours are from Frishberg and associates (242), and subsequent values are from Bhutani (289), Seidman (personal communication, 1998), Maisels and associates (290), and Wood and associates (240). Data for the 95th percentile are primarily obtained from the data of Bhutani and associates (289), but also from the studies of Newman and associates (203), and Maisels and associates (290). These data represent values that might be expected in a western, predominantly breast-fed (60% to 70%) population. In view of the significant variations in different populations (see Fig. 35-15), as well as the variations found in laboratory measurement (282,283), the values provided should be used only as rough guidelines. Nevertheless, this graph can be useful in plotting the course of neonatal jaundice, because it will demonstrate when the velocity of the TSB increase deviates significantly from the curves shown. *Note that the values must be plotted according to the infant's age in hours, not days.* Infants who have values that exceed the 95th percentile deserve an evaluation to determine a potential cause for the jaundice, and they require careful surveillance and followup to prevent the development of extreme hyperbilirubinemia. Infants who have none of the epidemiologic risk factors for hyperbilirubinemia (see Table 35-13) but who have TSB values that approach the upper percentiles, also should receive closer scrutiny. Conversely, those whose values fall well below the 50th percentile probably require minimal surveillance and followup for jaundice (289).

Pathologic Causes of Jaundice

Indirect-reacting Hyperbilirubinemia

Table 35-15 lists the causes of pathologic indirect-reacting hyperbilirubinemia in the neonate and Table 35-16 lists the causes of direct-reacting hyperbilirubinemia (cholestatic jaundice). For further discussion of neonatal cholestasis, please see Chapter 40.

TABLE 35-15 CAUSES OF INDIRECT HYPERBILIRUBINEMIA IN NEWBORNS

Increased production or bilirubin load on the liver

Hemolytic Disease

Immune mediated

Rh alloimmunization, ABO and other blood group incompatibilities

Heritable

Red cell membrane defects

Hereditary spherocytosis, elliptocytosis, pyropoikilocytosis, stomatocytosis

Red cell enzyme deficiencies

Glucose-6-phosphate dehydrogenase deficiency,^a
pyruvate kinase deficiency, and other erythrocyte enzyme deficiencies

Hemoglobinopathies

α -Thalassemia, β -thalassemia

Unstable hemoglobins

Congenital Heinz body hemolytic anemia

Other causes of increased production

Sepsis,^{a, b}

Disseminated intravascular coagulation

Extravasation of blood, hematomas, and pulmonary, abdominal, cerebral, or other occult hemorrhage

Polycythemia

Macrosomic infants of diabetic mothers

Increased enterohepatic circulation of bilirubin

Breast-milk jaundice

Pyloric stenosis^a

Small- or large bowel obstruction or ileus

Decreased Clearance

Prematurity

Glucose-6-phosphate dehydrogenase deficiency

Inborn errors of metabolism

Crigler-Najjar syndrome, types I and II

Gilbert syndrome

Hypopituitarism^b

^a Decreased clearance also part of pathogenesis.

^b Elevation of direct-reading bilirubin also occurs.

P.798

Increased Bilirubin Load: Hemolytic Disease

Immune-Mediated Hemolytic Disease

Rh Erythroblastosis Fetalis.

Pathogenesis. Hemolytic causes of hyperbilirubinemia are discussed fully in Chapter 46. Most cases of Rh immunization are a result of the Rh (D) antigen although alloimmunization can occur to other fetal red cell surface antigens including the other antigens of the Rh blood-group system (c, C, e, E, cc, and Ce) and those belonging to the Kell, Duffy, Kidd, and MNS systems (294,295,296). Rh alloimmunization occurs when fetal red blood cells from an Rh (D)-positive fetus cross the placenta into the circulation of an Rh-negative mother and less than 0.1 mL of fetal red cells is sufficient to result in sensitization. Although Kleihauer-Betke measurements indicate that fetal-maternal hemorrhage occurs in 75% of women, more sensitive molecular detection techniques show that fetal red cells enter the maternal circulation in all pregnancies (296). If the Rh-positive fetus is ABO

P.799

compatible with its mother, the likelihood of Rh immunization is 16%, but it is only 1.5% to 2% if they are ABO incompatible. This is because the fetal ABO-incompatible red blood cells are rapidly destroyed in the maternal circulation, diminishing the opportunity of the Rh antigen to induce an immune response (294). Once a primary immune response to Rh antigen has been mounted, however, ABO incompatibility between the mother and fetus conveys no protection against a secondary immune response (294). The risk of alloimmunization following induced abortion is 4% to 5%, and it is 2% following spontaneous abortion. Other invasive procedures, such as amniocentesis, chorionic villus sampling, and fetal blood sampling, all increase the risk of fetal maternal hemorrhage and, therefore, alloimmunization (296).

TABLE 35-16 CAUSES OF NEONATAL CHOLESTASIS

ARC syndrome (arthrogryposis, renal tubular dysfunction, and cholestasis)

From McKiernan P. Neonatal cholestasis. *Semin Neonatol* 2002;7:53-165, with permission.

The initial response to the foreign antigen in the maternal circulation is for the maternal immune system to produce immunoglobulin (Ig) M antibodies that do not cross the placenta. This response is followed by production of IgG antibodies, which then cross the placental barrier. The

secondary immune response to repeat exposure to the Rh antigen produces anti-D IgG antibodies. This response can be induced with as little as 0.03 ml of D-positive red blood cells (297). The degree of Rh sensitization is related to the dose of antigen exposure and, therefore, to the volume of transplacental hemorrhage (294).

Clinical Course.

Approximately 50% of affected infants do not require treatment; they are mildly anemic at birth and never develop severe hyperbilirubinemia. Approximately 25% to 30% will require intervention with phototherapy and/or exchange transfusion and approximately 20% to 25% are so severely affected that they develop hydrops *in utero* (296). About half of this last group become hydropic before 34 weeks' gestation and require direct intravascular fetal transfusion (294). A fetal hematocrit of less than 30% is generally considered an indication for intrauterine transfusion, which is performed, as required, until 34 to 35 weeks' gestation with delivery planned close to term (296).

Prevention of Rh Sensitization.

Rh sensitization can almost always be prevented by the administration of Rh immunoglobulin to Rh-negative women at 28 weeks of gestation and again within 72 hours of delivery of an Rh-positive infant (295). In the United States, the dose is 300 µg, but in many other countries it is 100 to 125 µg. If the Kleihauer-Betke test or the fetal red cell assay indicates that there is a transplacental hemorrhage of more than 30 mL of fetal blood (which occurs in 1 in 400 pregnancies) then the dose of Rh (D) immunoglobulin must be at least 10 µg/mL of fetal blood in the maternal circulation (296). Rh immunoglobulin must also be given after abortion or threatened abortion and after amniocentesis or chorionic villus sampling or any other invasive intrauterine procedure. These interventions have dramatically reduced the incidence of erythroblastosis fetalis caused by Rh (D) sensitization, which now has an estimated incidence of about 1 per 1,000 live births (298).

Some laboratories have replaced the Kleihauer-Betke assay with a fetal red blood cell assay (Fetalscreen, Ortho-Clinical Diagnostics, Raritan, NJ) (299). In this assay, an antihemoglobin F antibody is added to the mother's blood to tag hemoglobin F molecules in fetal red cells. Flow cytometry quantifies the number of fetal red cells (of a total of 50,000 maternal cells) so tagged. If less than 0.1% of the maternal cells are tagged it is considered a negative result. Positive results can be quantified to provide the volume of fetal blood in the mother's circulation and the appropriate dose of Rh (D) immunoglobulin to be given.

In mothers who are already sensitized, the administration of intravenous immunoglobulin (IVIg) in early pregnancy has had some benefit in cases of severe fetal alloimmunization (300). The mechanism of action of IVIg appears to involve blockage of Fc receptors on macrophages in the fetal reticuloendothelial system. In one study, fetal survival was 36% higher when high-dose IVIg treatment preceded intrauterine transfusion than it was with transfusion alone (300).

Hydrops Fetalis.

The pathogenesis of hydrops fetalis, with its attendant edema and serous effusions, is not clear. It commonly occurs when the fetal hemoglobin drops below 6 to 7 g/dL. The rapid production of severe anemia in fetal sheep produced hydrops associated with an increased central venous pressure and placental edema, whereas the same degree of anemia produced over a longer period did not result in hydrops, placental edema, or an increased central venous pressure (301). In Rh isoimmunization, fetal edema may result from the extensive erythropoiesis that takes place in the

fetal liver. This can disrupt the portal circulation and impair albumin synthesis (302,303). Fetuses with severe hydrops also have elevated concentrations of atrial natriuretic factor (304). Hypoxia produces myocardial dysfunction with increased umbilical venous pressure that leads to the release of atrial natriuretic factor (305). Severely affected infants die of progressive cardiorespiratory failure, in which asphyxia and hyaline membrane disease play a major role.

In one hydropic fetus with erythroblastosis fetalis, pulse-Doppler studies of left and right ventricular outputs were obtained over time. Despite severe anemia, cardiac outputs were normal and remained normal after *in utero* percutaneous intravascular transfusions, which reversed the hydrops. These measurements of normal cardiac output *in utero* suggest that high-output failure caused by anemia is not the mechanism for hydrops in these infants and supports the hypothesis that portal hypertension and disruption of normal liver function from extramedullary hematopoiesis is the primary mechanism for the development of hydrops in isoimmune hemolytic disease of the fetus (306).

Treatment of Infants with Rh Hemolytic Disease and Hydrops Fetalis.

See sections on Treatment, Phototherapy, and Exchange Transfusion, below.

Late Anemia.

A well-known late complication of intrauterine transfusion is the development of anemia in

P.800

the first months of life. This is commonly seen after about age 2 weeks and is characterized by a persistently low reticulocyte count. Although originally considered to be a hyporegenerative anemia (294,307), there is now some evidence that a decrease in erythropoietin production may not be the primary cause of this late anemia. Recent studies suggest that the anemia is most likely caused by persistence of anti-D antibodies and destruction of red blood cell precursors in the marrow or of reticulocytes in the peripheral circulation (308). In a study of 30 neonates with erythroblastosis, 18 of whom had received intrauterine transfusions and 12 who had not (308), blood samples were analyzed for hemoglobin, erythropoietin, and reticulocytes. As the hemoglobin declined between 10 and 80 postnatal days, there was a matching rise in erythropoietin, which occurred both in infants who had received intrauterine transfusions and those who had not. Thus, intrauterine transfusions, themselves, may not play such an important role in suppressing erythropoiesis. Furthermore, reticulocyte counts remained persistently low despite rising erythropoietin and falling hemoglobin levels. One possible explanation for this is the effect of circulating anti-D antibodies on the erythrocyte precursors in the bone marrow and on the reticulocytes in the peripheral circulation (308).

ABO Hemolytic Disease

Approximately 45% of Americans of western European descent have type O blood, and a similar percentage are type A. Types B and AB make up the balance. African Americans are 50% type O, 29% type A, 17% type B, and 4% AB (309). Hemolytic disease related to ABO incompatibility is generally limited to group A or B infants born to group O mothers, and it tends to run in families. One study found an 88% risk of recurrence of ABO hemolytic disease in ABO incompatible newborns born to parents whose first-born child was similarly affected (310).

In a prospective study of 4,996 consecutive live born infants (311) (Table 35-17), cord blood was analyzed for blood type, hematocrit, and results of the direct antiglobulin test (DAT or Coombs

test) and the indirect Coombs test (311). The DAT detects antibodies attached to the red cell, whereas the indirect Coombs test detects IgG antibody in the serum. Only 0.29% of type A, B, or AB infants who were incompatible with their type A or B mothers had a positive DAT result, whereas 32% of type A or B infants born to type O mothers had positive DATs. A positive DAT was the best predictor of an elevated bilirubin level, but only 20% of infants with a positive DAT developed TSB levels of ≥ 12.8 mg/dL (224 $\mu\text{mol/L}$) (311). This large prospective study confirms what was found in other smaller studies: although about one-third of group A or B infants born to group O mothers have anti-A or anti-B antibodies attached to their red cells, only 1 in 5 of those with a positive DAT have a *modest* degree of hyperbilirubinemia.

Coombs Test Results	Peak Serum Bilirubin ≥ 12.8 mg/dL (224 $\mu\text{mol/L}$)
Direct antiglobulin (Coombs) test positive	46/225 (20.4%)
Indirect Coombs test positive	29/309 (9.4%)
Both tests negative	38/488 (7.8%)

From Ozolek J, Watchko J, Mimouni F. Prevalence and lack of clinical significance of blood group incompatibility in mothers with blood type A or B. *J Pediatr* 1994;125:87–91, with permission.

Consequently, although ABO-incompatible DAT-positive infants are about twice as likely as their compatible peers to have moderate hyperbilirubinemia, severe jaundice in these infants is uncommon (311,312,313,314,315) and ABO hemolytic disease is a relatively rare cause of severe hyperbilirubinemia (Table 35-18).

Diagnosing ABO Hemolytic Disease.

There is a wide spectrum of severity in ABO hemolytic disease. Nevertheless, this diagnosis generally should not be made unless there is a positive DAT *and* clinical jaundice within the first 12 to 24 hours. Reticulocytosis and the presence of microspherocytes on the smear help to confirm the diagnosis (Table 35-19).

ABO Incompatibility, Hyperbilirubinemia, and a Negative Direct Antiglobulin Test.

Although the epidemiologic data suggest otherwise, most clinicians have seen the occasional ABO-incompatible infant in whom there is an early rising TSB level, yet the DAT is negative. In the past, we have often considered these to be cases of ABO hemolytic disease and have attributed the negative DAT to the technical vicissitudes of Coombs testing in the laboratory. Recent data, however, raise questions about alternative mechanisms.

One obvious possibility is that there is another cause for the hemolysis. Using measurements of end-tidal carbon

associates (316) identified four DAT-negative ABO-incompatible neonates who had elevated ETCOc levels. Further investigation revealed that two of these infants had G6PD deficiency and one had elliptocytosis. Can ABO incompatibility with a negative DAT nevertheless contribute to hyperbilirubinemia? Kaplan and associates (317) found that 43% of DAT-negative, ABO-incompatible infants who were homozygous for the variant UGT promoter associated with Gilbert syndrome, had a TSB level ≥ 15 mg/dL (256 $\mu\text{mol/L}$) versus none of the ABO-incompatible DAT-negative infants who were homozygous normal (for the variant promoter) (Fig. 35-17). There was no difference between ABO-incompatible and ABO-compatible DAT-negative newborns, as long as the ABO-incompatible neonates did not have Gilbert syndrome (see Inherited Unconjugated Hyperbilirubinemia). These observations confirm, for the first time, that if another icterogenic factor is present, then ABO-incompatible newborns are at risk for hyperbilirubinemia even if they are DAT negative (317).

TABLE 35-18 DISCHARGE DIAGNOSIS IN 306 INFANTS ADMITTED WITH SEVERE HYPERBILIRUBINEMIA^a

Diagnosis	Number	Percentage
Hyperbilirubinemia of unknown cause or breast-milk jaundice	290	94.8
Cephalhematoma or bruising	3	1.0
ABO hemolytic disease ^b	11	3.6
Anti-E hemolytic disease	1	0.3
Galactosemia	1	0.3
Sepsis	0	0

^a Infants were readmitted after discharge as newborns. Mean age at admission was 5 days (range, 2 to 17 days), and mean bilirubin level was 18.5 ± 2.8 mg/dL (range, 12.7 to 29.1 mg/dL).

^b Mother was type O, infant was type A or B, direct Coombs test was positive. From Maisels MJ, Kring E. Risk of sepsis in newborns with severe hyperbilirubinemia. *Pediatrics* 1992;90:741-743, with permission.

TABLE 35-19 CRITERIA FOR DIAGNOSING ABO HEMOLYTIC DISEASE AS THE CAUSE OF NEONATAL HYPERBILIRUBINEMIA

Mother group O, infant group A or B
and
 Positive DAT
 Jaundice appearing within 12-24 hours
 Microspherocytes on blood smear
 Negative DAT but homozygous for Gilbert's syndrome (317)

Should a blood type and DAT be performed on the cord blood of all infants of group O mothers?

In these days of cost containment, this is a commonly asked question. A recent survey found that 58% of hospital blood banks in the United States were routinely performing Coombs tests and blood typing on newborn cord bloods (318). Approximately 36% of hospitals tested all cord bloods

routinely, and 35% tested those of type O or Rh-negative mothers, even though the data suggest that such routine screening is not warranted (311,318). Furthermore, even when such testing is done, there is evidence that it is often ignored by the responsible pediatrician (318,319). The AAP notes that routine cord blood screening for infants of group O, Rh-positive mothers, is an option, but is not required "provided there is appropriate surveillance, and risk assessment before discharge and follow up" (76) so that significantly jaundiced infants are not missed.

Heritable Causes of Hemolysis

Red Cell Membrane Defects

The red cell membrane defects that may produce hemolysis and hyperbilirubinemia in the newborn include *hereditary spherocytosis*, *elliptocytosis*, *pyropoikilocytosis*, *pyknocytosis* and *stomatocytosis syndromes* (320,321). Detailed descriptions of their clinical presentation and management can be found elsewhere (320,321,322). The diagnosis of these disorders can be difficult, because newborns commonly exhibit a marked variation in red cell membrane size and shape (322).

In 75% of hereditary spherocytosis patients, inheritance is autosomal dominant so that a positive family history that includes anemia, jaundice, gallstones, and splenectomy can often be elicited. As in G6PD deficiency (see Glucose-6-Phosphate Dehydrogenase Deficiency below), the presence of jaundice severe enough to require phototherapy in newborns with hereditary spherocytosis is strongly related to an interaction with the Gilbert syndrome allele (323). Severe anemia and hydrops fetalis has occurred

P.802

in infants with hereditary spherocytosis associated with defective genes for band 3 or spectrin protein (321). The diagnosis can be made using the incubated osmotic fragility test which is a reliable diagnostic tool in newborns when coupled with fetal red cell controls (321,322).

Figure 35-17 Incidence of hyperbilirubinemia defined as TSB ≥ 15 mg/dL (≥ 256 $\mu\text{mol/L}$) in ABO-incompatible and ABO-compatible (control) infants according to the UGT promoter genotype. ABO-incompatible DAT-negative infants who were also homozygous for the variant UGT promoter (Gilbert syndrome) had a significantly higher incidence of hyperbilirubinemia than did ABO-incompatible DAT-negative infants who were homozygous normal for the UGT promoter. The former subgroup also had a significantly greater incidence of hyperbilirubinemia than any of the three UGT promoter genotype subgroups in the control (ABO-compatible) infants. (From Kaplan M, Hammerman C, Renbaum P, et al. Gilbert's syndrome and hyperbilirubinaemia in ABO-incompatible neonates. *Lancet* 2000;356: 652-653, with permission.)

Red Cell Enzyme Deficiencies

Glucose-6-Phosphate Dehydrogenase Deficiency

Epidemiology.

G6PD deficiency is the most common, clinically significant, red cell enzyme defect and affects as many as 4,500,000 newborns each year (324). Although known for its prevalence in the populations of the Mediterranean, the Middle East, the Arabian Peninsula, South East Asia, and Africa, immigration and intermarriage have transformed G6PD deficiency into a global problem (156). Nevertheless, most pediatricians in the United States do not think of G6PD deficiency when confronted with a jaundiced infant (325). They should, particularly in black infants. Although African American newborns, as a group, have lower TSB levels than white newborns (197,198, 205,206), G6PD deficiency is found in 11% to 13% of African American newborns. This means that some 32,000 to 39,000 black male G6PD-deficient hemizygote newborns will be born annually in the United States (326), and kernicterus has occurred in some of these infants (124,327,328 and 329). In a recent report, G6PD deficiency was considered to be the cause of hyperbilirubinemia in 19 of 61 (31.5%) infants who developed kernicterus (124).

Clinical Course.

Because G6PD deficiency in African American infants is a result of the less-severe Gd A⁻ mutation (326), most of these infants do not develop severe hyperbilirubinemia (326). If subjected to some oxidative stress, however, they can develop acute hemolysis with a sudden increase in the TSB (324). Although previous studies suggested otherwise (326), recent data show that, as a group, black G6PD-deficient infants are significantly more likely than controls to develop hyperbilirubinemia and three times more likely than control infants to require phototherapy (330).

Hemolysis and hyperbilirubinemia in G6PD-deficient neonates can be triggered by exposure to a number of agents (156,324,327). These include naphthalene (found in moth balls), agents for umbilical cord antisepsis, breast milk of a mother who has eaten fava beans (331), and perhaps exposure to a variety of household chemicals (324). Neonatal infection is also a well recognized trigger (156, 332). In most cases, however, no specific triggering agent or condition can be identified and an acute hemolytic event is the exception, rather than the rule (156,333). Most G6PD-deficient neonates have a more gradual onset of hyperbilirubinemia and there is evidence that this hyperbilirubinemia has its origins *in utero* (334).

Pathogenesis of Hyperbilirubinemia in G6PD Deficiency.

The G6PD gene (Gd) is located on the X chromosome and hemizygous Gd⁻ males have the full enzyme deficiency and can be identified by screening tests (324). But female heterozygotes have a wide range of enzyme activity and will frequently be missed by screening tests (335) even though they are also at risk for hyperbilirubinemia (335,336).

In most cases of hyperbilirubinemia in G6PD-deficient neonates, there is no overt evidence of hemolysis such as anemia and reticulocytosis (337,338), although in some populations the usual indices of hemolysis are found (339). Conversely, blood COHb and ETCOc concentrations are consistently elevated in G6PD-deficient infants (339,340,341). Nevertheless, Kaplan and associates found no difference in COHb levels between hyperbilirubinemic (TSB greater than 15mg/dL [256 μmol/L]) and nonhyperbilirubinemic G6PD-deficient infants (341). These investigators also found that although COHb values were higher in G6PD-deficient neonates than in normal neonates, there was no correlation between TSB levels and COHb values in the G6PD-deficient group (342). All of these observations suggest that while an increase in heme turnover is clearly present in G6PD-deficient neonates, with the exception of those who suffer an acute hemolytic event, hemolysis alone cannot be implicated as the primary mechanism responsible for hyperbilirubinemia.

HPLC measurements of conjugated bilirubin fractions provide an index of the hepatic conjugating capacity. Lower serum conjugated bilirubin fractions relative to serum total bilirubin concentrations indicate diminished conjugating capacity (343). In G6PD-deficient neonates who developed TSB levels greater than 15 mg/dL (256 μmol/L), serum total, mono- and di-conjugated bilirubin fractions were significantly lower than in nonhyperbilirubinemic G6PD-deficient infants (344), suggesting that impaired conjugation plays a role in the pathogenesis of hyperbilirubinemia.

Finally, a remarkable interaction between G6PD deficiency and Gilbert syndrome was demonstrated by Kaplan and associates (345). In this study of Israeli infants, neither the presence of the variant UGT promoter (for Gilbert syndrome) by itself, nor G6PD deficiency alone had a significant effect on the incidence of hyperbilirubinemia (TSB greater than 15 mg/dL [256 μmol/L]), but there was a significant increase in hyperbilirubinemia in G6PD-deficient infants who also had the variant UGT promoter (Fig. 35-18). The incidence of hyperbilirubinemia in G6PD-deficient neonates increased from 9.7% in normal homozygotes to 31.6% in the variant UGT promoter heterozygotes to 50% in homozygotes for the variant promoter. No significant effect of the variant UGT promoter was seen in the G6PD-normal infants (Fig. 35-18). Thus neither G6PD deficiency alone, nor the abnormal UGT promoter alone (Gilbert syndrome), caused an increased incidence of hyperbilirubinemia; both factors were needed to produce a significant increase in TSB levels. It is interesting, however, that in Italian G6PD-deficient neonates, homozygosity for the variant 7/7 promoter did not increase the risk of hyperbilirubinemia (346). Routine screening for G6PD deficiency is currently not performed in the United States, although such screening would be appropriate in the black

P.803

population (326). Table 35-20 summarizes the relationships and mechanisms involved in G6PD deficiency and hyperbilirubinemia.

Figure 35-18 Incidence of hyperbilirubinemia, defined as TSB ≥ 15.0 mg/dL (256 $\mu\text{mol/L}$), for G6PD-deficient and control neonates, stratified for the three promoter genotypes of the gene encoding the bilirubin conjugating enzyme UGT1A1. (From Kaplan M, Renbaum P, Levi-Lahad E, et al. Gilbert syndrome and glucose-6-phosphate dehydrogenase deficiency: A dose-dependent genetic interaction crucial to neonatal hyperbilirubinemia. Proc Natl Acad Sci U S A 1997;94:12128-12132, with permission.)

Treatment

The risk of kernicterus in G6PD-deficient infants with TSB levels above 20 mg/dL (342 $\mu\text{mol/L}$) appears to be comparable to that associated with Rh disease. Thus, in the presence of G6PD deficiency, more aggressive treatment of these infants is needed (339,347,348).

Pyruvate Kinase Deficiency

This autosomal recessive disorder is less prevalent than G6PD deficiency and, in contrast to G6PD deficiency, typically presents with jaundice, anemia, and reticulocytosis (322). Neonatal hyperbilirubinemia is common and kernicterus has been reported (321). This disorder should be considered in a hyperbilirubinemic neonate with a picture of nonspherocytic, DAT-negative hemolytic anemia (322).

Other Disorders of the Embden-Meyerhof Pathway

Conditions such as *hexokinase deficiency*, *glucose phosphate isomerase deficiency*, and *phosphofructokinase deficiency* occasionally are associated with hemolysis and neonatal hyperbilirubinemia (321). Jaundice and anemia have also been described in isolated cases of *2,3-bisphosphoglycerate mutase deficiency* and *phosphoglycerate kinase deficiency* (321).

TABLE 35-20 RESULTS OF STUDIES ON THE PATHOGENESIS OF HYPERBILIRUBINEMIA IN G6PD-DEFICIENT INFANTS

Increased red cell turnover (hemolysis) (339–341) although infants with TSB >15 mg/dL (256 μmol/L) did not have higher COHb levels than those with TSB <15 mg/dL (341)
Decreased conjugating capacity in infants with TSB >15 mg/dL (344)
No increase in TSB >15 mg/dL (vs. G6PD-normal infants) unless deficient infants are also heterozygotes or homozygotes for variant UGT promoter for Gilbert syndrome (345) (found in Israeli but not Italian neonates) (346)

Hemoglobinopathies

These conditions generally do not present in the newborn period. Fetal hemoglobin (hemoglobin [Hb] F) is composed of alpha (α) and gamma (γ)² chains. *Homozygous* α thalassemia (complete absence of α chain synthesis) results in profound hemolysis, anemia, hydrops fetalis, and almost always stillbirth or death in the immediate neonatal period (322). As there are no β chains in hemoglobin F, β -thalassemia does not manifest itself in neonates. *Sickle cell disease* is asymptomatic in the neonate (349) because of the inhibitory effect of Hb F on Hb S polymerization and cellular sickling (350). The expression of sickle cell disease is thus masked until Hb S levels increase to more than 75% at about 6 months (350).

Extravascular Blood

Cephalhematomas, bruising, intracranial or pulmonary hemorrhage, or any occult bleeding may lead to an elevated TSB level from breakdown of the extravascular erythrocytes (206,351,352 and 353). (The catabolism of 1 g of hemoglobin yields 35 mg of bilirubin.) In two reports, severe hyperbilirubinemia followed delayed absorption of intraperitoneal blood in infants who had received intraperitoneal fetal transfusions before birth (351,353). In both reported cases, despite multiple exchange transfusions, hyperbilirubinemia was not controlled until peritoneal lavage was performed. Massive adrenal hemorrhage has also caused severe hyperbilirubinemia (352).

In the VLBW infant, the presence of PIVH is associated with an increase in serum bilirubin levels in some studies (354,355) but not in others (356). Amato and colleagues (356) studied 88 infants with birth weights less than 1,500 g. Phototherapy was initiated only when serum bilirubin levels exceeded 12 mg/dL (205 μmol/L). The incidence of serum bilirubin levels greater than 12 mg/dL was

P.804

39% in the PIVH group and 46.8% in the infants without PIVH. There was no difference in the duration of phototherapy in the two groups.

Polycythemia

The catabolism of 1 g of hemoglobin produces 35 mg of bilirubin and it is often assumed that a high hematocrit is a risk factor for neonatal jaundice, because an increase in the erythrocyte mass should increase the bilirubin load presented to the liver. Nevertheless, mean bilirubin levels and the incidence of hyperbilirubinemia were similar in polycythemic infants randomly assigned to receive either partial exchange transfusions or symptomatic treatment (see Epidemiology of

Neonatal Jaundice) (231,232 and 233). In one study, however, infants were held 30 cm below the introitus after delivery. If cord clamping was delayed, the mean TSB level at 72 hours was 7.7 mg/dL (132 μ mol/L) compared with 3.2 mg/dL (55 μ mol/L) in the early clamped group (234).

Increased Enterohepatic Circulation

(See Physiologic Mechanisms of Neonatal Jaundice, Epidemiology of Neonatal Hyperbilirubinemia, and Breast-feeding and Jaundice for the contribution of the enterohepatic circulation to neonatal jaundice.) Intestinal obstruction or a delay in bowel transit time increases the enterohepatic circulation by decreasing caloric intake and allowing more time for bilirubin deconjugation and reabsorption. Jaundice is common in infants with small-bowel obstruction and occurs in infants with pyloric stenosis (357,358,359). Correction of the obstruction produces a prompt decline in bilirubin levels.

The pathogenesis of jaundice associated with pyloric stenosis has been debated for many years (358) and it was suggested that caloric deprivation, as well as a decrease in UGT activity, might play an important role (358). In Gilbert syndrome, caloric deprivation produces an increase in TSB levels and a low activity of UGT has been seen in jaundiced infants with pyloric stenosis (358,360). In a report of three formula-fed infants with hypertrophic pyloric stenosis and jaundice (359), two were homozygous for the UGT variant promoter for Gilbert syndrome and one infant was heterozygous for the promoter. These observations confirm a critical role for Gilbert syndrome in the pathogenesis of jaundice associated with pyloric stenosis (see Gilbert Syndrome below).

TABLE 35-21 INBORN ERRORS OF HEPATIC BILIRUBIN UGT EXPRESSION

Characteristic	Crigler-Najjar Type II		
	Crigler-Najjar Type 1	(Arias syndrome)	Gilbert Syndrome
Inheritance	Autosomal recessive	Autosomal recessive or dominant	Autosomal dominant or recessive
UGT1 activity	Absent	<10%	50%
Genetics	Nonsense or stop mutation	Missense mutation	Variant promoter
Hyperbilirubinemia	>20 mg/dL	5–15 mg/dL ^a	3–5 mg/dL
Kernicterus	High risk	Low risk ^a	No apparent risk

^a Marked hyperbilirubinemia can occur in some cases of Arias syndrome, which may place the infant at high risk for kernicterus.

From Watchko JF. Indirect hyperbilirubinemia in the neonate. In: Maisels MJ, Watchko JF, eds. *Neonatal jaundice*. London, UK: Harwood Academic Publishers, 2000:51–66, with permission.

Infants of Diabetic Mothers

Only macrosomic infants of mothers with insulin-dependent diabetes are at increased risk of hyperbilirubinemia (213). This is probably the result of increased bilirubin production (214,215,216) (see Epidemiology of Neonatal Hyperbilirubinemia: Maternal Factors).

Decreased Bilirubin Clearance

Inherited Unconjugated Hyperbilirubinemia—Inborn Errors of Bilirubin Uridine Diphosphoglucuronate Glucuronosyltransferase Activity

The structure and function of the UGT1A1 gene and the genomics of hyperbilirubinemia have been reviewed in detail (22,23). (See Fig. 35-7 and Structure and Function of the Uridine Diphosphoglucuronate Glucuronosyltransferase 1A1 Gene above) Because a single form of bilirubin UGT accounts for almost all of the bilirubin glucuronidation activity in the human liver, inherited defects of a single enzyme will cause jaundice. Three types of inherited UGT deficiency are recognized.

Crigler Najjar Syndromes.

Crigler-Najjar syndromes types I and II (CN-1, CN-2) are caused by one or more mutations in any of the five exons of the UGT1A1 gene (22,23), as well as mutations in the noncoding, intronic region of the gene (see Fig. 35-7 and Table 35-21) (22). More than 30 different genetic mutations have been identified in CN-1 syndrome and the gene frequency for CN-1 is estimated to be 1:1000 (23). Infants with CN-1 have almost

P.805

complete absence of bilirubin UGT activity. They develop severe hyperbilirubinemia in the first 2 to 3 days of life and often require exchange transfusion in the first week. Subsequently, intensive home phototherapy controls bilirubin levels to some extent, but as these children get older, increasing skin thickness and pigmentation and a decrease in the surface-area-to-body-mass ratio render phototherapy less effective. A "tanning bed" phototherapy configuration is necessary to obtain adequate irradiance and surface area exposure (see *Phototherapy* below) (361). Brain damage can occur at any time, including adulthood, and plasmapheresis has been used to reduce bilirubin concentrations during acute exacerbations of hyperbilirubinemia (362,363). One 16-year-old boy with CN-1 had 72 plasma exchanges over a period of 28 months before undergoing orthotopic liver transplantation (364). Liver transplantation is currently the only available definitive therapy, and serum bilirubin concentrations decline dramatically within hours of the procedure (365).

Another option is the use of human hepatocyte transplantation (366,367). Because hepatic architecture and function, except for bilirubin UGT activity, are normal in CN-1, transplantation of isolated liver cells is an attractive option. The infusion of hepatocytes (obtained from a donor liver) into the portal vein of a 10-year-old girl with CN-1 decreased TSB levels by 50% (366). Hepatic bilirubin UGT activity increased from 0.4% to 5.5% of mean normal enzyme activity, and more than 30% of the patient's bile pigments were now bilirubin glucuronides. The ultimate treatment of the Crigler-Najjar syndrome, however, lies in the development of effective gene therapy (368), although this has yet to be attempted in a human.

The administration of tin-protoporphyrin and tin-mesoporphyrin to children with CN-1 syndrome (369, 370) reduced TSB levels and the need for phototherapy. Administration of oral calcium phosphate significantly reduced TSB levels in patients with CN-1 who were receiving phototherapy (371).

The diagnosis of Crigler-Najjar syndrome is made by HPLC analysis of serum and duodenal bile, liver biopsy tissue enzyme assay, evaluating the response to phenobarbital (372,373), and by molecular analysis of the UGT1A1 gene (374). In CN-1 disease, phenobarbital has little or no effect on TSB concentrations, whereas in children with CN-2 disease, TSB levels can decrease by 30% to 80% during phenobarbital treatment (375). Phenobarbital acts via a phenobarbital-

responsive enhancer module that stimulates the UGT1A1 gene to induce production of glucuronosyltransferase (376). There is now a world registry for the CN-1 syndrome that is a unique source of information about this rare disease (377).

Suresh and Lucey (173) conducted a questionnaire survey of 42 patients ranging in age from 2 months to 21 years who had CN-1. Home phototherapy for 10 to 16 hours, principally at night, was the mainstay of postneonatal therapy. Additional therapies included oral agar, antioxidants, bilirubin oxidase, clofibrate, and cholestyramine, and liver transplantation was performed in 15 of the children. All patients grew normally; in 77% the neurodevelopmental status was normal. Those in school were doing well despite having had TSB levels of 15 to 29 mg/dL (257 to 496 $\mu\text{mol/L}$) for many years. Although it often is stated that sensorineural hearing loss is the most common form of bilirubin toxicity to the central nervous system, not one of 36 children evaluated had a sensorineural hearing loss, suggesting that bilirubin may not be as ototoxic as commonly believed. In these children it is important to avoid exacerbations of hyperbilirubinemia and to manage intercurrent infections promptly. Albumin infusions and plasmapheresis are effective in dealing with acute exacerbations of jaundice (173,372).

Infants with CN-2 disease (also known as Arias syndrome) generally have less-severe hyperbilirubinemia, although it can occur, and kernicterus has been reported in some infants. There is considerable overlap between CN-1 and CN-2 syndromes. Both infants and adults with CN-2 syndrome respond readily to phenobarbital therapy, with a sharp decline in serum bilirubin levels within 7 to 10 days. This response can be used to differentiate between the two syndromes (372).

Gilbert Syndrome.

People with Gilbert syndrome have a mild, benign, chronic or recurrent unconjugated hyperbilirubinemia with no evidence of liver disease or overt hemolysis. There is now evidence, however, that these individuals also have an increase in heme turnover (378) (see below). Gilbert syndrome is common, affecting approximately 6% to 9% of the general population, and both autosomal dominant and recessive patterns of inheritance have been suggested. Typically, the indirect-reacting hyperbilirubinemia is not recognized until after puberty and manifests itself during fasting or intercurrent illness.

The genetic basis for this disorder has been clarified (22,23,379,380) and involves mutations of the UGT1A1 gene promoter (see Fig. 35-7). In whites with Gilbert syndrome there is commonly a variant promoter for the gene encoding UGT1A1. (This is not the case in East Asian populations.) This promoter contains a two base-pair addition (TA) in the TATAA element that gives rise to seven (TA)₇ TAA(7/7) rather than the more usual six (TA)₆ TAA(6/6) repeats in affected subjects (379). There is an inverse relationship between the number of repeats and the activity of the promoter: as the number of TA repeats increases, UGT activity decreases (379,381). Subjects with Gilbert syndrome are homozygous for the variant promoter, providing a unique genetic marker for this disorder. Hetero-zygotes have one allele each of the wild-type and variant promoters (6/7) (379). The gene frequency for the 7/7 motif is 0.3 so that 9% of the general population are homozygous and 42% are heterozygous (382). Thus about half of the white population carries a Gilbert promoter on at least one allele.

Although most commonly diagnosed in young adulthood, it is now clear that Gilbert syndrome plays a role in the pathogenesis of neonatal jaundice (22,23). Several investigators have shown that neonates who are homozygous for the

variant 7/7 UGT gene promoter have a more rapid rise in their TSB levels (383) and higher TSB levels at age 96 hours (Fig. 35-19) (384). Of neonates with TSB concentrations greater than 13

mg/dL (222 $\mu\text{mol/L}$) 26.8% were homozygous for the variant 7/7 promoter versus 12.2% of those whose TSB levels were ≤ 13 mg/dL (385). In a population of Scottish, primarily breast-fed newborns with TSB levels of greater than 5.8 mg/dL (100 $\mu\text{mol/L}$) after 14 days of life, 31% were homozygous for the 7/7 Gilbert syndrome promoter genotype compared with only 6% of a control group with acute jaundice (259). Of 17 breast-fed Japanese infants with prolonged jaundice, 16 had at least 1 mutation of the UGT1A1 gene, primarily of the G71R type (260).

Figure 35-19 Newborn mean serum bilirubin levels as a function of postnatal age and presence of Gilbert promoter abnormality. Homozygous normal UGT genotype (6/6); heterozygous variant UGT genotype (6/7); homozygous variant UGT genotype (7/7). (Redrawn from Watchko JF. Indirect hyperbilirubinemia in the neonate. In: Maisels MJ, Watchko JF, eds. *Neonatal jaundice*. London, UK: Harwood Academic Publishers, 2000:51-66, with permission, from data of Roy-Chowdhury N, Deocharan B, Bejjanki HR, et al. Presence of the genetic marker for Gilbert syndrome is associated with increased level and duration of neonatal jaundice. *Acta Paediatr* 2002;91:100-101.)

Thus, Gilbert syndrome plays an ubiquitous role in the pathogenesis of neonatal hyperbilirubinemia. The combination of the Gilbert genotype with other icterogenic factors such as breast-feeding (259,260), G6PD deficiency (345), ABO incompatibility (317), and pyloric stenosis (359) dramatically increases a newborn's risk of hyperbilirubinemia.

Mutations of the Uridine Diphosphoglucuronate Glucuronosyl-transferase

1A1 Gene Coding Area Associated with Gilbert Syndrome. Unlike white populations with Gilbert syndrome, the TATAA promoter variations are rare in East Asian populations (22). In these populations, Gilbert syndrome appears to result from missense mutations in the coding area of the UGT1A1 gene. The most common of these is a G \rightarrow A transition at nucleotide 211, which causes arginine to replace glycine at position 71 of the corresponding protein product (386,387). This G71R variant is prevalent in Japanese, Korean, and Chinese populations (387) and other mutations have also been reported in association with Gilbert syndrome in these populations (388,389). The presence of these mutations could account for the higher TSB levels found in Japanese and other East Asian newborns.

Heterozygosity for Uridine Diphosphoglucuronate Glucuronosyl-transferase 1A1 Noncoding and Coding Area Mutations.

Because approximately 50% of the population carry a Gilbert type promoter on at least one allele, it is not surprising that some individuals may be heterozygous for the variant promoter gene and also heterozygous for a coding region mutation of the gene (22,23). Coinheritance of the Gilbert promoter and a coding region mutation of the gene can also lead to jaundice (23). This is true not only for patients who are homozygous for the Gilbert genotype, but also for compound heterozygotes of a Gilbert type promoter and a structural region mutation of the UGT1A1 (382). A striking example of this situation was recently described in twin girls who developed marked hyperbilirubinemia and kernicterus and were found to be compound heterozygotes for the Gilbert-type UGT promoter and a coding region mutation of the UGT1A1 gene (382).

Based on the gene frequencies for the Gilbert promoter and structural mutations of the UGT1A1 gene, at least 1 in 3,300 infants will be compound heterozygotes for Gilbert and UGT1A1 coding region mutations and at risk for significant hyperbilirubinemia (23,380). Watchko notes that the 1 in 3,300 likelihood of this compound heterozygosity is similar to the frequency of TSB levels greater than 30 mg/dL (greater than 513 $\mu\text{mol/L}$) (203,288).

We do not know if Gilbert syndrome plays an important role in the pathogenesis of extreme hyperbilirubinemia (TSB levels greater than 30 mg/dL [513 $\mu\text{mol/L}$]), but the fact that poor feeding and weight loss (a state resembling fasting) (124,390), as well as very low direct-reacting bilirubin fractions, are seen in some of these infants suggests that this is a possibility worthy of investigation.

Other Inborn Errors of Metabolism

Galactosemia.

Galactosemia is a rare disease (incidence, 1 in 35,000 to 60,000 live births), and jaundice may be one of the presenting features (391); but infants with significant hyperbilirubinemia caused by galactosemia almost all have some other manifestations of the disease, most often poor feeding, vomiting, excessive weight loss, irritability, and lethargy. Hyperbilirubinemia during the first week of life is almost exclusively unconjugated, and

P.807

the conjugated fraction tends to rise during the second week, probably reflecting liver damage. The presence of a positive family history, lethargy, poor feeding, or other signs of illness merit additional diagnostic evaluation, including testing the urine for reducing substances using Clinitest (Miles Inc., Diagnostic Division, Elkhart, IN). *Escherichia coli* sepsis is the most devastating complication in the newborn (391).

Tyrosinemia and Hypermethioninemia.

The relation between these inborn errors of metabolism and jaundice is primarily a result of the presence of neonatal liver disease, which initially may manifest as indirect-reacting hyperbilirubinemia but which generally is accompanied by some evidence of cholestasis (i.e., direct-reacting hyperbilirubinemia).

Hypothyroidism.

Prolonged indirect-reacting hyperbilirubinemia is one of the clinical features of congenital hypothyroidism (392,393,394 and 395), a condition that must be ruled out in any infant who has indirect-reacting hyperbilirubinemia beyond 2 to 3 weeks of age. Although widespread availability of screening programs for congenital hypothyroidism should allow early identification of this problem as a possible cause of jaundice, screening programs do not detect every infant, and errors are more likely to occur with early discharge of infants in whom the thyroxine (T₄) level may still be spuriously elevated.

The pathogenesis of hyperbilirubinemia associated with hypothyroidism is not clear, and administration of triiodothyronine to full-term and preterm infants does not lower peak serum bilirubin levels (396,397). In one infant with prolonged jaundice, UGT activity in a liver biopsy sample was unmeasurable (393), but the jaundice resolved following thyroxine administration. Conversely, when rats underwent thyroidectomy UGT activity *increased* and they also developed cholestasis (398).

Drugs

The use of pancuronium and chloral hydrate is associated with higher bilirubin levels in sick preterm infants (275,276 and 277), and chloral hydrate is associated with an increased risk of direct-reacting hyperbilirubinuria (276).

Breast-Milk Jaundice

See Epidemiology of Neonatal Hyperbilirubinemia, Breast-Feeding and Jaundice, above.

Prolonged Indirect-reacting Hyperbilirubinemia

Prolonged indirect-reacting hyperbilirubinemia is defined as indirect-reacting bilirubinemia persisting beyond 2 weeks of age in the full-term infant; Table 35-22 lists its causes. The association of prolonged indirect-reacting hyperbilirubinemia with pyloric stenosis is well described but the pathogenesis of this association has never been clear, although delayed gastric emptying and enterohepatic circulation were thought to play a role. In a report of three infants with pyloric stenosis and hyperbilirubinemia, two were homozygous, and one heterozygous for the variant promoter for Gilbert syndrome (359), implying a key role for Gilbert syndrome in the pathogenesis of the prolonged hyperbilirubinemia that sometimes occurs in pyloric stenosis.

TABLE 35-22 CAUSES OF PROLONGED INDIRECT HYPERBILIRUBINEMIA

Breast-milk jaundice	Pyloric stenosis
Hemolytic disease	Crigler-Najjar syndrome
	Gilbert syndrome
Hypothyroidism	Extravascular blood

Mixed Forms of Jaundice

Sepsis and Urinary Tract Infection

Jaundice is one sign of bacterial sepsis and some reports suggest that unexplained hyperbilirubinemia may be the only manifestation of sepsis in otherwise healthy-appearing newborns (399,400,401). Should newborns with unexplained hyperbilirubinemia be subjected to lumbar puncture and blood and urine cultures even if they appear otherwise well? I evaluated 306 newborns admitted within 21 days of birth with indirect-reacting hyperbilirubinemia (peak TSB level 18.5 ± 2.8 mg/dL; range: 12.7 to 29.1 [316 ± 48 $\mu\text{mol/L}$; range: 217 to 498]) (see Table 35-18). No case of sepsis was diagnosed (249).

In a study of 160 asymptomatic jaundiced infants presenting to an emergency department in Los Angeles, urine cultures (catheter specimens) were positive (greater than 10,000 colony-forming units [cfu]/mL) in 12 (7.5%) of the infants (402) (0 of 44 circumcised boys, 9 of 94 uncircumcised boys, and 3 of 62 girls). A positive urine culture was more likely when jaundice was first noted after 8 days of age and if there was an elevated direct-reacting bilirubin concentration (402). The authors recommended that all asymptomatic, jaundiced infants presenting to an emergency department (402) should have a urine culture, but this view has been questioned (403).

Given the prevalence of jaundice in the newborn, the presence of indirect-reacting hyperbilirubinemia as the *only* manifestation of bacteremia or incipient sepsis, must be a very rare occurrence. Furthermore, the finding of a positive blood or urine culture in a newborn with indirect-reacting hyperbilirubinemia does not prove that the infection is the cause of the jaundice. However, infants who appear sick or have late-onset jaundice after the initial icterus has resolved, or infants with direct-reacting hyperbilirubinemia or something else in the history, physical examination, or laboratory investigations that is out of the ordinary, should be evaluated carefully for possible sepsis or urinary tract infection.

Hypopituitarism

Prolonged jaundice that is predominantly cholestatic (elevated direct-reacting bilirubin) has been described in

P.808

infants with congenital hypopituitarism (404,405), although in some the hyperbilirubinemia is indirect. The pathogenesis of hyperbilirubinemia in this condition remains to be elucidated.

Other Causes

Congenital syphilis, the TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex) group of chronic intrauterine infections, and coxsackievirus B infection are the other important causes of mixed jaundice. The clinical features and diagnoses of these conditions are described in Chapter 48.

Newer Developments that Affect Our Approach to the Jaundiced Newborn

In the last several years, three factors have emerged that have colored our approach to the evaluation and management of neonatal jaundice. The first is a series of case reports indicating that kernicterus, thought to be almost extinct, is still occurring (124,133,328,329,390,406). The second is the decreasing hospital stay for newborn infants, and the third is an increase in the incidence of neonatal jaundice.

Kernicterus Still Occurs

Neonatologists still see occurrences of kernicterus and reports in the literature (124,133,328,329,390,406) suggest a "resurgence" of this devastating condition. Nevertheless, there are no appropriate data to support this perception, because there is no uniform surveillance for the reporting of kernicterus over the last 3 to 4 decades, no agreed on case definition for kernicterus, and, most important, no denominators (i.e., population base) for the case reports listed. Nevertheless, the fact that kernicterus, although rare, still occurs, demands our attention because it is nearly always preventable by relatively simple interventions (76).

A preliminary analysis of the reported cases of kernicterus suggests the possible root causes (124,407) listed in Table 35-23.

Early Discharge and the Risk of Jaundice

In addition to the global trend toward a shorter hospital stay for newborns, several studies (239,241,288) but not all (206,408), have found that early discharge itself is associated with an increased risk of significant hyperbilirubinemia and even kernicterus (124,328). Recognizing both the risk of unrecognized jaundice in infants discharged early, as well as the fact that, in infants discharged before 72 hours, the TSB level is almost always still rising, the AAP guidelines for followup of infants discharged before 72 hours are stringent (76) (see section on Preventing Extreme Hyperbilirubinemia and Kernicterus).

It is not clear why infants who are discharged early are at greater risk of developing significant hyperbilirubinemia. The vast majority of these hyperbilirubinemic infants are breast-fed, and it is possible that mothers who have longer postpartum stays are more rested, have more time to receive advice and counsel regarding breast-feeding, and are therefore able to nurse their babies more effectively. More frequent and effective lactation, as well as improved caloric intake, decreases the likelihood of hyperbilirubinemia (251,252,409). Early discharge also may have a negative effect on the ability of mothers to assimilate and process the information that they receive regarding lactation and infant care (410). As a result, they may nurse the infants less effectively.

TABLE 35-23 ROOT CAUSES OF REPORTED CASES OF KERNICTERUS

Early discharge with failure to ensure appropriate followup.
Failure to evaluate the measured TSB level based on the infant's age in hours.
Failure to recognize risk factors for severe hyperbilirubinemia.
Underestimating the severity of jaundice by clinical (i.e., visual) assessment.
Lack of concern regarding the neurotoxic potential of bilirubin.

Shorter hospital stays also have necessitated a readjustment in our thinking with regard to the meaning of specific bilirubin levels. To date, this has proved to be a difficult adjustment for pediatricians who are accustomed to using a specific TSB level (irrespective of the infant's age) as an indication for reassurance or

concern. The data of Bhutani and associates (289) graphically illustrate this point (Fig. 35-20). Clinicians commonly refer to jaundice occurring on “day 2 or day 3,” but reference to the data of Bhutani and associates (see Predischarge Measurement of the Bilirubin Level below) and Fig. 35-20 indicates just how misleading this thought process can be. A TSB level of 8 mg/dL at 24.1 hours is above the 95th percentile and calls for evaluation and close followup, whereas the same level at 47.9 hours is in the low-risk zone and probably requires no further concern—yet both of these values occur on “day 2” (289). One point is worth emphasizing: *If newborns are discharged at less than age 36 hours, their bilirubin levels (with very rare exceptions) can only be going in one direction—up.* The recognition that jaundice is now primarily an outpatient problem requires us to develop a consistent approach to the monitoring and surveillance of these infants if we are to prevent the development of extreme hyperbilirubinemia and kernicterus (76).

More Jaundiced Newborns

There is evidence that the incidence of neonatal jaundice is increasing. In the days of the major CPP (1959 to 1966), only 5% of infants had bilirubin levels ≥ 13 mg/dL (222 $\mu\text{mol/L}$) and less than 1% had a peak TSB level of ≥ 20 mg/dL (342 $\mu\text{mol/L}$) (205). However, in three more recent studies, the 95th percentile for a population of term and

P.809

near-term infants ranged from 15.5 to 18 mg/dL (289,290, 411). In a study of 11 Kaiser Permanente northern California hospitals, 2% of infants had peak TSB levels ≥ 20 mg/dL (203). Factors that may be responsible for this increase in jaundice include an increase in the number of infants breast-fed on discharge from the hospital (30% in the 1960s, 65% to 70% in 2001) (412,413) and shorter hospital stays (239,241,288).

Figure 35-20 Nomogram for designation of risk in 2,840 well newborns ≥ 36 week's gestational age with birth weight $\geq 2,000$ g or ≥ 35 weeks' gestational age and a birth weight $\geq 2,500$ g or more based on the hour-specific serum bilirubin values. The serum bilirubin level was obtained before discharge, and the zone in which the value fell predicted the likelihood of a subsequent bilirubin level exceeding the 95th percentile (high-risk zone) as shown in Table 35-27. Note that because of sampling bias (293) this nomogram should not be used to represent the natural history of neonatal hyperbilirubinemia. (From Bhutani VK, Johnson L, Sivieri EM. Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy-term and near-term newborns. *Pediatrics* 1999;103:6-14, with permission.)

Prevention, Identification, and Management of Neonatal Hyperbilirubinemia

The Approach to a Jaundiced Infant

The Institute of Medicine (IOM) issued a report in 2001 that describes a “chasm in health care quality” which needs to be crossed for patients to receive better care (414). The report calls for a “systems approach” drawing on the rapid evolution of knowledge about complex adaptive systems. The IOM report offers 10 “simple rules” to “redesign and improve care” (414) Palmer and associates (415) studied the care of newborns with hyperbilirubinemia in two large managed care organizations and describe how this care might be improved by using practical applications of the ideas about complex adaptive systems.

The recently published guideline of the AAP provides an approach to the evaluation and treatment of hyperbilirubinemia in the term and near-term newborn ≥ 35 weeks of gestation (76). Although bilirubin encephalopathy or kernicterus should almost always be preventable, it is still occurring in this group of infants. Table 35-24 lists the key elements of the recommendations provided in the AAP guideline. The discussion that follows deals primarily with infants ≥ 35 weeks of gestation, although the basic principles apply to the evaluation and management of hyperbilirubinemia in all infants.

Primary Prevention

Prenatal Testing

Screening for Isoimmunization

All pregnant women should be tested for ABO and Rh (D) typing and undergo a serum screen for unusual isoimmune antibodies (76). If such prenatal testing has not been performed, then a direct Coombs test, a blood type, and an Rh (D) type on the infant's cord blood should be done; this should always be done if the mother is Rh-negative. In addition to identification of potentially Rh-sensitized infants, this testing is obligatory because it identifies Rh-negative mothers who require anti-D gammaglobulin to prevent Rh (D) sensitization.

In infants of group O, Rh-positive mothers, the AAP recommends that routine testing for blood type and Coombs test is optional “provided there is appropriate surveillance

P.810

and risk assessment before discharge and followup (76) so that significantly jaundiced infants are not missed.” (See ABO Hemolytic Disease above.)

TABLE 35-24 KEY ELEMENTS OF THE AMERICAN ACADEMY OF PEDIATRICS GUIDELINE ON MANAGEMENT OF HYPERBILIRUBINEMIA IN THE NEWBORN INFANT ≥ 35 WEEKS OF GESTATION

1. Promote and support successful breast-feeding.
2. Establish nursery protocols for the identification and evaluation of hyperbilirubinemia.
3. Measure the TSB or TcB level on infants jaundiced in the first 24 hours.
4. Recognize that visual estimation of the degree of jaundice can lead to errors, particularly in darkly pigmented infants.
5. Interpret all bilirubin levels according to the infant's age in hours.
6. Recognize that infants <38 weeks' gestation, particularly those who are breast-fed, are at higher risk of developing hyperbilirubinemia and require closer surveillance and monitoring.
7. Perform a systematic assessment on all infants prior to discharge for the risk of severe hyperbilirubinemia.
8. Provide appropriate followup based on the time of discharge and the risk assessment.
9. Treat newborns, when indicated, with phototherapy or exchange transfusion.

TcB, transcutaneous bilirubin.

From Maisels MJ, Baltz RD, Bhutani V, et al. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114:297–316, with permission.

Preventing Hyperbilirubinemia

To prevent severe hyperbilirubinemia, we need to (a) identify infants who are at risk for developing hyperbilirubinemia, (b) follow them closely, and (c) treat them with phototherapy when indicated.

Ensuring Successful Breast-feeding.

Because exclusively breast-feeding an infant is strongly associated with an increased risk of hyperbilirubinemia (see Breast-Feeding and Jaundice above), the only *primary* preventive intervention available to us is to ensure the adequacy and success of breast-feeding. In many, but not all, cases of severe hyperbilirubinemia in breast-fed infants, poor caloric intake associated with inadequate breast-feeding (and manifested by increased weight loss) appears to play an important role (218,246,254,390). Exclusively breast-feeding an infant is also a well documented risk factor for dehydration (416), considered by some to be a cause of hyperbilirubinemia, although there is no plausible mechanism for this. It is much more likely that in breast-fed, dehydrated infants, it is the caloric deprivation and its effect on the enterohepatic circulation of bilirubin (see Table 35-14) that is primarily responsible for the severe hyperbilirubinemia (244).

Thus, the clinician's primary role in preventing hyperbilirubinemia is to help ensure that breast-feeding will be successful. The first step is to ask mothers to nurse their infants at least 8 to 12 times per day for the first several days (417), because increasing the frequency of nursing significantly decreases the likelihood of subsequent hyperbilirubinemia (251,252,409). Evidence of adequate intake in breast-fed infants also includes 4 to 6 thoroughly wet diapers within 24 hours and the passage of 3 to 4 stools per day by the fourth day. By the third to fourth day, the stools in adequately breast-fed infants should have changed from meconium to a mustard yellow, mushy stool (418). Weight loss must also be monitored. Unsupplemented breast-fed infants experience their maximum weight loss by day 3 and, on average, lose $6.1 \pm 2.5\%$ (SD) of their birth weight (243,246,251,261,419,420,421 and 422). Thus, approximately 5% to 10% of exclusively breast-fed infants lose 10% or more of their birth weight by day 3, suggesting that adequacy of intake should be evaluated and the infant monitored if weight loss is greater than 10% (423). These assessments will also help to identify breast-fed infants who, because of inadequate intake, are at

risk for dehydration.

In many hospitals it is a common practice to provide supplemental feedings of water or dextrose water to breast-fed infants in the mistaken belief that this will lower their TSB levels. As illustrated in Fig. 35-21, this practice does not decrease TSB levels (419,420) but it does interfere with the establishment of effective lactation (424).

Identifying the Jaundiced Newborn

Clinical Assessment

All infants should be monitored routinely for the development of jaundice and nurseries should have established protocols for the assessment of jaundice. In newborns, jaundice is detected by blanching the skin with digital pressure, thus revealing the underlying color of the skin and subcutaneous tissue. It is important for this assessment to be done in a well-lit room or, preferably, in daylight at a window.

The Cephalocaudal Progression of Jaundice

Dermal icterus is seen first in the face and then progresses in a caudal manner to the trunk and extremities so that, for a given bilirubin level, the skin of the face will appear more yellow than that of the foot. First observed more than 100 years ago and confirmed by several investigators using visual observation as well as transcutaneous bilirubinometry, the cephalocaudal progression of dermal icterus is a useful clinical tool but less reliable once the TSB level exceeds 12 mg/dL (205 $\mu\text{mol/L}$) (425,426,427,428,429,430,431 and 432).

Figure 35-21 Effect of supplementary feeding on serum bilirubin levels on day 6 in breast-fed newborns. Nursing infants were randomly assigned to receive supplemental water (n=15), dextrose water (n=17), or no supplement (n=17). Bilirubin levels on day 6 (mean \pm standard error of mean [SEM]) are shown. There were no significant differences between any of the groups. Drawn from the data in Nicoll A, Ginsburg R, Tripp JH. Supplemental feeding and jaundice in newborns. *Acta Paediatr Scand* 1982;71:759-761.

Mechanism of the Cephalocaudal Progression

Knudsen suggests that the cephalocaudal color difference in newborns is best explained by conformational change in the bilirubin-albumin complex (431). Following its formation, bilirubin is bound tightly to albumin, and the initial binding process is extremely rapid (within 10 milliseconds). This is followed by a train of slow, relaxing changes in the conformation of the bilirubin-albumin complex commencing within 1 to 30 seconds, final conformation being reached 8 minutes after the initial binding (433). This time course suggests that initially there is a lower bilirubin-binding affinity to albumin (until the final stage of conformation has occurred) and thus less-effective bilirubin-albumin binding in the blood immediately after it has left the reticuloendothelial system. The affinity increases after the blood reaches the distal portions of the body and the conformational changes in the bilirubin-albumin complex are completed. Knudsen suggests that some of the yellow color of the skin is the result of precipitated bilirubin acid and in the presence of reduced bilirubin-binding affinity to albumin, there is an increased precipitation of bilirubin acid and thus an increase in the yellow color of the skin (431). This is more likely to occur in the proximal parts of the body because of the conformational changes in the young bilirubin-albumin complexes. Consistent with this hypothesis, Knudsen (431) found that there was a significant and linear correlation among the cephalocaudal color difference, the plasma bilirubin concentration, and the square of the hydrogen ion concentration. The cephalocaudal color difference was inversely related to the reserve albumin concentration, thus suggesting that the conformational change in the young bilirubin-albumin complex enhances the precipitation of bilirubin acid in the skin of the proximal parts of the body. If this is the mechanism, then objective measurement of the yellow color of the skin using transcutaneous bilirubinometry could be a better predictor of potential bilirubin encephalopathy than a serum bilirubin measurement.

How Good Is the Visual Assessment of Jaundice?

The ability of clinicians to diagnose jaundice varies widely (235,425,426,434,435), although studies suggest that home health nurses (436) and some neonatologists (435) can effectively evaluate newborns for the presence and severity of jaundice, and that newborns whose TSB levels exceed 12 mg/dL (205 $\mu\text{mol/L}$) will almost always be identified as "jaundiced" (235,425). Nevertheless, visual estimation of actual bilirubin levels from the degree of jaundice can be unreliable and can certainly lead to errors (235,426,434). Errors are also more likely to occur in darkly pigmented infants. Consequently, a low threshold should be used for measuring the TSB. There is also a problem with relying on visual diagnosis in the first 24 to 36 hours. The difference between a TSB level of 5 mg/dL (85 $\mu\text{mol/L}$) and 8 mg/dL (137 $\mu\text{mol/L}$) cannot be perceived by eye, yet this is the difference between a TSB level at the 50th percentile and one that is at the 95th percentile (see Figs. 35-16 and 35-20). The potential errors associated with visual diagnosis have led some experts to recommend that all newborns should have a laboratory measurement of TSB prior to discharge (124) (see Pre-discharge Measurement of the Bilirubin Level). An alternative is the use of the newer noninvasive (transcutaneous) devices that can provide a valid estimate of TSB levels less than 15 mg/dL (257 $\mu\text{mol/L}$) (140,204,437,438).

Noninvasive Measurements of Bilirubin

The Ingram Ictrometer (Cascade Health Care Products, Salem, OR) is a piece of transparent plastic on which is painted 5 transverse strips of graded yellow hue. The instrument is pressed against the nose, the yellow color of the blanched skin is matched with the appropriate yellow stripe, and a jaundice score is assessed. This device is simple and inexpensive and, remarkably, as a screening tool, it performs as effectively as much more sophisticated instruments (439). It has also been used effectively by nurses and even parents in the home (425,440).

The Minolta Air Shields jaundice meter (Air-Shields, Hatboro, PA) was the first electronic device marketed for transcutaneous bilirubin measurement. With this instrument and its successors (models JM-102 and -103), pressure is applied to a photoprobe and a strobe light is generated by a xenon tube. The light passes through a fiberoptic element, penetrating the blanched skin and entering the subcutaneous tissue. The reflected light returns through a second fiberoptic bundle to the spectrophotometric module where the intensity of the yellow color, corrected for hemoglobin, is measured and displayed. In the original jaundice meter this number was displayed as an arbitrary unit—the transcutaneous bilirubin (TcB) index. The newer model, JM-103, displays a bilirubin value that corresponds closely to the measured TSB level. The JM-103 jaundice meter uses two wavelengths and a dual optical path system (204,438). The principle of operation includes the formation of two beams, one of which reaches only the shallow areas of the subcutaneous tissue, while the other penetrates the deeper layers. The differences between optical densities are detected by blue and green photocells. The measurement of bilirubin accumulated primarily in the deeper subcutaneous tissues should decrease the influence of other skin pigments such as melanin and hemoglobin (438).

Another transcutaneous device, the BiliChek (Respironics, Marietta, GA) employs multiple wavelengths and measures TcB by using the entire spectrum of visible light (380 to 760 nm) reflected by the skin. The absorption of hemoglobin, melanin, and the effect of dermal thickness are isolated mathematically, and absorption of light by bilirubin in the capillary bed and subcutaneous tissues is isolated by spectral subtraction.

To date, studies with the JM-103 and the BiliChek have shown a close correlation between TcB and TSB measurements in mixed racial populations (204,437,441,442). When compared with HPLC measurements of TSB, the BiliChek was as good or better than the TSB measured in the clinical laboratory (441) although the accuracy of the BiliChek in a Hispanic (Mexican) population has been questioned (202). In this population, the BiliChek tended to under estimate the TSB, particularly when the TSB was greater than 10 mg/dL (171 μ mol/L) (202). The JM-103 is less precise in black infants than in white infants, although the predominant tendency in black infants is for the TcB value to overestimate TSB levels (204) so that dangerous errors are unlikely to occur.

TcB measurements become less precise with decreasing gestation and are of questionable utility below 30 weeks' gestation (443). Because phototherapy bleaches the skin, both visual assessments of jaundice and TcB measurements in infants undergoing phototherapy are not reliable (444). It might be possible, however, to use existing TcB instruments in infants who are undergoing phototherapy if an area of skin used for TcB measurements is protected from light (444). Data are limited regarding the use of TcB measurements following phototherapy. In one study, TcB measurements 18 to 24 hours after discontinuation of phototherapy correlated well with the TSB and the correlation improved further after an additional 24 hours (444).

Because TcB measurements are so easy to perform, repeated measurements can be obtained over the course of an infant's stay in the nursery. Plotting serial measurements will provide a good indication of whether TcB levels are rising and crossing percentiles and must therefore be followed more closely (see Fig. 35-20) Although the TcB measurement provides a good estimate of the TSB level, as with any laboratory measurement, TcB levels should not be considered in isolation, nor should critical decisions be based on a single measurement.

Both the BiliChek and JM-103 have an acceptable level of diagnostic accuracy, particularly when used as a screening device to place infants in a risk category for followup, or as an indication for obtaining a TSB (445). In some populations, TcB measurements may not be able to identify the precise bilirubin level with an acceptable degree of accuracy ("the wrong job for the tool") (445).

Currently, it is probably inadvisable to rely entirely on TcB measurements as a substitute for TSB measurements but they can certainly be helpful in many ways. When used as a screening tool TcB measurements can help us to answer the questions "Should I worry about this infant?" and "Should I obtain a TSB on this infant?" (445). For both of these purposes, the physician can set a value for a TcB measurement (based on the infant's age in hours and other risk factors) above which a TSB level will always be obtained. In our nursery, the nurses currently measure the TcB on all infants and automatically obtain a TSB if the TcB is above the 75th percentile (289). In our study with the JM-103, the chance of a TcB measurement underestimating the TSB level by 3 mg/dL (51.3 μ mol/L) or more was only 0.6%, so an alternative approach is to ask, "If the real TSB value is TcB plus 3 mg/dL (51 μ mol/L), is there a reasonable chance that this will change my management?" If the answer is yes, a TSB should be measured. This allows the clinician to take into account other risk factors, including the gestation. In this manner, no infant with significant hyperbilirubinemia should be missed and many infants and their families will be spared the trauma, cost, and inconvenience of having a laboratory measurement of serum bilirubin. The ability to measure the TcB in the office or other outpatient settings, including the home, noninvasively and instantaneously, should prove of inestimable value in the monitoring and management of the jaundiced newborn infant and should largely avoid the potential errors associated with clinical estimation of bilirubin levels.

Laboratory Measurements of Bilirubin

Total Serum Bilirubin

This subject has been reviewed in detail ([284,446,447](#)) and addressed, most recently by Lo and associates ([282](#)). Although this is one of the most commonly performed

P.813

laboratory measurements in the newborn, the measurement of TSB concentration remains remarkably inaccurate. Repeated surveys over the last 3 decades have disclosed a high level of interlaboratory variation in the measurements of both total and direct-reacting serum bilirubin concentrations in neonatal sera. In a recent study, a sample with a known TSB concentration of 14.8 mg/dL (243 μ mol/L) was analyzed in 14 different university hospital laboratories. The mean (\pm SD) measured TSB was 15.2 ± 2.5 mg/dL (coefficient of variation 16.4%) and the range was 12.1 to 18.5 mg/dL (207 to 316 μ mol/L) ([283](#)). This remarkably wide range of values in skilled hands suggests that considerable caution is necessary before generalizing bilirubin levels from one institution to the wider universe of newborns. Within-laboratory variation generally is considered to be lower, but in the study of Vreman and associates ([283](#)), over time, the coefficient of variation for repeated measurements of the same sample was as high as 17.2% in one laboratory ([283](#)).

The most recent analysis of laboratory neonatal TSB measurements was conducted by Lo and associates ([282](#)) who examined data submitted by laboratories that participate in the College of American Pathologists (CAP) neonatal bilirubin and chemistry surveys. They compared the data from laboratories throughout the United States with the reference method for measuring TSB ([448](#)). They found an acceptable coefficient of variation ranging from 1.9% to 4.5%, in the four most commonly used laboratory instruments. When compared with the reference method, the mean values from these instruments differed from the reference method by -21.6% to 10.9% . The authors attributed these discrepancies to the use of different methods used (primarily with the Vitros instrument, Ortho-Clinical Diagnostics, Raritan, NJ) in the neonatal bilirubin versus the chemistry surveys of the CAP, as well as the presence of a nonhuman protein base and ditauobilirubin in the survey specimens ([115](#)). Lo and associates concluded that it is impossible to evaluate the accuracy of TSB measurements from the CAP surveys because the standard specimens consist of bovine serum containing a mixture of unconjugated bilirubin and ditauobilirubin. They recommend that survey specimens should consist of human

serum enriched with unconjugated bilirubin. The CAP has adopted this recommendation and is now using human-serum-based specimens in their neonatal bilirubin and chemistry surveys (BT Doumas, personal communication, October, 2003).

These variations between laboratories might explain the frequent occurrence in clinical practice of an infant being admitted for treatment of hyperbilirubinemia because an outside laboratory found a high TSB level, but when the test is repeated in the hospital laboratory, the TSB level is 5 or 6 mg/dL (85 to 103 $\mu\text{mol/L}$) lower. Of course, there is no way of knowing which value is correct. A 16.4% coefficient of variation between laboratories means that if the true serum bilirubin value is 20 mg/dL (342 $\mu\text{mol/L}$), the 95% confidence limits of a repeat measurement at another laboratory could fall anywhere between 14.4 and 26.6 mg/dL (246 to 455 $\mu\text{mol/L}$). Because our followup, surveillance, and intervention in jaundiced infants are based on TSB values, spurious underestimation of the TSB concentration might lead to withholding of necessary therapy, and overestimation will produce unnecessary clinical intervention.

Direct-Reacting and Conjugated Bilirubin

Similar concerns exist with regard to measurements of direct-reacting or conjugated bilirubin where laboratory measurements are considered, at best, “only an approximation to the true value” (449). In one study, measurements of direct-reacting bilirubin using the Dupont ACA (automatic clinical analyzer) or Coulter Dacos analyzer produced direct-reacting bilirubin levels in a population of full-term newborns at one hospital that were twice as high as those measured in a similar population at another institution, where a Kodak Ektachem 700 (now known as the Vitros) method was used (450). The Vitros method measures *conjugated bilirubin*, whereas the other methods measure *direct-reacting bilirubin*. Although often used synonymously, direct-reacting bilirubin is not the same as conjugated bilirubin. Direct-reacting bilirubin refers to the bilirubin that reacts directly with diazotized sulfanilic acid (i.e., without the addition of an accelerating agent), whereas conjugated bilirubin refers to bilirubin that has been made water soluble by binding with glucuronic acid in the liver.

Site of Blood Sampling—Capillary Versus Venous Blood Samples

Data regarding the differences in TSB levels when measured in capillary or venous samples are conflicting (451,452). It is useful to recall, however, that virtually all of the published data regarding the relationship of TSB levels to kernicterus or developmental outcome are based on capillary TSB levels. Thus, for the purposes of clinical decision making, capillary blood samples are the gold standard and there is no reason to delay initiation of treatment to obtain a venous blood sample

to “confirm” an elevated capillary TSB level.

Sampling Technique

Because of the well-known effects of light on bilirubin, laboratory manuals recommend that blood samples be protected from light until the serum is analyzed. Using serum samples with bilirubin levels of 16.0, 11.8, and 7.9 mg/dL (273, 202, and 135 $\mu\text{mol/L}$), Sykes and colleagues ([453](#)) found that, under the usual clinical conditions, there was no measurable effect of ambient light on serum bilirubin levels for at least 8 hours.

When Is Laboratory Measurement of Bilirubin Indicated?

A TcB and/or TSB level should be done on every infant who is jaundiced in the first 24 hours after birth ([407](#)). In a

P.814

cohort of 105,384 newborns of $\geq 2,000$ g birth weight and at least 36 weeks' gestational age, jaundice was noted in the medical record in only 2.8% of infants within 18 hours and in 6.7% within 24 hours ([454](#)). Compared with those who were not jaundiced on the first day, those jaundiced within 24 hours were much more likely to receive phototherapy (18.9% vs. 1.7%) and were three times more likely to develop a bilirubin level of 25 mg/dL (428 $\mu\text{mol/L}$) or higher ([454](#)). Thus, the presence of jaundice in the first 24 hours represents a significant risk factor for the subsequent development of severe hyperbilirubinemia and, as recommended by the AAP ([76](#)), a TSB should be measured in any infant who is jaundiced in the first 24 hours.

TABLE 35-25 LABORATORY EVALUATION OF THE JAUNDICED INFANT

Indications	Assessments
Jaundice in first 24 hours	Measure TSB
Jaundice appears excessive for infant's age	Measure TSB

Infant receiving phototherapy or TSB rising rapidly (i.e., crossing percentiles [see Fig. 35-20]) and unexplained by history and physical examination	Blood type and Coomb test, if not obtained with cord blood Complete blood count and smear Measure direct-reacting or conjugated bilirubin It is an option to do reticulocyte count, G6PD, ETCOc, if available Repeat TSB in 4–24 hours, depending on infant's age and TSB level
TSB approaching exchange levels or not responding to phototherapy	Do reticulocyte count, G6PD, albumin, and ETCOc, if available
Elevated direct (or conjugated) bilirubin level	Do urinalysis and urine culture; evaluate for sepsis if indicated by history and physical examination
Jaundice present at or beyond age 3 weeks, or sick infant	Total and direct-reacting (or conjugated) bilirubin level; if direct-reacting bilirubin elevated, evaluate for causes of cholestasis Check results of newborn thyroid and galactosemia screen; evaluate infant for signs or symptoms of hypothyroidism

ETCOc, end-tidal carbon monoxide corrected for ambient carbon monoxide; G6PD, glucose-6-phosphate dehydrogenase; TSB, total serum bilirubin concentration.

From Maisels MJ, Baltz RD, Bhutani V, et al. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114:297–316, with permission.

The need for and timing of a repeat TSB or TcB depends on the zone in which the TSB falls (see [Fig. 35-20](#)), the age of the infant, other clinical risk factors, and the subsequent evolution of the bilirubin level ([Table 35-25](#)). A TcB and/or TSB level should also be done if, at any time, the jaundice appears excessive for the infant's age. Recognizing the risk of error in the visual estimation of bilirubin levels ([235,425,426,434](#)), particularly in darkly pigmented infants, and depending on the clinical circumstances, a TSB or TcB should be measured if there is any doubt about the degree of jaundice ([76](#)).

Seeking a Cause for the Jaundice

[Table 35-25](#) lists the indications for laboratory evaluation of jaundiced newborns.

In some infants, the cause of hyperbilirubinemia is apparent from the history and physical examination. For example, jaundice in a severely bruised infant generally needs no further explanation. In addition, the usual laboratory tests (hematocrit, complete blood count, reticulocyte count, and smear) are neither specific nor sensitive and rarely identify a specific cause for the hyperbilirubinemia ([198,254](#)) even in infants who are readmitted to hospital with TSB levels of 18 to 20 mg/dL (308 to 340 $\mu\text{mol/L}$) or higher (see [Table 35-18](#)) (241, 249). One study, however, did find a good correlation between measurements of ETCOc and reticulocyte counts (corrected for the hematocrit) in infants with positive DATs ([455](#)). The cause of jaundice should be sought in an infant receiving phototherapy or whose TSB level is rising rapidly, that is, crossing percentiles (see [Fig. 35-20](#)), and is not explained by the history and physical examination. [Table 35-25](#) lists the appropriate laboratory tests.

Interpreting the Bilirubin Level

All TSB levels must be interpreted in terms of the infant's age in hours (see [Figs. 35-16](#) and [35-20](#)). An infant with a TSB that exceeds the 95th percentile, or in whom the rate of rise of the TSB crosses percentiles (see [Fig. 35-20](#)), or exceeds 0.2 mg/dL per hour deserves further evaluation and followup.

Elevated Direct-Reacting or Conjugated Bilirubin Levels

If the TSB is \leq mg/dL (85 $\mu\text{mol/L}$) or lower a direct-reacting or conjugated bilirubin of greater than 1.0 mg/dL (17.1 $\mu\text{mol/L}$) is considered elevated. For TSB values greater than 5 mg/dL (85 $\mu\text{mol/L}$) a direct-reacting or conjugated bilirubin of more than 20% of the TSB is considered abnormal. If the laboratory measures conjugated bilirubin using the Vitros system, any value greater than 1 mg/dL

P.815

(17.1 $\mu\text{mol/L}$) is considered abnormal. An infant who has an elevation of direct-reacting or conjugated bilirubin should have a urinalysis and a urine culture performed because this could be an early sign of urinary tract infection (see [Table 35-25](#)). A sepsis evaluation should also be considered. Late onset of jaundice (after the fourth or fifth day) has also been associated with urinary tract infection ([402](#)) (see also Pathologic Causes of Jaundice: [Sepsis](#) above).

Sick Infants and Infants Jaundiced Beyond Age 3 Weeks

These infants should have a measurement of total and direct-reacting or

conjugated bilirubin to identify cholestasis (see [Table 35-25](#)). If the direct-reacting or conjugated bilirubin level is elevated then additional evaluation is needed for the causes of cholestasis (see [Table 35-16](#) and [Chapter 40](#)). This approach is essential for the early identification of infants with biliary atresia. If these infants are to benefit from the operation of portoenterostomy, surgery should be performed as soon as possible and, ideally, before age 60 days ([456](#)). Infants who are jaundiced beyond age 3 weeks should also have the results of the newborn thyroid and galactosemia screen checked. [Table 35-22](#) lists the causes of prolonged indirect-reacting hyperbilirubinemia.

Preventing Extreme Hyperbilirubinemia and Kernicterus

Most of the cases of kernicterus reported in the last decade did not occur in infants who had ABO or Rh hemolytic disease, but in apparently healthy term and near-term newborns with extremely high bilirubin levels (usually well above 30 mg/dL [513 μ mol/L]) ([124,390,406](#)), in infants with G6PD deficiency ([124,133,328,329](#)), and in very sick newborns with low bilirubin levels ([43](#)). If we can prevent extreme hyperbilirubinemia we should be able to prevent almost all cases of kernicterus, but jaundice is very common and extreme hyperbilirubinemia (30 mg/dL [513 μ mol/L] or higher) is rare, occurring in only about 1 in 10,000 infants ([203](#)). To ensure that we do not miss these rare infants, however, we need to follow and measure serum bilirubin levels in many infants, and treat some infants with phototherapy who will never develop severe hyperbilirubinemia ([139,140](#)). Ip and associates have calculated that 5 to 10 infants with TSB levels between 15 and 20 mg/dL (257 to 342 μ mol/L) receive phototherapy to prevent 1 infant from reaching a TSB of 20 mg/dL (342 μ mol/L) ([139,140](#)).

Hospital Policies and Jaundiced Newborns

According to recommendation 2.2 of the AAP Clinical Practice Guideline ([76](#)), “clinicians should ensure that all infants are routinely monitored for the development of jaundice, and nurseries should have established protocols for the assessment of jaundice. Jaundice should be assessed whenever the infant's vital signs are measured, but no less than every 8 to 12 hours.” Recommendation 2.2.1 states that “protocols for the assessment of jaundice should include the circumstances in which nursing staff can obtain a TcB or order a TSB measurement.” Nursing staff have always assumed the responsibility for monitoring infants for jaundice but, for the first time, hospitals are now asked to develop protocols under which nurses can obtain a TcB or TSB without a physician order. Thus a nurse who notices jaundice in an infant who is younger than 24 hours old, will obtain a TcB or TSB and notify the physician of the result. If a TcB measurement is used as a screening tool, TSB measurements can be obtained by nurses whenever the TcB measurement is above a certain bilirubin percentile (see [Fig. 35-20](#) and *Noninvasive Measurements of Bilirubin* above).

Assessing the Risk of Severe Hyperbilirubinemia

Recommendation 5.1 of the AAP Clinical Practice Guideline ([76](#)) states: “Before

discharge, every newborn should be assessed for the risk of developing severe hyperbilirubinemia, and all nurseries should establish protocols for assessing this risk. Such assessment is particularly important in infants who are discharged before age 72 hours." The guideline continues, "The AAP recommends 2 clinical options used individually or in combination for the systematic assessment of risk: pre-discharge measurement of the bilirubin level using TSB or TcB and/or assessment of clinical risk factors" (76). This must be followed by appropriate evaluation, monitoring, surveillance, and followup to ensure that severe hyperbilirubinemia is identified early and treated appropriately.

Clinical Risk Factors

[Table 35-26](#) lists the risk factors for the development of hyperbilirubinemia.

Almost all of these factors can be identified readily without recourse to the laboratory but, because these risk factors are common and the risk of severe hyperbilirubinemia is small, individually, these factors are of limited use as predictors of severe hyperbilirubinemia. Nevertheless, if no risk factors are present, the risk of severe hyperbilirubinemia is extremely low, and the more risk factors that are present, the greater the risk of severe hyperbilirubinemia (206).

Some factors, such as breast-feeding, gestation age below 38 weeks, and significant jaundice (need for phototherapy) in a previous sibling, seem to be particularly important. It is remarkable that almost every recently described case of kernicterus occurred in a breast-fed infant, even when the infant had underlying G6PD deficiency (124,133,328,390).

Decreasing Gestation: The "Near-term" Newborn

Decreasing gestation has been repeatedly identified as a very important contributor to hyperbilirubinemia (197,206,211, [239,240,241](#)). We found that infants of 36 weeks or less gestation

P.816

are 13 times more likely than infants at 40 weeks' gestation to be readmitted for severe jaundice (241). Infants at 38 weeks of gestation are considered term babies yet they are 4 times more likely to develop a TSB. ≥ 25 mg/dL (428 μ mol/L) than those at 40 weeks (206). Although these near-term infants, at 35 to 38 weeks of gestation, are cared for in well-baby nurseries, they are much more likely to nurse ineffectively, receive fewer calories, and have a greater weight loss than their truly term counterparts. When combined with less effective hepatic clearance because of prematurity, it is not surprising that they often become more jaundiced.

TABLE 35-26 RISK FACTORS FOR DEVELOPMENT OF SEVERE HYPERBILIRUBINEMIA IN INFANTS \geq 35 WEEKS' GESTATION (IN APPROXIMATE ORDER OF IMPORTANCE)

Major risk factors

Predischarge TSB or TcB level in the high risk zone (see [Fig. 35-20](#)) ([289,437](#))

Jaundice observed in the first 24 hours ([454](#))

Blood group incompatibility with positive direct antiglobulin test, other known hemolytic disease (e.g., G6PD deficiency), elevated ETCOc

Gestational age 35 to 36 weeks ([206,241](#))

Previous sibling received phototherapy ([211,241](#))

Cephalhematoma or significant bruising ([206](#))

Exclusive breast-feeding, particularly if nursing is not going well and weight loss is excessive ([206,241](#))

East Asian race^a

Minor risk factors

Predischarge TSB or TcB in the high-intermediate risk zone (see [Fig. 35.20](#)) ([289,437](#))

Gestational age 37 to 38 weeks ([206,241](#))

Jaundice observed before discharge (241)

Previous sibling with jaundice ([211,241](#))

Macrosomic infant of a diabetic mother (216,582)

Maternal age \geq 25 years ([206](#))

Male gender ([206,241](#))

Decreased risk (these factors are associated with decreased risk of significant jaundice; listed in order of decreasing importance)

TSB or TcB in the low risk zone (see [Fig. 35-20](#)) ([289,437](#))

Gestational age \geq 41 weeks ([206](#))

Exclusive bottle feeding ([206,241](#))

Black race^a ([206](#))

^a Race as defined by mother's description.

From Maisels MJ, Baltz RD, Bhutani V, et al. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114:297–316, with permission.

Predischarge Measurement of the Bilirubin Level

We know that infants who are clinically jaundiced in the first few days are much more likely to later develop significant hyperbilirubinemia (239,241). Bhutani and associates (289) measured TSB concentrations in 13,003 infants prior to their discharge from the hospital. In 2,840 infants additional TSB levels were measured at least once in the 5 to 6 days following discharge. Infants with ABO incompatibility and positive Coombs tests were excluded, as were Rh-sensitized infants. The investigators plotted the TSB levels against the infant's age in hours and created a nomogram with percentiles that defined a high risk (above 95th percentile), a low risk (values less than 40th percentile), and an intermediate risk (40th to 95th percentile) zone (289) (see Fig. 35-20) Using this nomogram, these investigators found that of infants whose TSB levels fell in the high-risk zone, 39.5% subsequently had values above the 95th percentile. If the TSB level fell in the low-risk zone no baby subsequently developed a TSB above the 95th percentile. Table 35-27 shows these results. Note, however, that Fig. 35-20 does not describe the natural history of bilirubinemia in the newborn. Because only 2,840 (21.9%) of the 13,003 infants had subsequent TSB levels measured, there is a sampling bias (toward more jaundiced babies) particularly after 48 to 72 hours, so that the lower zones are spuriously elevated (293).

These data do show that obtaining a TSB level prior to discharge is a very useful way of predicting the risk (or absence of risk) of subsequent significant hyperbilirubinemia. The predictive value of a predischage TSB has been confirmed in several other studies (285,457,458,459), and it defines a group of infants who, at least as far as hyperbilirubinemia is concerned, may not require an early followup. This information is very useful in situations where early followup is difficult or impossible. Predischage TSB levels also will alert pediatricians to those infants who, because their TSB levels fall in the high-risk zone, require much more careful surveillance and followup until there is clinical or laboratory evidence supporting a declining bilirubin level.

TABLE 35-27 RISK ZONE AS A PREDICTOR OF HYPERBILIRUBINEMIA

TSB Before Discharge	Newborns (Total = 2,840), <i>n</i> (%)	Newborns Who Subsequently Developed a TSB Level >95th Percentile, <i>n</i> (%)
High-risk zone (>95th percentile)	172 (6.0)	68 (39.5)
High-intermediate-risk zone	356 (12.5)	46 (12.9)
Low-intermediate-risk zone	556 (19.6)	12 (2.26)
Low-risk zone	1756 (61.8)	0

From Bhutani VK, Johnson L, Sivieri EM. Predictive ability of a pre-discharge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy-term and near-term newborns. *Pediatrics* 1999;103:6-14, with permission.

P.817

Measuring Bilirubin Production

When heme is catabolized, CO is produced in equimolar quantities with bilirubin, and measurement of blood COHb concentration, CO production, or CO excretion provides a measurement of bilirubin production ([27,460](#)). The development of a simple noninvasive method for measuring ETCOc, provides a technique for quantifying hemolysis ([460](#)) and can identify those infants with high or low rates of bilirubin production. Although the measurement of ETCOc can identify the presence of hemolysis and is useful as a diagnostic test ([316,330,461](#)), it has not proved useful as a routine method of screening infants to predict the likelihood of subsequent hyperbilirubinemia ([285](#)).

Followup

Identifying the risk of subsequent severe hyperbilirubinemia before the newborn leaves the nursery is of little value unless appropriate follow-up is provided. Recommendation 6.1.1 in the AAP Guideline ([76](#)) states that: "All infants should be examined by a qualified health care professional in the first few days following discharge to assess infant well-being and the presence or absence of jaundice. The timing and location of this assessment will be determined by the length of stay in the nursery, presence or absence of risk factors for hyperbilirubinemia (see [Table 35-26](#) and [Fig. 35-20](#)) and the risk of other neonatal problems." This examination can take place in an office, clinic or home and can be done by a physician, physician assistant, or nurse. Although written and oral information should be provided to all parents about newborn jaundice, it is unfair and unreasonable to rely only on parents to identify a significantly jaundiced infant.

[Table 35-28](#) provides the AAP recommendations for the timing of followup. If, for geographic, climatic, socioeconomic, or other reasons, appropriate followup cannot be ensured and the pre-discharge assessment suggests the presence of a significant risk for severe hyperbilirubinemia, it may be necessary to delay discharge either until appropriate followup can be planned, or the period of greatest risk has passed (72 to 96 hours) ([76](#)).

At the time of the followup visit, the infant should be assessed for weight gain, adequacy of intake, the pattern of voiding and stooling, and the presence or

absence of jaundice. Unless a transcutaneous instrument is available or, at the time of discharge, a followup TSB has already been scheduled, clinical judgment is used to determine the need for a bilirubin measurement. Because of the potential for error in the visual estimation of bilirubin levels, however, a TSB or TcB should be measured if there is any doubt about the degree of jaundice. This is particularly important in darkly pigmented infants where the visual estimation of bilirubin levels can lead to significant error.

Information for Parents

An essential component of insuring the safety of a newborn is to make sure that parents are informed (among other things) about newborn jaundice. The AAP ([76](#)) recommends

P.818

that “all hospitals should provide written and oral information for parents at the time of discharge. This should include an explanation of jaundice, the need to monitor infants for jaundice and advice on how this should be done.” The AAP has produced a parent information document entitled “Jaundice FAQs” ([Appendix F](#)) which is available at <http://www.aap.org/family/jaundicefaw.htm>.

TABLE 35-28 AAP RECOMMENDATIONS FOR TIMING OF FOLLOW UP VISITS AFTER NEWBORN DISCHARGE

Followup should be provided as follows:

Infant Discharged	Should Be Seen by Age
Before age 24 hours	72 hours
Between 24 and 47.9 hours	96 hours
Between 48 and 72 hours	120 hours

For some newborns discharged before 48 hours, two followup visits may be required; the first between 24 and 72 hours, and the second between 72 and 120 hours. Newborns discharged at 48 to 72 hours should be seen for a followup visit at 72 to 120 hours. Clinical judgment should be used in determining followup. Earlier or more frequent followup should be provided for those who have risk factors for hyperbilirubinemia (see [Table 35-26](#)), while those discharged with few or no risk factors can be seen after longer intervals.

From Maisels MJ, Baltz RD, Bhutani V, et al. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation.

Pediatrics 2004;114:297–316, with permission.

TABLE 35-29 GUIDELINES FOR THE USE OF PHOTOTHERAPY AND EXCHANGE TRANSFUSION IN LOW-BIRTH-WEIGHT INFANTS BASED ON BIRTH WEIGHT

Total bilirubin level (mg/dL [μ mol/L] ^a)		
Birth Weights (g)	Phototherapy ^b	Exchange Transfusion ^c
≤1,500	5-8 (85-140)	13-16 (220-275)
1,500-1,999	8-12 (140-200)	16-18 (275-300)
2,000-2,499	11-14 (190-240)	18-20 (300-340)

Note that these guidelines reflect ranges used in neonatal intensive care units. They cannot take into account all possible situations. Lower bilirubin concentrations should be used for infants who are sick (e.g., sepsis, acidosis, hypoalbuminemia) or who have hemolytic disease.

^a Consider initiating therapy at these levels. Range allows discretion based on clinical conditions or other circumstances. Note that bilirubin levels refer to total serum bilirubin concentrations. Direct-reacting or conjugated bilirubin levels should not be subtracted from the total.

^b Used at these levels and in therapeutic doses, phototherapy should, with few exceptions, eliminate the need for exchange transfusions.

^c Levels for exchange transfusion assume that bilirubin continues to rise or remains at these levels despite intensive phototherapy.

Treatment

Hyperbilirubinemia can be treated in three ways: (a) exchange transfusion removes bilirubin mechanically; (b) phototherapy converts bilirubin to products that can bypass the liver's conjugating system and be excreted in the bile or in the urine without further metabolism; and (c) pharmacologic agents that interfere with heme degradation and bilirubin production, accelerate the normal metabolic pathways for bilirubin clearance, or inhibit the enterohepatic circulation of bilirubin. Phototherapy is the most common treatment in use for hyperbilirubinemia; exchange transfusions generally are reserved for phototherapy failures. The bilirubin level at which intervention is necessary is still a contentious issue.

TABLE 35-30 GUIDELINES FOR USE OF PHOTOTHERAPY AND EXCHANGE TRANSFUSION IN PRETERM INFANTS BASED ON GESTATIONAL AGE

Gestational Age (Weeks)	Total bilirubin level (mg/dL [μ mol/L])		
	Phototherapy	Exchange Transfusion	
		Sick ^a	Well
36	14.6 (250)	17.5 (300)	20.5 (350)
32	8.8 (150)	14.6 (250)	17.5 (300)
28	5.8 (100)	11.7 (200)	14.6 (250)
24	4.7 (80)	8.8 (150)	11.7 (200)

^a Rhesus disease, perinatal asphyxia, hypoxia, acidosis, hypercapnia.

Principles Underlying the Recommendations

Recommendations and guidelines for the use of phototherapy and exchange transfusion in term, near-term and preterm infants are provided in Tables 35-29 to 35-32 and Figs. 35-22 and 35-23. It would be ideal if the guidelines for the implementation of phototherapy and exchange transfusion relied on evidence-based estimates of when the benefit of these interventions exceeded their risks and costs (76). Ideally, these estimates should come from randomized trials or high quality, systematic observational studies but such studies are rare (139,140). Thus, treatment guidelines must rely on relatively uncertain estimates of risks and benefits

P.819

and the recognition that using a single TSB level to predict long-term behavioral and developmental outcomes is not reliable and will lead to conflicting results (139,140).

TABLE 35-31 GUIDELINES ACCORDING TO BIRTH WEIGHT FOR EXCHANGE TRANSFUSION IN LOW-BIRTH-WEIGHT INFANTS BASED ON TOTAL BILIRUBIN (mg/dL) AND BILIRUBIN-TO-ALBUMIN RATIO (mg/g) (WHICHEVER COMES FIRST)

	<1,250 g	1,250–1,499 g	1,500–1,999 g	2,000–2,499 g
Standard risk				
Total bilirubin	13	15	17	18
B:A ratio	5.2	6.0	6.8	7.2
High risk ^a				
Total bilirubin	10	13	15	17
B:A ratio	4.0	5.2	6.0	6.8

^a Risk factors: Apgar <3 at 5 minutes; PaO₂ <40 mm Hg ≥2 h; pH ≤7.15 ≥1 h; birth weight <1000 g, hemolysis; clinical or central nervous system deterioration; total protein ≤4 g/dL or albumin ≤2.5 g/dL. B:A ratio, bilirubin-to-albumin ratio.
 From Ahlfors CE. Criteria for exchange transfusion in jaundiced newborns. *Pediatrics* 1994;93:488-494, with permission.

The background to treatment decisions for hyperbilirubinemia has been provided (see section on Bilirubin Toxicity.) The basic principles underlining the recommendations given in Tables 35-29, 35-30, 35-31 and 35-32 and Figs. 35-22 and 35-23 are as follows:

- Phototherapy is a highly effective method for preventing and treating hyperbilirubinemia (see Phototherapy below). The main demonstrated value of phototherapy is that it reduces the need for exchange transfusion (177,217, 462,463). Ip and associates have calculated that about 5 to 10 term and near-term infants with TSB levels between 15 and 20 mg/dL (257 to 342 μmol/L) will need to receive phototherapy in order to prevent the TSB in 1 infant from reaching 20 mg/dL (the number needed to treat) (139,140). This means that about 8 to 9 of every 10 infants with these TSB levels will not reach 20 mg/dL (342 μmol/L), even if they are not treated. As phototherapy has proven to be a generally safe procedure, however, the (unnecessary) treatment of many infants is considered appropriate in order to prevent some infants from reaching TSB levels that are considered potentially dangerous (see Phototherapy below for a discussion of its safety and complications).
- The recommended TSB levels for exchange transfusion are intended to keep TSB levels below those at which kernicterus has been reported (124,139,140), although it is recognized that rare cases of kernicterus have occurred in apparently healthy infants and in sick infants at unexpectedly low TSB levels (43,124,139, 140). With rare exceptions, exchange transfusion is recommended only after intensive phototherapy has failed to keep the TSB level below the exchange transfusion level (76).
- As discussed above (see section on Bilirubin Toxicity) infants (particularly those with the risk factors listed in Tables 35-29,35-30 and 35-31 and Figs. 35-22 and 35-23) (43,45,154) and preterm infants (45,150,152,464) are at a greater risk for developing kernicterus at lower bilirubin levels than are well term infants, although

P.820

some studies have not confirmed all of these associations (152,178,179). On the other hand, there is no doubt that infants of lower gestation are at a greater risk of developing high TSB levels (203,206).

- Because one of the primary goals of treatment is to prevent further increases in the TSB levels, treatment is recommended at lower TSB levels at younger ages.

TABLE 35-32 GUIDELINES FOR INITIATING PHOTOTHERAPY AND EXCHANGE TRANSFUSIONS IN NICHHD NEONATAL RESEARCH NETWORK TRIAL (B. MORRIS, PERSONAL COMMUNICATION, 2002)

Birth Weight (g)	Aggressive Management		Conservative Management	
	Phototherapy Begins	Exchange Transfusion	Phototherapy Begins	Exchange Transfusion
501-750	ASAP after enrollment	≥13.0 mg/dL	≥8.0 mg/dL	≥13.0 mg/dL
751-1000	ASAP after enrollment	≥15.0 mg/dL	≥10.0 mg/dL	≥15.0 mg/dL

Enrollment is expected within 12-36 hours after birth, preferably between 12 and 24 hours. ASAP, as soon as possible.

From Maisels MJ, Watchko JF. Treatment of jaundice in low birthweight infants. *Arch Dis Child Fetal Neonatol* Ed 2003;88:F459-F463, with permission.

Figure 35-22 AAP guidelines for phototherapy in hospitalized infants of 35 or more weeks' gestation (76). *Note:* These guidelines are based on limited evidence and the levels shown are approximations. The guidelines refer to the use of intensive phototherapy which should be used when the TSB exceeds the line indicated for each category. Infants are designated as "higher risk" because of the potential negative effects of the conditions listed on albumin binding of bilirubin (77,96), the blood-brain barrier (60), and the susceptibility of the brain cells to damage by bilirubin (55).

"Intensive phototherapy" implies irradiance in the blue-green spectrum (wavelengths of approximately 430 to 490 nm) of at least 30 $\mu\text{W}/\text{cm}^2$ per nm (measured at the infant's skin directly below the center of the phototherapy unit) and delivered to as much of the infant's surface area as possible. Note that irradiance measured below the center of the light source is much greater than that measured at the periphery. Measurements should be made with a radiometer specified by the manufacturer of the phototherapy system.

If total serum bilirubin levels approach or exceed the exchange transfusion line (Fig. 35-23) the sides of the bassinet, incubator, or warmer should be lined with aluminum foil or white material (575). This will increase the surface area of the infant exposed and increase the efficacy of phototherapy (472).

If the total serum bilirubin does not decrease or continues to rise in an infant who is receiving intensive phototherapy, this strongly suggests the presence of hemolysis.

Infants who receive phototherapy and have an elevated direct-reacting or conjugated bilirubin level (cholestatic jaundice) may develop the bronze baby syndrome. See section on phototherapy for the use of phototherapy in these infants. (From Maisels MJ, Baltz RD, Bhutani V, et al. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114:297-316, with permission.)

It is recognized that it is quite often difficult, and sometimes impossible, to rule out an underlying hemolytic process. There is evidence, for example, that the majority of infants with elevated serum bilirubin levels in the first 2 to 4 days of life have an increase in heme turnover, if not frank hemolysis (465). Although measurements of ETCOc can identify the hemolyzing infant (316,336,455,461, 465), standard diagnostic tests for hemolysis, such as the reticulocyte count, hematocrit, or examination of the peripheral smear, are neither sensitive nor specific (218, 466). Nevertheless, a recent study did find a good correlation between measurements of ETCOc and reticulocyte counts (corrected for the hematocrit) in infants with positive Coombs tests (455).

Most term and near-term infants readmitted with hyperbilirubinemia do not have documented hemolytic disease (241,248,249,467). Of 61 cases of kernicterus, 10 (15%) were considered to have hemolysis and 19 of 61 (32%) were G6PD deficient (124). It is important to note that infants with G6PD deficiency are frequently not anemic and often have none of the classical manifestations of hemolytic disease (326,327).

Guidelines for Exchange Transfusion in Infants ≥ 35 Weeks

Note: These guidelines are based on limited evidence and the levels shown are approximations. During birth hospitalization exchange transfusion is recommended if TSB rises to these levels despite intensive phototherapy. For readmitted infants, if TSB is above exchange level, repeat TSB every 2-3hrs and consider exchange if TSB remains above levels indicated after intensive phototherapy for 6 hours.

Figure 35-23 AAP guidelines for exchange transfusion in infants who are 35 or more weeks' gestation (76). Note that these suggested levels are based on limited evidence, and the levels shown are approximations. See section on exchange transfusion for risks and complications of exchange transfusion. During birth hospitalization, exchange transfusion is recommended if the TSB rises to these levels despite intensive phototherapy. For readmitted infants, if the TSB level is above the exchange level, repeat TSB measurement every 2 to 3 hours and consider exchange if the TSB remains above the levels indicated after intensive phototherapy for 6 hours.

P.821

Risks

When used properly, phototherapy is a very effective and safe method of lowering the serum bilirubin concentration. Its use has drastically decreased the need for exchange transfusion (Figs. 35-24 and 35-25) and it has probably contributed to the virtual disappearance of kernicterus in the low-birth-weight infant.

Conversely, in full-term and near-term newborns, phototherapy can lead to separation of the mother and infant, increase parental concern, decrease the likelihood of successful breast-feeding, and adversely affect the

P.822

mother/infant relationship (356). At a time when pediatricians are trying to promote breast-feeding in the face of considerable odds (e.g., early discharge from hospital, the rapid return of mothers to the workforce, commercial marketing of formulas), attention should be given to an intervention that has a negative impact on the nursing mother.

Figure 35-24 Number of infants in different populations who received exchange transfusions between 1957 and 1997. (1) In Athens, Greece, exchange transfusions were performed on 134 infants of 30,830 live births (birth weight $\leq 2,500$ g) between 1957 and 1961 and on 91 infants of 180,594 live births between 1980 and 1992 (577). (2) At the University of Melbourne, Melbourne, Australia, between 1971 and 1980, exchange transfusions were performed in 114 infants of 41,057 live births and between 1981 and 1989, in 134 infants of 47,080 live births (all birth weights) (578). (3) Between 1988 and 1997 exchange transfusions were performed in 8 infants of 55,128 live births at William Beaumont Hospital, Royal Oak, MI (all birth weights) (579).

The risks of exchange transfusion include risks from the transfused blood and from the procedure (see section on Exchange Transfusion). Experience with exchange transfusion is decreasing (see Figs. 35-24 and 35-25) and with new types of phototherapy (463) and other interventions in immune hemolytic disease, it is likely to decrease even further (370,468,469). It is now common for a resident to complete a 3-year pediatric training program without ever having performed an exchange transfusion. Under the circumstances, the mortality and morbidity for this procedure is likely to increase in the years ahead.

Figure 35-25 Number of infants in different populations with birth weight $< 1,500$ g who received exchange transfusions between 1974 and 1997. (1) A total of 215 newborns weighing $< 1,500$ g in the NICHD Cooperative Phototherapy Trial were assigned to the control group (did not receive phototherapy) (540). Seventy-seven of 215 infants (35.8%) received a total of 161 exchange transfusions. In the phototherapy group, 17 of 196 (8.7%) infants received exchange transfusions. These data are included to illustrate the frequency of exchange transfusion before the introduction of phototherapy. (2) Of a total of 1,338 live births weighing $< 1,500$ g in the Netherlands in 1983, 37 infants (2.8%) required at least 1 exchange transfusion (580). (3) Of 833 live births (weighing 500 to 1,500 g) in a 17-county region in North Carolina, 2 infants required an exchange transfusion (0.24%) (182). (4) No exchange transfusions were performed in 1,213 live births weighing $< 1,500$ g at the William Beaumont Hospital, Royal Oak, MI between 1988 and 1997 (579).

Treating Full-Term and Near-Term Newborns

Most infants who are treated for neonatal jaundice have no identifiable pathology and no evidence of hemolytic disease (see Table 35-18) (218,241,248,249). Approximately 90% are fully or partially breast-fed (249). Guidelines for the treatment of full-term and near-term infants are given in Figs. 35-22 and 35-23. Table 35-33 is an example of a clinical pathway for the management of a newborn readmitted for phototherapy or exchange transfusion.

Breast-Fed Infants

Of infants who develop bilirubin levels high enough to require phototherapy and who do not have evidence of isoimmunization or other obvious hemolytic disease, 80% to 90% are fully or partially breast-fed (218,249). Table 35-34 provides an approach to the prevention and treatment of jaundice associated with breast-feeding. Observational studies show that increasing the frequency of breast-feeding during the first few days after birth decreases TSB levels (251,252,409). We performed a controlled trial in which mothers were randomly assigned to a frequent or demand breast-feeding schedule. We found no significant difference between the TSB levels measured in the two groups at an average age of 55 hours (470). Given the natural history of jaundice in breast-fed infants, however, it is certain that maximum TSB had not yet been achieved in these infants. However, the observational data of Yamauchi and Yamanouchi (252) show a very strong inverse and linear relationship between the frequency of nursing in the first 24 hours and the probability of hyperbilirubinemia on day 6.

TABLE 35-33 EXAMPLE OF A CLINICAL PATHWAY FOR MANAGEMENT OF THE NEWBORN INFANT READMITTED FOR PHOTOTHERAPY OR EXCHANGE TRANSFUSION

Treatment

Use intensive phototherapy and/or exchange transfusion as indicated in Figures 35-22 and 35-23.

Laboratory tests

TSB and direct bilirubin level

Blood type (ABO, Rh)

Direct antibody (Coombs) test

Serum albumin

Complete blood cell count with differential and smear for red cell morphology

Reticulocyte count

ETCOc (if available)

Glucose-6-phosphate dehydrogenase if suggested by ethnic or geographic origin, or if poor response to phototherapy

Urine for reducing substances

If history and/or presentation suggest sepsis, perform blood culture, urine culture, cerebral spinal fluid for protein, glucose, cell count, and culture

Interventions

If TSB \geq 25 mg/dL (428 μ mol/L) or \geq 20 mg/dL (342 μ mol/L) in a sick infant or infant $<$ 38 weeks' gestation, obtain a type and crossmatch, and request blood in case an exchange transfusion is necessary

In infants with isoimmune hemolytic disease and TSB rising in spite of intensive phototherapy or within 2–3 mg/dL (34–51 μ mol/L) of exchange level (see Fig. 35-24), administer intravenous immunoglobulin 0.5–1 g/kg over 2 hours and repeat in 12 hours if necessary

If infant's weight loss from birth is $>$ 12%, or if there is clinical or biochemical evidence of dehydration, recommend formula or expressed breast milk; if oral intake is in question, give intravenous fluids

For infants receiving intensive phototherapy

Breast-feed or bottle-feed (formula or expressed breast milk) every 2–3 hours
 If TSB \geq 25 mg/dL (428 μ mol/L) repeat TSB within 2–3 hours
 If TSB 20–25 mg/dL (342–428 μ mol/L), repeat within 3–4 hours; if TSB $<$ 20 mg/dL (342 μ mol/L) repeat in 4–6 hours; if TSB continues to fall, repeat in 8–12 hours
 If TSB is not decreasing, or is moving closer to level for exchange transfusion, or TSB: albumin ratio exceeds levels shown in Fig. 35-23 consider exchange transfusion; see Fig. 35-23 for exchange transfusion recommendations
 When TSB is below 13–14 mg/dL (239 μ mol/L) discontinue phototherapy
 Depending on the cause of the hyperbilirubinemia, it is an option to measure TSB 24 hours after discharge to check for rebound
 From Maisels MJ, Baltz RD, Bhutani V, et al. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114:297–316, with permission.

In many hospitals it is a common practice to provide supplemental feedings of water or dextrose water to breast-fed infants in the mistaken belief that this will lower their TSB levels. On the contrary, this practice does not lower TSB levels and should be abandoned (see Fig. 35-21) (419,420). Furthermore, Kuhr and Paneth (424) found that an increase in dextrose water intake in the first 3 days of life was significantly related to a decrease in breast-milk intake on the fourth day.

When the TSB in a breast-fed infant reaches a level at which intervention is being considered, a number of options exist (see Table 35-34). Two randomized controlled trials evaluated some of these interventions. When TSB levels reached 15 mg/dL (257 μ mol/L), Amato and associates (471) compared the effect of interrupting breast-feeding versus

P.824

phototherapy. There was no difference between the groups in the amount of time needed to reduce the bilirubin to less than 12 mg/dL (205 μ mol/L). When the TSB level reached 17 mg/dL (291 μ mol/L), Martinez and colleagues assigned 125 full-term breast-fed infants to one of four interventions (462); Table 35-35 shows the results. Although discontinuing breast-feeding and using phototherapy was the most effective strategy, in neither of these studies was intensive phototherapy used (472). Notwithstanding the options listed in Table 35-34, any interruption of nursing is undesirable and it is my practice to recommend that breast-feeding be continued while the infant is treated with intensive phototherapy unless very severe hyperbilirubinemia is present (TSB levels in excess of 25 mg/dL [428 μ mol/L]) (see Phototherapy below).

TABLE 35-34 APPROACHES TO THE PREVENTION AND TREATMENT OF JAUNDICE ASSOCIATED WITH BREAST-FEEDING

Prevention

1. Encourage frequent nursing (i.e., at least eight times per day)
2. Do not supplement with water or dextrose water

Treatment options

1. Increase frequency of nursing
2. Continue nursing, administer phototherapy
3. Temporarily interrupt nursing for 48 hours, substitute formula
4. If treating with phototherapy, supplement with expressed breast milk or formula if infant's intake is inadequate, weight loss is excessive, or the infant is dehydrated

Low-Birth-Weight Infants

The management of hyperbilirubinemia in low-birth-weight infants has been reviewed (473) and Tables 35-29,35-30 to 35-31 provide suggested guidelines from three different sources. Over the last 2 decades, there has been a remarkable decrease in the incidence of kernicterus found at autopsy in infants who died in NICUs. Some of this may be a result of the liberal use of phototherapy. Certainly, phototherapy has dramatically decreased the necessity for exchange transfusion, which, in low-birth-weight infants, is now almost exclusively carried out in the occasional infant with severe Rh hemolytic disease or extensive bruising (463).

TABLE 35-35 EFFECT OF INTERVENTIONS FOR JAUNDICE IN BREAST-FED INFANTS

	Group			
	1	2	3	4
	Continue Breast-feeding	Discontinue Breast-feeding, Substitute Formula	Discontinue Breast-feeding Substitute Formula, Use Phototherapy	Continue Breast-feeding, Use Phototherapy
No.	25	26	38	36
Serum bilirubin ≥20 mg/dL (342 μmol/L)	6 (24%)	5 (19%)	1 (3%) ^a	5 (14%)

When the serum bilirubin reached 17 mg/dL (291 μmol/L), infants were randomly assigned to one of the four interventions above. The number (%) of infants whose bilirubin level subsequently reached or exceeded 20 mg/dL (342 μmol/L) is shown. Conventional (not intensive) phototherapy was used.

^a Significantly different versus group 1 ($p = 0.013$) and group 2 ($p = 0.036$). From Martinez JC, Maisels MJ, Otheguy L, et al. Hyperbilirubinemia in the breast-fed newborn: a controlled trial of four interventions. *Pediatrics* 1993;91:470–473, with permission.

As shown in Tables 35-29,35-30 and 35-31, phototherapy generally is used according to a sliding scale: the lower the birth weight, the lower the TSB level at which phototherapy is instituted. In view of the known antioxidant properties of bilirubin, it is possible that maintaining very low TSB levels by the aggressive use of phototherapy might have other, less desirable, consequences (181) (see section on Bilirubin Toxicity-Premature Infants and Low Bilirubin Kernicterus and Physiologic Role of Bilirubin below). To address this and other issues the, NICHD Neonatal Research Network initiated a trial, the design of which is shown in Table 35-32 (192). The results of this important study should provide guidance with regard to the risks and benefits of phototherapy in the ELBW population.

Elevated Direct-Reacting or Conjugated Bilirubin Levels

There are no helpful data and, as a result, little guidance on how we should deal with the occasional infant who has a high TSB as well as a significant elevation of direct-reacting bilirubin. Because direct-reacting bilirubin is not toxic to the central nervous system, some practitioners have based their decisions for exchange transfusion on the level of indirect-reacting serum bilirubin level (rather than the TSB) as the sole criterion for exchange transfusion (76). The AAP makes a firm recommendation against this practice and notes that the direct-reacting (or conjugated) bilirubin should not be subtracted from the total.

Kernicterus has been described in infants who have elevated TSB levels but in whom the indirect-reacting bilirubin was well below 20 mg/dL (342 μmol/L) (135, 474). One infant had the bronze baby syndrome and another was a 54-hour-old male infant with erythroblastosis fetalis whose TSB level was 45.2 mg/dL (773 μmol/L), of which 31.6 mg/dL (540 μmol/L) was direct reacting. Thus, the total indirect-reacting bilirubin in this infant was only 13.6 mg/dL (135). I have seen the records of other, similar cases. Kernicterus in these infants may be the result of competitive displacement (by direct-reacting bilirubin) of unconjugated bilirubin from its binding site to albumin.

Ebbesen (475) found that infants with elevated direct-reacting bilirubin levels of 6.4 to 9.9 mg/dL (109 to 169 μmol/L) and the bronze baby syndrome had a decrease in reserve albumin-binding capacity. Conversely, some infants with extremely high, but predominantly direct-reacting, serum bilirubin levels have come to no harm.

Hemolytic Disease

As discussed previously, infants with hemolytic disease appear to be at a greater risk of developing bilirubin encephalopathy than are nonhemolyzing infants with similar TSB levels. The reasons for this are not clear. In the early studies of Rh disease, almost all infants were delivered prematurely (to prevent stillbirth); many were asphyxiated and severely ill. It is unlikely that the risk of kernicterus in infants with Rh disease, treated in today's intensive care environment and with similar TSB levels, would be nearly as great. Although it has been

suggested that infants with hemolytic disease may have a decrease in their bilirubin-binding capacity, when measured, this has not been found to be the case (476). Similarly, we have no obvious explanation for the increased risk of bilirubin encephalopathy in infants with G6PD deficiency.

Hydrops Fetalis

Hydropic infants generally suffer significant hypoxia *in utero*. Women who are to deliver such infants should be managed exclusively in perinatal centers capable of the full range of obstetric and neonatal intensive care. Hydropic infants, as well as infants who are severely anemic (hematocrit less than 35%) and asphyxiated, require immediate treatment. Exchange transfusion of about 50 mL/kg of packed cells soon after birth raises the hematocrit to approximately 40%. Phlebotomy should not be routinely performed on these infants because they usually are normovolemic and may be hypovolemic (306, 477,478). No manipulations of blood volume should be performed without appropriate measurements of central venous and arterial blood pressures. For accurate monitoring of central venous pressure, however, the umbilical venous catheter must enter the inferior vena cava by way of the ductus venosus. If the catheter is in a portal vein or the umbilical vein, the pressures so measured are meaningless and preclude interpretation of the infant's circulatory status. In addition, before making therapeutic decisions based on measurements of central venous pressure, the physician must also correct acidosis, hypercarbia, hypoxia, and anemia. Serum glucose levels should be monitored carefully, because hypoglycemia is common.

Phototherapy

For comprehensive reviews of this subject, the reader is referred to the monograph by Jahrig and associates (479), and to a recent chapter by the author (480).

It helps to understand how phototherapy works if we consider that light is an infusion of discrete photons of energy that correspond to the individual molecules of a drug in a conventional medication. Absorption of these photons by bilirubin molecules in the skin leads to the therapeutic effect in much the same way as binding of drug molecules to a receptor has a desired effect. Tables 35-36 to 35-38 list the factors that influence the dose and efficacy of phototherapy and define the radiometric quantities used in assessing the dose.

Terminology

Light Spectrum

The spectrum of light delivered by the phototherapy unit is determined by the type of light source and any filters used. Because of the optical properties of bilirubin and skin, the most effective lights are those with wavelengths that are predominantly in the blue-green spectrum (481).

TABLE 35-36 FACTORS THAT DETERMINE THE DOSE OF PHOTOTHERAPY

Spectrum of light emitted
Irradiance of light source
Design of phototherapy unit
Surface area of infant exposed to the light
Distance of infant from light source

TABLE 35-37 FACTORS THAT AFFECT THE DOSE AND EFFICACY OF PHOTOTHERAPY

Factor	Mechanism/Clinical Relevance	Implementation and Rationale	Clinical Application
Spectrum of light emitted	Blue-green spectrum most effective; at these wavelengths, light penetrates skin well and is absorbed maximally by bilirubin	Special blue fluorescent tubes or other light sources that have most output in the blue-green spectrum and are most effective in lowering TSB	Use special blue tubes or LED light source with output in blue-green spectrum for intensive PT

Spectral irradiance (irradiance in certain wavelength band) delivered to surface of infant	↑irradiance→ ↑rate of decline in TSB	Irradiance measured with a radiometer as W/cm ² /nm; standard PT units deliver 8–10 W/cm ² /nm; intensive PT requires 30 W/cm ² /nm tubes 10–15 cm above infant	If special blue fluorescent tubes used, bring tubes as close to infant as possible to increase irradiance; Note: cannot do this with halogen lamps because danger of burn ; special blue will produce an irradiance of at least 35 W/cm ² /nm
Spectral power (average spectral irradiance across surface area)	↑surface area exposed→ ↑rate of decline in TSB	For intensive PT expose maximum surface area of infant to PT	Place lights above and fiberoptic pad or special blue fluorescent tubes ^a below infant; for maximum exposure line sides of bassinet warmer bed, or incubator with aluminum foil
Cause of jaundice	PT likely to be less effective if jaundice caused by hemolysis or if cholestasis present (↑direct-reacting bilirubin)		When hemolysis present start PT at lower TSB levels. Use intensive PT. Failure of PT suggests hemolysis is cause of jaundice; if ↑direct-reacting bilirubin, watch for bronze baby syndrome or blistering
TSB level at start of PT	The higher the TSB, the more rapid the decline in TSB with PT		Use intensive PT for higher TSB levels; anticipate more rapid decrease in TSB when TSB >20 mg/dl (342 μmol/l)

LED, light-emitting diode; PT, phototherapy; TSB, total serum bilirubin.

P.826

There is a common misconception that ultraviolet (UV) light is used for phototherapy. None of the light systems described emit any significant amount of UV radiation, and the small amount of UV light that is emitted by fluorescent tubes is in longer wavelengths (>320 nm) than those that cause erythema (479). In any case, almost all UV light produced is absorbed by the glass wall of the fluorescent tube and by the Plexiglas cover of the phototherapy unit.

Irradiance

Irradiance is the radiant power incident on a surface per unit area of the surface.

TABLE 35-38 RADIOMETRIC QUANTITIES USED

Quantity	Dimensions	Usual Units of Measure
Irradiance (radiant power incident on a surface per unit area of the surface)	W/m ²	W/cm ²
Spectral irradiance (irradiance in a certain wavelength band)	W/m ² per nm (or W/m ²)	μW/cm ² per nm
Spectral power (average spectral irradiance across a surface area)	W/m	mW/nm

From Maisels MJ. Why use homeopathic doses of phototherapy? *Pediatrics* 1996;98:283–287, with permission.

The irradiance in a specific wavelength band is called the *spectral irradiance* and is expressed as μW/cm²/nm (see Table 35-38). There is a direct relationship between the efficacy of phototherapy and the irradiance used (Fig. 35-26) (482) and the irradiance is directly related to the distance between the light and the infant (Fig. 35-27) (472).

The Dose-Response Relationship of Irradiance

Figure 35-26 shows that there is a direct relationship between the irradiance used and the rate at which the serum bilirubin declines under phototherapy (482). The data in Fig. 35-26 suggest that there is a saturation point

P.827

beyond which an increase in the irradiance produces no added efficacy. We do not know, however, that a saturation point exists. As the conversion of bilirubin to excretable photoproducts is partly irreversible and follows first-order kinetics, there may not be a saturation point so we do not know the maximum effective dose of phototherapy.

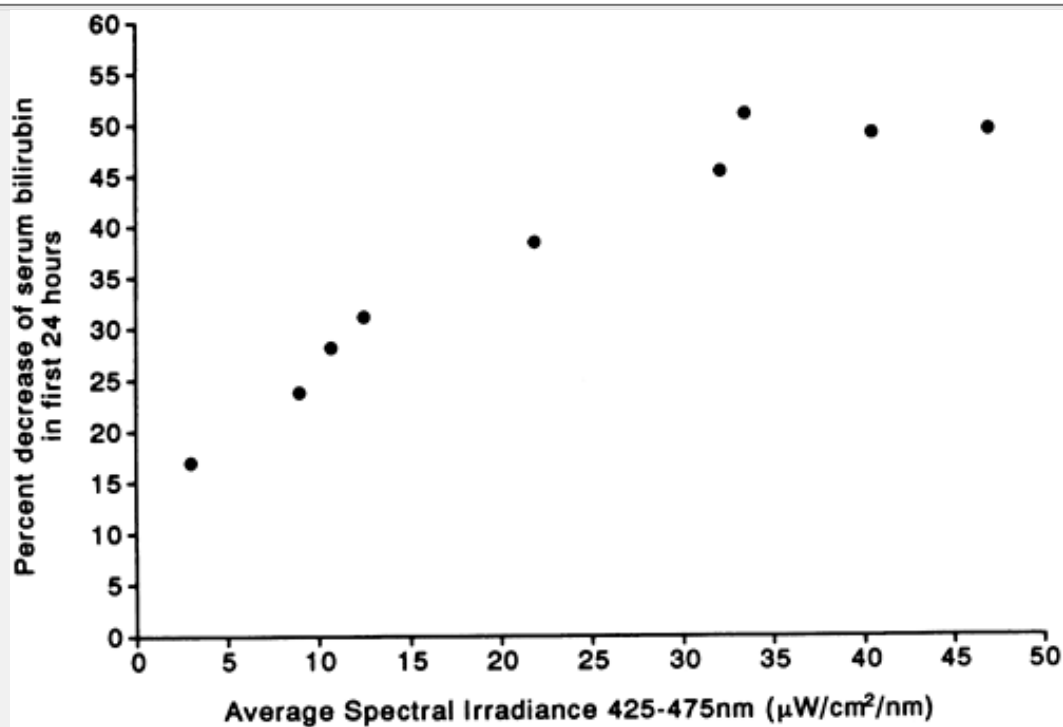

Figure 35-26 Relationship between average spectral irradiance and decrease in serum bilirubin concentration. Full-term infants with nonhemolytic hyperbilirubinemia were exposed to special blue light (Phillips TL 52/20W) of different intensities. Spectral irradiance was measured as the average of readings at the head, trunk, and knees. Drawn from the data of Tan (482). (From Maisels MJ. Why use homeopathic doses of phototherapy? *Pediatrics* 1996;98:283-287, with permission.)

Effect on Irradiance of the Light Spectrum and the Distance between the Infant and the Light Source.

Figure 35-27 shows that the light intensity (measured as spectral irradiance) is inversely related to the distance from the source. The relationship between intensity and distance is almost (but not quite) linear, indicating that these data do not obey the law of inverse squares, which states that the light intensity will decrease with the square of the distance (472). This law applies only to a point source of light and the light source in phototherapy units has features of a cylindrical and planar source, not a point source. Figure 35-27 also demonstrates the dramatic difference in irradiance produced within the 425- to 475-nm band by different types of fluorescent tubes.

Figure 35-27 Effect of light source and distance from the light source to the infant on average spectral irradiance. Measurements were made across the 425- to 475-nm band using a commercial radiometer (Olympic Bilimeter Mark II). The phototherapy unit was fitted with eight 24-inch fluorescent tubes. () Special blue, General Electric 20-W F20T12/BB tube; (◇) blue, General Electric 20-w F20T12/B blue tube; ([black up-pointing triangle]) daylight blue, four General Electric 20-W F20T12/B blue tubes and four Sylvania 20-W F20T1 2/D day light tubes; (^) daylight, Sylvania 20-W F20T12/D daylight tubes. Curves were plotted using linear curve fitting (True Epistat; Epistat Services, Richardson, TX). The best fit is described by the equation $y=Ae^{Bx}$. (From Maisels MJ. Why use homeopathic doses of phototherapy? *Pediatrics* 1996;98:283-287, with permission.)

Spectral Power

This is the product of the skin surface irradiance and the spectral irradiance across this surface area. Because irradiance and the surface area of the infant exposed to phototherapy are key elements in determining the efficacy of phototherapy, the use of spectral power is the only meaningful way to compare the dose of phototherapy received by infants under the different phototherapy systems (472). Calculations of spectral power show why a much more effective dose of phototherapy is delivered to the infant by using the appropriate fluorescent tubes than can be delivered using a fiberoptic phototherapy system (472).

Mechanism of Action

Phototherapy detoxifies bilirubin by converting it to photoproducts that are less lipophilic than bilirubin and can bypass the liver's conjugating system and be excreted without further metabolism (10). It is not known exactly where the process of phototherapy takes place, but it probably does not take place in the skin cells. It is more likely that it works on bilirubin bound to albumin in the superficial capillaries or in the interstitial space (483).

Bilirubin Photochemistry

When bilirubin absorbs light, photochemical reactions occur. Although many such reactions have been observed *in vitro*, only three have been shown to occur *in vivo* during phototherapy.

Configurational(Z → E) Isomerization

Isomers are substances that have the same molecular formula but different physicochemical properties. There are four possible configurational isomers of bilirubin (Fig. 35-28). In infants receiving phototherapy, the stable 4Z,15Z isomer is converted predominately to the 4Z,15E isomer (Figs. 35-28 and 35-29).(10) The formation of 4Z,15E bilirubin is spontaneously reversible in the dark and occurs rapidly in bile. Thus the 4Z,15E bilirubin formed in the skin and excreted by the liver is readily converted back to ordinary unconjugated bilirubin. The conversion of the 4Z,15Z isomer to the 4Z,15E isomer is also reversible by light (10).

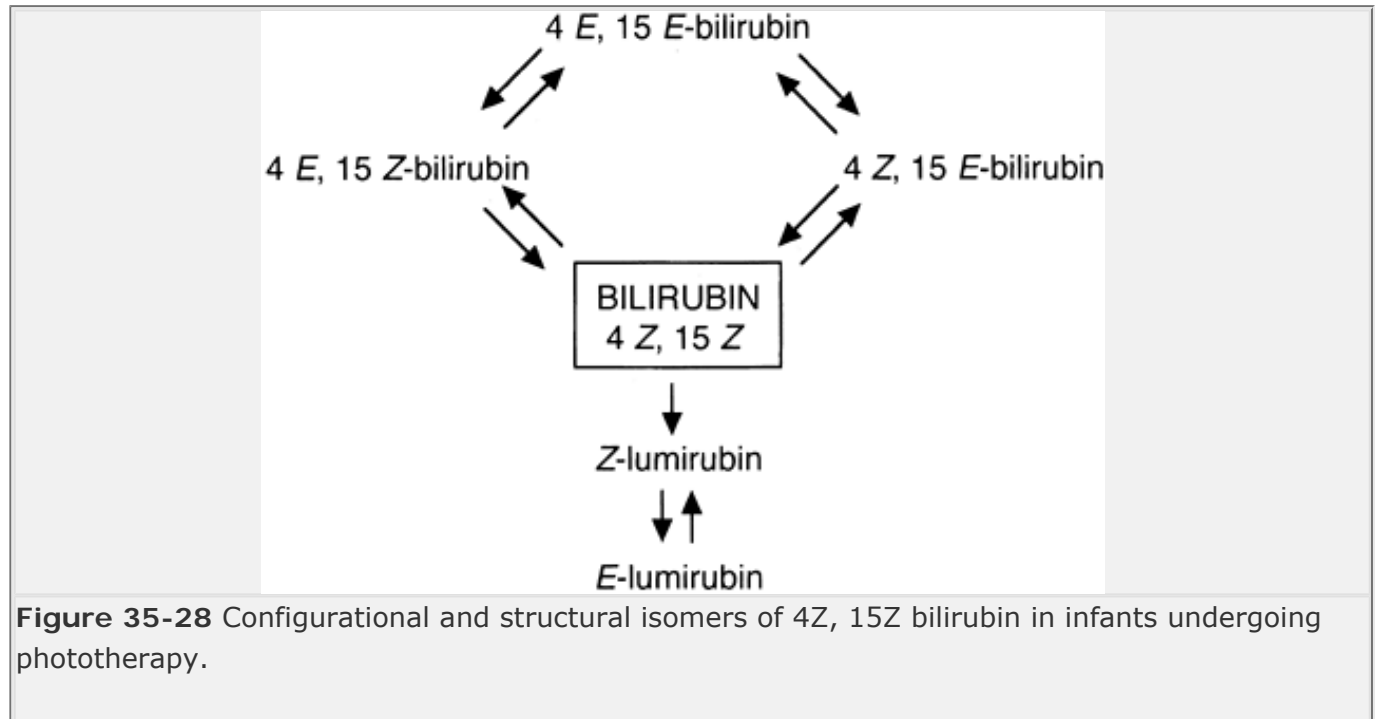

Figure 35-28 Configurational and structural isomers of 4Z, 15Z bilirubin in infants undergoing phototherapy.

P.828

When infants are exposed to phototherapy, photoisomerization occurs almost instantaneously, but the clearance of the light-generated 4Z,15E isomer is very slow ($T_{1/2} \sim 15$ hours). Thus, although configurational isomerization is extremely rapid and accounts for the bulk of the photochemical outcomes, it probably plays only a minor role in lowering the serum bilirubin concentration because "although it is formed fastest, it has nowhere to go" (484).

Structural Isomerization

In this reaction (Fig. 35-30), intramolecular cyclization of bilirubin (an irreversible process) occurs in the presence of light to form a substance known as lumirubin that can be excreted in bile (without the need for conjugation) and in urine (but at a much lower rate than in bile) (484). During phototherapy, the serum concentration of lumirubin is about 2% to 6% of the TSB, which is much lower than the concentration of the configurational isomers that form about 20% of the total bilirubin. But, because lumirubin is cleared from the serum much more rapidly than the 4Z,15E isomer, it is likely that lumirubin formation is mainly responsible for the phototherapy-induced decline in serum bilirubin in the human infant (484). It is quite possible, however, that the contribution of the other isomers, 4E,15Z and 4E,15E bilirubin, also is important (485).

Figure 35-29 Z-E carbon-carbon double-bond configurational isomerization of bilirubin in humans. (From McDonagh AF, Lightner DA. "Like a shrivelled blood orange"—bilirubin, jaundice and phototherapy. *Pediatrics* 1985;75:443-455, with permission.)

Figure 35-30 Intramolecular cyclization of bilirubin in the presence of light to form lumirubin. (From McDonagh AF, Lightner DA. "Like a shrivelled blood orange"—bilirubin, jaundice and phototherapy. *Pediatrics* 1985;75:443-455, with permission.)

Photooxidation

Bilirubin can be photooxidized to water-soluble, colorless products that can be excreted in the urine. This is a slow process and is probably only a minor contributor to the elimination of bilirubin during phototherapy.

Figure 35-31 summarizes the general mechanisms of phototherapy in neonatal jaundice.

Clinical Use and Efficacy of Phototherapy

There are more than 50 published controlled trials of the clinical use of phototherapy (see Maisels (217) for a description and analysis of these studies), confirming that phototherapy is effective in preventing and treating hyperbilirubinemia and dramatically reduces the need for exchange transfusion (217).

As described previously, there is a clear relationship between the dose of phototherapy and the

measured decrement in the serum bilirubin level (see Fig. 35-26) (482). Tables 35-36 and 35-37 list the factors that affect the dose and efficacy of phototherapy. The other important

P.829

factors that determine the efficacy of phototherapy are the cause of the hyperbilirubinemia (hemolytic conditions respond less well) and the initial bilirubin level, the rate of decline being proportional to the initial bilirubin concentration (159,486,487).

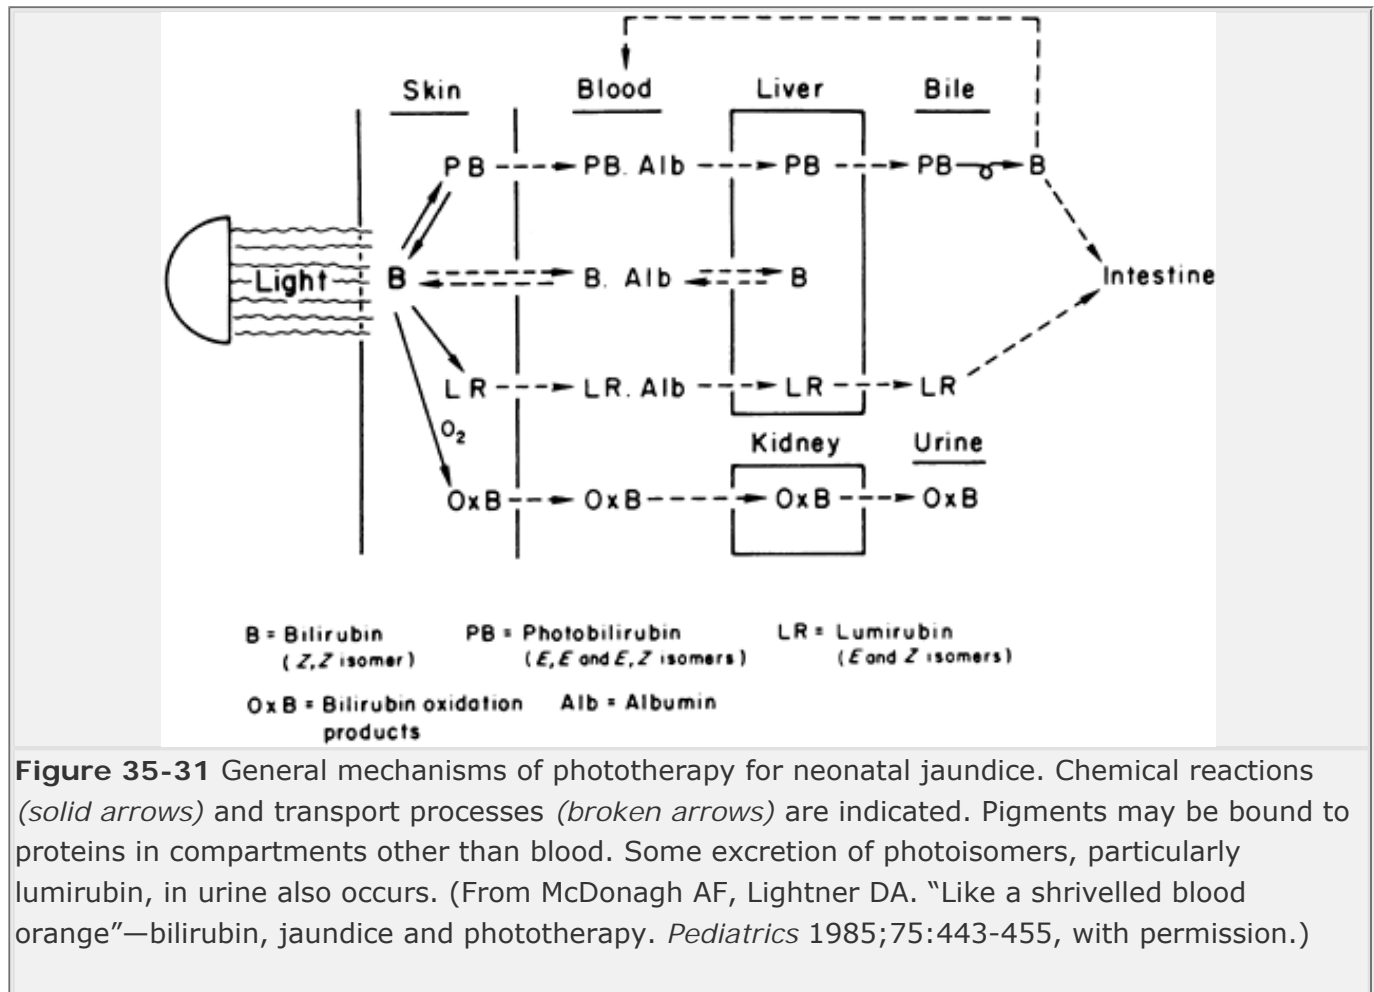

Figure 35-31 General mechanisms of phototherapy for neonatal jaundice. Chemical reactions (solid arrows) and transport processes (broken arrows) are indicated. Pigments may be bound to proteins in compartments other than blood. Some excretion of photoisomers, particularly lumirubin, in urine also occurs. (From McDonagh AF, Lightner DA. "Like a shrivelled blood orange"—bilirubin, jaundice and phototherapy. *Pediatrics* 1985;75:443-455, with permission.)

Light Sources

Fluorescent Tubes

Daylight or cool-white fluorescent tubes provide adequate phototherapy where the objective is to control a slowly rising serum bilirubin level in a preterm or term infant, but they are less effective than "special blue" tubes (see Fig. 35-27). Special blue fluorescent tubes are most effective because they provide light predominantly in the blue-green spectrum. At these wavelengths light penetrates skin well and is absorbed maximally by bilirubin (472,484). The imprint F20-T12/BB (General Electric, Westinghouse, Sylvania) or TL52/20W (Phillips, Eindhoven, The Netherlands) is found on special blue tubes. Note that these are different from regular blue tubes (labeled F20-T12/B) (484). Special blue tubes do impart a bluish tinge to the infant and this may obscure cyanosis. In the term nursery this is of little concern, and if used in the NICU, monitoring by pulse oximetry is all that is necessary. Turquoise fluorescent light (Osram, Denmark) has recently been compared with special blue light in the treatment of preterm infants (488). The emission peak of the turquoise lamps is at 490 nm with a bandwidth of 65 nm. Ebbesen and associates found that these lamps were as effective as special blue lamps but required 23% less irradiance than special blue lamps to produce the same effect on the bilirubin levels (488). They suggest that the use of

less irradiance could be associated with fewer side effects.

Light-Emitting Diodes

A new method of delivering high-intensity, narrow-band light has been described (468,489). The use of high-intensity gallium nitride light-emitting diodes (LEDs) permits high irradiance in the spectrum of choice (blue, blue-green, etc.) with minimal heat generation. The device is low weight, low voltage, low power, and portable, and could be an effective means of providing intensive phototherapy in the hospital or at home. Although only limited clinical trials have been performed to date (489), an LED phototherapy unit is commercially available (Natus Inc., San Carlos, CA).

Halogen Lamps

These lamps have the advantage of being more compact than fluorescent systems but, unlike fluorescent lamps, *they cannot be brought close to the infant (to increase the irradiance) without incurring the risk of a burn*. In addition, the surface area covered by most halogen lamps is relatively small, and the spectral power will be less than that produced by a bank of fluorescent lights.

Fiberoptic Systems

These systems consist of a light that is delivered from a tungsten-halogen bulb through a fiberoptic cable and emitted from the sides and ends of the fibers inside a plastic pad (472,490). These systems have the advantage of not requiring eye patches. They are less bulky than conventional phototherapy equipment and provide a convenient way to deliver double phototherapy when it is necessary to expose more of the infant's surface area (see following). They also are useful for home phototherapy. Their major disadvantage is that they have very low spectral power because of their small surface area. This is the result of the inverse relationship between surface area and irradiance. For a given light source, enlarging the pad means that the light must be distributed over a greater area, thus reducing the irradiance (when compared to a small pad and the same light source). To achieve high levels of spectral irradiance, manufacturers must compromise by reducing the size of the pad, which exposes a relatively small surface area of the infant to the light (490). Conversely, because VLBW infants are so small, fiberoptic pads can be used quite effectively in these infants (491,492,493) and fiberoptic phototherapy does not attenuate the normal post prandial increase in intestinal blood flow (493) (see *Blood Flow* below).

Full-Term and Near-Term Infants—Using Phototherapy Effectively

Phototherapy initially was used in low-birth-weight and full-term infants primarily to prevent slowly rising serum bilirubin levels from reaching levels that might require an exchange transfusion. Today, phototherapy is often used in full-term and near-term infants who have left the hospital and are readmitted on days 4 to 7 for treatment of TSB levels of 20 mg/dL (342 $\mu\text{mol/L}$) or more. These infants need a full therapeutic dose of phototherapy (now termed *intensive phototherapy*) to get the bilirubin level down as soon as possible (472,487). Intensive phototherapy implies the use of high levels of irradiance in the 425- to 490-nm band (usually $\geq 30 \mu\text{W/cm}^2$ per nm) delivered to as much of the infant's surface area as possible. How this can be achieved is described below. The light spectrum, the irradiance, and the infant's exposed surface area are the key elements in determining the bilirubin response to phototherapy (see Tables 35-36 and 35-37). Thus, to provide the most effective phototherapy for these full-term and near-

term infants, we use special blue fluorescent tubes and bring them as close to the infant as possible. To do this, a full-term infant should be in a bassinet, not an incubator, because the top of the incubator prevents the light from being brought sufficiently close to the infant. In a bassinet it is possible to bring the fluorescent lights within about 10 cm of the infant and to produce a spectral irradiance of more than 50 $\mu\text{W}/\text{cm}^2$ per nm (see Fig. 35-27). This does not overheat naked full-term infants. Note, however, that *halogen phototherapy lamps cannot be positioned closer to the infant than recommended by the manufacturers without incurring the risk of a burn.*

P.830

To increase the exposed surface area fiberoptic pads should be placed below the infant. This type of "double phototherapy" is approximately twice as effective as single phototherapy in low-birth-weight infants and almost 50% better in full-term infants (494,495). Another way of increasing the surface area of the infant exposed to light is to place a reflecting material (a white sheet or aluminum foil) within or around the bassinet or incubator so that light is reflected onto the infant's skin. Different systems of surrounding the infant with fluorescent lights have been described (487,496,497). Using such a system, Hansen (487) reported declines in serum bilirubins of 10 to 11 mg/dL (170 to 185 $\mu\text{mol}/\text{L}$) within 2 hours. On occasion, I have used two or even three fiberoptic pads to cover almost the entire lower surface of the infant. Although data from Tan (482) suggest that there is a saturation point beyond which an increase in the irradiance produces no added efficacy, we do not know that a saturation point exists. Given that the conversion of bilirubin to excretable photoproducts is partly irreversible and follows first-order kinetics, there may not be a saturation point. Certainly with existing equipment there is probably no such thing as an overdose of phototherapy.

Because phototherapy acts on bilirubin that is present in the extravascular space as well as in the superficial capillaries, it has become a common practice to turn the infant at intervals from supine to prone and back. Two randomized studies suggest that this is not a good idea. Yamauchi and associates (498) found that turning term infants every 6 hours did not improve the efficacy of phototherapy compared with those who are not turned. Shinwell and associates (499) turned infants from prone to supine every 2.5 hours. They found that infants who were not turned had a significantly more rapid decrease in their TSB levels in the first 24 hours of phototherapy than did those who were turned (499).

Measuring the Dose of Phototherapy

Table 35-38 shows the radiometric quantities used in measuring the phototherapy dose. The quantity most commonly reported in the literature is the spectral irradiance. In the nursery, spectral irradiance can be measured using commercially available radiometers. These instruments take a single measurement across a band of wavelengths, typically 425 to 475 nm or 400 to 480 nm. Unfortunately, there is no standardized method for reporting phototherapy dosages in the clinical literature so it is difficult to compare published studies on the efficacy of phototherapy and manufacturer's data for the irradiance produced by different systems. Measurements of irradiance from the same system, using different radiometers, can also produce significantly different results. The width of the phototherapy lamp's emissions spectrum (narrow vs. broad) will affect the measured irradiance. Measurements under lights with a very focused emission spectrum (e.g., blue-light-emitting diode) will vary significantly from one radiometer to another as the response spectra of the radiometers vary from manufacturer to manufacturer. Broader-spectrum lights (fluorescent and halogen) have fewer variations among radiometers. Manufacturers of phototherapy systems generally recommend the specific radiometer to be used in measuring the dose of phototherapy when their system is used.

It is also important to recognize that the measured irradiance will vary widely depending on where the measurement is taken. Irradiance measured below the center of the light source can be more than double that measured at the periphery, and this drop off at the periphery will vary with different phototherapy units. Ideally, irradiance should be measured at multiple sites under the area illuminated by the unit and the measurements averaged. The International Electrotechnical Commission (500) defines the *effective surface area* as the intended treatment surface that is illuminated by the phototherapy light. The commission uses 60 × 30 cm as the standard-sized surface.

Is it Necessary to Measure Phototherapy Doses Routinely?

Although it is not necessary to measure spectral irradiance before each use of phototherapy, it is important to perform periodic checks of phototherapy units to make sure that an adequate irradiance is being delivered.

Preterm Infants

Conventional phototherapy with daylight or cool-white fluorescent lights, halogen lamps, or fiberoptic pads have all been effective in decreasing TSB levels and the number of exchange transfusions performed in low-birth-weight infants (see Fig. 35-25) (217). For those with severe bruising or hemolytic disease, however, intensive phototherapy (as described previously) should be used.

Prophylactic Phototherapy in Extremely Low-Birth-Weight Infants

Earlier data suggested that phototherapy, initiated prophylactically from birth in infants weighing less than 1,250 g, was no more effective than phototherapy initiated when the TSB reached 5 mg/dL (85 μmol/L) (501). In a recent study of infants weighing less than 1,000 g, those who received prophylactic phototherapy from birth had significantly lower peak TSB levels than did those who received phototherapy when their TSB levels reached 150 μmol/L (8.8 mg/dL). There was no difference between the groups in the duration of phototherapy (502).

Intermittent Versus Continuous Phototherapy

Clinical studies comparing intermittent with continuous phototherapy have produced conflicting results (479). In practice, on-off cycles complicate nursing care and probably are more trouble than they are worth. There is no doubt, however, that in the majority of circumstances phototherapy does not *need* to be continuous. It can and certainly should be interrupted during feeding or brief

P.831

parental visits. On the other hand, when bilirubin levels are very high, intensive phototherapy should be administered continuously until a satisfactory decline in the TSB has occurred.

Hydration and Feeding

Breast-fed infants who are readmitted to the hospital with TSB levels commonly have excess weight loss as a result of a combination of mild dehydration and poor caloric intake. In these infants, it makes sense to provide supplemental calories and fluids using a milk-based formula, because formulas inhibit the enterohepatic circulation of bilirubin and help to lower the bilirubin

level. Because lumirubin is excreted in the urine, maintaining adequate hydration and good urine output also helps to improve the efficacy of phototherapy. Routine supplementation (with dextrose water) of all infants receiving phototherapy is not indicated.

Biologic Effects and Complications

Even though phototherapy has been used in millions of infants for more than 30 years, reports of significant toxicity are exceptionally rare. Human, animal, and *in vitro* studies suggest that the products of photodecomposition have no neurotoxic effects (503,504).

Skin

Bilirubin is a photosensitizer and, in some circumstances, could act as a photodynamic agent in the presence of light and produce damage. Severe blistering and photosensitivity during phototherapy for jaundice have been described in infants with congenital erythropoietic porphyria (505). The presence of congenital porphyria or a family history of porphyria are absolute contraindications to the use of phototherapy. Rarely, bullous eruptions have occurred in infants with hemolytic disease and transient porphyrinemia who received phototherapy (506,507). All of these infants had significant cholestasis (elevated direct-reacting bilirubin levels), and plasma proto- and coproporphyrin levels were elevated in the two infants in whom they were measured. Other photosensitizers may also be hazardous in infants receiving phototherapy. A 32-weeks' gestation neonate who received intravenous fluorescein for angiography was subsequently exposed to phototherapy (508). This infant developed a partial-thickness burn, which was probably related to the phototoxicity from the fluorescein that produces photosensitization by generation of a superoxide anion when exposed to light at a wavelength of 418 nm in the visible light range (508).

A partial-thickness burn occurred on the back of a 25-weeks' gestation 800-g infant receiving phototherapy with a fiberoptic system (509). This infant required assisted ventilation and inotropic support and died at age 85 hours. There was an extensive, erythematous, denuded area of skin on the back, similar to a partial thickness burn and from which serous fluid oozed. The Ohmeda Company issued a medical device safety alert on January 26, 1996, in which it reported that four extremely premature infants (≤ 25 weeks' gestation) had developed purplish-red necrotizing lesions during the use of the BiliBlanket phototherapy system. In all of these infants, conditions were present that might reduce skin integrity such as birth trauma, hypotension, poor perfusion of the skin or bacterial contamination of the incubator or bed. It is unlikely that these were thermal burns although it is important to note that skin of these extremely premature infants is remarkably fragile. Two neonates have been described who developed erythema (one was blistering) following exposure to daylight fluorescent lamps without Plexiglas shielding (510).

Children with the Crigler-Najjar syndrome receiving phototherapy for 2 to 3 years often develop pigmented lesions and tanning as well as skin atrophy.

The Bronze-Baby Syndrome

When infants with cholestatic jaundice are exposed to phototherapy they may develop a grayish-brown discoloration of the skin, serum, and urine known as the bronze baby syndrome (511). The pathogenesis of this syndrome is unknown, but it may be related to an accumulation of porphyrins and other metabolites in the plasma of infants who develop cholestasis (511,512). Although it occurs exclusively in infants with cholestasis, not all infants with cholestatic jaundice develop the syndrome. An animal model of the bronze baby syndrome has been produced by ligating the common bile duct in adult Wistar rats and subjecting them to phototherapy (513).

This syndrome generally has had few deleterious consequences, although a full-term infant with the bronze baby syndrome who died was shown to have kernicterus at autopsy (474). The maximal TSB level in this infant was 18 mg/dL (308 μ mol/L) and the direct-reacting bilirubin was 4.1 mg/dL (70 μ mol/L). If there is a need for phototherapy, the presence of direct-reacting hyperbilirubinemia should not be considered a contraindication to its use. Because the products of phototherapy are excreted in the bile, the presence of cholestasis will decrease the efficacy of phototherapy. Nevertheless, infants with direct-reacting hyperbilirubinemia often show some response to phototherapy. In infants receiving phototherapy who develop the bronze baby syndrome, exchange transfusion should be considered if the TSB is in the intensive phototherapy range and phototherapy does not promptly lower the TSB. Because of the paucity of data, firm recommendations cannot be made. Note, however, *that the direct-reacting serum bilirubin should not be subtracted from the TSB concentration in making decisions about exchange transfusions* (76) (see Fig. 35-23).

Eye Damage

Because light can be toxic to the retina, the eyes of infants receiving phototherapy should be protected with appropriate eye patches (514). Note that displaced eye patches may

P.832

obstruct the nares and produce apnea and that shielding infant's eyes and depriving them of visual stimuli could be harmful. The pattern of visual evoked potentials in preterm infants whose eyes had been shielded until they reach 32-weeks postconceptional age where compared with those in infants with unshielded eyes (515). At 41 and 50 weeks postconception, and at age 3 years, no differences between the groups were found in the visual evoked responses (515). Commercially available eye shields, if properly applied, prevent more than 98% of light transmission (516). Note, however, that in addition to the potential risk of irritation or even corneal abrasion from eye patches, investigators have found an increase in bacterial pathogen isolation and purulent conjunctivitis in infants whose eyes are patched (517).

Insensible Water Loss and Thermal Regulation

Acute changes in the thermal environment occur directly after the initiation of phototherapy (518), and infants receiving phototherapy have an increase in peripheral blood flow that may increase the insensible water loss. Term and preterm infants receiving phototherapy from fluorescent tubes and studied naked in an incubator with an ambient relative humidity of 50% and a servocontrolled environment, showed no increase in water loss from the skin (519). However, a group of Israeli investigators studied 31 preterm infants (gestations 25 to 36 weeks) and measured transepidermal water loss in 7 body areas before and during phototherapy (under fluorescent tubes). They found a mean increase of 26.4% in transepidermal water loss during phototherapy (520). Grünhagen and associates (521) also found an increase in transepidermal water loss of approximately 20% during halogen spotlight phototherapy despite constant skin temperature and relative humidity. These authors suggest that it is appropriate to increase maintenance fluids for preterm infants by 0.35 mL/kg per hour while they are receiving halogen light phototherapy. On the other hand, this may not be necessary if the infant's fluid status is monitored regularly by means of urine output, urine specific gravity, serum electrolytes and change in weight, and fluids adjusted accordingly.

Blood Flow

Under normal circumstances, enteral feedings induce a significant increase in blood flow velocity in the superior mesenteric artery and conventional phototherapy will blunt this postprandial

mesenteric blood flow in term and preterm infants (493,522). In preterm infants, Pezzati and associates (493) showed that fiberoptic phototherapy, unlike conventional phototherapy, did not attenuate the post prandial increase in intestinal blood flow. They also found nonstatistically significant increases in the passage of loose, watery, stools and abdominal distention in infants receiving conventional versus fiberoptic phototherapy. They concluded that fiberoptic phototherapy is preferable to conventional phototherapy for treating hyperbilirubinemia in preterm infants.

Cell Damage

Phototherapy can produce DNA strand breaks in cell cultures and DNA strand breakage increases when cells are irradiated in the presence of bilirubin (523). Because light penetrates the thin scrotal skin and perhaps even reaches the ovaries, it has been suggested that shielding the gonads with diapers maybe indicated during phototherapy (524). There is no human or animal evidence, however, to support this practice, and the limited depth of penetration of light makes the possibility of DNA damage to gonads quite unlikely.

Other Complications

The products of photodecomposition have no direct neurotoxic effects. Although phototherapy can produce DNA strand breaks in cell cultures, there is no evidence that this occurs in humans. A relationship has been described between the use of phototherapy and the risk of patent ductus arteriosus in very-low-birth-weight infants (525, 526). The possible mechanisms for this effect are not clear, but may be related to a mechanism similar to nitric oxide-induced vasorelaxation (526).

Intravenous Alimentation

Intravenous alimentation solutions should be protected from phototherapy lights. The exposure of amino acid solutions to light in the blue spectrum produced a significant reduction in tryptophan (527). In addition, when a multivitamin solution was added to the amino acids, a 40% reduction in methionine and 22% reduction in histidine occurred (527).

Diarrhea

Infants receiving phototherapy have an increased incidence of diarrhea (528) and stools become darker and have a greenish tinge (479). These changes are most likely related to the increased excretion of unconjugated bilirubin into the gut.

Home Phototherapy

The economic and social pressures for early discharge of infants from hospital after delivery have led to the widespread use of home phototherapy. Because most of the devices commonly used for home phototherapy do not provide the same degree of irradiance or surface area exposure as those available in the hospital, home phototherapy, of necessity, is used in the prophylactic rather than in the therapeutic mode. Nevertheless, when used appropriately, home phototherapy poses no obvious hazards to the infant and is certainly much cheaper than hospital treatment (529,530,531,532,533). The use of fiberoptic systems and other compact devices has made it easier to administer phototherapy at home.

appropriate. Home phototherapy avoids parent-child separation and there is evidence that mothers of infants who receive phototherapy at home are less likely to stop breast-feeding during the period of phototherapy and, if stopped, are more likely to resume breast-feeding than are mothers whose infants are treated in the hospital (534). When compared with other interventions used in the home such as apnea monitors, nasal oxygen, and ventilators, phototherapy must certainly rank among the more benign.

Sunlight Exposure

In their original description of phototherapy, Cremer and associates (535) demonstrated that exposure of newborns to sunlight would lower the serum bilirubin level. Although sunlight provides sufficient irradiance in the 425- to 475-nm band to provide phototherapy, the practical difficulties involved in safely exposing a naked newborn to the sun either inside or outside (and avoiding sunburn) preclude the use of sunlight as a reliable therapeutic tool and it is therefore not recommended.

Crigler-Najjar Syndrome

Other than liver transplantation, the only therapy available to children with the Crigler-Najjar syndrome is phototherapy. This is achieved in most of these children by means of specially designed (noncommercial) home phototherapy devices that provide adequate phototherapy to the growing child and even the adolescent. As the child gets older, phototherapy becomes less effective presumably as a consequence of thickening of the skin, an increase in skin pigmentation, a decrease in surface area relative to body mass, and the need to provide phototherapy only during sleep to allow the normal activities of childhood during the day. The most satisfactory systems provide a "tanning bed" configuration. The child lies on a transparent surface directly above special blue fluorescent tubes. Bubble wrap and plastic "lilos" have been used for this purpose but, because of their low porosity, produce patient discomfort (361,536,537). Job and associates have used a standard mesh or high transmission fabric stretched over an adjustable tension frame (361). This is similar to a traditional hammock and permits adequate transmission of blue light as well as patient comfort.

Exchange Transfusion

Watchko has comprehensively reviewed this subject ([538](#)) and Edwards and associates ([539](#)) have reviewed the basic indications for, and contraindications to, performing exchange transfusions. A few issues are discussed here. The prevention of Rh hemolytic disease with Rh immunoglobulin and the more effective use of phototherapy has led to a dramatic decline in the number of exchange transfusions performed ([463](#)) (see [Figs. 35-24](#) and [35-25](#)). It is now quite possible for a pediatric resident to complete a 3-year training program without ever having performed an exchange transfusion or even witnessed one. As fewer and fewer of these procedures are done, it is quite likely that the risks of complications will increase.

Exchange Transfusion Risks

[Table 35-39](#) lists potential complications of exchange transfusion and the overall risks of exchange transfusion were reviewed by Ip and associates ([139](#)).

Reporting the morbidity and mortality associated with exchange transfusion is difficult because both are significantly dependent on the clinical state of the infant before the exchange transfusion. Morbidity and mortality are much lower in term infants with idiopathic hyperbilirubinemia than in sick preterm infants who might be critically ill at the time of the exchange transfusion. In addition, definitions of exchange transfusion-related mortality are not consistent between studies and it is difficult to determine from the literature whether the exchange transfusion procedure itself, or other morbidities were responsible for the deaths of these infants. In addition, many of the published studies refer to infants born before 1970 and there are few U.S. studies of infants born after 1990. Contemporary information

P.834

on the mortality of exchange transfusions is difficult to obtain, given the infrequency of the procedure. In full-term and near-term infants who are relatively well, the risk of death is low ([540,541,542](#)). The overall mortality is approximately 3 in 1,000 procedures ([540,541,543](#)). In the NICHD cooperative phototherapy study ([540](#)), morbidity (apnea, bradycardia, cyanosis, vasospasm, thrombosis) was observed in 22 of 328 (6.7%) of exchange transfusions performed. Of the 22 adverse events, however, 6 were mild episodes of bradycardia associated with calcium infusion. Excluding those infants, as well as two who experienced transient arterial spasms, the incidence of significant morbidity associated with the procedure was 5%.

TABLE 35-39 POTENTIAL COMPLICATIONS OF EXCHANGE TRANSFUSION

Cardiovascular	Arrhythmias
	Cardiac arrest
	Volume overload
	Embolization with air or clots
	Thrombosis
	Vasospasm
Hematologic	Sickling (donor blood)
	Thrombocytopenia
	Bleeding (overheparinization of donor blood)
	Graft-versus-host disease
	Mechanical of thermal injury to donor cells
Gastrointestinal	Necrotizing enterocolitis
	Bowel perforation
Biochemical	Hyperkalemia
	Hypernatremia
	Hypocalcemia
	Hypomagnesemia
	Acidosis
	Hypoglycemia
Infectious	Bacteremia
	Virus infection (hepatitis, cytomegalovirus)
	Malaria
Miscellaneous	Hypothermia
	Perforation of umbilical vein
	Drug loss
	Apnea

From Watchko JF. Exchange transfusion in the management of neonatal hyperbilirubinemia. In: Maisels MJ, Watchko JF, eds. *Neonatal jaundice*. London, UK: Harwood Academic, 2000:169–176, with permission.

Jackson ([541](#)) reported a 15-year experience (1980 to 1995) of exchange transfusion in 106 infants at the Children's Hospital and University of Washington Medical Center in Seattle. Eighty-one were healthy, and there were no deaths in these infants, although one child developed severe necrotizing enterocolitis requiring surgery. There were 25 sick infants, 3 (12%) of whom had serious complications from the exchange transfusion and 2 (8%) died; three additional deaths were considered "possibly due" to the exchange transfusion. Thus, the total number of deaths in sick infants that were possibly caused by the exchange was 5 of 25 (20%). Most recently, adverse events associated with exchange transfusions were reviewed at two perinatal centers in Cleveland, Ohio, between

1992 and 2002 ([542](#)). Over a 10.5-year period in two large perinatal centers, only 67 infants were identified who had exchange transfusions for hyperbilirubinemia—an average of about 3 exchange transfusions per year in each institution. The gestational ages ranged from less than 32 weeks (n=15) to term infants (n=22). Adverse events occurred in 74% of the exchanges, with thrombocytopenia (44%), hypocalcemia (29%), and metabolic acidosis (24%) being the most common. There were only two serious adverse events, both in infants who had other preexisting, serious neonatal morbidities. The one infant who died was a critically ill 25-weeks' gestation infant with a birth weight of 731 g. The investigators also found that exchange transfusions performed using both umbilical venous and arterial catheters were significantly more likely to be associated with adverse events than when done through the umbilical vein alone or via other routes ([542](#)).

Although the risk is very low, exchange transfusion nevertheless carries the usual risk of any blood product. The risk estimates (risk per tested unit) for transfusion transmitted viruses in the United States for the period from 1991 to 1993 were as follows: human immunodeficiency virus, 1:493,000; human T-cell lymphotropic virus, 1:641,000; hepatitis C virus, 1:103,000; and hepatitis B virus, 1:63,000 ([544](#)).

Bilirubin Dynamics During and After Exchange Transfusion

During exchange transfusion, bilirubin from the extravascular space is drawn into the plasma, and partial equilibration between extravascular and plasma bilirubin occurs almost instantaneously ([545](#)). Thus, by the end of a double-volume exchange, in which only about 15% of the circulating erythrocytes remain, the serum bilirubin is still 45% to 60% of the preexchange level ([545,546,547](#)). Immediately after the exchange, further equilibration takes place, which is completed within 30 minutes and produces the early rebound of plasma bilirubin to 60% to 80% of the preexchange level ([545](#)).

Repeat Exchange Transfusions

In general, the criteria for repeat exchange transfusions are similar to those used for the initial exchange.

Pharmacologic Treatment

Pharmacologic agents used in the management of hyperbilirubinemia can accelerate the normal metabolic pathways for bilirubin clearance, inhibit the enterohepatic circulation of bilirubin, and interfere with bilirubin formation by either blocking the degradation of heme or inhibiting hemolysis.

Acceleration of Normal Metabolic Pathways for Bilirubin Clearance

Phenobarbital

Phenobarbital is a potent inducer of microsomal enzymes that increases bilirubin conjugation and excretion and increases bile flow. When given in sufficient doses to the mother, the infant, or both, phenobarbital is effective in lowering serum bilirubin levels in the first week of life ([226,548](#)). However, concerns about long-term toxicity when given to pregnant women militate against its use for this purpose ([549,550](#)).

Decreasing Bilirubin Production by Inhibiting Heme Oxygenase

Tin Mesoporphyrin

As illustrated in [Fig. 35-1](#), the enzyme microsomal heme oxygenase is necessary for the conversion of heme to biliverdin, one of the first steps in the formation of bilirubin from hemoglobin. Certain synthetic metalloporphyrins are powerful competitive inhibitors of heme oxygenase and suppress the formation of bilirubin. The inhibition of heme degradation to bilirubin does not result in the accumulation of heme; the heme is excreted unchanged in the bile in quantities that compensate for the decreased excretion of bilirubin ([226](#)).

In a series of controlled clinical trials in Greece and Argentina, Kappas and colleagues demonstrated that tin mesoporphyrin (SnMP) is a potent inhibitor of heme oxygenase and is highly effective in reducing TSB levels and the requirements for phototherapy in term and preterm

neonates ([370,551,552](#)). They also showed that SnMP in a single dose of 6 $\mu\text{mol/}$

kg was more effective than special blue-light phototherapy in the treatment of term and near-term neonates with established hyperbilirubinemia ([551,552](#)). SnMP was equally effective in controlling hyperbilirubinemia in infants with G6PD deficiency ([553](#)); a U.S. trial of term and near-term infants showed similar results ([554](#)). The only side effect seen so far has been a transient, non-dose-dependent erythema that disappeared without sequelae in infants who received (white light) phototherapy after SnMP administration ([555](#)). SnMP has been used in the treatment of the Crigler-Najjar syndrome and has achieved a temporary reduction in TSB levels ([369,556](#)), and SnMP has prevented the need for exchange transfusion in Jehovah's Witness newborns with Rh hemolytic disease ([557](#)). Kappas reviewed the published controlled clinical trials performed with SnMP ([370](#)). Of 279 infants in the control groups, 129 (46%) received phototherapy versus 13 of 443 (3%) of the infants who received SnMP.

The idea of using an inhibitor of bilirubin production is very attractive. It requires no apparatus, infants do not need to be blindfolded, no hospitalization is required, and there is no separation of mother from infant. Phototherapy is a relatively cumbersome and slow method of lowering serum bilirubin levels, whereas SnMP prevents the production of bilirubin and is more efficient than phototherapy. To date, more than 500 newborns have received SnMP in controlled trials, but the drug is still awaiting FDA approval, although it can be obtained for compassionate use (Wellspring Pharmaceutical Corp, Neptune, NJ). If approved, SnMP could find immediate application in preventing the need for exchange transfusion in infants who are not responding to phototherapy ([557](#)).

Inhibiting the Enterohepatic Circulation of Bilirubin

A number of agents have been administered to infants in an attempt to interrupt the process of the enterohepatic absorption of bilirubin. These include charcoal, agar, and cholestyramine, but they have failed to produce clinically significant reductions in TSB ([226](#)). There is evidence that bilirubin in the neonatal gut may be bound to unabsorbed fat ([262](#)), and that impairing fat absorption could enhance fecal excretion of unconjugated bilirubin. The administration of orlistat, a substance that binds fat in the intestine, significantly reduced bilirubin levels in Gunn rats ([31](#)). To date, there have been no clinical trials of this intriguing concept in the human newborn.

Decreasing Bilirubin Production by Inhibiting Hemolysis

Intravenous Immunoglobulin

Controlled trials have confirmed that the administration of IVIg to infants with Rh hemolytic disease will significantly reduce the need for exchange transfusion ([469,558,559](#)). It also is likely that IVIg will help to mitigate the course of severe ABO hemolytic disease ([560](#)) and other isoimmune causes of hemolysis. The doses used have ranged from 500 mg/kg given over 2 hours soon after birth to 800 mg/kg given daily for 3 days. In Rh hemolytic disease, anti-D-coated erythrocytes are removed from the circulation through antibody-dependent lysis by cells of the reticuloendothelial system. The mechanism of action of IVIg is unknown, but it is possible that it might alter the course of Rh hemolytic disease by blocking Fc receptors, thereby inhibiting hemolysis. The risks of IVIg therapy are certainly lower than those of exchange transfusion.

Physiologic Role of Bilirubin

Despite its potential toxicity, bilirubin may have an important and positive physiologic role ([278,561](#)). Bilirubin is a powerful antioxidant *in vitro* ([278](#)) and there is a positive relationship between serum bilirubin levels and antioxidant activity in term and preterm infants ([562,563,564](#)). Bilirubin may have a physiologic role as an antioxidant in the human neonate ([279,564,565](#)). In sick neonates who have circulatory failure, asphyxia or sepsis, the rate of rise of TSB is less than in control infants ([279,565](#)) suggesting that bilirubin is consumed to cope with oxidative stress ([561](#)). Because of the possibility that oxidative injury might play a role in the development of retinopathy of prematurity, investigators have evaluated the relationship between bilirubin levels and retinopathy of prematurity ([181,181,566,567,568,569](#) and [570](#)). Of eight published studies, however, six show no protective effect of an elevated TSB level ([567,568,569,570,571,572](#)). In adults there is clear evidence that decreased TSB levels are associated with an increased risk of coronary artery disease and peripheral vascular disease ([561](#)), but we have yet to identify newborns who have suffered a bad outcome because they have too little bilirubin in their serum.

Acknowledgment

I thank Anthony McDonagh, PhD, for his critical review of portions of this chapter.

Chapter 36

Calcium and Magnesium Homeostasis

Winston W. K. Koo

Reginald C. Tsang

Calcium (Ca) is the most abundant mineral in the body and, together with phosphorus (P), forms the major inorganic constituent of bone. Magnesium (Mg) is the fourth most abundant cation and is the second most common intracellular electrolyte in the body. The maintenance of Ca and Mg homeostasis requires a complex interaction of hormonal and nonhormonal factors; adequate functioning of various body systems, particularly the renal, gastrointestinal, and skeletal systems; and adequate dietary intake. From a clinical perspective, mineral homeostasis is reflected in the maintenance of circulating concentrations of Ca and Mg in the normal range and integrity of the skeleton.

In the circulation, the amount of Ca and Mg is less than 1% of their respective total body content; however, disturbances in serum concentrations of these minerals are associated with disturbances of physiologic function manifested by numerous clinical symptoms and signs. Chronic and severely lowered serum concentrations of these minerals also may reflect the presence of a deficiency state.

At all ages, the total body content of Ca and Mg in the skeleton are about 99% and 60%, respectively. Thus, the skeleton is a reservoir for mineral homeostasis in addition to its role providing structural and mechanical support; disturbances in mineral homeostasis can result in osteopenia and rickets in infants and children, and osteomalacia and osteoporosis in adults.

The mechanisms to maintain mineral homeostasis in neonates are the same as for children and adults. However, the newborn infant has a number of unique challenges to maintain mineral homeostasis during adaptation to extrauterine life and to continue a rapid rate of growth. These include an abrupt discontinuation of the high rate of intrauterine accretion of Ca (approximately 120 mg/kg/day) and Mg (approximately 4 mg/kg/day) during the third trimester; a smaller skeletal reservoir available for mineral homeostasis; a delay in establishment of adequate nutrient intake for at least a few days or longer, particularly in sick and preterm infants; and a high requirement for Ca and Mg for the most rapid period of postnatal skeletal growth, with an average gain in length of more than 25 cm during the first year. There also may be diminished end-organ responsiveness to hormonal regulation of mineral homeostasis, although the functional capacity of the gut and kidney improves rapidly within days after birth. The effects of these issues are exaggerated in infants with heritable disorders of mineral metabolism, such as extracellular calcium-sensing receptor (CaR) mutations, and in infants who have experienced adverse antenatal events such as maternal diabetes, intrapartum problems such as perinatal asphyxia or maternal Mg therapy, or postnatal problems such as immature functioning of multiple organs from premature birth.

Increased understanding of the physiology and molecular basis of mineral metabolism allows a better understanding of the pathophysiology of the resultant clinical disorder. This

in turn allows a more rational management to minimize the adverse impact from disturbed mineral homeostasis and to prevent iatrogenic causes precipitating or prolonging these problems.

TISSUE DISTRIBUTION

In the fetus, about 80% of minerals are accrued between 25 weeks of gestation and term. During this period, the estimated daily accretion per kilogram of fetal body weight is 2.3 to 2.98 mmol (92 to 119 mg) Ca and 0.1 to 0.14 mmol (2.51 to 3.44 mg) Mg. The peak accretion rates occur at 36 to 38 weeks of gestation. In newborn term infants, the total body Ca and Mg contents average approximately 28 grams and 0.7 grams, respectively (1,2).

After birth, 99% of total body Ca is in bone. The tissue distribution of Mg varies according to the extent of bone mineralization and rate of soft tissue growth. Near the end of the third trimester, however, about 60% of the body's Mg is in bone, 20% in muscle, and most of the remainder is found in the intracellular space of other tissues.

CIRCULATING CONCENTRATION

Calcium

Serum Ca (1 mmol/L = 4 mg/dL) occurs in three forms: approximately 40% is bound, predominantly to albumin; approximately 10% is chelated and complexed to small molecules such as bicarbonate, phosphate, or citrate; and approximately 50% is ionized. Complexed and ionized Ca are ultrafiltrable.

Total Ca concentrations (tCa) in cord sera increase with increasing gestational age. Serum tCa may be as high as 3 mmol/L in cord blood of infants born at term, and the concentrations are significantly higher than paired maternal values at delivery (3,4,5,6). Serum tCa reaches a nadir during the first 2 days after birth (7,8,9,10,11,12,13); thereafter, concentrations increase and stabilize at a level generally above 2 mmol/L (14). In infants exclusively fed human milk, the mean serum tCa increases from 2.3 to 2.7 mmol/L over the first 6 months postnatally. Normally serum tCa in children and adults remains stable, with a diurnal range of less than 0.13 mmol/L. During the third trimester of pregnancy, a modest reduction in maternal serum tCa concentration (average 0.1 mmol/L) is associated with a decrease in serum albumin concentration.

Serum ionized Ca (iCa) concentration is the best indicator of physiologic blood Ca activity. Measurement of serum iCa is firmly established in clinical medicine, and simple, rapid, and direct determination of iCa from whole blood, plasma, and serum by ion-selective electrodes is freely available. Whole-blood iCa analyzers are gaining popularity because they are adaptable for "point of care" testing. However, some differences exist in values from different iCa analyzers, particularly for whole-blood iCa values (15), as a result of differences in the design of the reference electrode, formulation of calibrating solutions, and lack of a reference system for iCa. Thus, normative data should be generated according to the subject's age, the instrument, and the type of sample used for iCa

measurement.

Serum iCa decreases in the presence of high serum albumin, P, bicarbonate, and heparin. Serum iCa increases with increased Mg and is inversely related to blood pH. The effect of the latter may be minimized by the immediate analysis of serum samples for iCa. Freezing serum samples in 5% carbon dioxide-containing tubes may minimize the impact of pH variations if measurement of iCa is delayed for 1 week.

One report showed a wide range of cord whole-blood iCa of 0.4 to 1.85 mmol/L from apparently normal pregnancies (16). This is a much wider range compared with multiple reports based on cord sera, although the range for whole-blood iCa becomes much narrower within hours after birth and similar to serum iCa values. Cord-serum iCa increases with increasing gestational age and is higher than values in paired maternal sera. In healthy term neonates, serum iCa averages 1.25 mmol/L with 95% confidence limits of 1.1 to 1.4 mmol/L (4.4 to 5.6 mg/dL), and there is a decline in serum iCa in the first 48 hours of life with a nadir at 24 hours (17). Serum iCa generally changes in parallel with tCa in healthy humans. However, serum iCa is stable and normal during pregnancy in contrast to a slight reduction in tCa. Serum tCa and iCa are correlated in infants and adults, but the correlation is inadequate to predict one from the other with sufficient accuracy.

The concentration of iCa is critical to many important biologic functions with the extracellular Ca concentration normally maintained within a narrow range. The Ca ion is well established as an intracellular second messenger, but identification of the extracellular CaR has established that iCa also functions as a messenger outside cells. Ca homeostasis also involves the maintenance of an extremely large Ca concentration gradient across the cellular plasma membrane. In the cell, distribution of Ca is not uniform. The cytosolic compartment contains 50 to 150 nmol of Ca per liter of water; a larger intramitochondrial Ca pool contains 500 to 10,000 nmol of Ca per liter of cell water. In contrast, the concentration of iCa in extracellular fluid is 1 million nmol/L (1 mmol/L). There are at least two adenosine triphosphate-dependent mechanisms involved in the maintenance of the Ca concentration gradient across the plasma membrane. The measurement of intracellular Ca continues to improve with better instrumentation and probes, but it is not yet freely available.

Magnesium

Approximately 30% of serum Mg (1 mmol/L = 2.4 mg/dL) is in the protein-bound form, with the remainder in the ultrafiltrable portion. Seventy percent to 80% of ultrafiltrable Mg is in ionic form, and the remainder is complexed to anions, particularly phosphate, citrate, and oxalate. Cord-serum total Mg (tMg) is higher than paired maternal values. Serum tMg of 0.92 ± 0.13 mmol/L (mean ± 2 SD) in children is slightly higher than the adult values of 0.88 ± 0.13 mmol/L (18). Ion-selective electrodes are used in the measurement of ionized Mg (iMg) in whole blood and sera. iMg concentrations average 62% to 70% of the tMg concentration in cord and postnatal sera. Cord-serum iMg is also higher than that in maternal serum (19,20,21). The clinical role of iMg (versus tMg) in a number of disease states appears limited (22).

Cellular Mg content of most tissues is 6 to 9 mmol/kg wet weight, and most of this Mg is localized in membrane structures (e.g., microsome, mitochondria, plasma membrane). The much smaller pool of free Mg in the cell is maintained at about 1 mmol/L and is in an

exchanging equilibrium with membrane-bound Mg. Unbound intracellular Mg has a critical role in cellular physiology and catalyzes enzymatic processes concerned with the transfer, storage, and use of energy. Intracellular Mg usually remains stable despite wide fluctuations in serum Mg. In Mg-deficient states, however, the intracellular content of Mg can be low despite normal serum concentrations. The measurement of intracellular Mg continues to improve with better instrumentation and probes but is not freely available.

P.849

PHYSIOLOGIC CONTROL

Calcitropic hormones, including parathyroid hormone (PTH), 1,25 dihydroxyvitamin D [$1,25(\text{OH})_2\text{D}$], and possibly calcitonin (CT), appear to maintain Ca homeostasis by intermodulation of their physiologic effects on each other and on the classic target organs: kidney, intestine, and bone. Dietary intake of Ca, Mg, P, and other nutrients including sodium, glucose, and protein also may significantly contribute to the regulation of mineral homeostasis. PTH serves as the major component of the rapid response to hypocalcemia, whereas $1,25(\text{OH})_2\text{D}$, with its major effect on elevating intestinal absorption of Ca, is responsible for a slower but more sustained contribution to the maintenance of normocalcemia. CT, on the other hand, appears to function in the opposite role to PTH but with the capacity to stimulate the production of $1,25(\text{OH})_2\text{D}$, which in theory may serve an additional regulatory role in the maintenance of Ca homeostasis.

In contrast, the control of Mg homeostasis by calcitropic hormones under physiologic conditions appears to be limited. However, Mg is critical to the maintenance of Ca homeostasis since Mg regulates the production and secretion of PTH, acts as a cofactor for the 25-hydroxyvitamin D 1α hydroxylase enzyme in the production of $1,25(\text{OH})_2\text{D}$, and maintains adequate sensitivity of target tissues to PTH. Furthermore, Mg is considered a mimic/antagonist of Ca as it often functions synergistically with Ca, yet competes with it in the gut and kidney for transport and other metabolic pathways.

Parathyroid Hormone

In humans, parathyroid glands are derived from the third and fourth pharyngeal pouch. The PTH gene, along with the genes for insulin, β -globulin, and CT, is located on chromosome 11p15 (23), and restriction site polymorphisms near the PTH gene have been detected. The initial translational product of the mRNA is a 115-amino-acid prepro-PTH. Prepro-PTH then undergoes proteolytic cleavage in the endoplasmic reticulum to remove a 25-residue amino-terminal signal sequence to form pro-PTH. The prohormone-specific region is cleaved further during subsequent intracellular processing to generate the 84-amino-acid secreted form of the intact hormone with a relative molecular mass (M_r) of 9,500. PTH is synthesized by the chief cells and stored in secretory granules. It is collocated and secreted with chromogranin A, a protein that may act in autocrine- or paracrine-regulated release of PTH.

About 50% of the newly generated PTH is proteolytically degraded intracellularly, and some of the inactive fragments are also secreted. After release into the circulation, the intact PTH molecule has a serum half-life of 5 to 8 minutes and undergoes a series of

cleavages by endopeptidases in the liver and kidney. The amino-terminal fragments contain the biologically active fractions, with the 1-34 fragment having the most calcemic activity; modifications at the amino terminal, particularly at the first two residues, can abolish its biologic activity. The midregion and carboxyl-terminal fragments are biologically inert, although the latter may have some *in vitro* biological activity.

Circulating immunoreactive PTH is a complex mixture of intact 1-84 PTH, multiple peptide fragments from the amino- and carboxyl-terminals, and mid-molecular regions. Normally there are greater amounts of middle and carboxyl fragments than intact hormone in the circulation because of metabolic breakdown of the short-lived, intact hormone, coupled with glandular secretion of inactive fragments. The fragments are cleared from the blood virtually exclusively by glomerular filtration. Intact PTH and amino-terminal fragments constitute less than 20% of PTH immunoreactivity in the peripheral circulation. PTH molecules reactive in the widely used commercial immunoradiometric assays (IRMA), designed to detect both amino- and carboxyl-terminal epitopes of the peptide, have been considered as "intact" PTH (IPTH). However, there have been reports that the large 7-84 fragment of PTH is also detected by these assays. This large fragment is biologically inactive and present in greater concentrations in uremic states or hyperparathyroidism. The conventional IPTH technique increases the PTH concentration by 30% to 50%, compared to the latest chemiluminescence or IRMA techniques that measure the "whole" or "bio-intact" PTH. Therefore, the treatment of secondary hyperparathyroidism based on data from conventional IPTH assays theoretically may lead to overtreatment and oversuppression of biologically active PTH, although the clinical significance of this possibility remains to be defined. In any case, consistency of the PTH assay methodology and serial measurements are critical to the interpretation and management of pathologic states.

PTH concentrations in cord blood frequently are low and do not correlate with PTH concentrations in maternal sera (4,24). Earlier studies of higher levels of bioactive PTH in cord sera from cytochemical assays may be related to elevated concentrations of parathyroid hormone-related protein (PTHrP), since PTH-like bioactivity was tightly correlated with levels of PTHrP in sheep and pig. Small amounts (approximately 5%) of perfused fragments (35-84, 44-68, and 65-84 amino acids) but probably not the whole PTH molecule are reported to cross the human placenta. Serum PTH concentrations increase postnatally coincidentally with the fall in serum Ca in both term and preterm infants (4,24-27). The rise in serum IPTH is greater for preterm infants with hypocalcemia compared to term infants reflecting appropriate PTH response. Serum PTH concentrations are similar for children and adults but are increased in the elderly. Serum concentrations of intact PTH as measured by IRMA showed no change during normal pregnancy. In adults, serum intact PTH is present in picomolar concentrations. It has a significant circadian periodicity, spontaneous episodic pulsatility with distinct peak property and a significant temporal coupling with serum iCa and P concentrations and prolactin secretion.

PTH effects on end-organ systems appear to be mediated through its binding to specific receptors. The type 1 PTH/PTHrP receptor has been identified in bone, cartilage, kidney, intestine, aorta, urinary bladder, adrenal gland, brain, and skeletal muscle. It binds equally to PTH and PTHrP and belongs to a superfamily of guanine-nucleotide-binding (G) protein-coupled cell membrane receptors (GPCR) including those for CT, secretin, growth hormone-

releasing hormone, corticotrophin-releasing hormone, glucagon, vasoactive intestinal polypeptide, and others. Another PTH receptor (type 2) responds only to PTH, although its main endogenous ligand appears to be a 39-amino-acid peptide, hypothalamic tubular infundibular peptide. It has been found in the brain, pancreas, and intestines, but the physiologic significance of this receptor remains ill defined.

The gene for the PTH/PTHrP receptor is located on chromosome 3p21.1-p24.2. It contains 17 exons and encodes a mature glycoprotein of 593 amino acids (28). The type 1 PTH receptor consists of extended extracellular, ligand-binding amino-terminal and intracellular G-protein-associated carboxyl-terminal domains and seven transmembrane domains. Signal transduction mediated by G proteins results in multiple second messenger pathways to affect both stimulatory and inhibitory end-organ responses. The strongest and best-characterized second messenger signaling pathway is the PTH-stimulated coupling of the type 1 PTH receptor to the stimulating G protein (G_s ; composed of 3 subunits: α , β , and γ , and encoded by the *GNAS1* gene localized to 20q13.3), which activates adenylyl cyclase, an enzyme that generates cyclic AMP (cAMP). However, coupling of the type 1 PTH receptor to the G_q class protein activates phospholipase C, which generates inositol phosphate (IP_3) and diacylglycerol (DAG). These second messengers in turn lead to stimulation of protein kinases A and C and Ca transport channels and result in a variety of hormone-specific tissue responses.

In physiologic terms, PTH acts synergistically with $1,25(OH)_2D$ and is the most important regulator of extracellular Ca concentration. PTH acts directly on bone and kidney, and indirectly on intestine. Immediate control of blood Ca is probably due to PTH-induced mobilization of Ca from bone and increased renal distal tubular reabsorption of Ca. PTH also decreases proximal tubular and thick ascending limb reabsorption of sodium, Ca, phosphate, and bicarbonate. PTH effects on kidney are mediated primarily through stimulation of sodium/calcium exchange, calcium transport proteins and renal 25 OHD- 1α -hydroxylase, but a decrease in sodium-dependent phosphate cotransporter, NPT-2. Maintenance of steady-state Ca balance is probably from increased intestinal Ca absorption secondary to increased $1,25(OH)_2D$ production. PTH increases acutely within minutes the rate of Ca release from bone into blood. Chronic effects of PTH are to increase the numbers of osteoblasts and osteoclasts and to increase the remodeling of bone. Continuous exposure to elevated concentrations of PTH leads to increased osteoclastic resorption of bone. In contrast to its classic action on Ca mobilization from bone, the amino-terminal fragments of PTH and PTHrP, and small pulses of PTH have an anabolic effect on bone, independent of its resorptive action. Other PTH effects on bone include enhanced collagen synthesis, activities of alkaline phosphatase, ornithine and citrate decarboxylases, and glucose-6-phosphate dehydrogenase; DNA, protein and phospholipid synthesis.

Extracellular Ca is the most potent regulator of PTH secretion and is mediated by the cell-surface CaR, which detects minute perturbations in the extracellular iCa concentration and responds with alterations in cellular function that normalize iCa . Thus, iCa functions as extracellular as well as intracellular messenger. The human CaR gene is located on chromosome 3q13.3-q21 and encodes a cell-surface protein of 1,078 amino acids. The CaR gene is developmentally upregulated, and CaR transcripts are present in numerous tissues including chief cells of the parathyroid glands, kidneys (in particular the thick ascending limb), brain and nerve terminals, breast, lung, intestine, adrenal and skin, and also the

precursor and mature osteoblasts and osteoclasts. CaR is a member of the GPCR superfamily with a seven-member membrane-spanning domain. It contains at least seven exons, of which six encode the large (approximately 600-amino-acid) amino-terminal extracellular domain and/or its upstream untranslated regions, while a single exon codes for the remainder of the receptor including a cytoplasmic carboxyl-terminal intracellular domain. Signal transduction mediated by G proteins results in activation of phospholipase C that generates IP₃ and DAG, and subsequent stimulation of protein kinase C (PKC) and Ca transport channels.

Low or falling serum Ca concentrations result in active secretion of preformed PTH within seconds. There is a sigmoidal type of PTH secretion in response to decreased serum Ca, which is most pronounced when serum Ca is in the mildly hypocalcemic range. PTH secretion is 50% of maximal at a serum iCa of about 1 mmol/L (4 mg/dL); this is considered the calcium set point for PTH secretion (29). Sustained hypocalcemia increases PTH mRNA within hours. Protracted hypocalcemia leads within days to cellular replication and increased gland mass. High serum Ca suppresses PTH secretion via activation of CaR. It in turn activates phospholipase C and generation of IP₃ and DAG and probably increases the proteolytic destruction of preformed PTH. Hyperphosphatemia stimulates PTH secretion, probably by lowering the serum Ca concentration.

In the kidney, CaR decreases the basal and PTH-stimulated paracellular reabsorption of Ca, Mg, and sodium via multiple mechanisms including inhibition of cAMP accumulation; stimulation of phospholipase A2 activity. The release of free arachidonic acid is promoted which is metabolized via the lipoxygenase pathway to P450 metabolites that inhibit the activities of the sodium-potassium-chloride cotransporter and potassium channel; and possibly affect renal water regulation by inhibition of vasopressin-abated water flow. In chronic renal failure, downregulation in the

P.851

expression of renal CaR may account for the development of secondary hyperparathyroidism (30), and downregulation of PTH receptors may account for the skeletal resistance to the calcemic effect of PTH (31). Extracellular Ca exerts numerous other actions on parathyroid function, including modulation of the intracellular degradation of PTH, cellular respiration, membrane voltage, and the hexose monophosphate shunt.

Maintenance of Ca homeostasis through other organs also may be possible, for example, through the presence of CaR in intestinal cells (32), and probable modulation of CT secretion from changes in intracellular Ca (33). Furthermore, expression of CaR in gastrin-secreting G cells and acid-secreting parietal cells, together with data indicating that CaR exhibits selectivity for L-aromatic amino acids, appears to provide a molecular explanation for amino acid sensing in the gastrointestinal tract, regulation of PTH secretion and urinary Ca excretion, and the physiologic interaction between Ca and protein metabolism.

Decrease in serum Mg concentration stimulates PTH secretion (34,35), although chronic hypomagnesemia inhibits secretion of PTH (34,36). Hypomagnesemia is also associated with an increased target tissue resistance to PTH probably from inactivity of adenylate cyclase, a Mg-requiring enzyme. Hypermagnesemia rapidly decreases the secretion of PTH *in vivo* in human subjects, and PTH concentration remains depressed despite concomitant hypocalcemia, presumably in part due to stimulation of CaR by other divalent cations such as Mg. Vitamin D and its metabolites, 25-hydroxyvitamin D (25-OHD) and 1,25(OH)

$1,25$ (OH) $_2$ D, acting through vitamin D receptors, decrease the level of PTH mRNA. Additional systemic factors (growth hormone, insulin-like growth factor 1, estrogen, progesterone, CT, cortisol, catecholamines, prostaglandins, and somatostatin) and local factors (interleukin-1 [IL-1]) modulate PTH secretion and function, although their role in the regulation of Ca and Mg metabolism under physiologic conditions is not clear.

Calcitonin

CT is secreted primarily from thyroid C cells and also from many extrathyroidal tissues including placenta, brain, pituitary, mammary gland, and other tissues. Developmentally, CT-containing cells and parathyroid gland cells are thought to derive from the same tissue source as the neural crest. In the rat, the number of thyroid C cells and secretion of CT increase from fetal life to suckling, a period of rapid growth (37). There is probably no placental crossover of CT; the human placental tissue is able to produce CT in response to the presence of Ca in the culture medium. In human neonates, the CT content in crude tissue preparations of thyroid is larger than that of the adult thyroid (38).

There are two calcitonin genes, α and β , located on chromosome 11p15.2 near the genes for β -globulin and PTH. Two different RNA molecules are transcribed from the α gene. It is comprised of six exons with the fourth exon translated into the precursor for CT and the fifth translated into the precursor for CT gene-related peptide-I (CGRP-I). The initial translational product of the mRNA is prepro-CT, a 141-amino-acid peptide. It is cleaved by endopeptidase at the endoplasmic reticulum to form pro-CT, a 13-kDa 116-amino-acid peptide. CT (between the sixtieth and ninety-first positions of the pro-CT peptide) and equimolar amounts of non-CT secretory peptides, corresponding to the flanking peptides linked to the amino and carboxyl terminals of the prohormone, are generated during precursor processing. Further structural modifications to the CT molecule occur intracellularly prior to release into the circulation. These modifications include formation of a disulfide bridge between two cysteine remnants in position 1 and 7, and hydroxylation of the C-terminal proline residue; both are essential for binding of CT to its receptor. The CT monomer is a 32-amino-acid peptide (M_r 3,400). CGRP-I is synthesized wherever the CT mRNA is expressed, e.g., in medullary carcinoma of thyroid, although there is no translational product from the CGRP-I sequence.

The β or CGRP-II gene is transcribed into the mRNA for CGRP predominantly in nerve fibers in the central and peripheral nervous systems, blood vessels, thyroid and parathyroid glands, liver, spleen, heart, lung, and possibly bone marrow. CGRP, a 37-amino-acid peptide (M_r 4,000), is also generated from the larger precursor molecule pro-CGRP, a 103-amino-acid peptide. Seventy-five amino-terminal residues of the preprohormones for CT and CGRP are predicted to be identical.

Classic bioactivity of human CT (hCT) is present in the full 32-amino-acid structure or its smaller fragments, such as hCT 8-32 and hCT 9-32; the ring structure of CT enhances, but is not essential for, hormone action. Basic amino acid substitutions confer a helical structure in this region as found in salmon and other nonmammalian CT, resulting in greater potency in lowering serum Ca and probably a longer circulating half life. The kidney appears to be the dominant organ in the metabolism of human CT. A small percentage of the metabolic clearance rate of CT in humans may be accounted for by enzymatic degradation in blood. Injected hCT monomer disappears from the blood *in vivo* with a half-

life of approximately 10 minutes; in contrast, the half-life of hCT in plasma incubated *in vitro* at 37°C may be longer than 20 hours (39). Depending on the animal species, other sites such as the liver, intestine, and bone may be involved in the metabolism of CT.

Circulating immunoreactive CT and CGRP are a heterogeneous mixture of different molecular forms and are recognized as long as the antigenic epitopes recognized by the antiserum are expressed. Immunoreactive CT or CGRP concentration is expressed in gravimetric or molar equivalents of synthetic CT or CGRP. Sample preparation with initial extraction, gel chromatography, and high-performance liquid chromatography separation, and the use of two-site immunoassay can improve the sensitivity and specificity of CT measurements. Serum CT concentrations during pregnancy are variable. They are high at birth compared to paired maternal CT concentrations (40).

P.852

Serum CT further increases during the first few days after birth and may reach levels five- to ten-fold higher than adult CT concentrations. Serum CT concentrations decrease progressively during infancy; however, in preterm infants up to 3 months after birth, the mean serum CT concentrations may remain twice the adult value. There is also a small peak of serum CT concentration during late childhood. In human adults, the basal serum CT concentration may be lower in women than in men, but the concentration is not affected by increasing age. The CT secretory response to Ca infusion is lower in women and with increasing age. In human adults, serum CT and CGRP concentrations are found in the picomolar range. Diurnal variability has been reported for serum CGRP but not for serum CT. In normal individuals, larger precursor molecules of CT such as procalcitonin are not detected.

CT function is mediated by binding to receptors linked to G proteins, members of the GPCR superfamily, and by activation of adenylate cyclase and phospholipase C (41). CT receptors (CTR) have been identified in the central nervous system, testes, skeletal muscle, lymphocytes, and placenta. The function of CTR can be influenced by accessory proteins, receptor isoforms, genetic polymorphisms, developmental and/or transcriptional regulation, feedback inhibition, and the specific cellular or tissue background. The CTR gene is located on chromosome 7q21.2-q21.3 and encodes a 490-amino-acid G-protein-linked receptor with seven transmembrane domains. Two isoforms of human CTR arise by alternative splicing of an exon of 48 nucleotides that encodes a 16-amino-acid insertion within the first intracellular loop. The isoform with the insertion (hCTR-1) activates only adenylate cyclase, whereas the other isoform (hCTR-2) activates both adenylate cyclase and phospholipase C. CGRP functions are also mediated by receptors (42).

The presence of receptor-activity-modifying proteins (RAMPs) can posttranslationally modify the initially orphan calcitonin receptor-like (CL) receptor and CTR to exhibit different receptor functions, i.e., functional modification of G-protein-coupled receptors is possible. RAMP1, 2, and 3 thus far identified are single transmembrane domain proteins with intracellular C-terminals of up to 10 amino acids and extracellular N-terminals of about 120 amino acids. Noncovalent association of a RAMP with the CL receptor or CTR results in heterodimeric RAMP/receptor complexes at the cell surface. The CL receptor functions as a CGRP receptor when coexpressed with RAMP1, whereas CL receptor/RAMP2 and CL receptor/RAMP3 are adrenomedullin 1 and 2 receptor subtypes, respectively. CTR, with 60% homology to the CL receptor, predominantly recognizes CT in the absence of RAMP. When CTR is coexpressed with RAMP1, it transforms into an amylin/ CGRP receptor.

When CTR is coexpressed with RAMP3, it interacts only with amylin. Thus, two class II G-protein-coupled receptors, the CL receptor and CTR, are associated with three RAMPs to form high-affinity receptors for CGRP, adrenomedullin, or amylin.

Secretion of CT is stimulated by an increase in serum Ca and Mg concentrations and by gastrin, glucagon, and cholecystokinin (along with several other structural analogues of these hormones, e.g., pentagastrin, prostaglandin E₂), glucocorticoid, norepinephrine, and CGRP; secretion is suppressed by hypocalcemia, propranolol and other adrenergic antagonists, somatostatin, chromogranin A and vitamin D. CT gene transcription is positively regulated by glucocorticoids and negatively regulated by PKC, Ca, and vitamin D. Calcitonin may activate the 1-hydroxylase system independent of PTH (43), whereas 1,25(OH)₂D decreases CT gene expression in adult rats but is ineffective in 13-day-old suckling rats (44). The latter observation may be related to fewer 1,25(OH)₂D receptors in C cells of immature rats. Calcitonin induces refractoriness to its own actions by downregulation, and functional reduction of receptor mRNA is a well-known phenomenon. Clinically, it is manifested as the "escape" phenomenon during therapy with calcitonin.

In humans, changes in Ca (and P) metabolism are not seen despite extreme variations in CT production. In the neonate, there is neither an identifiable hypocalcemic response to the postnatal surge in serum CT nor a blunting of CT secretion in the presence of hypocalcemia. In adults, there are no definite effects attributable to CT deficiency (e.g., totally thyroidectomized patients receiving only replacement thyroxine) or CT excess (e.g., patients with medullary carcinoma of thyroid), except for the chronic suppression of bone remodeling. The clinical significance of CT is related to its use as a tumor marker in the management of medullary carcinoma of the thyroid and its pharmacologic effect to inhibit osteoclast-mediated bone resorption and increase renal Ca clearance. The pharmacologic activities of CT are useful for the suppression of bone resorption in Paget disease, for limited use in the treatment of osteoporosis, and for early phase treatment of severe hypercalcemia. In addition, CT also increases renal clearance of Mg, P, and sodium and free water clearance. The net effect of CT is a lowering of serum Ca and P concentrations. Thus, the bioactivity of CT on calcium metabolism frequently is opposite that of PTH; CT probably modulates the effect of PTH on target organs.

Noncalcium-related actions of CT and associated molecules are increasingly being discovered. For example, CT and CTR may play important roles in a variety of processes as wide ranging as embryonic development and sperm function/physiology. In addition, pro-CT detectable in the plasma is not produced in the C cells of the thyroid and is being explored as a marker of bacterial-induced inflammation/sepsis. Production of pro-CT after exposure to bacterial endotoxin and inflammatory cytokines tumor necrosis factor (TNF) and IL-6 appears to be primarily from neuroendocrine cells in the lung and intestine. Cells of neuroendocrine origin express all proteins related to CT (CGRP-I and -II and amylin) derived from the same family of genes, and it is speculated that "inflammatory" pro-CT may be coded by the same gene family. There are no enzymes in the plasma that can break down pro-CT, and when it is secreted into the circulation, it has a half-life of 25 to 30 hours, thus increasing serum pro-CT. After

administration of endotoxin, the peak circulating concentrations of TNF, IL-6, pro-CT, and C-reactive protein occur at approximately 90 minutes, 180 minutes, 6 to 8 hours, and 24

hours, respectively.

CGRP primarily affects catecholamine release, vascular tone and blood pressure, and cardiac contractility. Its clinical role probably also lies in its potential pharmacologic effect. The influence of CGRP on Ca and P homeostasis is minor compared to that of CT. However, amylin, a pancreatic islet-derived or synthetic 37-amino-acid peptide, is a member of the CGRP family with a potent hypocalcemic effect despite sharing only 15% of its amino acid sequence with human CT. The hypocalcemic effect of amylin is probably mediated by the CTR on osteoclasts, and it is 100-fold more potent than CGRP (45). Both CT and CGRP inhibit gastric acid secretion and food intake.

Vitamin D

Vitamin D (M_r 384) can be obtained from diet or synthesized endogenously. It must undergo several metabolic transformations primarily in the liver and kidney to form the physiologically most important metabolite, $1,25(\text{OH})_2\text{D}$, which functions as a hormone in the maintenance of mineral homeostasis. Under *in vivo* conditions, there are more than 30 other vitamin D metabolites, with and without putative functions.

Dietary vitamin D ($1\ \mu\text{g} = 40\ \text{IU}$) is derived from plants as ergocalciferol (vitamin D_2) and from animals as cholecalciferol (vitamin D_3). Dietary vitamin D is absorbed from the duodenum and jejunum into lymphatics, and about 50% of the vitamin D in chylomicron is transferred to vitamin D-binding protein (DBP) in blood before uptake by the liver.

In animals, vitamin D_3 can be synthesized endogenously in the skin (46). During exposure to sunlight, the high-energy UV photons (290 to 315 nm) penetrate the epidermis and photochemically cleave the bond between carbons 9 and 10 of the sterol B-ring of 7-dehydrocholesterol (7-DHC or provitamin D_3) to produce previtamin D_3 . It then undergoes a thermally induced isomerization to vitamin D_3 that takes 2 to 3 days to reach completion. Thus, cutaneous synthesis of vitamin D_3 continues for many hours after a single sun exposure. Previtamin D_3 is photolabile; continued exposure to sunlight causes the isomerization of previtamin D_3 to biologically inert products, principally lumisterol. No more than 10% to 20% of the initial provitamin D_3 concentrations ultimately end up as previtamin D_3 , thus preventing excessive production of previtamin D_3 and vitamin D_3 .

Vitamin D_3 synthesis in the skin is directly dependent on the amount of sunlight exposure and is affected by time of day, season, and latitude. Peak sunlight at midday, in summer, and at lower latitudes are optimal conditions; the amount of skin area exposed and duration of sunlight exposure directly affect vitamin D_3 synthesis. Melanin in the skin competes with 7-DHC for ultraviolet photons, but the production of vitamin D_3 can be adjusted by increasing the duration of sunlight exposure. Use of topical sunscreen blocks ultraviolet photons, and aging decreases the capacity for cutaneous synthesis of vitamin D_3 .

The term "vitamin D" is frequently used generically to describe vitamins D_2 and D_3 and their metabolites. In mammals, vitamins D_2 and D_3 appear to metabolize along the same

pathway, and there is little functional difference between their metabolites. However, differences in affinity to DBP and receptors between D₂ and D₃ and their metabolites support the contention that vitamin D₃ is more bioavailable than D₂.

In the circulation, vitamin D and its metabolites are bound to proteins, mainly DBP (approximately 85%) and albumin (approximately 15%). The DBP gene is located on chromosome 4q11-13. It is a member of the albumin multigene family of proteins that includes albumin and α -fetoprotein. DBP is an approximately 53-kDa globulin in humans, and its x-ray crystallographic structure has been determined (47). Plasma DBP concentration (4 to 8 μ M) is approximately 20-fold higher than that of the total circulating vitamin D metabolites (approximately 100 nM), i.e., it is normally less than 5% saturated with vitamin D metabolite. The amount of unbound or free 25-OHD and 1,25(OH)₂D, important in determining bioactivity, is less than 1% of the total concentration.

In the liver, vitamin D is hydroxylated at carbon 25 to 25-OHD. Quantitatively, 25-OHD (1 nmol/L = 0.4 ng/mL) is the most abundant vitamin D metabolite in the circulation and is a useful index of vitamin D reserve. Regulation of 25-hydroxylase activity is limited, and there are few limitations to the production of 25-OHD. However, *in vivo* administration of 1,25(OH)₂D (48) inhibits hepatic production of 25-OHD, and Ca deficiency (49) increase the metabolic clearance of 25-OHD with subsequently decrease circulating 25-OHD.

In the kidney, 25-OHD is hydroxylated further to 1,25(OH)₂D by 25-OHD-1 α -hydroxylase (CYP1 α), and to 24,25-dihydroxyvitamin D (24,25(OH)₂D) by 25-OHD-24-hydroxylase (CYP24). The hydroxylation occurs primarily in the mitochondria of renal proximal tubules. The genes for these enzymes have been localized to chromosome 12q13-14 and 20q13.3, respectively. The human gene encoding CYP1 α is 5 kb in length and is comprised of nine exons and eight introns; its exon/intron organization is similar to other cloned mitochondrial P450 enzymes.

The activity of CYP1 α and therefore production of 1,25(OH)₂D are tightly regulated. It is the rate-limiting hormonally regulated step in the bioactivation of vitamin D. PTH increases transcriptional activity of the CYP1 α gene promoter and therefore increases mRNA for 1,25(OH)₂D. Decreases in serum or dietary Ca or P increase mRNA for and serum concentration of 1,25(OH)₂D independent of PTH (49,50,51). However, hypophosphatemia in renal wasting disorders does not elicit appropriate phosphate conservation or an increase in 1,25(OH)₂D production. These disorders include X-linked hypophosphatemic rickets (XLH), autosomal-dominant hypophosphatemic rickets (ADHR), and tumor-induced osteomalacia. They have

P.854

similar phenotypic manifestations characterized by hypophosphatemia, decreased renal phosphate reabsorption, normal (and thus inappropriately low) or low serum calcitriol concentrations, normal serum Ca and PTH, and defective skeletal mineralization.

XLH results from mutations in the PHEX (phosphate-regulating gene with homologies to endopeptidases on the X chromosome, Xp22.1) gene, which encodes a membrane-bound endopeptidase (52), whereas ADHR is associated with mutations of the gene encoding fibroblast growth factor 23 (FGF23) and is linked to chromosome 12p13.3 (53). The latter

is a small heat-sensitive molecule less than 25 kDa that inhibits sodium-dependent phosphate wasting and probably inhibits CYP1 α . The endopeptidase, PHEX, degrades native FGF23 which provides the biochemical link among these clinical syndromes. XLH rickets also has been associated with mutations in CLCN5, a voltage-gated chloride channel gene located on Xp11.22.

Other factors that enhance 1,25(OH)₂D production include estrogen, prolactin, growth hormone, insulin-like growth factor I, and PTHrP. 1,25(OH)₂D production is feedback regulated and is inhibited by chronic deficiency of or low circulating Mg (36). Mg deficiency also lowers serum 1,25(OH)₂D response to a low-Ca diet but does not appear to limit 1,25(OH)₂D production in animals (54). The effect of Mg on 1,25(OH)₂D metabolism is presumably related in part to its role as a cofactor of the CYP1 α enzyme. In contrast to the rapid increase within minutes in the secretion and serum concentration of PTH, measurable alterations in serum 1,25(OH)₂D concentrations usually occur hours after exposure to an appropriate stimulus. Extrarenal production of 1,25(OH)₂D in macrophages, particularly in granulomatous disease states, may not be tightly regulated; is stimulated by γ -interferon (55), but is not responsive to changes in dietary Ca intake.

The degradation of 1,25(OH)₂D is also tightly regulated. 1,25(OH)₂D strongly induces the enzyme 25-hydroxyvitamin D-24 hydroxylase (CYP24) in all target cells for vitamin D. CYP24 catalyzes several steps of 1,25(OH)₂D degradation, collectively known as the C24 oxidation pathway, which starts with 24-hydroxylation and culminates in the formation of the biliary excretory form, calcitroic acid. CYP24 expression is inhibited by PTH and by dietary phosphate restriction. In the kidney and intestine in particular, upregulation of the CYP24 enzyme in response to 1,25(OH)₂D treatment is rapid and occurs within 4 hours (56). Physiologic production of 24,25(OH)₂D is therefore an important means to regulate the circulating concentration of 1,25(OH)₂D and catabolism of vitamin D, although it may also have a role in bone integrity and fracture healing in the chick model. Most of the other vitamin D metabolites are derived primarily from further metabolic alterations to 25-OHD and 1,25(OH)₂D through oxidation or side chain cleavage and have poorly defined physiologic functions. However, many analogues of vitamin D metabolites are being studied for the numerous potential pharmacologic actions that involve less calcemic-inducing and more maturation and differentiation effects.

Like other steroid hormones, 1,25(OH)₂D function is mediated primarily through modulation of the cellular genome by binding to a specific nuclear receptors, vitamin D receptor, VDR, a 424-amino-acid phosphoprotein for which the x-ray crystallographic structure has been determined (47). The VDR gene contains nine exons and is located on chromosome 12q13-14 near the site of the gene for CYP1 α (57). VDR is a member of the subfamily of nuclear receptors with ligand-binding domains that bind classic hormones including thyroid hormone, androgens, estrogens, progesterone, glucocorticoids, aldosterone, hormonal forms of vitamin A, and 1,25(OH)₂D. It has several functional domains including a 110-residue N-terminal DNA-binding domain with two zinc fingers, C-terminal hormone-binding domain, and hinge region important for nuclear localization. The VDR interacts with the 9-*cis* retinoic acid nuclear receptor retinoid X receptor (RXR) to form

a heterodimeric RXR-VDR complex that binds to specific DNA sequences, termed vitamin D-responsive elements (VDREs). After $1,25(\text{OH})_2\text{D}$ binds to the receptor, it induces conformational changes (58) that result in the recruitment of a multitude of transcriptional coactivators that stimulate the transcription of target genes. VDR also can adopt a dual role as a repressor in the absence of ligand and then subsequently as a coactivator when a ligand binds. VDR is upregulated by $1,25(\text{OH})_2\text{D}$ at both the mRNA and protein levels and is increased during growth, gestation, and lactation; however, it shows an age-dependent decrease in mature animals and humans, supporting the notion that VDR may be up- or downregulated, depending on Ca needs.

Although $1,25(\text{OH})_2\text{D}$ regulates more than 60 genes whose actions include those associated with Ca homeostasis and immune responses, as well as cellular growth, differentiation, and apoptosis, two basic clinical functions define the major classic actions of vitamin D. The first is that vitamin D is required to prevent rickets in children and osteomalacia in adults. The second is the prevention of hypocalcemic tetany. These functions are maintained by $1,25(\text{OH})_2\text{D}$ through its effect on a number of target tissues, primarily intestine, kidney, and bone, with modulating effects from other hormones including PTH and CT.

The genomic action of $1,25(\text{OH})_2\text{D}$ can be preceded by more rapid nongenomic actions that occur in minutes and involve membrane-associated events such as increased Ca transport, and PKC and mitogen-activated protein kinase activation. This nongenomic rapid increase in cytosolic Ca within seconds to minutes is reported to occur in various cell types from the intestine and parathyroid, osteoblasts, myocytes, and leukemic cells (59).

Quantification of vitamin D and its metabolites has been achieved by several different methods, including high-performance liquid chromatography, with detection by ultraviolet absorbance or binding assays, and immunoassays based on antibodies raised to vitamin D metabolite conjugates. Values from different laboratories cannot be compared without making direct comparison of their assay procedures. Interlaboratory coefficients of variation for the

P.855

measurement of 25-OHD, $24,25(\text{OH})_2\text{D}$, and $1,25(\text{OH})_2\text{D}$ may range between 35% and 52%. Furthermore, differences between the affinities of vitamins D_2 and D_3 to DBP and VDR, and different chromatographic behavior on various preparative chromatographic systems demand that great care be taken with assay techniques when dealing with patients who have significant vitamin D_2 intake. To ensure reliable results, appropriate vitamin D standards must be used for standard curve generation in performing competitive protein binding assays of these compounds.

Maternofetal transfer of vitamin D and its metabolites varies, depending on the species. In humans, the cord-serum vitamin D concentration is very low and may be undetectable; the 25-OHD concentration is directly correlated with, but is lower than, maternal values, consistent with placental crossover of this metabolite; and $1,25(\text{OH})_2\text{D}$ concentrations also are lower than maternal values, but there is no agreement on the maternofetal relationship of this and other dihydroxylated vitamin D metabolites (3,60-62). However, the placenta,

like the kidney, produces $1,25(\text{OH})_2\text{D}$, making it difficult to ascertain just how much fetal $1,25(\text{OH})_2\text{D}$ results from placental crossover versus placental synthesis. $24,25(\text{OH})_2\text{D}$ also crosses the placenta, and its concentration in the sera of mothers and newborns varies with the seasons, being highest in autumn. It appears that the human fetus receives the bulk of its vitamin D already metabolized to 25-OHD.

Seasonal and racial variations in serum 25-OHD concentrations occur, presumably from variations in endogenous production. The concentration of serum 25-OHD, as with $24,25(\text{OH})_2\text{D}$, is lower in winter. These changes may be reflected in cord-serum values. In normal adults, serum $1,25(\text{OH})_2\text{D}$ concentrations are relatively constant and maintained within approximately 20% of the overall 24-hour mean, and show no seasonal variation, which is consistent with the tightly regulated $\text{CYP}1\alpha$ activity. African American mothers, infants, and young children tend to have lower 25-OHD and higher $1,25(\text{OH})_2\text{D}$ concentrations than their white counterparts. Serum $1,25(\text{OH})_2\text{D}$ in the newborn becomes elevated within 24 hours after delivery and appears to vary with to Ca and P intake.

The circulating half-life of vitamin D is about 24 hours and for 25-OHD is 2 to 3 weeks, although the latter half-life is decreased in vitamin D-deficient individuals. $1,25(\text{OH})_2\text{D}$ has a much shorter half-life of 3 to 6 hours. Metabolites of 25-OHD and $1,25(\text{OH})_2\text{D}$ may undergo enterohepatic circulation after exposure to intestinal β -glucuronidase. The physiologic role of enterohepatic circulation of vitamin D metabolites has not been precisely quantitated.

NONCLASSIC CONTROL OF CALCIUM AND MAGNESIUM HOMEOSTASIS

Factors other than the classic calciotropic hormones, PTH, CT, and $1,25(\text{OH})_2\text{D}$, whether acting systemically or locally on multiple effector organs, are increasingly being recognized as important to the maintenance of mineral homeostasis in certain circumstances. The ultimate effect on mineral homeostasis often involves bone formation and/or resorption and flux of Ca and Mg between extracellular fluid and bone, with or without direct involvement by calciotropic hormones. Skeletal health, particularly in the growing skeleton, requires the integrated actions of classic calciotropic hormones, endocrine modulators of growth, numerous cytokines and growth factors and their receptors and endogenous modulators.

Many factors, such as growth hormone, insulin-like growth factor I, estrogen, progesterone, cortisol, and TNF, can affect the secretion or function of one or more of the calciotropic hormones. In turn, many factors such as insulin-like growth factor I; transforming growth factor- β_1 ; IL-1, -2, -4, and -6; TNF- α , and interferon- γ (IFN- γ) can be modulated by calciotropic hormones.

Local factors such as transforming growth factor- β_1 , lymphotoxin, TNF- α , IFN- γ , IL-1, and IL-6 acting in a paracrine (i.e., cell-to-cell) or autocrine (i.e., cell-to-self) fashion may influence Ca flux of bone cells. The effects on Ca flux based on these interactions are probably more important under pathologic situations. IFN- γ from activated macrophages

(55,63) stimulates CYP1 α mRNA and enzyme production, with little or no feedback inhibition by 1,25(OH) $_2$ D, which potentially may compromise Ca homeostasis.

Interaction between systemic and local factors can occur, and some factors such as PTHrP may act both systemically and locally (64). PTHrP is also known as PTH-like peptide, PTH-like protein, or human humoral hypercalcemic factor. PTHrP and PTH genes appear to be members of the same gene family. PTHrP mRNA encodes a 177-amino-acid protein consisting of a 36-amino-acid precursor segment and 141-amino-acid mature peptide. The mature PTHrP contains several structural or functional domains. The N-terminal 1-13 region has eight of 13 residues in common with PTH. The amino acids 34-111 segment is highly conserved among species while amino acid 118 to the C-terminus is poorly conserved. PTHrP gene expression is found in an extensive variety of endocrine and nonendocrine tissues. PTHrP biologic activity and immunoreactivity for PTHrP mRNA have been found in many tissues, by as early as 7 weeks of gestation, including the fetus, placenta, lactating breasts, and milk in human and in various tissues in the sheep (65) and pig (66). Both PTH and PTHrP appear to bind to the same G-protein-linked receptor. Synthetic and recombinant PTHrPs can mimic the effects of PTH on the classic PTH target organs, involving activation of adenylate cyclase and other second messenger systems.

Several PTHrP assays with varying sensitivities and specificities have been developed which account for the variability reported between assays (67). The stability of PTHrP in plasma samples may be enhanced if sample collection is done in the presence of protease inhibitors. Circulating immunoreactive PTHrP concentrations are low or undetectable in normal subjects. Serum PTHrP is

P.856

increased during pregnancy (5,6) and is similar to or lower than umbilic cord PTHrP concentrations. In cord sera, PTHrP concentration is 10- to 15-fold higher than that of PTH. Amniotic fluid PTHrP concentrations at mid-gestation and at term are 13- to 16-fold higher than the cord or maternal levels (68), and the concentration of PTHrP in milk is 100-fold higher. PTHrP concentrations correlate positively with total milk calcium (69).

PTHrP concentrations in the circulation of individuals with humoral hypercalcemia of malignancy (HBM) are elevated (67). The amino-terminal fragment PTHrP 1-74 appears to be specific for HBM, whereas the carboxyl-terminal fragment PTHrP 109-138 is elevated in the serum of patients with HBM or renal failure. The levels of PTHrP in these patients are similar to the concentration of PTH (10^{-12} to 10^{-11} mol/L).

Clinically, PTHrP is the humoral mediator secreted by tumors that results in the syndrome of HBM, and the measurement of PTHrP is of clinical utility primarily as a tumor marker in HBM. Physiologically, PTHrP is an important paracrine regulator of several tissue-specific functions that may directly or indirectly affect fetal and neonatal mineral homeostasis, probably through its effect on smooth muscle relaxation, placental Ca transport, lactation, fetal bone development, and control of cellular growth and differentiation.

DISTURBANCES IN SERUM MINERAL CONCENTRATIONS

Hypocalcemia

Neonatal hypocalcemia may be defined as a serum tCa concentration of less than 2 mmol/L (8 mg/dL) in term infants and 1.75 mmol/L (7 mg/dL) in preterm infants with iCa below 1.0 to 1.1 mmol/L (4.0 to 4.4 mg/dL), depending on the particular ion-selective electrode used. Whole-blood iCa shows similar values to serum iCa and is often used to determine hypocalcemia. However, the appropriate range used is also subject to the type of instrument used (15).

The definition of hypocalcemia is based on the clinical perspective because serum Ca concentrations are maintained within narrow ranges under normal circumstances, and the potential risk for disturbances of physiologic function increases as the serum Ca concentration decreases below the normal range. Furthermore, improvements in physiologic function, e.g., changes in cardiac contractility, blood pressure, and heart rate, are reported in hypocalcemic infants undergoing Ca therapy (70,71,72), and a higher mortality rate has been reported for children with hypocalcemia in pediatric intensive care settings (73).

Clinically, there are two peaks in the occurrence of neonatal hypocalcemia. An early form typically occurs during the first few days after birth, with the lowest concentrations of serum Ca being reached at 24 to 48 hours of age; late neonatal hypocalcemia occurs toward the end of the first week. These findings reflect in part the traditional clinical practice of screening for biochemical abnormalities in small or sick hospitalized infants during the first few days, and in symptomatic infants during hospitalization and after hospital discharge. However, the nadir of serum Ca concentration may occur at less than 12 hours (9 to 12) or not until some weeks after birth (74,75), and many neonates, particularly those with genetic defects in Ca metabolism, may be hypocalcemic but remain asymptomatic and undetected during the early neonatal period. This also may contribute to the less frequent diagnosis of late neonatal hypocalcemia compared to early neonatal hypocalcemia. Additionally, increased understanding of the mechanisms of disturbed Ca metabolism would support the approach to neonatal hypocalcemia based on risk factors and pathophysiologic basis rather than the traditional "early" or "late" onset.

Pathophysiology

Multiple risk factors for neonatal hypocalcemia (Table 36-1) support the existence of varied and frequently interrelated pathophysiologic mechanisms (Table 36-2). However, the pathophysiologic mechanisms are not fully defined for all cases of hypocalcemia. In most cases of neonatal hypocalcemia, there is a decrease in both tCa and iCa, although iCa may be decreased without lowering tCa.

There are common bases for the occurrence of hypocalcemia, particularly for "early" onset hypocalcemia. These include the abrupt discontinuation of placental Ca supply at birth, limited or no dietary Ca, transient limited increase

P.857

in the serum PTH concentration, possibly end-organ resistance to PTH and 1,25(OH)₂D, and elevated serum CT concentration. Many illnesses may preclude early enteral feeding but many clinicians do not use parenteral nutrition that contains Ca for 1 or more days after birth, thus increasing the risk for hypocalcemia. Even in healthy term infants, the

amount of Ca retention from milk feeds probably is less than 20 mg/kg body weight on the first day, rising to at least 45 to 60 mg/kg on the third day; these amounts are significantly lower than the daily *in utero* Ca accretion of more than 100 mg/kg during the third trimester (2).

TABLE 36-1 RISK FACTORS FOR NEONATAL HYPOCALCEMIA

Maternal

- Insulin-dependent diabetes
- Hyperparathyroidism
- Vitamin D or magnesium deficiency
- Medications: calcium antacid and anticonvulsant (?)
- Narcotic use (?)

Peripartum

- Birth asphyxia

Infant

Intrinsic

- Prematurity
- Malabsorption
- Malignant infantile osteopetrosis
- Parathyroid hormone: impaired synthesis, secretion, regulation, or responsiveness
- Mitochondrial fatty acid disorder (?)

Extrinsic

- Diet
 - Inadequate calcium
 - Excess phosphorus
- Enema: phosphate
- Exchange transfusion with citrated blood
- Infectious diarrhea (?)
- Clinical therapy (?): phototherapy, alkali, high rate of intravenous lipid

TABLE 36-2 PATHOPHYSIOLOGY OF NEONATAL HYPOCALCEMIA

Physiologic Basis	Mechanism	Clinical Association
Calcium (Ca)	Decreased reserves	Prematurity
	Decreased intake or absorption	Prematurity, malabsorption syndrome
	Increased Ca complex	Chelating agent (e.g., citrated blood for exchange transfusion, long-chain free fatty acid)
Magnesium (Mg)	Decreased tissue store	IDM, maternal hypomagnesemia

	Decreased intake or absorption	Prematurity, malabsorption syndrome, specific Mg malabsorption (rare)
	Increased loss	Intestinal fistula, enterostomy, or renal (primary or secondary)
Phosphorus (P)	Increased load	Exogenous (e.g., dietary, enema) phosphate loading
pH	Increased	Respiratory or metabolic alkalosis (e.g., shifts Ca from ionized to protein-bound fraction)
Parathyroid hormone (PTH)	Inadequate or defective synthesis or secretion	Maternal hypercalcemia, DiGeorge association, hypoparathyroidism, hypomagnesemia, PTH gene mutations
	Impaired regulation	CaR activating mutations, autosomal-dominant or sporadic hypocalcemia with hypercalciuria
	Impaired responsiveness	Chronic hypomagnesemia, type 1 PTH receptor inactivating mutation (?), pseudohypoparathyroidism
Calcitonin	Increased	IDM, birth asphyxia, prematurity
Vitamin D	Deficiency	Severe maternal deficiency
	Decreased response to 1,25(OH) ₂ D	Prematurity
Osteoclast activity	Absent	Malignant infantile osteopetrosis
Miscellaneous	Increased anabolism	Hungry bone/refeeding syndrome
	Others ?	Mitochondrial fatty acid disorder, rotavirus diarrhea, phototherapy, narcotic withdrawal

1,25(OH)₂D, 1,25-dihydroxyvitamin D; IDM, infant of insulin-dependent diabetic mother;
CaR, calcium-sensing receptor

Hypocalcemia (in varying degrees of severity) may occur in association with “transient” congenital hypoparathyroidism (TCHP), i.e., suppression of fetal and neonatal parathyroid function from maternal hyperparathyroidism (74,75) and maternal use of high doses of calcium carbonate (76) as antacid, and thus, impaired PTH response to the interruption of placental supply of Ca at birth. Neonatal hypocalcemia is often the first manifestation that leads to the diagnosis of maternal hyperparathyroidism.

In the neonate, hypocalcemia frequently occurs in the presence of rising concentrations of PTH in the circulation. It is possible that this represents either a relative inadequate response of the parathyroid gland or end-organ resistance to PTH. Resistance to

pharmacologic doses of $1,25(\text{OH})_2\text{D}$, demonstrated *in vitro* (77) and *in vivo* in infants (11,12), may also contribute to hypocalcemia.

Despite the hypocalcemic effects of CT, the role of CT in the development of neonatal hypocalcemia remains uncertain. Serum CT concentrations continue to increase after birth in neonates of normal and diabetic pregnancies (9,26) irrespective of the variation in serum Ca; in neonates with birth asphyxia (9); and in preterm infants (25). The stimulus for the postnatal rise in serum CT, despite falling serum Ca, is unknown. There are conflicting reports on the effect of Ca supplementation to suppress the postnatal surge in CT secretion. However, serum CT is increased after an intravenous bolus of Ca during exchange blood transfusion (78).

The above problems are exaggerated in the preterm infant and account for the inverse relationship between the frequency of hypocalcemia versus birth weight and gestational age; more than 50% of preterm very-low-birth-weight neonates may have hypocalcemia (10,11,12). Infants with intrauterine growth retardation may have hypocalcemia if they are also preterm or have birth asphyxia; otherwise, there is apparently no increased incidence of hypocalcemia related to growth retardation (13).

P.858

Hypomagnesemia may be contributory to hypocalcemia in infants of mothers with insulin-dependent diabetes (79), although gestational diabetics may (80) or may not (81) have disturbed mineral metabolism. Both hypocalcemia and hypomagnesemia may be the result of a common insult from the diabetic pregnancy, and rigid control of maternal glucose levels during pregnancy may significantly diminish these complications (82). Severe and persistent hypomagnesemia from any cause can result in hypocalcemia (see hypomagnesemia section). Deficiency of various minerals, including Ca, Mg, and trace minerals such as zinc, can result from chronic intestinal malabsorption and fistula or enterostomy loss. During infancy, congenital or acquired short-bowel syndrome and any chronic diarrheal condition, especially if associated with steatorrhea, are leading causes of malabsorption and possibly impaired enterohepatic circulation of vitamin D and vitamin D metabolites.

Excessive P load can result in hypocalcemia. Cow milk and even "humanized" cow-milk-derived formulae (83,84) with "lower" P content compared with cow milk but higher compared with human milk, and cereals which usually have high P content are typical sources of dietary P load. Accidental overdose of oral phosphate supplement (85) or phosphate-containing enema (86) are less frequent causes of excessive P load.

Neonatal hypocalcemia from impaired synthesis or secretion of PTH in the newborn may be secondary to maternal hypercalcemia or to developmental defects of the parathyroid gland. A variety of mutations of PTH or CaR genes, some with Mendelian modes of inheritance, can affect the synthesis, metabolism, and function of PTH and result in hypocalcemia.

Relative inadequacy or the transient nature of the PTH response to the abrupt withdrawal of the placental transfer of Ca contributes to the fall in serum Ca after birth. This also may be responsible for the hypocalcemia induced by exchange transfusion using citrated blood (78,87) or feeding of the relatively high P content of cow-milk formula (83,84). The ability of the neonatal parathyroid glands to respond to hypocalcemic stress increases with postnatal age. Neonates with TCHP may have prolonged hypocalcemia that requires

treatment until late infancy or early childhood, and hypoparathyroidism may recur in later childhood (88,89,90).

Hypoparathyroidism in the infant is a heterogeneous group of disorders and may occur sporadically or with differing Mendelian modes of inheritance (91,92,93). Synthesis of defective PTH can occur in the autosomal-dominant form with a point mutation in the signal peptide-encoding region for prepro-PTH. The autosomal-recessive form is associated with a mutation in the donor splice site leading to transcriptional loss of the second exon and prevention of translation. The X-linked recessive form is associated with embryonic dysgenesis of parathyroid glands. Hypo-parathyroidism from fetal parathyroid hypoplasia or dysgenesis usually requires lifelong treatment to prevent hypocalcemia.

Deletion of chromosome 22q11.2 is associated with varied phenotypic manifestations including DiGeorge and velocardiofacial/Shprintzen syndromes. Both syndromes may represent different degrees of the same disorder with partial or complete absence of derivatives of the third, fourth, and possibly fifth pharyngeal pouches, and are often associated with defective development of the third, fourth, and sixth aortic arches. It is estimated that up to 30% of these patients may have hypoparathyroidism, although far fewer patients develop hypocalcemia (94). Delayed motor development, cognition and neurodevelopment, and behavior and temperament problems are frequently reported in more than 50% of affected patients (95,96). Early screening and intervention for these problems are advised. Multiple other organ systems (94,97) may be involved and include some combination of congenital heart disease, primarily involving the aortic arch, decreased T-cell number or function, and possibly thyroid C-cell deficiency. DiGeorge association may be inherited in an autosomal-dominant fashion (98).

Dysregulation of PTH can result from activating mutations of CaR with a reduction in EC_{50} (concentration of extracellular Ca required to elicit half of the maximal increase in intracellular inositol phosphate) to suppress PTH synthesis. It is manifested as autosomal dominant or as sporadic cases of hypocalcemia with hypercalciuria (99,100). The latter is an effect of the mutated CaR in the kidneys. Hypocalcemia is usually mild and asymptomatic, and diagnosis is often delayed beyond the neonatal period, although hypocalcemia was likely present during the immediate newborn period.

Relative defective response to PTH can result in neonatal hypocalcemia. The inactivating mutation of the type 1 PTH receptor gene, as documented in Blomstrand chondrodystrophy, is present in the prenatally lethal form of short-limb dwarfism (101). Theoretically this defective response to PTH may result in hypocalcemia but the regulation of serum Ca has not been evaluated *in vivo*.

Impaired end-organ response to PTH occurs with chronic hypomagnesemia and may involve simultaneous impairment in both PTH and $1,25(OH)_2D$ pathways (36). End-organ unresponsiveness to PTH associated with genetic defect is classically manifested as pseudohypoparathyroidism type 1a (PHP-1a) or Albright hereditary osteodystrophy. The biochemical basis of the defect is proximal to cAMP production (102). It is inherited in an autosomal-dominant fashion with heterozygous inactivating mutations in the maternal *GNAS1* exons that encode the α subunit of G_s ($G_s\alpha$). The gene *GNAS1* is located on chromosome 20q13.3 and encodes 13 exons that are alternatively spliced to yield four $G_s\alpha$ proteins. Multiple mutations have been reported and include abnormalities in splice

junctions associated with deficient mRNA production and point mutations that result in diminished amounts and activities of the G proteins. The inactivating mutation of the gene impairs the production of the adenylate cyclase second messenger system, leading to resistance to multiple hormones (including PTH, vasopressin, and

P.859

thyrotropin) that activate $G_{s\alpha}$. Clinical manifestations include short stature, round face, brachymetacarpals and brachymetatarsals, dental dysplasia, subcutaneous calcifications, abnormalities in taste, smell, hearing, and vision, and developmental delay. Biochemical abnormalities include hypocalcemia, hyperphosphatemia, increased circulating PTH, and insensitivity to the administration of exogenous PTH (unaltered urinary Ca, P, and cAMP) in the absence of compromised renal function. The extent of resistance to other hormones is variable, and the complete biochemical picture is usually not evident until 2 to 3 years after birth.

Parent-specific methylation with parental imprinting of the *GNAS1* gene, involving selective inactivation of either the maternal or paternal allele, is possible and leads to different phenotypic expression. In the case of the $G_{s\alpha}$ gene, it is paternally imprinted (silenced) so that the disease PHP-1a is not inherited from the father carrying the defective allele but only from the mother (103). However, the defective allele is not imprinted or silenced in all tissues and reflects haplotype insufficiency. For example, PHP-1b is characterized by isolated resistance to PTH without the accompanying skeletal manifestations. Paternal isodisomy of chromosome 20q in patients that lack the maternal-specific methylation pattern within *GNAS1* results in normal $G_{s\alpha}$ protein and activity in the fibroblast but not in the renal proximal tubules (104). There is a third type, PHP-1c, reported in a few patients that differs from PHP-1a only in having normal erythrocyte levels of $G_{s\alpha}$; presumably there is a post- $G_{s\alpha}$ defect in adenylyl cyclase stimulation. All type 1 PHP individuals show a deficient urinary cAMP response to the administration of exogenous PTH. Individuals with pseudopseudohypoparathyroidism have typical clinical manifestation of PHP-1a but have normal serum Ca and normal response of urinary cAMP to exogenous PTH. The mutated *GNAS1* gene is inherited from the father, i.e., paternal imprinting, with suppression of the mutant copy in selected tissues, and there is a 50% reduction in the amount of $G_{s\alpha}$.

Infants with neonatal hypocalcemia seizures and "transient" biochemical features of pseudohypoparathyroidism have been reported (105). These infants have elevated serum PTH and P with hypocalcemia at diagnosis. Administration of exogenous human PTH 1-34 showed little phosphaturic effect although there was brisk response in plasma and urine cAMP and alkaline phosphatase. After initial treatment for hypocalcemia, the serum Ca and PTH spontaneously normalized before 6 months of age.

Maternal anticonvulsant therapy with phenytoin and phenobarbital also may result in neonatal hypocalcemia, presumably from increased clearance of vitamin D secondary to the induction of the hepatic cytochrome P450 enzyme system. However, other maternal factors including seasonal variation in sunlight exposure, increased maternal age and parity, and poor socioeconomic status, may contribute to development of neonatal hypocalcemia, presumably in part from varied and probably deficient maternal vitamin D. Furthermore, there is no seasonal variation in the rate of early neonatal hypocalcemia (106) despite seasonal variation in maternal and fetal vitamin D status, as indicated by

maternal and cord 25-OHD concentrations. Thus, maternal vitamin D or Mg deficiency probably predisposes to but is not the primary cause of hypocalcemia in the neonate.

Malignant infantile osteopetrosis may present with neonatal hypocalcemia, presumably reflecting continued Ca uptake from unopposed bone formation (107). Rapid replenishment of nutrients in severe deficiency, including prolonged starvation, often leads to disturbed blood biochemistries including hypokalemia, -phosphatemia, -magnesemia and -calcemia. This is known as the "refeeding syndrome" or "hungry bone syndrome" with excessively rapid shift of electrolytes and minerals intracellularly in various tissues, particularly muscle and bone (108,109).

The pathophysiology in some situations with hypocalcemia remains ill defined. Approximately 40% of infants with severe diarrhea from rotavirus have hypocalcemia, and it resolves with symptomatic support and improvement in diarrhea (110). Mitochondrial fatty acid disorders have been associated with severe metabolic anomalies including hypoglycemia, hypocalcemia, hyperkalemia and metabolic acidosis, and organ dysfunction including hepatic and cardiac failure (111).

Decreases in serum iCa can occur without decreases in serum tCa. Agents that complex Ca in the blood would be expected to decrease iCa. Such agents include citrate, which is used as an anticoagulant for blood storage. During "exchange blood transfusion," iCa can decrease to 0.5 mmol/L in spite of administration of conventional amounts of Ca (i.e., 0.5 to 1 mL of 10% Ca gluconate for each 100 mL of blood exchanged) during the transfusion. Increased levels of long-chain free fatty acids from intravenous lipid emulsion can complex Ca and reduce iCa *in vitro*; thus, hypocalcemia potentially can occur with excessive rates of intravenous lipid infusion. Alkalosis can result in shifts of Ca from the ionized state to the protein-bound fraction. Because alkalosis increases neuromuscular hyperirritability, the combination of decreased serum iCa and alkalosis may precipitate clinical tetany in an infant with borderline serum Ca status. In clinical practice, administration of sodium bicarbonate in the therapy of metabolic acidosis often occurs in situations with high risk of hypocalcemia such as prematurity or perinatal asphyxia, but it is not known if it has an independent role in the development of hypocalcemia. The mechanisms for hypocalcemia in some situations are not known. For example, neonates with severe hyperbilirubinemia tend to have lower iCa (112), the use of phototherapy may be associated with hypocalcemia (113), and infants born to narcotic-using mothers are reported to have a lower serum iCa if they manifest withdrawal symptoms (114).

Diagnosis

Suspicion of hypocalcemia must be confirmed by measurement of serum tCa and iCa since clinical manifestations are

P.860

many and varied and may be indistinguishable from other common neonatal diseases (Table 36-3). Confirmation of hypocalcemia as the cause of clinical manifestations is its reversibility when serum tCa or iCa has been normalized.

TABLE 36-3 DIAGNOSTIC WORKUP FOR NEONATAL HYPOCALCEMIA

History

Screen for risk factors (Table 36-1)

Physical examination

General examination with focus on peripheral and central nervous and cardiovascular systems

Associated features, e.g., infant of a diabetic mother, prematurity, birth asphyxia, congenital heart disease, pseudohypoparathyroidism, etc.

Investigations^{a, b, c}

Serum total and ionized calcium (tCa and iCa), magnesium (Mg), phosphorus (P), total protein and albumin, and simultaneous "intact" or "whole" parathyroid hormone (PTH)

Acid-base status

Complete blood count (lymphocyte count)

Electrocardiogram (Q-Tc > 0.4 sec or Q_o-Tc > 0.2 sec)

Chest x-ray (thymic shadow, aortic arch)

Urine Ca, P, Mg, and creatinine

Meconium and urine screen for narcotics

Maternal serum tCa and iCa, Mg and P, urine Ca and P, if suspect maternal or heritable calcium disorder is suspected, particularly in persistent neonatal hypocalcemia

Additional workup as indicated: vitamin D metabolites, T-cell number and function, malabsorption studies, response to exogenous PTH, molecular genetic studies (deletion of 22q11.2, PTH receptor and end-organ responsiveness abnormalities, and calcium-sensing receptor defects, etc.) and family screening.

^a If serum tCa and iCa are normal, diagnostic workup should focus on non-calcium related causes of clinical symptomatology, e.g., serum glucose, sepsis workup, screen for excretion of illicit drugs, neuroimaging studies, etc.

^b Resolution of clinical symptomatology when serum tCa or iCa has been normalized confirms the role of hypocalcemia.

^c Maternal and family screening for calcium disorders is indicated in the absence of specific diagnosis for the neonatal hypocalcemia.

The less mature the infant, the more subtle and varied are the clinical manifestations; in addition, the infant is frequently asymptomatic. Clinical manifestations may include irritability, jitteriness or lethargy, poor feeding with and without feeding intolerance, abdominal distention, apnea, cyanosis, and seizures, which may be confused with manifestations of hypoglycemia, sepsis, meningitis, anoxia, intracranial bleeding, and narcotic withdrawal. The degree of irritability of the infants does not appear to correlate with serum Ca values. Frank convulsions are seen more commonly with "late" neonatal hypocalcemia. In newborn infants, the classic signs of tetany from peripheral hyperexcitability of motor nerves, including carpopedal spasm (spasm of the wrists and

ankles, Trousseau sign), facial spasm (Chvostek sign), and laryngospasm (spasm of the vocal cords), are uncommon.

The level of iCa that determines which feature of tetany will be manifested varies among individuals and is affected by other components of the extracellular fluid, e.g., hypomagnesemia and alkalosis lower, whereas hypokalemia and acidosis raise, the threshold for tetany. At physiologic concentrations of hydrogen and potassium ions, tetany may develop in older infants at an iCa less than 0.8 mmol/L (3.2 mg/dL), and will almost always be manifested (with the possible exception of preterm infants) at an iCa less than 0.6 mmol/L (2.4 mg/dL). If serum albumin concentrations are normal, the corresponding serum tCa concentrations usually are less than 1.8 mmol/L (7.2 mg/dL). In the preterm infant, serum iCa may not decrease to the same extent as tCa, presumably in part because of the sparing effect of lower serum albumin and acidosis found frequently in these infants. This also may partially explain the frequent lack of clinical signs of hypocalcemia in preterm infants. The measurement of electrocardiographic QT intervals, corrected for heart rate, and standard nomograms relating serum tCa and total protein to iCa, have little value for the prediction of neonatal serum iCa. Serum tCa is correlated with iCa but is also inadequate for the prediction of one from the other.

Management

Symptomatic hypocalcemia, manifested as seizures for example, should be treated promptly with parenteral Ca. It is possible that neonatal hypocalcemia may resolve spontaneously. However, asymptomatic hypocalcemia probably also should be corrected, as Ca potentially can alter important cellular functions in which Ca serves either as a first or second messenger in cellular activity.

Any neonate with seizures should have blood drawn for diagnostic tests before therapy. Intravenous administration of Ca salts is the most effective and most rapid means of elevating serum Ca concentrations. Gradual or abrupt decreases in heart rate during the infusion is an indication to slow or stop the infusion. In neonates, 10% Ca gluconate (0.45 mmol [18 mg] elemental Ca/kg) can effectively increase serum iCa, heart rate, cardiac contractility, and blood pressure (70,71,72) (Table 36-4). In children, small equimolar doses (0.07 mmol [2.8 mg] elemental Ca/kg) of 10% Ca chloride compared to 10% Ca gluconate may result in higher mean arterial blood pressure with a slightly greater mean increase (0.06 mmol/L [0.2 mg/dL]) in the measured serum iCa (115). Prolonged use of Ca chloride in high doses may be associated with acidosis and probably should be avoided. With intravenous Ca therapy, bolus infusion may be associated with a transient slight decrease in blood pH and serum P and with hypercalcemia. Continuous infusion probably is more efficacious than intermittent therapy because renal loss of Ca may be greater with the latter method; a dose of 1.25 to 2.0 mmol (50 to 80 mg) elemental Ca/kg/day has been used successfully in the treatment and prevention of neonatal hypocalcemia. Intravenous Ca supplements should be rapidly weaned or replaced with Ca-containing parenteral nutrition if the infant is not expected to tolerate enteral feeding.

Arterial infusion of Ca in high concentrations is potentially fraught with many dangers and should be avoided.

Massive sloughing of soft tissue may occur in the distribution of the arterial supply; for

example, inadvertent administration into a mesenteric artery theoretically can lead to necrosis of intestinal tissues. If an umbilic venous catheter is used, the tip should be in the inferior vena cava and not intracardiac, as administration of Ca directly into the heart may result in arrhythmia. Parenteral nutrition solutions containing standard mineral (including Ca) content can be safely infused through appropriately positioned umbilic venous or arterial catheters. Direct admixture of Ca preparations with bicarbonate or phosphate solutions will result in precipitation and must be avoided.

TABLE 36-4 MANAGEMENT OF NEONATAL HYPOCALCEMIA

Acute phase therapy

- Correction of hypomagnesemia, acid-base problem, etc, if possible
- Intravenous 10 to 20 mg elemental Ca/kg as 10% Ca gluconate or 10% Ca chloride (provides 9 mg elemental Ca/mL or 27.2 mg/mL, respectively) with dextrose water or normal saline infused over 5 to 10 minutes under constant ECG monitoring; repeat as necessary until resolution of severe symptomatology, such as seizures.
- In infants who are not fed enterally, this is followed by intravenous continuous infusion at 50 to 75 mg elemental Ca/kg/d. Alternately, parenteral nutrition containing 50 mg elemental Ca/100 mL is preferred and continued until feeding
- In asymptomatic infants, oral 50 to 75 mg elemental Ca/kg/d in 4 to 6 divided doses. One mL of calcium carbonate, glubionate, gluceptate, gluconate, lactate, or chloride contains 40, 23, 18, 9, 13, and 27 mg elemental Ca, respectively.
- Once serum tCa is normalized, cut the dose of the Ca supplement in half daily for 2 days, then discontinue
- Serial serum tCa (+/-iCa) every 12-24 hours until clinically stable, every 24 hours until normalized, and at 24 hours after Ca supplement discontinued

Maintenance therapy: treat underlying disorder, if possible

- Low phosphorus (P) formula if serum P is high (>2.6 mmol/L or 8 mg/dL) until serum Ca and P normalized
- Prolonged and higher Ca doses, and 1,25(OH)₂D may be needed, e.g., hypoparathyroidism
- 1,25 (OH)₂D, 1,25-dihydroxyvitamin D; ECG, electrocardiogram.

Oral Ca supplements at a similar dosage to parenteral Ca (1.87 mmol [75 mg] elemental Ca/kg per day in four to six divided doses) should be started if the infant is expected to tolerate it, and the serum Ca is normalizing after the initial intravenous Ca therapy. All oral Ca preparations are hypertonic, and there is a theoretical potential for precipitating necrotizing enterocolitis in infants at risk for this condition. Oral Ca preparations generally contain higher Ca concentration than intravenous preparations, for example, Ca glubionate, gluceptate, and carbonate have respectively 2.88, 2.25 and 2.5 mmol (115, 90, and 200 mg) elemental Ca per 5 mL, and are useful for infants, particularly those requiring fluid restriction. Syrup-based oral Ca preparations have high sucrose content that may constitute a significant carbohydrate and osmolar load for small preterm infants, and may be associated with an increase in frequency of bowel movements. Alternately, an

intravenous preparation can be used orally if the fluid volume is tolerated. Treatment of asymptomatic hypocalcemia can be instituted with oral Ca supplement in the same dosage.

The duration of supplemental Ca therapy depends on the underlying cause of hypocalcemia and usually lasts several days for most cases of neonatal hypocalcemia, or may be prolonged as in the case of hypocalcemia caused by malabsorption or hypoparathyroidism. The serum Ca concentrations should be measured daily during the first few days of treatment and for 1 or 2 days after discontinuation, until serum tCa and iCa concentrations are stabilized. Persistently low serum Ca concentrations should prompt further investigations even in the absence of suspicious history or physical features associated with pathologic causes of hypocalcemia.

Vitamin D metabolites, 1,25(OH)₂D at 0.05 to 0.2 µg/kg/day intravenously or orally and 1α-hydroxyvitamin D at 0.33 µg bid orally, and exogenous PTH have been used in the treatment of neonatal hypocalcemia. However, there is no practical advantage to the use of these agents in place of Ca for the treatment of acute hypocalcemia.

For severe persistent hypocalcemia, vitamin D or one of its analogues is often used in addition to Ca supplementation. The use of 1,25(OH)₂D is preferred because it can raise serum Ca within 1 to 2 days after initiation of therapy and leaves no residual effects within several days of its discontinuation. Vitamin D has a slower onset of action of 2 to 4 weeks and the residual effect also lasts several weeks after its discontinuation, thus making dosage adjustment more difficult.

Successful management of neonatal hypocalcemia also depends on the resolution, if possible, of the primary cause of hypocalcemia. For example, a poor response to Ca therapy may often result from concurrent Mg deficiency. Hypomagnesemia, if present, must be treated to obtain maximal response to Ca therapy. In phosphate-induced hypocalcemia, high-phosphate formulae and solids should be discontinued, and human milk or low-phosphate formula should be substituted. Use of aluminum hydroxide gel to bind intestinal phosphate should be avoided because of potential risk for aluminum toxicity (116).

Early milk feeding and the use of Ca-containing parenteral nutrition within hours after birth are the best means to minimize the development and recurrence of hypocalcemia, and they may negate the need for Ca supplementation. Delaying premature delivery and minimizing perinatal asphyxia, judicious use of bicarbonate therapy and mechanical ventilation, for example, during intentional induction of alkalosis in the treatment of persistent pulmonary hypertension, are also useful measures to minimize neonatal hypocalcemia. Maintenance of normal maternal vitamin D status with exogenous vitamin D supplement, if needed, in theory may be helpful in maintaining normal fetal vitamin D status and may secondarily prevent hypocalcemia in some neonates. Early feeding and provision of Ca to the gut in the neonate may be important

P.862

to enhancing the ability of vitamin D metabolites to prevent hypocalcemia.

Pharmacologic prevention of neonatal hypocalcemia has focused primarily on the prophylactic use of Ca salts or vitamin D metabolites. In newborn infants, Ca supplementation results in sustained lowering of serum IPTH concentrations compared to unsupplemented controls (27). Theoretically, Ca supplementation may decrease the

metabolic stress from hypocalcemia and minimize the potential for depletion of tissue Ca stores. Early studies used up to 1.8 to 2.0 mmol (72 to 80 mg)/kg/day of oral Ca supplement and about half this amount intravenously to prevent hypocalcemia. However, it should be noted that a similar amount of Ca can be provided from an intake of 150 to 200 mL/kg/day of standard term infant formula or human milk. Standard preterm infant formula can provide almost 5 mmol (200 mg) of Ca/kg/day, and parenteral nutrition with 1.25 to 1.5 mmol (50 to 60 mg) Ca/100 mL can easily provide 1.5 mmol (60 mg) of Ca/kg/day. These amounts of Ca are well tolerated as they have been the standard practice in most neonatal nurseries for more than a decade. Early feeding or parenteral nutrition must be considered as the best means to prevent neonatal hypocalcemia, particularly for the preterm infant. Vitamin D₃ and its metabolites have been used in attempts to prevent neonatal hypocalcemia with variable degrees of success. In small preterm infants, serum Ca was normalized only at pharmacologic doses of 1,25(OH)₂D.

Complications of hypocalcemia vary with the clinical manifestations and may be related to the therapy and underlying pathophysiology. Acute complications are associated with clinical manifestations, including seizure, apnea, cyanosis and hypoxia, bradycardia, and hypotension. Therapy-related complications, such as cardiac arrhythmia, arterial spasm, tissue necrosis, and extravasation of Ca solution, can be avoided by continuous electrocardiogram monitoring during Ca infusion, avoiding infusion of Ca into the arterial line, and checking for venous patency before Ca infusion. There is also a risk for metastatic calcification from aggressive Ca treatment in the presence of hyperphosphatemia. In situations in which PTH is absent or nonfunctional, its protective hypocalciuric action cannot occur; therefore, markedly raising the serum Ca concentration may cause hypercalciuria, renal stones, nephrocalcinosis, and possible renal damage. These complications were reported during therapy in patients with an activating CaR mutation, even while the patients were normocalcemic (100). Isolated transient hypocalcemia even in symptomatic cases has not been associated with long-term sequelae. Long-term outcomes depend on the underlying causes, for example, patients with 22q11.2 deletion syndromes frequently have defects of multiple organ systems and neurodevelopmental delay unrelated to hypocalcemia (94,95,96,97).

Regular clinical follow-up and laboratory monitoring such as for serum Ca and IPTH are necessary in infants with "transient" hypoparathyroidism since some of these infants are at risk for "recurrence" of hypoparathyroidism and hypocalcemia as late as adolescence (88,89,90).

Hypercalcemia

Hypercalcemia in infants occurs much less frequently than hypocalcemia. However, it is increasingly being diagnosed because serum Ca is usually part of a panel of chemistry tests and because of increasing knowledge of its pathogenesis. Hypercalcemia is present when serum tCa is greater than 2.75 mmol/L (11 mg/dL) or when iCa is greater than 1.4 mmol/L (5.6 mg/dL), depending on the particular ion-selective electrode used. In pathologic hypercalcemia, elevation of serum iCa usually occurs simultaneously with elevation of tCa; however, elevated tCa may occur without elevation of iCa. Elevation of protein available to bind Ca (e.g., prolonged application of tourniquet before venipuncture, with resultant transudation of plasma water into tissues, shown in adult patients with multiple myeloma

and possibly adrenal insufficiency) may result in elevation of serum tCa. A change in serum albumin of 1 g/dL generally results in a parallel change in tCa of about 0.2 mmol/L. Conversely, reduced albumin binding of Ca may result in normal serum tCa in the presence of elevated iCa.

Pathophysiology

Hypercalcemia may occur within hours after birth or be delayed for weeks or months. It may result from increased intestinal or renal Ca absorption, increased bone turnover, or iatrogenic causes.

In the neonatal intensive care setting, hypercalcemia is often iatrogenic from inadequate provision of dietary phosphate during and after hospitalization, as with the use of low- or no-phosphate parenteral nutrition or human milk without fortifier in very-low-birth-weight infants (117,118,119,120,121) (Table 36-5). Phosphate deficiency or hypophosphatemia stimulates CYP1 α and synthesis of 1,25(OH)₂D, which enhances intestinal absorption and renal reabsorption of Ca and P. Increased Ca absorbed in the presence of increased 1,25(OH)₂D cannot be deposited in bone in the absence of phosphate and contributes to hypercalcemia. Hypercalcemia is more likely if there is concomitant use of Ca supplements, a common practice for the prevention or treatment of hypocalcemia in preterm infants. Decreased renal Ca excretion in the neonate or from underlying illness also may exaggerate the extent of hypercalcemia.

Neonatal hyperparathyroidism frequently results in marked hypercalcemia. It may be a sporadic congenital occurrence, show Mendelian inheritance, or be secondary to maternal hypocalcemia.

Hereditary primary hyperparathyroidism manifested in neonates is associated with inactivating mutations of CaR. The severity of hypercalcemia is related to the extent of CaR mutation. Mild hypercalcemia (serum tCa less than 3.0 mmol/L [12 mg/dL]) associated with heterozygous mutated CaR is manifested clinically in most patients with familial hypocalciuric hypercalcemia (FHH). The normal urinary Ca excretion despite hypercalcemia is an effect of the mutated CaR in the kidneys. Serum PTH is usually

P.863

within the normal range but is higher than expected for the degree of hypercalcemia. FHH has been reported in patients from 2 hours to 82 years of age and is usually diagnosed in infants as part of a screening procedure after diagnosis of a family member with hypercalcemia or familial multiple endocrine neoplasia. It is inherited as an autosomal-dominant trait with a high degree of penetrance (122). There usually is significant hypophosphatemia and a modest increase in serum Mg concentration, and functional parathyroid glands are needed for full expression. Neonatal hyperparathyroidism associated with FHH that resolves spontaneously over several months has been reported (123). More severe hypercalcemia with serum tCa of 3 to 3.3 mmol/L (12 to 13 mg/dL) has been attributed to coexpression of the normal and mutated CaR, with the latter having a functional equivalent of a "dominant-negative" effect. The most marked hypercalcemia (serum Ca greater than 4 mmol/L [16 mg/dL]) occurs in neonatal severe hyperparathyroidism with homozygous inactivating germline mutations of the CaR gene. This severe disorder can be lethal within the first few weeks after birth (124, 125).

TABLE 36-5 PATHOPHYSIOLOGY OF NEONATAL HYPERCALCEMIA

Phosphate deficiency

Low or no phosphate, but calcium-containing parenteral nutrition

Very-low-birth-weight infants fed human milk or, less commonly, standard formula

Parathyroid related

Hereditary primary hyperparathyroidism

- Calcium-sensing receptor inactivating mutations: familial hypocalciuric hypercalcemia, neonatal severe hyperparathyroidism
- Parathyroid hormone receptor activating mutation
- Secondary hyperparathyroidism
- Maternal: hypocalcemia, renal tubular acidosis
- Neonatal: renal tubular acidosis

Parathyroid hormone-related protein-secreting tumors

Vitamin D

Excessive intake

- Mother: high-dose vitamin D
- Neonate: high-dose vitamin D prophylaxis, overfortification of milk
- Increased 1,25-dihydroxyvitamin D
- Subcutaneous fat necrosis
- Histiocytic disorders, disseminated tuberculosis with septic shock and hemophagocytic syndrome (?)

Calcitonin response impairment (?) in congenital hypothyroidism

Vitamin A excess

Uncertain pathophysiologic mechanism

Chromosomal/gene abnormalities

- Idiopathic infantile hypercalcemia/Williams syndrome
- Severe infantile hypophosphatasia
- Microdeletion of 4q

Heritable metabolic defect

- Blue diaper syndrome
- Glycogen storage disease type 1a, congenital lactase or sucrase-isomaltase deficiency, disaccharidase deficiency

Extracorporeal membrane oxygenation therapy

Activating mutations of the PTH/PTHrP receptor gene in Jansen metaphyseal dysplasia presumably have the receptor defects in the kidney, bone, and chondrocytes at the growth plate. The clinical manifestations include postnatal-onset short-limb dwarfism with radiographic rachitic changes, and mild hypercalcemia occurs in about 50% of the affected

patients (126).

Neonatal hyperparathyroidism may be secondary to various causes of maternal hypocalcemia including maternal hypoparathyroidism (127) and maternal (128) or neonatal (129) renal tubular acidosis. Presence of metabolic acidosis independently increases bone resorption and enhances the renal effects of hyperparathyroidism; the hypercalcemic effects are augmented by decreased renal excretory capacity of the neonate.

Elevated serum PTHrP and hypercalcemia are found in increasing numbers of infants with a variety of tumors (130,131,132,133), including malignant hepatic sarcoma, infantile fibrosarcoma, renal adenoma, and rhabdoid tumors. There is also associated mortality in some cases, although the relative contribution to death from hypercalcemia versus the underlying disease is not clear.

Hypercalcemia was reported in 34% of neonates and infants from intermittent high-dose vitamin D (600,000 IU every 3 to 5 months) prophylaxis (134). Hypercalcemia also has been reported in infants given human milk with very high vitamin D content (7,000 IU/L), from high-dose vitamin D therapy for maternal hypoparathyroidism, from milk with excessive vitamin D fortification from errors during processing, and in preterm infants given chronic vitamin D supplementation in addition to high-Ca and high-P milk formulae. Neonates with extensive subcutaneous fat necrosis often have a history of perinatal asphyxia and may develop hypercalcemia after a period of low or normal serum Ca concentrations (135). There is an anecdotal report that body cooling for the treatment of birth asphyxia may augment the development of subcutaneous fat necrosis. Hypercalcemia is reported to occur between 2 and 16 weeks, most commonly at 6 to 7 weeks after the development of subcutaneous fat necrosis. Increased prostaglandin E activity, increased release of Ca from fat and other tissues, and unregulated production of $1,25(\text{OH})_2\text{D}$ from macrophages infiltrating fat necrotic lesions, have been postulated to be responsible for the hypercalcemia in this condition. Histiocytic disorders and disseminated tuberculosis with septic shock and hemophagocytic syndrome may be complicated with hypercalcemia in infants; it is not known if this is also related to nonrenal production of $1,25(\text{OH})_2\text{D}$. Vitamin A toxicity is associated with hypercalcemia, presumably secondary to the retinoic acid stimulation of osteoclastic activity and bone resorption. Vitamin A toxicity in infants may occur at intakes as low as 2,100 IU/100 kcal and can be fatal (136).

Hypercalcemia may develop before and during thyroxine therapy of infants with congenital goitrous hypothyroidism

P.864

(137). In theory, deficient CT response to Ca loading or an increased degradation of CT may be responsible for the hypercalcemia.

Neonatal hypercalcemia is reported in other situations in which the pathophysiology remains uncertain. Idiopathic infantile hypercalcemia, often considered as part of Williams syndrome, is associated with varying manifestations including hypercalcemia, mental retardation, elfin facies, and supra-aortic stenosis. There also may be prenatal and postnatal growth failure. The presence of hypercalcemia in infants with Williams syndrome is variable, and serum Ca may be normal, but the presence of nephrocalcinosis and soft-tissue calcifications in some of these infants suggests that hypercalcemia may have occurred previously. An exaggerated response to pharmacologic doses of vitamin D_2 and a

blunted CT response to Ca loading and PTH infusion may contribute to the pathogenesis of hypercalcemia in idiopathic infantile hypercalcemia. Several genetic defects in idiopathic infantile hypercalcemia, including hemizygoty at the elastin gene on the long arm of chromosome 7, have been reported (138,139). No mutations of the CT/CGRP gene has been detected. However, the cellular mechanism that leads to the phenotypic expression remains unknown.

Severe infantile hypophosphatasia is associated with hypercalcemia. It is a rare autosomal-recessive disorder associated with decreased synthesis of tissue-nonspecific alkaline phosphatase from a deletion or point mutation in its gene located on chromosome 1. These patients have severe bone demineralization, low serum alkaline phosphatase, and elevated urinary pyrophosphate and phosphoethanolamine. The condition may be lethal *in utero* or shortly after birth because of inadequate bony support of the thorax and skull, although milder phenotypes are compatible with survival to adulthood (140).

Microdeletion of the long arm of chromosome 4 has been associated with hypercalcemia and cardiac failure (141).

Blue diaper syndrome is a rare familial disorder with impaired intestinal transport of tryptophan. The blue discoloration of the urine results from the hydrolysis and oxidation of urinary indican, an end product of intestinal degradation of unabsorbed tryptophan and hepatic metabolism of its intermediate metabolites. Blue discoloration of the urine has been reported within weeks after birth, although hypercalcemia and nephrocalcinosis are not reported until some months after birth. Glycogen storage disease type 1a, congenital lactase deficiency, and congenital sucrase-isomaltase deficiency with chronic diarrhea have been associated with hypercalcemia and nephrocalcinosis. Hypercalcemia apparently resolves without specific treatment following treatment for disaccharidase deficiency.

Transient hypercalcemia occurs in infants during extracorporeal membrane oxygenation (ECMO) therapy varying in frequency from less than 5% to about 30%, depending on whether the cut-off point used is greater than 2.5 or 2.25 mmol (12 mg/dL or 11 mg/dL), respectively (142, 143).

Diagnosis

Neonates with hypercalcemia may be asymptomatic despite the onset of hypercalcemia at birth. In these cases, there are often delays of weeks or months before diagnosis is made, coincidental to a chemistry panel screening during the course of other illness or because of hypercalcemia in another family member.

The presence of a family history of Ca disorders or anatomic anomalies (e.g., elfin facies, evidence of congenital heart disease, subcutaneous fat necrosis) on physical examination of the infant may be helpful in arriving at the diagnosis (Table 36-6).

Symptoms and signs are frequently nonspecific and include lethargy, irritability, poor feeding with or without feeding intolerance, constipation, polyuria, dehydration, and failure to thrive. Hypertension associated with hypercalcemia may occur in infants, although it may be in part linked to treatment-related relative fluid overload, as in many infants who require ECMO therapy.

Management

Therapy depends on the extent of elevation of serum Ca and whether the infant is symptomatic. For mildly elevated

P.865

serum tCa (less than 12 mg/dL) in the presence of an iatrogenic cause, e.g., phosphate-free parenteral nutrition or the use of Ca supplements without any dietary phosphate intake, resolution of the underlying cause should also clear up the Ca problem. Hypercalcemia induced by dietary P deficiency is becoming less common with the increasing use of commercial fortifier for human milk fed to preterm infants and the use of high Ca- and high P-containing infant formulae and parenteral nutrition for the preterm infant. In patients with low serum P concentrations, large amounts of phosphate supplement may cause hypocalcemia and the possibility of metastatic calcification. Phosphate supplements given orally may result in diarrhea.

TABLE 36-6 DIAGNOSTIC WORKUP FOR NEONATAL HYPERCALCEMIA

History

- Familial or maternal disturbances in calcium (Ca) or phosphorus (P) metabolism
- Gestational age, difficult labor, extracorporeal membrane oxygenation (ECMO) therapy and pre-ECMO therapy
- Mother's and infant's intake of Ca, P, vitamins D and A

Physical examination

- General examination with focus on growth parameters, hydration status, heart rate, blood pressure, cornea for band keratopathy (rare)
- Associated features (e.g., subcutaneous fat necrosis, elfin facies, congenital heart disease, developmental delay)

Investigations

- Serum total and ionized Ca, magnesium, P, creatinine (Cr), total protein and albumin, alkaline phosphatase (total and bone specific), simultaneous "intact" or "whole" parathyroid hormone (PTH), 25-hydroxyvitamin D and 1,25 dihydroxyvitamin D
- Acid-base status
- Urine Ca, P, Cr, amino acids
- X-ray of chest, hands, and long bones
- Ultrasound of kidneys and abdomen, ophthalmologic examination, electrocardiogram (shortened QT interval, bradycardia) for complications
- If the above do not yield diagnosis, other tests depend on associated history and symptomatology
 - Parental (both parents) serum and urine Ca, P, and Cr
 - Molecular studies
 - Family screening depends on the primary diagnosis
 - Serum PTH-related protein and screen for occult tumors
 - Screen for metabolic defects and unusual dietary supplements

With moderate to severe hypercalcemia, the initial treatment is nonspecific with expansion of the extracellular fluid compartment (10 to 20 mL/kg of 0.9% sodium chloride intravenously) and furosemide (2 mg/kg)-induced diuresis (Table 36-7). Care should be taken to avoid fluid and electrolyte imbalance with careful monitoring of fluid balance and serum Ca, Mg, sodium, potassium, and osmolality at 6- to 12-hour intervals. Furosemide therapy may be repeated at 4- to 6-hour intervals. Prolonged diuresis also requires replacement of Mg losses.

Minimal information is available on the use of hormonal and other drug therapy for neonatal hypercalcemia. Nonmammalian sources of CT, e.g., salmon CT (4 to 8 IU/kg every 12 hours subcutaneously or intramuscularly), have greater hypocalcemic effects and longer durations of action, compared with recombinant hCT. However, salmon CT has greater potential for allergic reaction and induction of antibody formation. The hypocalcemic effect decreases after a few days of any CT treatment. Steroid (prednisone 0.5 to 1 mg/kg per day) therapy may result in significant problems including hypertension, hyperglycemia, and gastrointestinal hemorrhage, and thus is not recommended for long-term therapy. Bisphosphonates, oral etidronate (25 mg bid), and intravenous pamidronate (0.5 mg/kg) have been used for hypercalcemia in the mother and neonate. Long-term use of pamidronate in infants and children with osteogenesis imperfecta decreases serum iCa with a compensatory increase in PTH (144). The effects on growth plate, bone production, and mineralization remains unknown, and its use should be restricted to acute short-term therapy. Dialysis in the neonate is not without technical or metabolic complications. Rarely, parathyroidectomy may be necessary, although it is not always effective. Development of calcimimetic agents able to amplify the sensitivity of the CaR to iCa and suppress PTH levels, with a resulting decrease in blood iCa, offer potential for noninvasive therapy of hypercalcemia.

Treatment for chronic conditions also includes restriction of dietary intake of vitamin D and Ca and minimizing exposure to sunlight to decrease endogenous vitamin D production. A low-Ca, low-vitamin D₃, low-iron infant formula is available for the management of hypercalcemia in infants. This formula contains only trace amounts of Ca (less than 10 mg/100 kcal) and no vitamin D. Long-term use of this formula alone will lead to calcium depletion; iatrogenic vitamin D deficiency is also a concern in this situation, and both can result in deleterious consequences.

TABLE 36-7 MANAGEMENT OF NEONATAL HYPERCALCEMIA

Acute

- Remove etiologic factor, if possible, e.g., discontinue vitamin D and calcium (Ca) supplements
- Intravenous normal saline (20 mL/kg) and loop diuretic (furosemide 2 mg/kg). Reassess and repeat every 4 to 6 hours as necessary. Monitor fluid balance and serum Ca, magnesium (Mg), sodium, potassium, phosphorus (P), and osmolality every 6 to 12 hours. Prolonged diuresis may require Mg and potassium replacement
- Use lower Ca content milk or parenteral nutrition, if possible, to maintain nutrition
- In neonates with low serum P (<1.3 mmol/L; 4 mg/dL), oral phosphate supplement at 0.5 to 1 mmol (15 to 30 mg) elemental P/kg/day in 4 divided doses given judiciously may normalize serum P and Ca. In infants not being fed, use parenteral

nutrition containing usual amount of phosphate (1 to 1.5 mmol [31 to 46 mg]/100 mL) but no Ca until serum Ca returned to normal

- Minimal data on the use of hormones, e.g., subcutaneous or intramuscular recombinant human calcitonin (4 to 8 IU/kg every 6 hours), +/-oral glucocorticoid (prednisone 0.5 to 1 mg/kg/day). Other drugs, e.g., bisphosphonates (oral etidronate 25 mg bid, intravenous pamidronate 0.5 mg/kg) are experimental
- Peritoneal or hemodialysis with a low-Ca dialysate may be considered in severely symptomatic patients refractory to medical therapy
- Parathyroidectomy may be needed when patient is clinically stabilized

Maintenance

- Depends on underlying cause
- Additional general therapy may be needed: low Ca, no vitamin D infant formula (Calcilo XD, Abbott Laboratories Columbus, OH); keep in minimize sunlight exposure to lower endogenous synthesis of vitamin D

Complications of hypercalcemia vary with the clinical manifestations at presentation. Persistent hypercalcemia may result in ectopic calcification, which involves the ectopic deposition of a solid phase of calcium and phosphate in walls of blood vessels and in connective tissue about the joints, gastric mucosa, renal parenchyma, and cornea, especially when accompanied by normal or elevated levels of serum P. Prolonged therapy, such as severe limitation of Ca and vitamin D intake, may be associated with hypocalcemia and bone demineralization (145). Severe hypercalcemia can be fatal, although some of the infants have other potentially lethal underlying conditions. Long-term complications usually depend on the underlying cause of hypercalcemia, including failure to thrive and nephrocalcinosis.

Neonatal hypercalcemia may not develop until some weeks after the onset of the insult and may resolve spontaneously, as in subcutaneous fat necrosis. Therefore, serum Ca should be monitored at regular intervals in certain situations to determine the onset of hypercalcemia and to determine

P.866

the continued need for treatment. Family screening for hypercalcemia should be done unless a specific nonfamilial cause for hypercalcemia is established in the index case.

Hypomagnesemia

Hypomagnesemia is present when serum tMg is less than 0.6 mmol/L (1.5 mg/dL). There are no data on the level of iMg during hypomagnesemia. Tissue Mg deficiency, however, may be present despite normal serum Mg concentrations.

Pathophysiology

Decreased tissue accretion of Mg is a major cause of hypomagnesemia (Table 36-8). The compensatory response at birth of abrupt termination of placental transfer of Mg will be

impaired if there is reduced tissue Mg. The severity and prevalence of hypomagnesemia in infants of insulin-dependent diabetic mothers is directly related to the severity of maternal diabetes, which is thought to reflect the severity of maternal Mg deficiency (146). Mg infusion in infants results in greater increases in serum Ca and PTH in those with initially low serum Mg concentrations and in children with insulin-dependent diabetes, compared to normal control subjects.

Maternal hyperparathyroidism has been associated with neonatal hypomagnesemia (147). Negative Mg balances may occur with hyperparathyroidism, which may account for neonatal hypomagnesemia. Alternately, neonatal hypoparathyroidism in this situation may lead to hypomagnesemia from reduced PTH mobilization of bone Mg to extracellular fluid.

In theory, chronic maternal Mg deficiency from any cause may result in decreased tissue Mg accretion for the fetus. Hypomagnesemia occurs more frequently in infants with intrauterine growth retardation compared to infants with appropriate weight for gestational age.

TABLE 36-8 NEONATAL HYPOMAGNESEMIA

Decreased tissue accretion

- Infants of mothers with insulin-dependent diabetes or hyperparathyroidism
- Small-for-gestational-age infants
- Chronic maternal magnesium deficiency

Decreased absorption

- Extensive small-intestine resection
- Specific intestinal magnesium malabsorption

Increased loss

- Intestinal fistula or diarrhea
- Hepatobiliary disorders
- Decreased renal tubular reabsorption

- Primary: transient receptor potential channel protein mutation, renal tubulopathies with hypo- or hypercalciuria
- Secondary: extracellular fluid compartment expansion, osmotic diuresis, drugs (e. g., loop diuretic, aminoglycoside, ibuprofen overdose)

Others

- Increased phosphate intake
- Exchange transfusion with citrated blood

Intestinal resection, particularly of the jejunum and ileum, the major sites of Mg absorption; malabsorption; and rapid intestinal transit time may lead to Mg deficiency and hypomagnesemia. Mg content in bile, gastric fluid, and pancreatic secretion varies from 0.2 to 5.0 mmol/L (0.5 to 12 mg/dL). Diarrheal Mg content may be as high as 7.1 mmol/L (17 mg/dL). Thus, chronic losses from diarrhea, intestinal fistula, or enterostomy may be associated with significant Mg loss.

Infants with congenital biliary atresia and neonatal hepatitis may have low serum Mg concentrations. This is thought to be partly related to increased aldosterone-related renal

Mg losses.

Hypomagnesemia can occur as a primary defect in Mg transport in the intestine or kidney or in conjunction with a variety of inherited hypokalemic salt-losing tubulopathies.

Mutation in a member of the long transient receptor potential channel protein *TRPM6*, which encodes for a bifunctional protein that combines Ca- and Mg-permeable cation channel properties with protein kinase activity and is expressed in intestinal epithelia and kidney tubules, can result in hypomagnesemia (148). Genetic mapping and analysis of a balanced translocation breakpoint have localized some cases of recessively inherited familial hypomagnesemia to chromosome 9q (149).

Renal tubulopathies may be subclassified further into a hypercalciuric group consistent with classic Bartter syndrome, which usually presents in infancy with failure to thrive and episodes of dehydration. Mutations in *PCLN-1*, which encodes the renal tight junction protein paracellin-1 (claudin-16), resulting in impaired tubular reabsorption of Mg and Ca in the thick ascending limb of Henle's loop have been reported (150). These patients typically present with urinary tract infection, polyuria, hematuria, hypomagnesemia, hypercalciuria, nephrocalcinosis, and progressive renal failure. A variant syndrome with hypocalciuria is thought to present later with short stature, substantially lower serum Mg, and more episodes of tetany.

Secondary defects in renal tubular reabsorption of Mg may result from extracellular fluid expansion caused by excessive glucose, sodium, or fluid intake, or from osmotic diuresis, diuretics such as furosemide, high doses of aminoglycosides such as gentamicin, and ibuprofen overdose.

Increased phosphate intake may lead to decreased Mg absorption, and infants on high-phosphate milk preparations have lowered serum Mg concentrations. Elevation of serum phosphate concentrations decreases serum Mg. It is not known if these changes are related to decreased Mg absorption or to the shift of Mg from extracellular to intracellular compartments. In infants with uremia, serum Mg concentrations may be decreased, possibly in relation to higher blood phosphate concentrations (151). Patients

P.867

with renal failure, however, become hypermagnesemic at Mg loads that do not affect people with normal renal function.

Exchange blood transfusions using citrate as an anticoagulant result in complexing of citrate with Mg, which leads to hypomagnesemia, especially after multiple exchanges (87,152).

Diagnosis

Suspicion of hypomagnesemia must be confirmed by measurement of serum tMg and iMg, if available, since clinical manifestations are many and varied and may be indistinguishable from those of other common neonatal diseases. The less mature the infant, the more subtle and varied are the clinical manifestations, and the infants frequently are asymptomatic.

The typical deficit required to produce symptomatic hypomagnesemia is approximately 0.5 to 1.0 mmol (12 to 24 mg)/kg of body weight. However, critical assessment of Mg

deficiency is difficult because more than 99% of total body Mg is found in intracellular fluids or is complexed in the skeleton. It has been proposed that high Mg retention after a Mg load may be a test to reflect Mg deficiency. Infants generally retain large amounts of infused Mg, however, and there are large variations in response; the clinical utility of this test thus appears limited in infancy. Confirmation of hypomagnesemia as the cause of clinical manifestations is its reversibility when serum tMg or iMg has been normalized.

Infants with hypomagnesemia associated with malabsorption, or increased losses from the gut or kidney, also are at risk for concurrent hypocalcemia, hypokalemia, and possible disturbance of the acid-base status. The loss of other nutrients such as zinc also may be considerable. Symptoms and signs of hypomagnesemia, which often coexists with hypocalcemia, may be indistinguishable. Thus, simultaneous measurement of serum Ca (total and ionized, if available), P, potassium, sodium, chloride and bicarbonate, urea nitrogen and creatinine, and zinc status may be indicated. Measurement of urine and intestinal fluid content of Mg also may be helpful in diagnosis and management. Additional investigations depend on the underlying etiology, and the status of other nutrients also may need to be considered.

Typically, hypomagnesemia is associated with decreased circulating PTH concentrations, decreased production of active vitamin D metabolites, in particular 1,25(OH)₂D, and resistance to PTH and 1,25(OH)₂D. When hypomagnesemia coexists with hypocalcemia, a trial infusion of 6 mg of elemental Mg/kg over 1 hour with pre- and postinfusion measurements of total and ionized Ca and PTH may be helpful in the diagnosis of the primary defect. An increase in serum PTH after Mg infusion is indicative of hypoparathyroidism and hypocalcemia secondary to Mg deficiency, whereas no change or a decrease in serum PTH supports the diagnosis of hypocalcemia unrelated to Mg deficiency.

Management

Clinical manifestations of symptomatic hypomagnesemia such as seizures should be treated promptly with parenteral Mg. Asymptomatic hypomagnesemia probably also should be corrected, as Mg potentially can alter important cellular functions and may lead secondarily to hypocalcemia with its attendant complications. Hypocalcemia occurring under this circumstance is corrected only when the Mg disturbance is corrected.

Any neonate with seizures should have blood drawn for diagnostic tests before therapy. The treatment of choice for acute hypomagnesemic seizures is 50% Mg sulfate, 0.05 to 0.1 mL/kg (0.1 to 0.2 mmol/kg or 2.5 to 5.0 mg of elemental Mg/kg) given by slow intravenous infusion over 15 to 20 minutes, or by intramuscular route. The frequency of Mg administration depends on the clinical response and rate of increase in serum Mg. Repeat doses may be given at 2- to 12-hour intervals. Infants receiving parenteral Mg therapy should receive continuous cardiorespiratory monitoring. Serum Mg concentrations should be measured daily or more frequently as clinically indicated to evaluate efficacy and safety until values are stable.

Concomitantly, oral Mg supplements can be started if oral fluids are tolerated. Fifty percent Mg sulfate can be given at a dose of 0.2 mL/kg per day. In specific Mg malabsorption, daily oral doses of 1 mL/kg per day may be required. Oral Mg salts are not well absorbed, and large doses may cause diarrhea. The maintenance Mg supplement should be diluted five-

to six-fold to allow for more frequent administration, maximizing gut absorption and minimizing side effects. Some oral preparations of Mg (e.g., Mg L-lactate dihydrate), especially those in a sustained-release form, may have greater bioavailability than other sources of Mg (e.g., Mg oxide, hydroxide, citrate). However, practical experience with the use of Mg salts other than Mg sulfate in infancy is limited.

Potassium and zinc deficiency frequently coexists with Mg-deficient states, especially when there are abnormal gastrointestinal losses or malabsorption. Appropriate replacement therapy is needed. Treatment of underlying disorders (e.g., closure of gastrointestinal fistula) should be pursued actively. Chronic Mg therapy is needed if the underlying cause persists, such as a genetic defect in Mg transport.

Complications of hypomagnesemia vary with clinical manifestations and may be related to therapy and underlying pathophysiology. Prolonged dietary Mg deprivation in human adults leads to personality change, tremor, muscle fasciculations, spontaneous carpopedal spasm, and generalized spasticity, as well as hypomagnesemia, hypocalcemia, and hypokalemia. Mg depletion in pregnant rats results in fetal mortality, malformations, hypomagnesemia, decreased skeletal Mg content, hemolytic anemia, hypoproteinemia, and edema.

In infants, acute complications are associated with clinical manifestations including seizure, apnea, cyanosis, hypoxia, bradycardia, and hypotension. Possible complications of

P.868

intravenous infusion include systemic hypotension and prolongation or even blockade of sinoauricular or atrioventricular conduction. Isolated transient hypomagnesemia even in symptomatic cases has not been associated with long-term sequelae. Long-term outcome of neonatal hypomagnesemia depends on the underlying cause and adequacy of therapy, and severe neurodevelopmental deficit has been reported, presumably from suboptimal therapy and recurrent seizures.

Hypermagnesemia

Hypermagnesemia is present when serum Mg is more than 1.04 mmol/L (greater than 2.5 mg/dL). There are insufficient data to define hypermagnesemia based on the measurement of serum iMg alone.

Pathophysiology

Hypermagnesemia may result from a combination of excessive Mg load and a relatively low capacity for renal excretion of Mg (Table 36-9). Neonatal hypermagnesemia most commonly occurs after maternal Mg sulfate administration for preeclampsia. In mothers given Mg sulfate, serum Mg concentrations have been reported from 1.1 to 5.8 mmol/L (2.6 to 14.0 mg/dL), with umbilic cord-serum Mg concentrations from 0.8 to 4.8 mmol/L (2.0 to 11.5 mg/dL) (153,154); concomitant maternal hypocalcemia also may occur secondarily to decreased serum PTH concentrations. Variations in parenteral Mg intake (118,119, 155) resulting from high Mg content or high rate of infusion of parenteral nutrition fluids may result in hypermagnesemia, particularly in critically ill neonates. The use of Mg-containing antacids or enemas can cause hypermagnesemia. Prematurity and perinatal asphyxia may aggravate hypermagnesemia, presumably because of decreased renal Mg excretion.

Diagnosis

Most neonates with hypermagnesemia, particularly preterm infants, are asymptomatic, even at serum Mg concentrations of more than 1.25 mmol/L (3 mg/dL) (118,119,153-155). Clinical signs may not correlate with serum Mg concentrations, although there does appear to be a correlation with the duration of maternal Mg sulfate therapy, possibly representing tissue Mg content. With judicious use of Mg sulfate in the mother, however, signs of Mg intoxication should be uncommon in the infant. In adults with hypermagnesemia, hypotension and urinary retention occur at serum Mg concentrations of 1.67 to 2.5 mmol/L (4.0 to 6.0 mg/dL); central nervous system depression, hyporeflexia, and electrocardiographic abnormalities (i.e., increased atrioventricular and ventricular conduction time) at 2.5 to 5.0 mmol/L (6.0 to 12.0 mg/dL); and respiratory depression, coma, and cardiac arrest above 5.0 mmol/L (12.0 mg/dL). Clinical signs of neuromuscular depression with floppiness, lethargy, and respiratory depression are frequent manifestations of severe neonatal hypermagnesemia. Acute hypotonia, apnea, hypotension, and refractory bradycardia mimicking septic shock syndrome have been reported in premature infants accidentally overdosed with Mg in parenteral nutrition (156).

TABLE 36-9 NEONATAL HYPERMAGNESEMIA

Increased load

Maternal magnesium sulfate administration
Neonatal magnesium therapy

- Parenteral nutrition
- Antacid
- Enema

Decreased excretion

Prematurity and asphyxia

Serum Ca concentrations may be normal, increased, or decreased and should be measured in all infants with suspected hypermagnesemia. Hypermagnesemia might in theory displace bound Ca in the circulation and lead to elevation of serum iCa concentration.

Hypermagnesemia may suppress PTH and 1,25(OH)₂D production and may result in lower serum Ca concentrations (157,158). Rickets has been reported when maternal Mg therapy is prolonged (e.g., in tocolysis to prevent preterm delivery). It is speculated that excess Mg interferes with normal mineralization of fetal bone.

In newborn infants, a delay in passage of meconium (i.e., meconium plug syndrome) has been thought to be related to neonatal hypermagnesemia. In pregnant and newborn rats and dogs, however, hypermagnesemia does not have an effect on intestinal motility or the consistency of meconium.

Management

In asymptomatic infants with normal renal function, serum Mg generally returns to normal within several days after adequate hydration and nutritional support and elimination of further Mg intake. These infants should be cared for in a facility that can provide cardiorespiratory support in case additional complications develop.

For symptomatic infants, intravenous Ca given in the same dosage as for treatment of hypocalcemia may be useful for acute therapy, since Ca is a direct antagonist of Mg. Loop diuretics (e.g., furosemide) with adequate fluid intake may hasten Mg excretion. Exchange blood transfusion with citrated blood is an effective treatment for severely depressed hypermagnesemic infants. Citrated donor blood is particularly useful because the complexing action of citrate will expedite removal of Mg from the infant. Peritoneal and hemodialysis may be considered in refractory patients.

In infants, acute complications are associated with clinical manifestations including respiratory depression and hypoxia, bradycardia, and hypotension; and potential

P.869

complications associated with therapy such as exchange transfusion. Isolated transient hypermagnesemia even in symptomatic cases has not been associated with long-term sequelae.

SKELETAL MANIFESTATIONS OF DISTURBED MINERAL HOMEOSTASIS

Pathophysiology

Skeletal manifestations of disturbed mineral metabolism in infants usually present as osteopenia or rachitic changes on standard radiographs. True fetal or congenital rickets is rare. It may result from severe maternal nutritional osteomalacia associated with Ca and vitamin D deficiency, maternal hypo- or hyperparathyroidism, or prolonged maternal treatment with Mg sulfate or phosphate-containing enemas (74,75,159-163) (Table 36-10).

The most frequent cause of skeletal abnormalities in infancy is nutritional deficiency, although it may occur secondarily to disorders of metabolism of multiple organs including gut, pancreas, liver, and kidney. In the Western world, rickets and osteopenia presenting during infancy occur most frequently in small preterm infants and may occur in more than 30% of extremely low-birth-weight (less than 1 kg) infants. The rate of occurrence depends on the nutrient intake and is associated most frequently with prolonged low-Ca and/or low-P parenteral nutrition and prolonged intake of soy formula or unfortified human milk (2). The primary underlying cause in preterm infants appears to be mineral deficiency, particularly Ca and P, which was demonstrated more than 2 decades ago (164) and confirmed by many investigators (2); vitamin D deficiency is of secondary importance. Unfortified human milk fed to preterm infants or standard milk formula for term infants often have low serum concentrations of 25-OHD. The major reason for the low serum 25-OHD in these situations is the increased metabolism of 25-OHD with mineral deficiency. Unfortunately, vitamin D deficiency secondary to mineral deficiency is still frequently misdiagnosed as the primary cause of osteopenia, fracture, and rickets in preterm infants, and is treated with more vitamin D supplement without improving the mineral and general nutritional support.

**TABLE 36-10 RISK FACTORS FOR DEVELOPMENT OF OSTEOPENIA AND RICKETS
IN INFANTS**

in utero

Severe maternal nutritional osteomalacia
(i.e., vitamin D +/-calcium deficiency)
Maternal hypoparathyroidism and hyperparathyroidism
Prolonged maternal magnesium or phosphate treatment
Birth weight <1 kg

Postnatal

Prolonged organ dysfunction: intestine, kidney, liver,
pancreas

Nutritional

- Preterm infants
 - Prolonged low calcium and/or low phosphate total parenteral nutrition
 - Soy formula or unfortified human milk for small preterm infants
 - Chronic loop diuretic therapy given to preterm infants
- Term infants
 - Vitamin D deficiency
 - Calcium deficiency
 - Macrobiotic diet
- Toxin contamination: aluminum (?)

Inherited Defects

- Renal tubular disorder
- Disorders of vitamin D or parathyroid hormone metabolism
- Hypo- or hyperphosphatasia

Chronic diuretic therapy, commonly used in infants with bronchopulmonary dysplasia may aggravate the Ca deficiency. Contamination of nutrients with toxins such as aluminum is an added risk factor (116). The extent, however, to which each specific risk factor is responsible for the development of osteopenia, fractures, and rickets is difficult to define in critically ill infants receiving multiple therapies and suboptimal nutritional support (2). Isolated nutritional deficiency of copper and ascorbic acid has been reported in preterm infants with clinical and radiographic manifestations similar to rickets.

In infants born at term, insufficient endogenous production or exogenous supply of vitamin D is important in the cause of rickets and osteopenia. In one report, almost all children with vitamin D deficiency had ethnocultural risk factors, and 80% of the mothers were also vitamin D deficient (165). However, Ca deficiency also is important in older infants and young children (166). Clinical risk factors thus include prolonged exclusive human milk feeding, limited sunshine exposure, macrobiotic diet, and prolonged total parenteral nutrition.

Acquired and heritable forms of rickets that develop despite adequate availability of

vitamin D usually are associated with renal tubular disorders and metabolic defects in vitamin D and PTH metabolism. Both hypo- and hyperphosphatasia are autosomal-recessive disorders associated with disturbed bone resorption and formation. These causes of rickets are rare, but their skeletal manifestations may present during infancy.

Diagnosis

A history of significant nutritional defects in the mother, either from self-selected dietary restriction or cultural habits, e.g., extensive covering of the body with lack of sunlight exposure or a family history of metabolic disorders and disturbed bone mineral metabolism, should raise the awareness of the potential for nutritional and skeletal problems in both the mother and infant.

Infants with congenital rickets may be asymptomatic at birth, leading to a delay in diagnosis unless investigations are performed as part of the workup for disturbances in

P.870

maternal mineral metabolism. Most postnatal cases of rickets and osteopenia are diagnosed incidentally during the radiographic investigation of skeletal complications such as fractures, or nonskeletal problems such as respiratory illness. Radiographic features such as generalized bone demineralization and widening, cupping, and fraying of the distal metaphyses confirm the presence of osteopenia and rickets. Some investigators have derived a scoring system for the assessment of osteopenia and rickets based on the extent of radiographic changes (167,168,169). The use of dual-energy x-ray absorptiometry (DXA) allows a more accurate quantification of the degree of bone mineralization (170,171), although its role in the diagnosis of bone disorders remains to be defined.

Classic clinical features of rickets such as severe skeletal deformities, including kyphoscoliosis and bowing of the legs, may not be present if the diagnosis is made early in infancy, before significant growth and weight-bearing have occurred. This is particularly true for the preterm infant whose skeletal problems typically are diagnosed between 2 and 6 months postnatally (172). With the current practice of early discharge of preterm infants from neonatal units, it is possible that some nutritional rickets could be diagnosed after hospital discharge; if there are associated fractures, it may be misdiagnosed as child abuse, as is the case with fractures from other medical illnesses. Clinical hypotonia is probably due to a decrease in the intracellular phosphate pool of the skeletal muscle.

Serial biochemical changes (117,173,174) commonly include persistently low serum inorganic phosphate, elevated serum alkaline phosphatase activity more than five times the normal adult upper limit, and elevation of other bone turnover markers in serum and urine. Serum Ca is usually normal except in late severe nutritional vitamin D deficiency rickets. Vitamin D deficiency as indicated by low or undetectable serum 25-OHD is possible; however, it is more likely in preterm infants to be secondary to mineral deficiency. There may be elevated serum $1,25(\text{OH})_2\text{D}$ and IPTH. The elevated IPTH and $1,25(\text{OH})_2\text{D}$ still may be relatively insufficient to maintain Ca and P homeostasis if the Ca and P intake remain low. Urine changes may reflect increased serum IPTH with increased urine P excretion and Ca conservation. However, in chronic P deficiency, urine findings may reflect changes of P-deficiency-related PTH resistance, in which case urine P would be minimal while there is calciuria. Measurement of specific trace mineral status may be useful if deficiency is suspected (175,176). Additional investigations are needed if inherited

renal tubular disorders or disorders of vitamin D and PTH metabolism are suspected.

Treatment and Prevention

Rickets and fractures from nutritional deficiencies respond well to adequate nutrient intake. The best treatment for nutritional osteopenia, fractures, and rickets is prevention. For preterm infants, the use of high Ca and high P parenteral nutrition, until establishment of enteral feeding with human milk containing commercial fortifiers, or formulae designed specifically for preterm infants is appropriate (2,177,178). Human milk alone is likely to be inadequate in a number of nutrients including protein, sodium, Ca, P, and possibly other nutrients for the needs of the very small preterm infant. All human-milk-fed small preterm infants, particularly those with birth weights less than 1,500 grams, should receive commercial fortifier containing multiple nutrients in human milk during their hospital stay and probably posthospital discharge.

The use of Ca and P supplementation alone is inappropriate for the treatment or prevention of osteopenia with or without fractures or rickets, since bone growth requires protein and multiple other nutrients for matrix formation and mineralization. In addition, further large increases in Ca and P intake beyond the current recommended intake is probably not advisable because of the risks of bezoar and even intestinal obstruction with excessive oral intake, and hyperphosphatemia with intravenous intake. In preterm infants, most fractures have significant callus formation at diagnosis and only require splinting support; short-term analgesia is needed if the fracture is recent and without callus formation.

Human milk or standard infant formulae should provide adequate amounts of Ca and P for healthy term infants. Other appropriate nutrients also should be introduced during the latter half of infancy to maintain adequate nutritional status for all infants.

In preterm infants receiving infant formulae with lower Ca and P content (compared to the preterm infant formulae currently available in the United States), normal vitamin D status as indicated by serum 25-OHD concentrations has been reported in infants who received daily supplements of 400 to 2,000 IU vitamin D. However, for enterally fed preterm infants given adequate volumes of high Ca-, high P-, and vitamin D-fortified preterm infant formula, or human milk fortified with commercial human milk fortifiers, a daily total intake of 400 IU vitamin D should be adequate; additional vitamin D supplementation may be excessive.

Prophylactic vitamin D supplementation has been recommended for all breastfed term infants (179) since adequate endogenous production of vitamin D cannot be assured with infants living in varied geographic regions and in families with varied ethnocultural practices.

For infants who require parenteral nutrition as the major source of nutritional support, 25 to 40 IU vitamin D/dL of parenteral nutrition solution with a maximum total daily intake of 400 IU is sufficient to maintain vitamin D status regardless of the gestational age of the infant (180).

For infants with established nutritional vitamin D deficiency, a daily supplementation of 400 IU vitamin D (181) in addition to adequate overall nutritional support is also adequate. Provision of pharmacologic doses of vitamin D to the infants is associated with hypercalcemia, nephrocalcinosis, and hypertension.

and usually include one or more of the following: Ca, phosphate, and 1,25(OH)₂D.

Monitoring and Followup

The goal is for the affected infants to grow normally without residual defect. Regular clinical assessment and growth measurements are essential. On followup during infancy (172,173,181), there were no major residual physical deformities with the use of 400 IU vitamin D for the treatment of rickets for infants born at term or preterm. Skeletal maturation as assessed by ossification centers of the wrists for preterm infants is similar to term infants at 1 year of age (172). However, long-term linear growth in the extremely low-birth-weight infants may remain delayed, suggesting that bone mineral status in the smallest preterm infants still may be suboptimal (182) despite the relatively uncommon occurrence of radiographic rickets and fractures on followup. Current data on DXA-measured total body bone mineral content in the small preterm infant are difficult to interpret because of inconsistencies in the techniques used among different studies (183,184).

Biochemical monitoring of nutritional rickets includes measurement of serum Ca, P, and alkaline phosphatase and avoiding hypercalciuria (less than 0.15 mmol [6 mg/kg/day], especially in human-milk-fed preterm infants) at 1- to 2-week intervals until stable and then at 1- to 2-month intervals. Bone turnover markers, IPTH, vitamin D metabolites, and any other abnormal biochemical parameters should be monitored at 1- to 2-month intervals. All biochemical monitoring should be continued until standard radiographs show completion of healing and remodeling of skeletal defects. Radiographs of the wrists and fracture site(s) should be taken at 2- to 4-month intervals. Standardization of the DXA measurement in infants with serial measurements at 2- to 3-month intervals should provide an added means to better understand bone mineral status in the developing skeleton (185,186). Screening for other affected family members and molecular studies may be warranted in heritable conditions. Other specific monitoring depends on the underlying cause of the skeletal defect.

Chapter 37

Carbohydrate Homeostasis

Edward S. Ogata

Glucose homeostasis results from the net balance between systemic organ requirements and the production and regulation of glucose. The neonate's ability to maintain glucose homeostasis is less well developed than the older child or adult because it is in a metabolic transition period. The abrupt switch from intrauterine life, in which glucose and metabolic fuels are provided in a well-regulated manner, to a situation in which meals are intermittent and which necessitates regulation of exogenous glucose and production of endogenous glucose. As the capability to perform these functions continues to develop in the neonate, clinical disorders that can afflict the neonate may perturb this balance, resulting in hypoglycemia or hyperglycemia. In addition, antecedent intrauterine events can alter the development of glucoregulatory capabilities in the fetus, resulting in altered neonatal glucose homeostasis.

To understand the processes responsible for glucose homeostasis in the normal neonate, an appreciation of the development of glucoregulatory capabilities in the fetus is necessary. This chapter reviews this information and its relation to the clinical disorders associated with altered neonatal glucose homeostasis. Information on the perinatal aspects of diabetes in pregnancy also is presented.

MATERNAL METABOLISM DURING PREGNANCY

Although the metabolic alterations that develop in the pregnant woman throughout gestation favor the growth and development of the fetus, the first half of gestation is also a critical period for maternal anabolism. The increased calories ingested by the woman during early gestation sustain fetal growth and facilitate maternal fat deposition. This is important preparation for the second half of gestation, a period of exponential fetal growth during which these maternal stores are mobilized to meet fetal needs. The storage of maternal energy stores is facilitated by the increased secretion of insulin that occurs in women with normal carbohydrate metabolism (1,2,3,4,5).

Changes in maternal insulin secretion and action are dramatic during the second half of pregnancy. During the first half, basal insulin secretion is normal, and insulin secretion mediates the laying down of metabolic fuels (6). In the second half of gestation, insulin secretion is greatly exaggerated (7,8). Intravenous glucose tolerance testing indicates that by the third trimester, normal pregnant women secrete three times the insulin than they do in the nonpregnant state (1).

The development of insulin resistance during the second half of pregnancy is responsible for this exaggerated insulin secretion. Responsiveness to insulin develops 40% to 60% during the second half of gestation (7,8). The conceptus causes this insulin resistance in part by the generation of human placental lactogen, progesterone, and estrogen which become available in ever increasing amounts as gestation progresses (9,10,11). These directly antagonize the effect of maternal insulin. Insulin resistance increases in liver, adipose tissue, and skeletal muscle (12). Insulin binding appears to be normal during late gestation, indicating that insulin resistance is mediated by events distal to receptor/insulin binding. It is possible that tyrosine kinase inhibition may also contribute to insulin resistance (12,13).

Preexisting maternal diabetes potentiates the effects of the antiinsulin factors, causing an excessive provision of glucose and other metabolic fuels to the fetus. This is the basic perturbation responsible for the problems of the infant of the diabetic mother (Fig. 37-1) (1,14).

Metabolic fuel availability is guaranteed to the fetus even during brief maternal fasting. After an overnight fast, pregnant women have significantly lower plasma glucose concentrations than fasted nonpregnant women (8,15); however, glucose production in the mother is significantly increased (16,17). This increased production ensures the provision of glucose to the fetus.

Prolonged maternal fasting does alter fuel provision to the fetus. As the fast progresses, maternal ketogenesis progressively increases (15,18). The human fetal brain at early gestation can use ketones (Fig. 37-2) (19). However, this ability to use an alternative fuel may be harmful rather than beneficial to the fetus. Offspring of mothers who were ketotic during pregnancy appear to have an increased incidence of cognitive and psychomotor delay at 3 and

P.877

5 years of age (20). The mechanisms responsible for this potential association between ketone body oxidation and impaired brain function are unknown. Because of this uncertainty, maternal fasting, even foregoing breakfast, should be avoided during pregnancy.

DEVELOPMENT OF GLUCOSE-PRODUCING AND GLUCOREGULATORY CAPABILITIES IN THE FETUS

To understand the problems of neonatal glucose homeostasis, the development of glucose production and regulatory capabilities in the fetus must be understood.

Glycogen

The third trimester of the human pregnancy is the first period in gestation during which some of the energy and substrate available to the fetus can be channeled from meeting needs for ongoing growth and development to energy storage. As the third trimester progresses, fat deposition and

hepatic glycogen storage increase (21). The human fetus can synthesize and mobilize glycogen and respond to the signals that regulate these processes as early as the ninth week of gestation (22). However, only minute quantities of hepatic glycogen are present in early gestation as the great bulk of hepatic glycogen accumulates during the third trimester (22,23).

Several types of infants are at risk for neonatal hypoglycemia as a result of limited hepatic glycogen stores. Infants delivered prematurely have an abbreviated or no third trimester and thus have limited glycogen stores. Fetuses who are growth-retarded (i.e., small-for-gestational-age [SGA]) on the basis of limited metabolic fuel availability and diminished gaseous exchange (i.e., uteroplacental insufficiency) will use these fuels for growth and not for glycogen synthesis. Perinatal stress causes neonatal hypoglycemia in part because of catecholamine-stimulated mobilization of hepatic glycogen stores. This can occur at birth or during the antepartum period. In the latter situation, fetuses might recover from stress and be delivered without difficulty. As newborns, such infants have depleted glycogen stores and are at risk for hypoglycemia.

Figure 37-2 Enzymatic activity of the three key enzymes necessary for the oxidation of ketones (i.e., [A5]β-hydroxybutyrate and acetoacetate). The activities of these enzymes are present in substantial quantities in the human fetal brain during early gestation. (From Felig P, Lynch V. [Starvation in human pregnancy: hypoglycemia, hypoinsulinemia, and hyperketonemia.] *Science* 1970; 170:990-992, with permission.)

Gluconeogenesis

For many years, it was believed that maternally derived glucose was the sole metabolic fuel for the fetus and that the fetus could not produce glucose. As indicated, the fetus can use other fuels such

as the ketones and can, under special circumstances, mobilize hepatic glycogen. The fetus also can carry out gluconeogenesis to a limited degree, although it is likely that under normal circumstances it does not need to call on this function. Data from human abortuses have demonstrated that the four key gluconeogenic enzymes are present in fetal liver by 2 to 3 months of gestation (24,25). The activities of these

P.878

enzymes are believed to increase throughout gestation and the neonatal period. Thus, all appropriately grown newborns, including the very premature, probably have some degree of gluconeogenic capability. However, the growth-retarded neonate may have impaired gluconeogenic capability.

Endocrine Regulation

Insulin and glucagon, important hormones for regulating glucose, can be measured in fetal plasma as early as 12 weeks of gestation (26). Although plasma concentrations of these hormones are low, the relative content of these hormones in the fetal pancreas is quite high (27,28). These high concentrations may result from the limited ability of the fetal islets to secrete these hormones. Both premature and term infants have limited capacity to secrete these hormones in response to a glucose challenge in the newborn period. This indicates that the fetus also has limited secretory capability (Fig. 37-3) (28,29,30). Of note, amino acids have a greater effect in stimulating insulin and limiting glucagon secretion than glucose in the fetus (31,32).

Insulin may be more important for enhancing growth than for regulating metabolic fuels during fetal life. Insulin stimulates the growth of specific tissues (e.g., adipose, hepatic, connective, skeletal, cardiac muscle) (33,34). Excessive insulin secretion during fetal life resulting from such conditions as maternal diabetes causes the disproportionate growth of insulin-sensitive tissues, resulting in macrosomia (1,14,35,36). A lack of insulin, as in infants with transient neonatal diabetes mellitus, always is accompanied by fetal growth retardation.

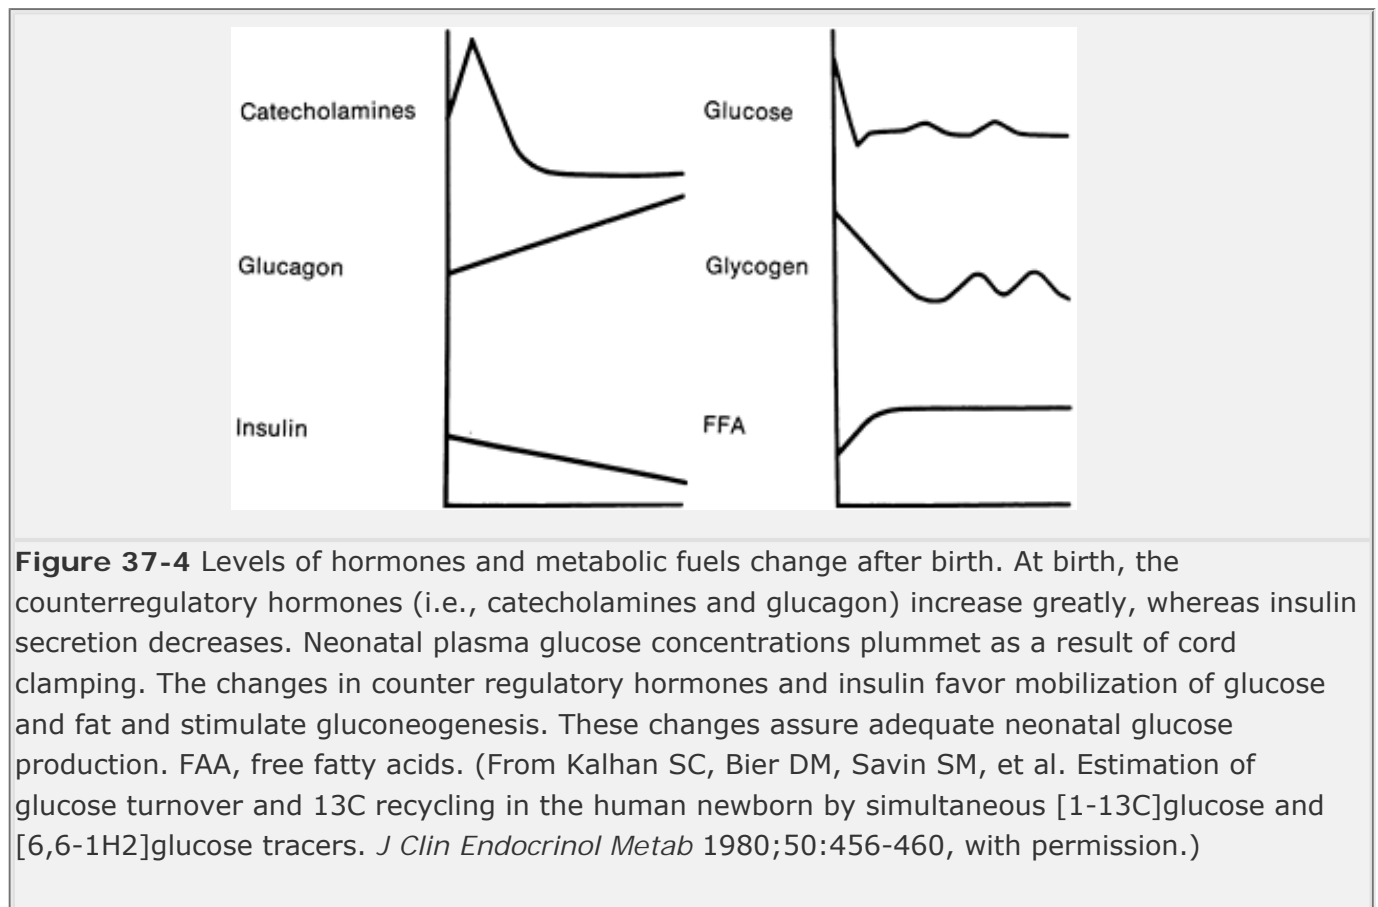

Figure 37-3 Insulin secretion after glucose challenge in premature infants. Whereas normal adults secrete insulin briskly in response to glucagon, premature infants in the neonatal period secrete insulin only sluggishly. (From Assan R, Buillet J. Pancreatic glucagon and glucagon-like material in tissues and plasma from human fetuses 6 to 26 weeks old. In: Jonxis JHP, Visser HKA, Troelstra JA, eds. *Metabolic processes in the fetus and newborn infant, nutrition symposium*. Baltimore: Williams & Wilkins, 1971: 210-212, with permission.)

Glucagon or a critical glucagon/insulin ratio is important for inducing gluconeogenic enzymes. Glucagon stimulates the induction of gluconeogenic enzymes *in vitro* and *in vivo* (37,38). Fetal plasma glucagon concentrations increase progressively during fetal life, and this is associated with a concomitant increase in gluconeogenic enzyme activity. At birth, plasma glucagon concentrations surge, coinciding with the rapid postnatal increase in gluconeogenic activity (39). Insulin may modulate glucagon's effect because it can inhibit gluconeogenic enzyme induction (37). Thus, a balance between these two hormones controls gluconeogenic enzyme induction during perinatal life.

Adrenergic mechanisms can stimulate hepatic glycogenolysis during fetal life, much as in the adult. As labor progresses, fetal sympathoadrenal activity increases, resulting in a considerable increase in circulating catecholamine levels (40,41). Cord clamping triggers an increase in glucagon secretion (42). As plasma glucose concentrations plummet with cord clamping, insulin secretion slowly decreases. These adjustments, particularly the remarkable increase in catecholamine secretion, stimulate glycogenolysis and gluconeogenesis in the neonate (Fig. 37-4).

Islet cell function remains unresponsive for several weeks of neonatal life in term infants. Newborn infants increase insulin and limit glucagon secretion sluggishly in response to glucose challenge. Limited data indicate that these responses become adult-like between the first and second weeks of life (43). This adaptation is critically important because the neonate, unlike the fetus, must

regulate glucose production and storage through feeding and fasting cycles. Little is known about the premature infant's ability to regulate glucose in the neonatal period. The ability to modulate insulin and glucagon secretion probably develops as the neonatal period progresses.

Glucose Transporters

Glucose transporters (Glut) are a family of structurally similar proteins encoded by a family of genes and expressed in a tissue-specific manner in most mammalian tissues (44). Several isoforms have been described in the human fetus and placenta. Because Gluts facilitate transfer of glucose from the maternal to fetal circulation and also uptake of glucose by most fetal and neonatal tissues, they are critically important for growth and development.

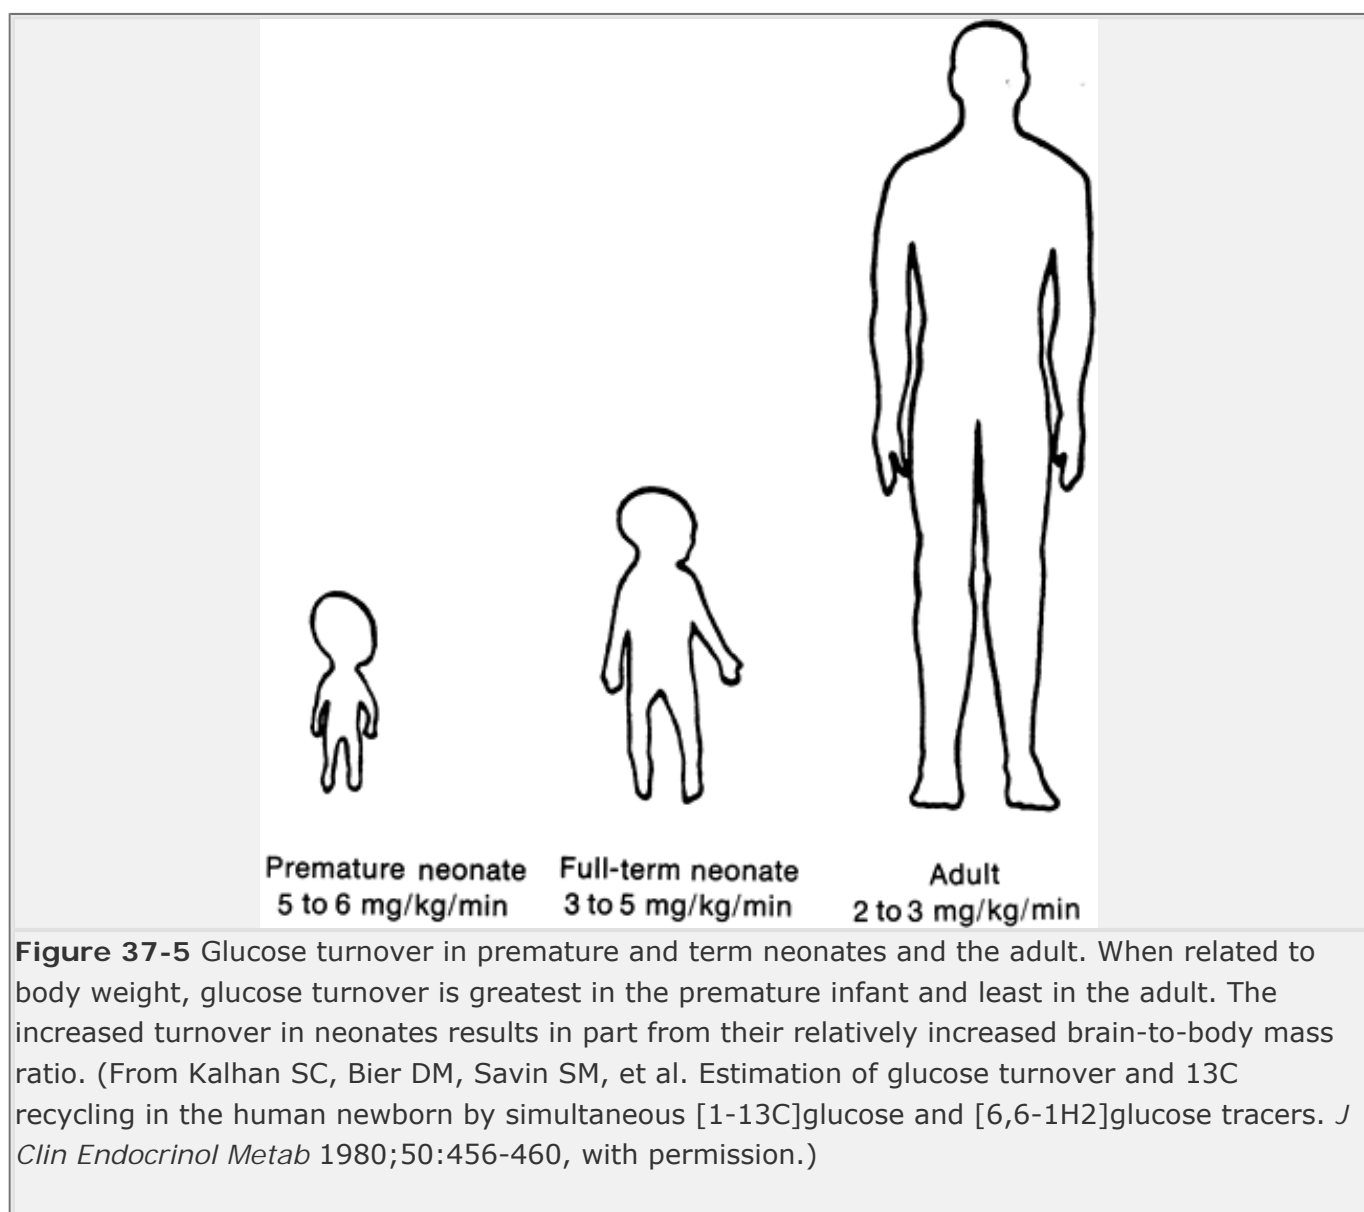

Glut₁ is the dominant isoform in most fetal tissues and the placenta (45,46). Insulin, insulin-like growth factors, and other hormones and peptides regulate its activity and expression. The Gluts are developmentally regulated. The appearance of Glut isoforms varies in time of appearance and type (Glut₂ in liver, Glut₄ in muscle) during intrauterine and neonatal life (47). Glut₁ and Glut₃ are expressed in various tissues, including the placenta. Ambient glucose can affect both glucose transport activity and expression of Glut genes. Glut₁ expression appears to increase with gestation. In placentas of women with diabetes, Glut₃ decreases with gestation, suggesting an attempt by the placenta to limit glucose transport in the face of maternal hyperglycemia (48).

NEONATAL GLUCOSE REQUIREMENTS

The clinician makes a leap of faith in using the chemical or paper strip determination of plasma or blood glucose concentration to judge the adequacy of tissue glucose provision in the neonate. A normal plasma concentration is interpreted to mean that glucose supply to the brain and other organs is adequate for ongoing metabolic needs. To appreciate glucose requirements, glucose

kinetics must be understood.

Glucose turnover represents the rate of production of glucose by the liver and other organs and the simultaneous use or uptake of glucose by the brain and other organs. Turnover is usually expressed as milligrams of glucose per kilogram of body weight per minute. Although stable isotope technology has allowed quantification of glucose turnover in neonates, this methodology cannot be directly applied for clinical purposes. Thus, the clinician must rely on the measurements of glucose concentrations, which are static, as representative of the dynamic rate of glucose production and use in a neonate. In general, plasma glucose concentrations roughly correlate with glucose turnover. Diminished plasma glucose concentrations suggest that glucose production is limited or that glucose use is increased (i.e., need is outstripping production). Elevated plasma glucose concentrations suggest that either production is excessive or, more likely, organ uptake and use are diminished. These are the dynamic physiologic conditions that define hypoglycemia and hyperglycemia.

In the neonate, glucose production correlates directly with brain and body mass, confirming the critical role of glucose as a metabolic fuel (49,50,51,52). This holds even in the most immature of premature infants (53). Glucose turnover for newborn infants, when related to body mass, significantly exceeds that of adults (Fig. 37-5). Premature infants have even greater turnover values than term neonates. This in part reflects the ratio of brain to body mass, which is greatest in premature infants and least in adults. These relations emphasize the importance of glucose as the primary fuel for the brain (Fig. 37-6).

Neonatal Hypoglycemia

A variety of blood and plasma glucose concentration values based on screening of neonates or clinical experience have been recommended as values defining hypoglycemia (54,55). All of these are somewhat arbitrary because they cannot be correlated directly with glucose use rate or severity of symptoms. Because plasma or blood glucose concentrations only roughly reflect glucose turnover, a plasma glucose concentration less than 40 mg/dL should be used to define hypoglycemia. When glucose turnover is sufficient to meet the needs of the organism, concentrations usually

P.880

exceed this value. It also is important to note that values somewhat less than 40 mg/dL still can be associated with adequate glucose provision.

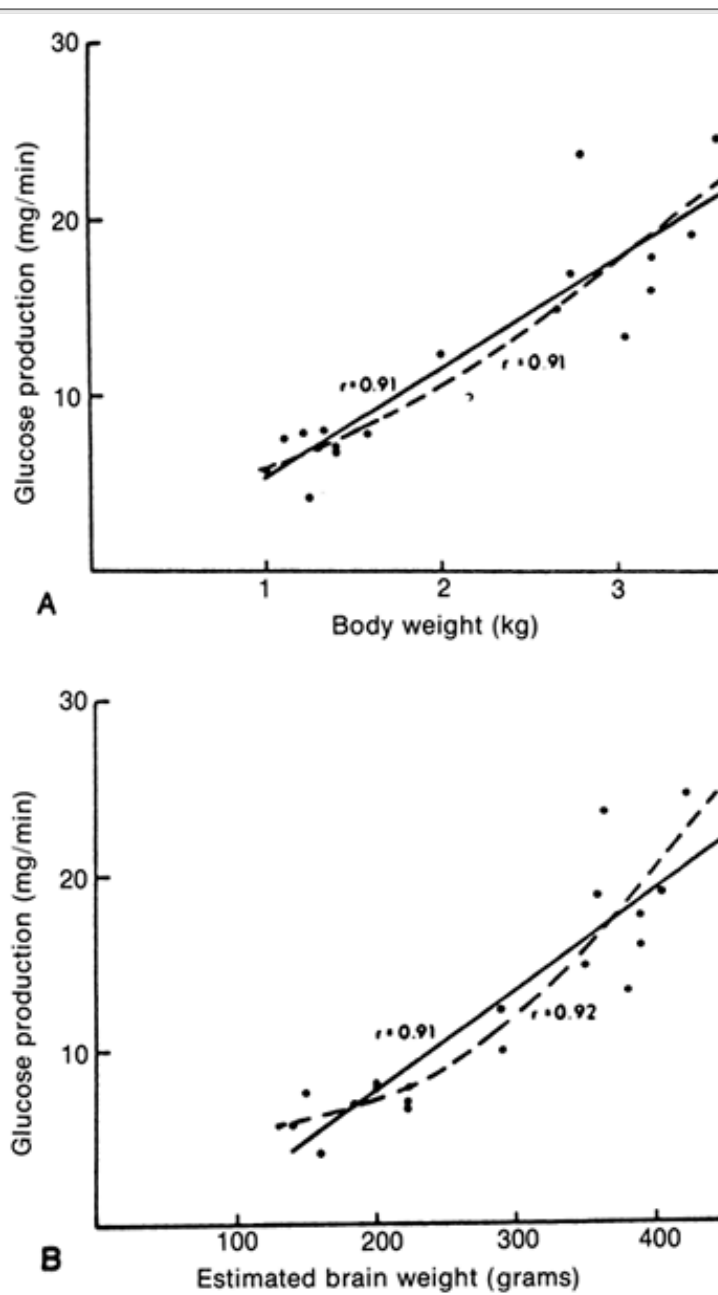

Figure 37-6 Linear and curvilinear regression analyses indicate strong relations between glucose turnover and body mass (A), and between glucose turnover and brain mass (B), in newborn human infants. (From Devaskar SU, Mueckler MM. The mammalian glucose transporters. *Pediatr Res* 1992;31:1-13, with permission.)

The chemical definition of hypoglycemia must take into account the methodology of glucose determination. Glucose concentration in whole blood is approximately 10% to 15% lower than that in plasma. Delay in determination after blood sampling may result in glucose oxidation by erythrocytes, causing falsely low values. Although the use of paper strip methods to estimate glucose concentrations quickly is acceptable, their results should be corroborated by true chemical determinations.

The clinical manifestations of inadequate glucose provision to the neonatal brain range from no symptoms to lethargy or mild tremors to frank convulsions (Table 37-1). The degree of glucose limitation necessary to cause brain damage is unknown. The lack of clearly defined data on this problem and the prevailing opinion concerning the potentially damaging effects of hypoglycemia mandate that infants at risk be monitored and that asymptomatic and symptomatic infants be appropriately treated.

TABLE 37-1 SYMPTOMS OF HYPOGLYCEMIA
Jitteriness
Tremors
Apnea
Cyanosis
Limpness/lethargy
Seizures

All conditions associated with the development of hypoglycemia in the neonate result from one or a combination of two basic mechanisms: inadequate production or excessive tissue use. Inadequate glucose production results from a lack of glycogen stores, an inability to synthesize glucose, or both (Fig. 37-7). Excessive tissue use results from increased insulin secretion. Table 37-2 categorizes infants at risk for hypoglycemia in relation to these basic mechanisms.

Inadequate Glucose Production as a Result of Limited Glycogen Stores

Premature Infants

As indicated, the third trimester of pregnancy is an important period for hepatic glycogen deposition. An infant delivered prematurely without the benefit of part of or the entire third trimester will have limited hepatic glycogen stores. The greater the degree of prematurity, the less glycogen will be present. SGA premature infants are at extremely

P.881

high risk for development of hypoglycemia because available nutrients during intrauterine life are channeled toward growth, with little set aside for glycogen storage. For this reason, SGA premature infants have extremely limited glycogen stores (55,56,57).

Normoglycemia

Hypoglycemia

Figure 37-7 The rates of glucose production and utilization are represented by the faucet and drain of the sink. The level in the sink is equivalent to plasma or blood glucose concentrations. If production from glycogenolysis and gluconeogenesis is adequate, and use is not excessive, normoglycemia exists and the plasma or blood glucose concentration (i.e., the level in the sink) is normal. Hypoglycemia develops if production is inadequate to meet body needs or if use outstrips production. This results in decreased glucose concentrations (i.e., diminished level in sink). (From Kalhan SC, Bier DM, Savin SM, et al. Estimation of glucose turnover and ¹³C recycling in the human newborn by simultaneous [1-¹³C]glucose and [6,6-¹⁴H₂]glucose tracers. *J Clin Endocrinol Metab* 1980; 50:456-460, with permission.)

^aIDM, infant of diabetic mother; LGA, large for gestational age; SGA, small for gestational age; UA, umbilical artery.

Infants Who Have Suffered Perinatal Disease

Infants who are stressed *in utero* are at increased risk for development of hypoglycemia as neonates. Hypoxia, acidosis, and alterations in fetal blood pressure and flow can stimulate catecholamine secretion *in utero*, which in turn will mobilize hepatic glycogen stores. In addition, hypoxia increases the rate of anaerobic glycolysis, thereby accelerating glucose use. These events deplete fetal glycogen stores and place the infant at risk for hypoglycemia after delivery.

Glycogen Storage Disease

Intrinsic defects in glycogen synthesis, storage, or breakdown result in complex metabolic problems (see Chapter 41). Several types of glycogen storage disease (e.g., Ia, I, VI, 0) include hypoglycemia as one of many associated complications (54,58).

Inadequate Glucose Production as a Result of Limited Gluconeogenesis

Small-for-Gestational-Age Infants

Full-term and premature SGA neonates are at great risk for development of hypoglycemia as a result of inadequate hepatic glycogen stores. With treatment, the hypoglycemia is usually short lived. Approximately 1% of SGA infants in whom hypoglycemia develops have a prolonged course requiring intravenous therapy for days. A delay in the induction of gluconeogenic capability probably is responsible for this prolonged hypoglycemia. These SGA neonates have elevated plasma concentrations of gluconeogenic precursors, suggesting an inability to convert exogenous gluconeogenic precursors, such as alanine, to glucose (59,60).

In animal models of intrauterine growth retardation, the induction of one gluconeogenic enzyme, phosphoenolpyruvate carboxykinase, is delayed (61,62). This occurs despite appropriate increases in glucagon and decreases in insulin; these relations should favor enzyme induction. Why some SGA infants fail to induce gluconeogenic capability is unclear. Corticosteroid therapy can be used to treat prolonged hypoglycemia. The success of this practice probably results in part from the ability of corticosteroids to induce hepatic gluconeogenic enzymes.

Many SGA infants have heightened metabolic requirements during the neonatal period. The mechanisms for this are not understood, but they may represent an attempt to compensate for the preceding intrauterine deprivation (63). This may explain the increased glucose requirements demonstrated by some hypoglycemic SGA infants.

Congenital Absence of Gluconeogenic Capability

Unlike SGA infants in whom gluconeogenic capability eventually develops, a few infants have been reported to have permanent congenital lack of gluconeogenic enzymes (64). A single infant who was unable to secrete glucagon also has been reported (65).

Excessive Tissue Use or Hyperinsulinism

A variety of disorders are associated with fetal and neonatal hyperinsulinism. In some disorders, the mechanisms for heightened beta-cell function are well understood, whereas in others, the pathogenesis is unclear. In the former category are infants of diabetic mothers (IDM) and infants

with altered pancreatic islets caused by conditions such as nesidioblastosis and pancreatic adenoma. Those for whom an etiology is not clear include infants with erythroblastosis and Beckwith-Wiedemann syndrome. The finding of a hypoglycemic infant who is macrosomic and requires high rates of glucose infusion (10 to 20 mg/kg body weight per minute) suggests a hyperinsulinemic state.

Infants of Diabetic Mothers

IDM are at great risk for development of hypoglycemia as a result of the carryover of the fetal hyperinsulinemic state into neonatal life. They have elevated plasma insulin concentrations and release insulin briskly in response to glucose challenge. The problems of the IDM are presented in the following sections.

P.882

Nesidioblastosis—Persistent Hyperinsulinemic Hypoglycemia of Infancy

This condition is characterized by macrosomia and profound prolonged neonatal hypoglycemia due to hyperinsulinism. Several different accidents of development at the cell morphologic and molecular level cause persistent fetal and neonatal hyperinsulinism. Classically, in nesidioblastosis, pancreatic ductular cells are found in acinar tissue. In persistent hyperinsulinemic hypoglycemia, there can be focal hyperplasia of pancreatic islet cells or diffuse lesions of the entire pancreas (66,67,68). Focal lesions correspond to somatic defects and are, in some cases, related to mutations of sulfonylurea receptor 1 (69,70,71). Other forms of persistent hyperinsulinemic hypoglycemia of infancy include mutations of the potassium-linked ATP channel in beta cells (72).

Nesidioblastosis or persistent hyperinsulinemic hypoglycemia of infancy should be considered whenever a macrosomic infant has hypoglycemia with elevated plasma insulin concentrations over several days. Rebound hypoglycemia in response to excessive glucose administration is another characteristic. Increased insulin/glucose ratios and glucose requirements exceeding 10 mg/kg/min support the possibility of nesidioblastosis.

Surgical excision of a portion of the pancreas can provide definitive diagnosis and therapy. However, over the long term this may result in the development of diabetes mellitus in the patient. Both somatostatin and diazoxide have been used successfully to limit insulin secretion for as long as several months and may produce remission (73,74)

Unexplained Neonatal Hyperinsulinemia and Hypoglycemia

Infants with Beckwith-Wiedemann syndrome, erythroblastosis fetalis, and those whose mothers took chlorpropamide or benzothiazides are at risk for development of hypoglycemia as a result of hyperinsulinism. In 1964 Beckwith and colleagues (75) and Lazarus and associates (76) independently reported exophthalmos-macroglossia-gigantism syndrome. Such infants frequently have omphalocele, muscular macroglossia, macrosomia, and neonatal hypoglycemia. The hypoglycemia and macrosomia are caused by hyperinsulinism resulting from beta-cell hypertrophy. Some of the morbidity and mortality originally associated with this syndrome was related to unrecognized hypoglycemia. Thus, early recognition and prevention of hypoglycemia is mandatory. The gene responsible for many of the features of this syndrome is found on chromosome 11p15.5 (77). Because the insulin and insulin-like growth factor genes are closely located, combined gene dosage imbalance probably also contributes to the development of hyperinsulinism and hypoglycemia (78).

Infants with erythroblastosis fetalis caused by Rh incompatibility were reported in the past to be at

risk for hypoglycemia from hyperinsulinism secondary to beta-cell hyperplasia (79). The mechanisms responsible for islet cell hyperplasia are unknown, although it was proposed that elevated plasma glutathione concentrations may stimulate the fetal beta cell to increase insulin secretion (80). The advent of direct intravascular transfusion of Rh-affected fetuses may reduce the risk of hypoglycemia. With this therapy, severely affected Rh fetuses that receive serial intravascular transfusions by the percutaneous umbilic technique are normoinsulinemic despite originally having elevated glutathione concentrations. Hypoglycemia does not develop in these fetuses after birth (81).

It is important to note that infants undergoing exchange transfusion are at risk for development of hypoglycemia because of stimulation of insulin secretion by glucose instored erythrocytes (74). Checking for hypoglycemia during and after an exchange transfusion is therefore important.

Maternal use of chlorpropamide and benzothiazide can directly increase insulin secretion in the neonate (82,83). β -sympathomimetic agents used to stop premature labor have been reported to cause neonatal hypoglycemia (84). These drugs stimulate glycogen breakdown and gluconeogenesis in the mother and fetus (85). Both the increased availability of maternal glucose and the β -sympathomimetic agent that crosses the placenta stimulate fetal insulin secretion, resulting in neonatal hyperinsulinism and hypoglycemia. For these reasons, infants whose mothers received tocolytic therapy shortly before delivery should be monitored for hypoglycemia.

Some debate exists as to whether glucose administered to the mother during labor and delivery stimulates fetal beta-cell secretion and causes neonatal hyperinsulinism and hypoglycemia. Acute maternal glucose loading may stimulate fetal insulin secretion and increase the risk of neonatal hypoglycemia (86). If glucose infusion is well controlled, the likelihood of this is minimized. Control of maternal glucose administration is particularly important in situations in which the fetus is suspected of having heightened beta-cell sensitivity (e.g., maternal diabetes, Rh incompatibility) because under these circumstances even moderate excursions of glucose may stimulate fetal insulin secretion.

Malposition of the tip of an umbilic artery catheter at a level between the tenth thoracic and second lumbar vertebrae may result in glucose-stimulated hyperinsulinism. Several infants have been reported in whom hypoglycemia was relieved only when the tip of the umbilic artery catheter was repositioned. It has been proposed that glucose from the malpositioned catheter flows into the celiac axis, thereby stimulating insulin secretion (87). Animal studies have confirmed this possibility (88), which should be considered in unexplained cases of hypoglycemia.

Large-for-gestational-age (LGA) infants whose mothers do not have diabetes mellitus are at risk for transient hypoglycemia. This is particularly true of LGA infants of obese women (89). The mechanisms responsible for hypoglycemia are unknown, although limited data suggest that hyperinsulinism is not a major factor.

P.883

Sepsis in a neonate is often heralded by hypoglycemia or hyperglycemia. The mechanisms for this are not understood. Several studies have indicated rapid glucose disposal rates after intravenous challenge in septic term neonates. Although this suggests a hyperinsulinemic state, insulin secretion in these neonates was normal (90,91). The hyperglycemia and hypoglycemia that often precede the other signs of sepsis in premature infants may be catecholamine mediated.

Hypoglycemia is a well-acknowledged complication of neonatal polycythemia-hyperviscosity syndrome (92). Although polycythemia is more likely to occur in SGA and LGA infants who are at risk for hypoglycemia for other reasons, hypoglycemia also occurs at an increased rate in polycythemic appropriately grown infants. Animal studies have documented diminished cerebral glucose uptake with polycythemia; however, the mechanisms responsible for decreasing glucose

provision are unknown (93). The increased erythrocyte mass is not sufficient to reduce glucose availability. The diminished plasma volume resulting from polycythemia may limit glucose provision. These possibilities remain to be confirmed.

Congenital hypopituitarism is a rare disorder in the neonate resulting from a spectrum of developmental accidents (94,95). Congenital absence of the anterior pituitary is the common cause of this disorder, although holoprosencephaly and optic disk dysplasia also have been associated. Affected male neonates have microphallus, whereas girls have normal external genitalia (96). Neonatal hypoglycemia often develops and can be severe. The endocrine alterations resulting from congenital hypopituitarism are complex, and the mechanisms by which they cause hypoglycemia are not understood. Congenital syphilis has been reported to cause hypopituitarism and this syndrome (97). Growth hormone is important in this regard because it can reverse hypoglycemia. Because hypoglycemia can develop later in the postnatal period, infants should have growth hormone therapy initiated for the long term.

Infants who have suffered hypothermia are at increased risk for development of hypoglycemia (98). This may result from increased availability of catecholamines (99), which would deplete glycogen reserves. Tissue use of glucose might also be increased under these conditions.

Other unusual clinical conditions reported in association with hypoglycemia include salicylate administration (100), congenital adrenal hyperplasia (101), and trisomy 13 mosaicism (102). The mechanisms for these phenomena are not known.

Hypoglycemia has been noted to sometimes occur in infants who suffer poor calorie intake for prolonged periods as a consequence of inadequate maternal breast milk production. The mechanisms for this are not known but probably involve glycogen depletion and diminished release of gluconeogenic precursors by striated muscle. Severe hepatic damage, most likely a result of impaired substrate transport and gluconeogenic capability, can also cause hypoglycemia. Disruption of intravenous glucose administration or rapid reduction in the rate of a glucose infusion can be associated with rebound hypoglycemia as a result of sluggish beta-cell responsiveness; insulin secretion may not decrease with appropriate rapidity and in response to cessation of exogenous glucose.

Neonatal Hyperglycemia

Hyperglycemia occurs primarily in three major groups of infants: those who are very premature, those who have neonatal diabetes mellitus, and those who are septic. Altered glucoregulation in response to sepsis was discussed in the preceding section (see Unexplained Neonatal Hyperinsulinemia and Hypoglycemia) (103,104).

The Very Premature Infant

Advances in perinatal care have improved the survival rate of the very premature infant. With this, the problem of glucose intolerance has greatly increased because the risk of hyperglycemia is at least 18 times greater in infants weighing under 1,000 grams than in those weighing more than 2,000 grams. Depending on the definition, age at screening, and type of intravenous solution administered, the incidence of hyperglycemia in very premature infants has been reported to range from 20% to 86% (103,104). In general, the smaller and more premature an infant, the greater the likelihood that he or she will not tolerate exogenous glucose at maintenance rates (4 to 6 mg/kg/minute). It is not uncommon to administer glucose at 1 to 2 mg/kg/minute or less and still observe plasma glucose concentrations exceeding 200 mg/dL.

Several basic mechanisms are probably responsible for glucose intolerance in very premature infants. Many probably do not secrete glucoregulatory hormones appropriately. In addition, end-organ response to these hormones may be blunted. Thus, endogenous glucose production may

continue while tissue glucose uptake is limited despite intravenous glucose therapy. Limited data indicate that the premature infant will only slowly increase insulin secretion in response to glucose challenge (105,106,107,108,109). The amount secreted may not be sufficient to regulate glucose. Such infants may (108) or may not (110) decrease glucagon in response to glucose. In addition, very premature infants can be resistant to insulin (111). This resistance is accentuated by catecholamines, which are often quite elevated. These factors contribute to the limited ability of the premature infant to reduce glucose production in the same manner as the adult when exogenous glucose is provided (Fig. 37-8).

Neonatal Diabetes Mellitus

This is a rare disorder characterized by hypoinsulinism, progressive wasting, polyuria, and glycosuria during the neonatal period. Such infants usually are not ketotic. Of note, they are always SGA (112,113). The intrauterine growth

P.884

retardation results from limited fetal insulin secretion and exemplifies the importance of insulin as a fetal growth-stimulating hormone. This disorder may be heterogeneous with respect to etiology. Synthesis of an abnormal, poorly functioning insulin molecule or receptor deficiencies are other possible causes. Neonatal diabetes mellitus usually is transient; the early acute period calls for standard diabetic therapy (i.e., monitoring caloric intake and administering exogenous insulin).

Figure 37-8 Hepatic glucose production rates in human premature neonates, full-term neonates, and adults during either saline (open symbols) or glucose (closed symbols) infusion. With glucose infusion, adults and full-term infants but not preterm infants reduce endogenous glucose production. Many preterm infants are apparently unable to regulate glucose production; this contributes to the development of hyperglycemia in these infants. (From Bower BD, Jones LF, Weeks MM. Cold injury in the newborn. A study of 70 cases. *Br Med J* 1960;5169:303-309, with permission.)

DIAGNOSIS AND TREATMENT

Hypoglycemia

All infants at risk for development of hypoglycemia should undergo frequent plasma glucose determinations. The commercially available paper strip indicators are widely used. Because their accuracy is fair, it is desirable to confirm values close to hypoglycemia or hyperglycemia with laboratory chemical determinations. Infants at risk for hypoglycemia should be checked frequently during the first 4 hours of life and then at 4-hour intervals until the risk period has passed. If an infant is feeding, blood sampling should be done before feeding. For IDM and SGA infants, the screening should continue for at least 24 hours.

Infants who have borderline asymptomatic hypoglycemia, who do not have respiratory distress syndrome (RDS) or other serious disorders, and who are capable of enteral feedings may receive either 5% dextrose solution or formula as their initial treatment. In general, this approach can be used for infants at term who are LGA or SGA. However, because this mode of therapy is not always successful, plasma or blood glucose concentrations must be checked shortly after feeding.

Intravenous administration of glucose in a quantity sufficient to meet tissue requirements is the treatment of choice for hypoglycemia. The administration of 10% or 15% dextrose solution at 5 to 10 mL/kg body weight, followed by a continuous infusion at 5 to 6 mg/kg body weight/minute, will increase plasma glucose concentrations to 40 mg/dL or greater and acutely meet tissue requirements. The maintenance rates may require adjustment depending on the etiology of hypoglycemia.

Glucagon and epinephrine increase glucose production. Because both mobilize hepatic glycogen stores, their efficacy in treating hypoglycemia is variable, particularly in infants with limited hepatic stores. The numerous cardiovascular effects of epinephrine also limit its usefulness in infants.

Infants who are hypoglycemic for prolonged periods as a result of an inability to produce glucose can be treated with corticosteroids (hydrocortisone 5 mg/kg/day every 12 hours; prednisone 2 mg/kg/day orally). Steroids exert some of their effects by inducing gluconeogenic enzyme activity.

Hyperglycemia

Hyperglycemia in low-birth-weight infants traditionally has been treated by reducing the rate of administration of exogenous glucose. This is something of a clinical paradox because such a reduction can theoretically limit glucose availability to the brain. Attempts in the past to provide exogenous insulin as a means to regulate glucose met with variable success, primarily because of technical difficulties in providing insulin (111,114,115). New insulin delivery systems designed for children and adults provide the means to deliver minute amounts of insulin under controlled conditions. These systems have finely tuned programmable pumps and tubing that does not bind insulin (116). Application of this technology has met with preliminary success (117). Individualized continuous insulin infusion to infants at 26 weeks of gestation weighing 700 to 800 grams

enhanced glucose infusion and parenteral energy intake. Weight gain was significantly greater over 7 to 21 days compared with infants managed conventionally (Fig. 37-9). If further studies confirm these observations and clarify the potential metabolic consequences of this therapy, this method may prove beneficial in treating hyperglycemia in low-birth-weight infants.

Figure 37-9 Mean glucose infusion rates per day in insulin-treated (solid line) and control (dashed line) very-low-birth-weight infants. The controlled administration of insulin significantly increased glucose infusion from day 2 to 16. (From Johansson EDB. Plasma levels of progesterone in pregnancy measured by a rapid competitive binding technique. *Acta Endocrinol (Copenh)* 1969;61: 607-617, with permission.)

P.885

CONSEQUENCES

Hypoglycemia

The clinical manifestations of inadequate glucose provision to the brain range from no symptoms to mild tremors to seizures. The issue of potential long-term sequelae of hypoglycemia remains unclear. This issue is complicated by the fact that hypoglycemia often occurs in infants who have coexisting conditions that also can cause brain damage. The observations suggesting that asymptomatic hypoglycemia poses less of a risk compared to symptomatic hypoglycemia are limited, as are the observations that associate prolonged hypoglycemia with a greater risk of brain damage than brief hypoglycemia. Limited data suggest that seizures associated with hypoglycemia worsen prognosis (118,119,120,121,122,123,124,125,126,127). Because of the uncertainty in this area, all hypoglycemic infants, symptomatic or not, should be appropriately treated.

Hyperglycemia

Hyperglycemia has been associated with an increased incidence of mortality, intracranial hemorrhage, and developmental delay in very premature infants. Whether hyperglycemia causes these problems or is merely associated with their development is unclear. Increased serum osmolarity resulting from hyperglycemia might disrupt cell-serum balance and cause cell injury (103). In addition, hyperglycemia can alter cell glucose transport, which may perturb cell

metabolic functions.

Infants of Diabetic Mothers

Table 37-3 lists the frequently occurring problems of IDM categorized according to proposed mechanisms. The fetal and neonatal hyperinsulinism central to many of these problems results from exaggerated provision of maternal metabolic fuels to the fetus, resulting in pancreatic beta-cell hypertrophy, hyperplasia, and hyperfunction (1,14). The alterations in maternal metabolism resulting from diabetes mellitus that are responsible for these and other effects on the fetus have been reviewed.

TABLE 37-3 PROBLEMS OF THE INFANT OF A DIABETIC MOTHER

Macrosomia or birth stress
Hypoglycemia
Respiratory distress syndrome
Intrauterine growth retardation
Hypocalcemia
Hyperbilirubinemia
Polycythemia or hyperviscosity
Cardiomyopathy
Congenital anomalies
Hyperinsulinism
Altered metabolic fuels, uteroplacental insufficiency
Decreased parathormone
Increased erythrocyte destruction, bruising

Altered Fetal Growth

Macrosomia, a clinical term suggesting excessive weight for gestational age, is a well-known characteristic of IDM (Fig. 37-10). Macrosomia in IDM results primarily from increased adiposity because IDM have both adipocyte hyperplasia and adipocyte hypertrophy (128). IDM also have excess nonfatty tissue. The liver and heart often are enlarged, and skeletal muscle increased. Much of this excess tissue is located in the shoulders and intrascapular area. Because IDM have normal brain growth, this results in a disproportionality between head and shoulder size and greatly increases the risk of shoulder dystocia (Fig. 37-11). This

P.886

birth complication occurs far more frequently in macrosomic IDM than in large infants of mothers who do not have diabetes. Macrosomia is responsible for the great risk of birth trauma, meconium aspiration syndrome, persistent pulmonary hypertension, and high incidence of cesarean section delivery of IDM.

Figure 37-10 A macrosomic infant of a diabetic mother (IDM) has head circumference and length that are at the 90th percentile; the IDM's body weight greatly exceeds the 90th percentile. The IDM has considerable fat deposition in the shoulder and intrascapular area.

Figure 37-11 Lateral skull and neck radiograph of an infant of a diabetic mother after a difficult vaginal delivery. Infants of diabetic mothers are at extreme risk for shoulder dystocia, which can result in severe complications, such as separation of the C1-C2 cervical spine.

Because insulin has both mitogenic and anabolic effects in the fetus, the fetal hyperinsulinemic state is central to the development of macrosomia. The augmented production of insulin by the fetus stimulates the growth of insulin-sensitive tissues (e.g., adipose, muscle, connective) to cause macrosomia. Hepatic glycogen storage is exaggerated. The effect of insulin probably is mediated to some extent through stimulation of insulin-like growth factors (129). It is not surprising that head growth is normal in IDM during intrauterine life because insulin does not stimulate brain growth to any great extent.

The excess fat in IDM develops during the third trimester; IDM delivered before 30 weeks of gestation rarely are LGA. Serial fetal ultrasound measurements confirm that the fetal IDM does not exceed normal growth limits until 28 to 30 weeks of gestation (30). Despite improved maternal therapy, 20% to 30% of insulin-dependent diabetic women continue to bear macrosomic infants (130). Women with gestational diabetes, the mildest form of carbohydrate intolerance, have as great an incidence of macrosomia as women with preexisting diabetes.

Intrauterine growth retardation is another well-known complication of diabetes in pregnancy. The development of growth retardation has been attributed to maternal vascular disease, causing

uteroplacental insufficiency. More recent data suggest that growth retardation may result from alterations in maternal metabolic fuel availability during early gestation (131).

Figure 37-12 Beta-cell response to intravenous glucose challenge in infants of diabetic mothers (IDM) and infants of mothers with normal carbohydrate metabolism (INM). C-peptide is cleared from the proinsulin molecule when the beta cell is stimulated to secrete insulin. The measurement of C-peptide represents insulin on an equimolar basis and is a more accurate measure of beta-cell secretion than insulin in IDM. IDM exuberantly secrete insulin in response to glucose challenge. This adult-like response differs greatly from the normally expected sluggish insulin response of the INM. The significantly increased insulin concentration in IDM before glucose challenge (i.e., 0 minutes) indicates that basal insulin secretion also is elevated. The increased beta-cell function in IDM is responsible for their high incidence of hypoglycemia.

Hypoglycemia

Approximately 25% to 50% of all IDM who manifest hypoglycemia will do so within the first 24 hours of life. Hypoglycemia is particularly likely to occur in macrosomic IDM because hyperinsulinism is responsible for both fetal overgrowth and hypoglycemia (Fig. 37-12) (132). Several studies also suggest that these IDM may fail to release glucagon or catecholamines in response to hypoglycemia (133). These hormonal alterations result in both increased glucose clearance and diminished glucose production.

Hypocalcemia and Hypomagnesemia

Hypocalcemia develops in 10% to 20% of IDM during the neonatal period. This usually occurs in association with hyperphosphatemia and occasionally with hypomagnesemia. Parathormone concentrations are significantly lower in IDM than in infants of nondiabetic mothers during the first 4 days of life (Fig. 37-13). This may be a result of hypomagnesemia, which limits parathormone secretion even in the presence of hypocalcemia. Maternal hypomagnesemia, which may occur from increased renal loss secondary to diabetes, is believed responsible for fetal and neonatal hypomagnesemia (134,135). Birth asphyxia, which frequently occurs in IDM, also causes hypocalcemia.

Figure 37-13 Parathormone (PTH) and calcium concentration in infants of diabetic mothers (circles) and full-term control (triangles) infants. Infants of diabetic mothers have lower plasma calcium and PTH concentrations during the first 6 days of life. (From Lucas A, Morley R, Cole TJ. Adverse neurodevelopmental outcome of moderate neonatal hypoglycaemia. *BMJ* 1988;297:1304-1308, with permission.)

Hyperbilirubinemia

Indirect hyperbilirubinemia develops in 20% to 25% of IDM. Their carbon monoxide production is increased as a result of increased hemoglobin breakdown and bilirubin production (136). The increased rate of erythrocyte breakdown in IDM is probably linked to altered erythrocyte membrane composition resulting from changes in maternal fuel availability. Polycythemia frequently occurs in IDM, and the normal breakdown of this increased erythrocyte mass also causes hyperbilirubinemia. Macrosomic IDM are often bruised at birth; the resultant resorption of blood also contributes to hyperbilirubinemia.

Hyperviscosity

IDM have a 10% to 20% risk of being polycythemic and developing neonatal hyperviscosity syndrome. Several factors are responsible for this. The hematocrit of umbilic-cord blood at birth

tends to be elevated, probably as a result of increased erythropoiesis (137).

The increased incidence of renal vein thrombosis reported in IDM may be related to hyperviscosity, although this disorder does occur in IDM with normal hematocrits.

Unexpected Fetal Death

In the past, a high incidence of unexpected fetal death occurred in late gestation. Improvement in metabolic control of maternal diabetes throughout pregnancy and new methods to assess fetal status have decreased the incidence of this tragic complication. The mechanisms of unexpected fetal death are not completely understood. In the fetal sheep, sustained hyperglycemia is associated with increased insulin secretion, elevated fetal oxygen consumption, acidosis, and death (138). This could explain the association between poor maternal metabolic control and the increased risk of fetal death.

Respiratory Distress Syndrome

IDM are at increased risk of developing RDS. In the past, IDM were at a four- to six-fold greater risk for RDS than infants of nondiabetic mothers (139). This incidence has been reduced substantially by the recent emphasis on tight control of maternal metabolism. The increased risk of RDS in poorly regulated diabetic women is due in great part to fetal hyperinsulinism. Insulin adversely affects fetal lung maturation by inhibiting the development of enzymes necessary for the synthesis of the phospholipid components of surfactant (140). Standard methods to assess fetal lung maturity antenatally may not be applicable to a diabetic pregnancy. The measurement of phosphatidylglycerol has greatly improved this capability.

Cardiomyopathy

IDM are at increased risk for various cardiomyopathies (141). Many have thickening of the interventricular septum and left or right ventricular wall. The increased cardiac muscle mass results from the fetal hyperinsulinemic state. Most of these infants are asymptomatic, and the thickening is detected by electrocardiogram or echocardiogram. In a small fraction of infants, outflow obstruction severe enough to cause left ventricular failure may occur. These abnormalities generally regress over 3 to 6 months, and the condition appears to have no permanent effect on the myocardium. Those infants with congestive heart failure who survive the initial period with medical management also improve spontaneously.

Occasionally, IDM have severe congestive heart failure at birth. Frequently, these infants have suffered intrapartum asphyxia and are hypoglycemic and hypocalcemic. Such infants generally respond to assisted ventilation and correction of their metabolic abnormalities and usually recover completely. It is unclear whether heart failure results from the combined effects of hypoglycemia, hypocalcemia, and asphyxia on an inherently normal myocardium, or whether the myocardium is abnormal and therefore more susceptible to failure.

Figure 37-14 Magnetic resonance image of an infant of a diabetic mother. The infant has spinal agenesis-caudal regression syndrome. The spinal cord is interrupted, and hip-femur relationships are malformed.

P.888

Congenital Abnormalities

Major congenital malformations occur two to four times more frequently in IDM than in infants born to nondiabetic women. Although many abnormalities occur in IDM, ventricular septal defects, transposition of the great arteries, and spinal agenesis-caudal regression syndrome occur with particular frequency (Fig. 37-14). Neural tube defects, gastrointestinal atresia, and urinary tract malformations also are relatively common. A transient anomaly unique to IDM is known as the neonatal small left colon, microcolon, or lazy colon syndrome. This condition presents as gastrointestinal obstruction, and barium contrast studies suggest congenital aganglionic megacolon. Unlike infants with Hirschsprung disease, these infants have normal innervation of the bowel and ultimately have normal bowel function.

Poor control of maternal diabetes during the first trimester, a critical period of organogenesis, has been proposed as the mechanism for the increased incidence of malformations (142,143). IDM with congenital abnormalities generally have normal karyotypes (144). *In vitro* studies using embryos of laboratory animals have demonstrated that altering metabolic fuels can produce profound malformations (145). Clinical studies, however, have not confirmed a relation between birth defects and alterations in maternal metabolic variables (146).

Postnatal Problems

The postnatal problems of IDM are consistent in the Barker hypothesis which links intrauterine disorders with adverse adult outcomes (147). IDM are at increased risk for development of obesity in later life, compared to infants of mothers with normal carbohydrate metabolism (148). Studies suggest that *in utero* hyperinsulinism may be responsible for this postnatal phenomenon. IDM who become obese during childhood have the severest hyperinsulinism *in utero* (149).

Whether maternal diabetes adversely affects the long-term cognitive development of the offspring remains unanswered. In the past, the increased incidence of birth trauma and neonatal disorders probably contributed to an increased risk of poor outcome. Studies suggest that altered maternal metabolic fuel availability also may have an effect. An inverse correlation has been reported between childhood IQ and degree of abnormality of second- and third-trimester maternal lipid metabolism (150). This is consistent with the potential detrimental effect of ketones on fetal brain

development.

A yet unanswered question is whether IDM develop diabetes mellitus during postnatal life. Children and adults who were IDM have an increased incidence of diabetes mellitus. Limited data suggest that offspring of fathers with insulin-dependent diabetes have a five-fold greater risk for development of diabetes mellitus than offspring of insulin-dependent diabetic mothers. Although diabetes is in part a genetic disorder, it has not been possible to delineate precisely the mode of inheritance in IDM. It is possible that the altered metabolic state of the diabetic pregnancy may modulate this genetic predisposition. Noninsulin-dependent diabetes mellitus occurs by age 20 years in 45.5% of infants of insulin-dependent diabetic mothers but in only 8.6% and 1.4% of prediabetic and nondiabetic mothers, respectively. The mechanisms by which alterations in maternal glucose and other metabolic fuels alter fetal beta-cell function are unknown.

Chapter 38

Congenital Anomalies

Scott Douglas McLean

Much of our practice of pediatrics and neonatology is geared toward the provision of acute care, such as resuscitation, antibiotics, and intravenous fluids. When we encounter a newborn with one or more birth defects, this acute-care paradigm remains—and appropriately so—in the forefront of our clinical perspective. However, the child with a congenital anomaly must also be simultaneously considered from a different perspective, one that looks far back and far forward in time. When did this structural abnormality have its origin? Was there a teratogenic exposure during a critical period of organogenesis? Has a new mutation occurred in one of the parents' germ cells? Are some of the DNA alterations in this newborn ancient relics that only now reveal themselves in the living world? Is this congenital anomaly a clue to the presence of other pathology? Will our best efforts have a reasonable chance of ensuring long-term health? Will siblings or offspring be similarly affected?

Over the past several decades, research has dramatically improved our insights into the genetic and environmental causes of many isolated birth defects, multiple congenital anomaly syndromes, and other genetic conditions. In some instances, the molecular pathology has been dissected in impressive detail, such as for cystic fibrosis (CF) and the CF transmembrane regulator gene on chromosome 7q31. For other conditions, such as the VACTERL association, we have yet to understand the genomic origins but have accumulated much clinical and epidemiologic data that allow us to formulate helpful diagnostic criteria, predict prognosis, and estimate recurrence risks. For any individual newborn with a congenital anomaly, establishing an accurate diagnosis is the key to intelligent clinical management in both the short and long term.

In a busy nursery, caring for a newborn with a congenital malformation is nearly a daily activity. Although the consultative services of a clinical geneticist or dysmorphologist often are quite helpful, this resource may not be available, and the attending pediatrician or neonatologist must assume that role, at least temporarily. Naturally, such a task brings many challenges—cognitive, managerial, and emotional—for which the practitioner often feels underprepared. Useful tools include a careful prenatal history, three-generation pedigree, meticulous physical examination, and sensitivity for the emotional and social impact of the birth of a malformed child. A dramatically visible departure from the norm multiplies a parent's fear, concern, worry, and guilt and might also become very stressful for nurses and physicians. Consequently, to optimize care for the infant and to instill confidence and control in an intrinsically unsettling situation, the clinical leaders of the health care team should prepare themselves by becoming familiar with a general strategy for diagnosis and management of an infant with congenital malformations.

In aggregate, birth defects are ubiquitously common and have likely been so throughout human history. Epidemiologic studies consistently place the incidence of major malformations in newborns at 2% to 3% (1,2). Many other neonates harbor occult anomalies that are eventually detected later in childhood, giving a cumulative rate of major birth defects of approximately 4%, or one of every 25 newborn children. In the United States, 150,000 children with birth defects are born each year. Congenital anomalies are the leading cause of infant mortality and the second leading cause of death in children between the ages of 1 and 4 years (3). Excluding the intangible costs of pain and suffering, the lifetime economic cost per child in 1992 ranged from \$75,000 to \$503,000 (4). The Centers for Disease Control and the National Birth Defects Prevention Network conduct and facilitate a number of research and surveillance activities, central to which is the commitment of individual practitioners to diagnose and report all congenital defects accurately and reliably.

DEFINITIONS AND CLASSIFICATIONS

A congenital anomaly is any alteration, present at birth, of normal anatomic structure. It may be major or minor, isolated or part of a larger constellation of defects, of clear or uncertain cause. Several genetic and environmental etiologies are well delineated (Table 38-1), but the fundamental etiology of nearly half of all birth defects is unknown (5).

The nomenclature for various birth defects and malformation syndromes can be a source of confusion for both the novice and veteran clinician alike. Categories of anomalies

may seem arbitrary and capricious, but a developmental or embryologic perspective often will cast light on the rationale behind a particular designation. The term "birth defect," enjoys wide usage and conveys immediate meaning for parents. "Congenital anomaly" is fundamentally equivalent, indicating an abnormality of anatomic structure present at birth and may be further refined in terms of severity ("major" and "minor"), pathogenesis ("malformation," "deformation," "disruption," "dysplasia"), or pattern ("isolated," "syndromic"). These terms are defined in Table 38-2.

TABLE 38-1 CAUSES OF MALFORMATIONS IN NEWBORNS^a

	Percent
Chromosome abnormalities	10.1
Single mutant genes	3.1
Familial	14.5
Multifactorial inheritance	23.0
Teratogens	3.2
Uterine factors	2.5
Twinning	0.4
Unknown cause	43.2

^a Modified from Nelson K, Holmes LB. Malformations due to presumed spontaneous mutations in newborn infants. N Engl J Med 1989; 320:19, with permission.

The great majority of congenital anomalies occur in isolation, as a single phenomenon, and are postulated to arise because of a primary, intrinsic malformation of a fetal structure that occurs at 10 weeks of gestation or earlier. On occasion, other family members are similarly affected, implying the presence of a single gene mutation that behaves as an autosomal dominant, autosomal recessive, or X-linked trait. More commonly, however, the family history is entirely bereft of other affected individuals. Classic mendelian genetics does not adequately explain this situation, but another model—multifactorial inheritance—has proven quite useful.

TABLE 38-2 Terminology

Major anomaly	An anatomic abnormality severe enough to reduce normal life expectancy or compromise normal function; e.g., neural tube defect, cleft lip.
Minor anomaly	A structural alteration that either requires no treatment or can be corrected in a straightforward manner, with no permanent consequences, and present in less than 4% of the normal population; e.g., preauricular skin tag, small ventricular septal defect.
Minor variant	A physical feature, often familial, that is present in only a small proportion (1%-5%) of normal individuals, e.g., simian crease of the palm, epicanthal folds.
Malformation	A morphologic defect of an organ, part of an organ, or region due to an <i>intrinsically abnormal developmental process</i> ; e.g., microphthalmia, ectrodactyly.
Deformation	An abnormal form, shape, or position of a part of the body caused by <i>unusual mechanical forces on normal tissue</i> ; e.g., club foot, plagiocephaly.
Disruption	A morphologic defect due to extrinsic interference with a normal developmental process resulting in <i>breakdown of normal tissue</i> ; e.g., amniotic band sequence, fetal alcohol syndrome.
Sequence	Several anomalies that occur due to a cascade of events, caused by a single initiating event or anomaly; e.g., Potter sequence, Pierre Robin sequence.
Developmental field defect	A set of morphologic defects that share a common or contiguous region during embryogenesis; e.g., hemifacial microsomia.

Association	A nonrandom set of anomalies in which the specific components occur together more frequently than would be expected by chance and for which cause is not established; e.g., VACTERL association, CHARGE association.
Syndrome	A recognizable pattern of anomalies that “run together;” e.g., Down syndrome, Smith-Lemli-Opitz syndrome.
VACTERL: Vertebral defects, imperforate Anus, congenital Cardiac anomalies, Tracheo Esophageal fistula, Radial defects, Renal dysplasia, and other Limb malformations.	
CHARGE: Coloboma, Heart disease, Atresia choanae, Retarded growth and development and/or CNS anomalies, Genital hypoplasia, and Ear anomalies or deafness.	

In the multifactoral model, a constellation of influences, including multiple genes inherited from each parent, and poorly defined environmental influences, seems to allow a developing fetal structure to cross a threshold of “liability,” beyond which morphogenesis proceeds abnormally (6). These birth defects tend to recur at a low rate, approximately 3% to 5% for each subsequent pregnancy for the parents of one affected child, 10% to 15% if two siblings have previously been similarly affected.

Multiple congenital malformations, on the other hand, are caused by a very different spectrum of fundamental problems. For a child with several major anomalies, the underlying cause is more likely to be a malformation sequence, developmental field defect, association, or syndrome, each of which may in turn may be caused by a chromosomal anomaly, a single-gene mutation, a teratogen, or unknown factors. Minor anomalies deserve special attention because, in terms of diagnostic significance, they are frequently the equals of the major malformations (7), often providing the linchpin of clinical recognition of a rare

P.894

syndrome. A single minor anomaly is present in 13% of neonates, but more than one is decidedly less common—two minor anomalies occur in only 1%, and three minor anomalies in just 0.05% (8). As the numbers of minor anomalies increase, the search for occult major anomalies and the consideration that a syndromic diagnosis is possible should increase proportionately.

MANAGEMENT STRATEGY

Since the last edition of this textbook, the American College of Medical Genetics (ACMG), under the sponsorship of the New York State Department of Health, has published clinical guidelines for health care practitioners who care for newborn infants with one or more birth defects (9). This document incorporates expert opinion from a broad array of disciplines and describes practical, detailed components of the history, physical examination, differential diagnosis, diagnostic stratagem, genetic counseling, and record keeping. As such, the ACMG guidelines represent a significant step forward in promoting a national standard of care with which neonatologists, pediatricians, and family practitioners should become familiar.

The fundamental approach to managing an infant with one or more congenital anomalies is much the same as the management of any other clinical scenario. Effective clinical intervention is organized around an understanding of the natural history of the condition at hand. History taking begins with conception and includes a detailed three-generation pedigree. Physical features must be scrutinized, measured, and documented with precision, and confirmatory studies must be carefully chosen and accurately interpreted. Common pitfalls include incomplete ascertainment of all relevant information, impetuous diagnosis and prognostication, and failure to communicate with parents in a straightforward and compassionate manner.

Neonates with congenital malformations present with extremely variable clinical needs, so a “one size fits all” strategy for management has limited practical value. However, a number of algorithmic approaches have proven useful. In the ACMG clinical management algorithm (Fig. 38-1), an early determination of whether the malformation is isolated or multiple helps organize subsequent clinical activity. Beyond this, the major thrust of activity is devoted to pursuing and establishing a precise diagnosis, the essential starting point for understanding natural history, designing effective intervention, and educating the family about recurrence risks and prenatal management options for subsequent pregnancies. Another, more integrated approach suggested by Dr. Judith Hall (10) delineates three parallel and simultaneous lines of activity, as outlined in Fig. 38-2. Urgent interventions for the infant are undertaken immediately. Also, from the outset, the family is provided with support in the form of information, preliminary interpretation, and acknowledgment of their distress and concern. The third concurrent activity is data collection—history, physical, laboratory studies and imaging, and preliminary definition of the nature of the problem. All efforts should be made to verify information and to amass

a complete database.

History

Prenatal information, beginning with conception, must be specifically sought from both the mother and her obstetric records. The nature and timing of maternal illnesses, such as rubella or cytomegalovirus infections, including febrile episodes, can suggest a direct infectious disruption. Maternal use of alcohol, drugs, medications, or tobacco—degree, gestational timing, and duration—should be documented. Quickening, the date at which there is maternal sensation of fetal movement, and the subsequent vigor and frequency of fetal activity, reflects central nervous system integrity and peripheral muscular function. Prenatal ultrasonography, especially if performed serially and in detail, may yield critical information regarding the amount of amniotic fluid and malformations of the kidneys, brain, heart, skeleton, and gastrointestinal system. Recent reports have suggested an association between in vitro fertilization and several genetic conditions, such as Angelman syndrome (11), retinoblastoma (12) and Beckwith-Wiedemann syndrome (13). Chorionic villus sampling has previously been suspected to cause limb-reduction deformities, but recent studies by the World Health Organization affirm its safety for first-trimester prenatal diagnosis (14). A review of the ultrasound studies and the obstetric record, and a discussion with the attending obstetrician or perinatologist, can save valuable time and effort. Maternal serum and amniotic fluid α fetoprotein levels and prenatal chromosome studies should be verified and documented in the infant's medical record. Late trimester problems with fetal position, such as transverse or breech lie, potentially indicate neuromuscular or structural abnormalities of the fetus. Fetuses with significant neuromuscular problems often encounter perinatal distress and have a poor transition to extrauterine life. Finally, it often is useful to inquire about any prenatal event or factors that the parents suspect, even remotely, may have caused their infant's problems. Concerns about witnessing a solar or lunar eclipse, for example, are best made explicit, if only for the purpose of assuaging guilt.

Family History

A systematic and detailed inquiry into the age, health, development, and congenital anomalies of all members of the immediate family comprises the core of an adequate family history. All second-degree relatives, such as grandparents, aunts, uncles, nieces, and nephews, should be considered, and more distant relatives may contribute valuable data. A three-generation pedigree provides a concise picture of patterns of inheritance. One must specifically clarify the biologic parentage for each individual. Spontaneous abortions, miscarriages, stillbirths, and infant deaths clearly are germane, but parents typically omit this information unless the interviewer specifically inquires. Consanguinity also should be directly but tactfully questioned. A "quick pedigree" is an

P.895

oxymoron; routinely the entire process requires patience and time. With this in mind, the interviewer will be sympathetic, on the day of delivery, to parents who are understandably terrified, exhausted, and disoriented. After rest, time, and a chance to speak with relatives, they may be more prepared to help refine and expand on their complete family history.

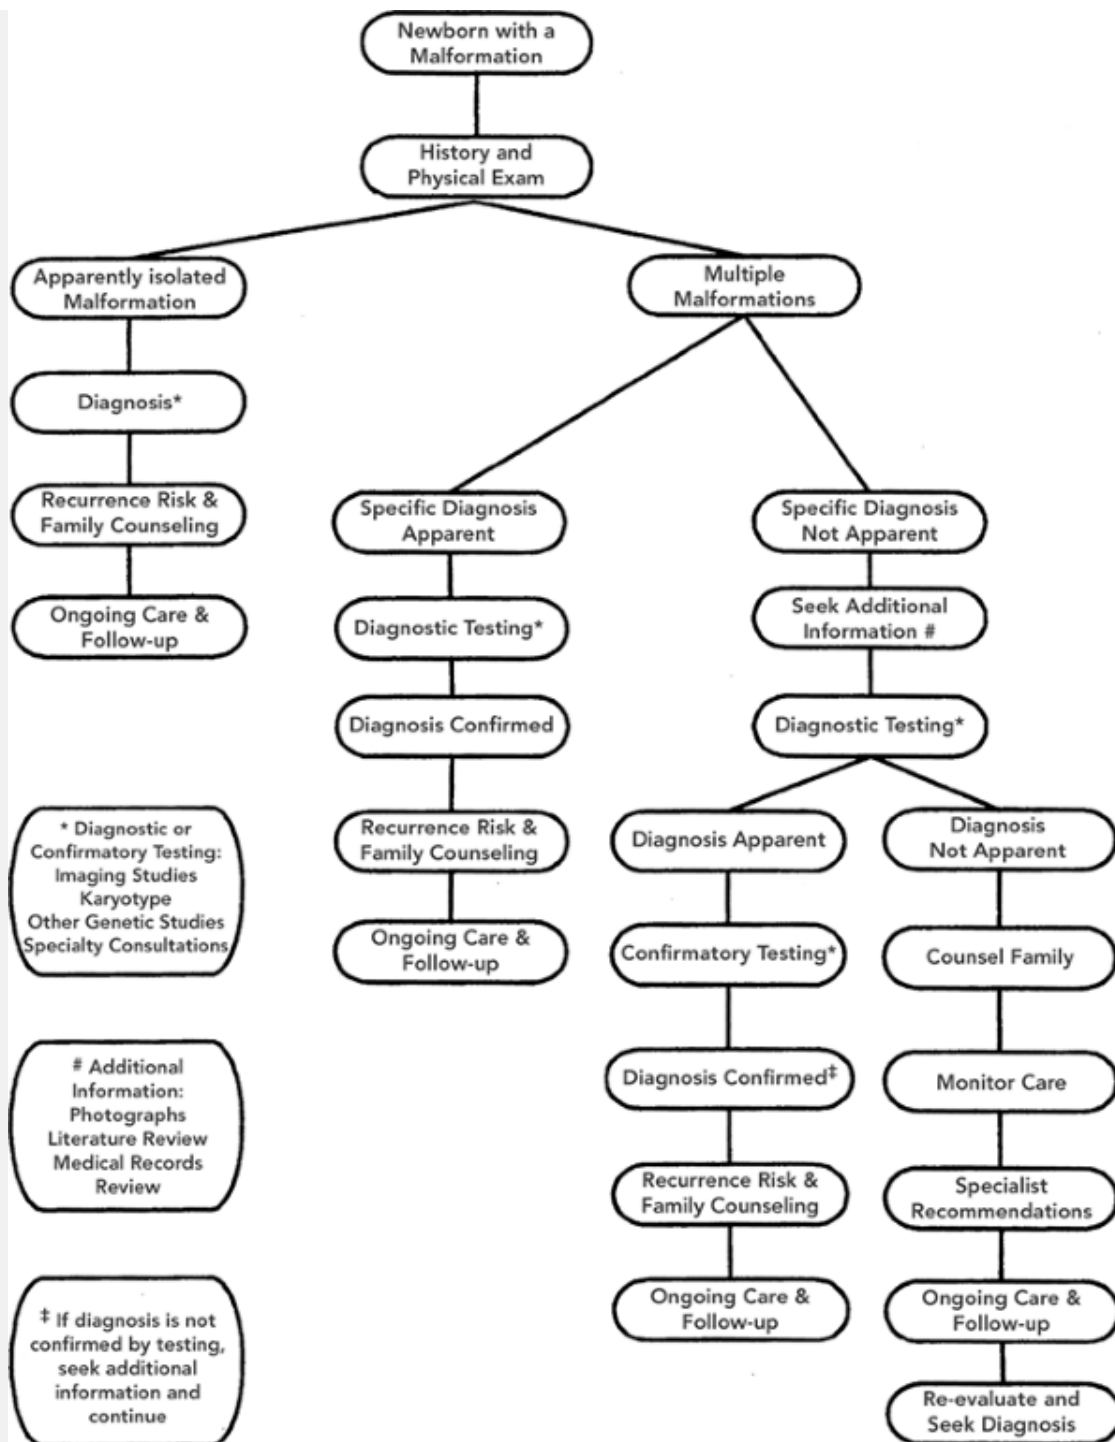

Figure 38-1 Management algorithm for the infant with multiple congenital anomalies. Evaluation of the newborn with single or multiple congenital anomalies: a clinical guideline. May 1999. Available at <http://www.health.state.ny.us/nysdoh/dpprd/main.htm>. Accessed 1/1/05, with permission.

Physical Examination

It is axiomatic that a proper newborn physical examination is detailed and complete. The careful observer, especially one who repeats the examination several times, will recognize departures from the norm. Several points are worth keeping in mind when examining infants with a malformation or a generalized dysmorphic appearance.

- Be alert. There is a heightened chance that additional, initially unsuspected anomalies are present. Although a malformation may be minor in severity, it might represent the most important, critical clue to the diagnosis

Collect "clues" systematically, by closely examining each topographical segment of the body and by scrutinizing progressively more detailed regions. For example, on

initial observation it may be noted that the fingers are disproportionately short; a closer examination may reveal that the fourth and fifth fingers are stiff and rigidly extended, with faint flexion creases, especially at the distal interphalangeal joints, that the nails are short and narrow, almost absent on the fifth finger. The placenta may be examined with the obstetrician or pathologist to seek evidence of cryptic twinning, umbilical cord anomalies, or amniotic bands

- Document the examination with great care, using appropriate morphologic terms and sufficient detail, and strongly consider supplementing written findings with clinical photographs. Parental consent for photographs should be documented.
- Measure those features that are obviously or potentially abnormal in size, shape, position, or symmetry. Normal standards are available for virtually any anatomic structure, encompassing all ages from preterm infant to adulthood (15,16). Hall (7) admonishes, "Never make a clinical judgment on a measurable parameter without measuring it."
- Examine both parents, if possible, seeking any signs of similar anomalies. Dominant conditions frequently manifest a subtle but distinctive phenotype in adults.

Simultaneous Activities:

<u>Gather Data</u>	<u>Therapeutic Intervention</u>	<u>Psychosocial Support</u>
History	Resuscitation	family
prenatal		staff
perinatal	Urgent procedures	Within 24 hours
family		meet with family
Physical examination	Formulate overall plan	define anomalies
detailed		discuss
multisystem	Define long-term issues	investigation
measurements		intervention
family members	Preventive measures	At regular intervals
Ancillary studies	Genetic counseling	review diagnosis
photographs		reformulate plans
radiographs	Reevaluate plans and	continue support
cytogenetics	therapies regularly	
DNA analysis		
Define problem(s)		
categorize process		
<u>diagnosis</u>		

Adjunctive Investigations

The emerging clinical picture will dictate imaging studies and consultations with pediatric subspecialists. For example, a newborn with Down syndrome, even when a cardiac murmur is absent, merits the attention of a pediatric cardiologist, because significant structural defects of the heart are present in 50% but may be missed on clinical examination. A newborn girl with puffy hands and feet, a webbed neck, and coarctation of the aorta also should receive a renal ultrasound, because kidney malformations commonly are associated with Turner syndrome. When the diagnosis is unclear and several malformations are present, occult anomalies of the central nervous system, heart, kidneys, vertebrae, and eyes are reasonable to pursue, especially when the known birth defects are multiple and severe. Renal ultrasounds are often ordered when the neonate has a single umbilical artery or an ear malformation, such as a preauricular pit. In the absence of supporting findings, such as other malformations, a family history of deafness or renal anomalies, or maternal diabetes, this investigation is unlikely to be useful (17). Skeletal films, to include hands, feet, long bones, pelvis, vertebrae, chest, and cranium, are helpful when length is less than the 5th percentile for gestational age or when the limbs are disproportionately short. These studies often require interpretation by a pediatric radiologist skilled in this area.

Chromosomal Analysis

Forty-six chromosomes are present in most normal human cells. Formation of ova and sperm, however, is a surprisingly error-prone process: nearly two-thirds of all fertilizations result in aneuploidy or abnormal chromosomal number or structure, with subsequent reproductive loss. Some of this prenatal loss occurs late enough to be recognized as a miscarriage or spontaneous abortion, but most wastage is occult. Ninety-eight percent of these chromosomal defects are lethal (13).

An abnormal karyotype occurs in one of 170 liveborn infants. Among chromosomally abnormal neonates, one-third have an extra sex chromosome with mild or no phenotypic manifestations in the newborn period, one-fourth have trisomy of an autosome, such as trisomy 21 or trisomy 18, and 40% have a variation of chromosomal structure, such as a deleted or duplicated segment or a translocation. Of the latter, most (79%) are balanced and generally do not cause birth defects. Approximately 10% of infants who die in the perinatal period secondary to multiple congenital malformations have abnormal cytogenetic studies (13).

Which infants deserve chromosomal studies? Truly isolated malformations are very infrequently caused by a cytogenetic defect. On the other hand, neonates with multiple major malformations or a generalized dysmorphic appearance, and stillborn infants, with or without malformations, should have cytogenetic testing. Between these extremes lies a sizable gray area. Factors in favor of chromosomal testing include intrauterine growth retardation, an abnormal neurologic exam, a major malformation accompanied by several minor malformations, and a history

P.897

of multiple pregnancy losses for the mother or in close relatives.

Peripheral blood lymphocytes are the tissue of choice for most cytogenetic analysis, but many other tissues can be used, including skin fibroblasts, bone marrow, placenta, and pericardium, usually harvested postmortem. Two to three milliliters of venous or arterial blood, collected in a sodium heparin (green top) tube, are generally sufficient and should be kept at room temperature or refrigerated, never frozen, in transit. The cells usually will remain viable for 1 or 2 days, but the shortest possible transit time increases the chances for useful results. If the sample is shipped, an overnight courier is recommended. The lymphocytes are separated, incubated in the presence of a mitogen to stimulate cell division, which is then abruptly halted with colchicine, and the cell membranes are disrupted gently while being placed on a glass slide. After enzymatic preparation and staining, the "spread" of chromosomes is analyzed in approximately 20 cells. Generally, 550 or more bands are visible with Giemsa staining of 46 chromosomes at metaphase. Several cells are photographed and arranged in standard groupings, a karyotype. Turnaround time for cytogenetic analysis is typically three to four days, although some laboratories are able to provide results in slightly less time. Because of the high percentage of dividing cells in bone marrow, karyotypes from this tissue may be obtained in a matter of hours, although the quality of the banding frequently is inadequate for high-resolution analysis of small or subtle abnormalities. To achieve the latter, a special request for prometaphase analysis should accompany a peripheral blood sample.

In the past several years, an increasing number of syndromic conditions have been found to be caused by very small chromosomal deletions that are not visible by routine karyotyping, even at pro-metaphase levels of detail. Molecular probes that will hybridize at these loci with great specificity have been developed. These DNA probes are complexed with a fluorescent marker and become powerful tools for detecting submicroscopic chromosomal deletions. This technique, termed fluorescent in situ hybridization (FISH), has also been adapted for whole, entire chromosomes and can identify the nature of many chromosomal anomalies, such as translocations. A metaphase spread can, in essence, be painted with several single-locus or whole-chromosome FISH probes simultaneously, providing a highly specific, and colorful, picture of genomic structure.

Among children with mental retardation of unknown etiology, in whom extensive investigations, including standard cytogenetic studies, are normal, approximately 5% harbor very small, occult chromosomal deletions or unbalanced translocations. A recently developed technique—subtelomeric probe analysis—uses FISH and/or other molecular tools to ascertain whether the regions just proximal to the tips of each of the 46 chromosomes are present in their normal locations. Although initially designed to investigate subnormal intelligence in older children, subtelomeric analysis appears to also be useful for some infants with congenital anomalies in whom standard investigations have not been fruitful. This technology seems to have better diagnostic success for individuals with intrauterine growth retardation, microcephaly, and a positive family history (19).

Metabolic Studies

Inborn errors of metabolism are often assumed to have a purely biochemical or neurologic phenotype, but metabolic disease is well recognized as an occasional cause of dysmorphic facial features and congenital malformations (20). For instance, ambiguous genitalia are seen in some cases of 21-hydroxylase deficiency and other types of congenital adrenal hyperplasia, and infants with pyruvate dehydrogenase deficiency may have agenesis of the corpus callosum and facial features that resemble fetal alcohol syndrome. A number of the congenital disorders of glycosylation feature congenital malformations of the heart, limbs, and central nervous system (21). Many peroxisomal conditions result in distinctive phenotypes: Zellweger syndrome, also known as cerebro-hepato-renal syndrome, and rhizomelic chondrodysplasia punctata (RCDP) exemplify this class of disease. For the Zellweger spectrum of peroxisomal abnormalities, serum levels of very long chain fatty acids will be elevated; in RCDP the very long chain fatty acids are normal but phytanic acid is elevated.

Synthesis and Analysis of Data

Every clinician develops a unique, individual strategy of diagnosis. Acquiring a deep and broad fund of knowledge is arguably fundamental and, oftentimes, sufficient in itself. Unfortunately, the sheer numbers of conditions and syndromes impose some limits on the “brute force” approach; the London Dysmorphology Database, for instance, contains over 3,000 multiple congenital anomaly syndromes (22).

Precise diagnosis is neither possible nor necessary in the immediate newborn period for many neonates with a multiple congenital anomaly syndrome. More than half of all individuals with congenital anomalies never receive a firm diagnosis, even after the most definitive of workups, and remain an “unknown.” Categorization of an anomaly as a malformation, disruption, or deformation, however, is a feasible and useful first step. These terms have been defined and discussed previously. An isolated major anomaly in the absence of any similarly affected relative would suggest a multifactoral etiology. If there are multiple malformations, one of the following strategies may be useful:

- Instant recognition, or gestalt diagnosis, which depends on the clinician's previous experience and strength of visual memory. Certain caveats apply, however: many disorders have a considerable range of phenotypic variation, and other conditions, or phenocopies, may mimic the one that has instantly come to mind
- Perusal of an atlas or illustrated text, such as Smith's Recognizable Patterns of Human Malformation, to match a photograph with the patient. This simple strategy often yields excellent results.

- Pattern analysis, in which all phenotypic and clinical “problems” are enumerated, grouped, combined,

recombined, and weighed to discern developmental relationships, sequences, and influences. Major organ systems or classes of disease (e.g., skeletal dysplasias) then become entry points for further comparison, matching the patient's pattern against published descriptions while attempting to take into account phenotypic variability

- Focusing the initial investigation on the anomaly that is most distinctive, rare, or unusual. Clinodactyly of the fifth finger is very common, but a coloboma of the iris is fairly unusual. A variety of texts or electronic databases then can be consulted and a relatively short list of diagnostic possibilities generated.

Once a preliminary analysis has generated a differential diagnosis, all reasonable efforts are made to test each competing hypothesis. Often, a clinical finding can corroborate a possibility. For instance, a lateral radiograph of the knee may allow confirmation of chondrodysplasia punctata by demonstrating the typical stippled, punctate mineralization of the epiphyses. Although many diagnoses are purely clinical, molecular tools are becoming extremely helpful. An electronic literature search or querying an internet resource, such as Online Mendelian Inheritance in Man, can help determine whether a novel approach using direct deoxyribonucleic acid (DNA) sequence analysis, FISH, or linkage analysis has been developed for the disease in question.

More often than not, the diagnostician will not be able to establish an etiology. When this is the case, there is a temptation to "force" a diagnosis, analogous to hammering a somewhat square peg into a slightly round hole. This may not be in the best interests of the patient so that, in these situations, there is honor in admitting ignorance. Certain characteristics of many syndromic conditions, such as the so-called "elfin" facies of Williams syndrome, are not apparent in the newborn period. The most useful diagnostic decision may be to wait and start afresh at a later time, recollecting data, recombining features into new patterns, and researching the literature. The assistance of a clinical geneticist or dysmorphologist during all phases of evaluation frequently optimizes the diagnostic process. If such services are not immediately available via direct consultation, telephonic or telemedicine consultation may be highly effective.

Other Management Issues

Communication with the parents of a child with congenital anomalies requires a compassionate, timely, and honest presentation of the facts. One's choice of terminology is important but often challenging. Many parents find it quite helpful for the principal caregiver to examine the infant in their presence, pointing out the features that seem to be unusual, and delineating those that are normal. Parents naturally feel responsible for the birth defect, which they might interpret as a reflection of their own shortcomings, real or imagined. Guilt is as common for the parents of a malformed child as pride is for the parents of a normal newborn. Although it is not always possible to convince parents to set aside unreasonable guilt, they can at least be reassured that they had no control over the events causing the abnormality and that they have permission to not feel guilty.

Expect the full spectrum of grief from both parents. They have experienced the loss of a much-anticipated "normal" child. Shock, denial, bargaining, and acceptance will all occur, even when their child does not have a lethal condition. The physicians and nursing personnel involved in the care of the malformed infant work as a team to keep track of this process and be alert for dysfunctional grief. Social work services, clergy, and support groups are important adjuncts. The National Organization for Rare Disorders, the Alliance of Genetic Support Groups, and specific support groups can provide up-to-date information and lay contacts for interested parents.

Not uncommonly, parents and relatives seek and find extensive information about birth defects, syndromes, chromosomal anomalies, and teratogenic conditions on the internet. In some cases, this information is more detailed and current than that available to a busy clinician who relies on brief textbook entries. Based on this information, parents may become firm, even strident and argumentative, demanding specific tests and management. This situation requires judgment, tact, and an open mind on the part of the attending physician, because this information may be quite useful, and parents who remain your allies will positively influence the entire spectrum of medical management. As correct and cutting edge as this information may be, parents will appreciate your pointing out that the clinical acumen and experience of the neonatal team is essential to assess the extent to which generic recommendations may be helpful for any particular patient. An imperative component of this process will be to verify the reliability of the information and ascertain whether it is based on credible scientific data.

If the malformed infant dies and there is any question regarding the precise diagnosis, a full, unrestricted autopsy can prove extremely useful. Visceral, central nervous system, and skeletal anomalies frequently come

to light at postmortem examination. Clinical photography and cytogenetic analysis of fibroblasts obtained from sterile skin biopsy, fascia, or pericardium also may yield important insights. Tissue, cells in culture, and extracted DNA can be stored in a long-term repository and later reanalyzed in light of new research or collaboration.

Families often are reluctant to grant permission for an autopsy. In many instances, however, this procedure has profound implications for the parents' reproductive options and even those of distant relatives. Cultural and social beliefs and practices must, of course, be carefully respected regarding the care of the child's body after death. Nevertheless, an autopsy can be recast in the light of a final gift of the child to his family, perhaps even to the world, if in fact a diagnosis is thereby established or medical science advanced.

P.899

SELECTED EXAMPLES

Teratogenic Conditions

A teratogen, from the Greek root *teras*, meaning monster or marvel, is any environmental factor that causes a structural or functional abnormality in the developing fetus or embryo. These environmental agents include infections, medications, drugs, chemicals, and maternal metabolites, such as phenylalanine (Table 38-3). By their very nature, teratogens induce a disruption or sequence of disruptions of inherently normal tissue. Extensive compendia of these agents have been studied in humans and laboratory animals, and several excellent resources are available for the clinician. Additionally, both professionals and patients can access regional teratogen hot lines.

Ethanol, the most common human teratogen, is estimated to affect as many as 1 in 300 newborns, primarily as a neurotoxin, with consequences ranging from cerebral palsy to learning disability. Up to one-fifth of mental retardation (usually mild) is attributable to fetal alcohol syndrome (FAS), but numerous structural anomalies have also been reported (Table 38-4). Although the syndrome has been recognized for over 30 years, the dysmorphisms and other clinical signs of FAS are still often overlooked in the newborn nursery (23).

Multifactorial Disorders

The multifactorial model of inheritance, as previously discussed, provides a conceptual basis for understanding the pathogenesis and recurrence risks of isolated, nonsyndromic congenital malformations. The central concept of this model is that multiple genes and environmental factors influence whether a particular anatomic structure may develop abnormally. The susceptibility, or genetic liability, of a malformation in a population is described in terms of

P.900

a continuous distribution of susceptibility factors in which there is a point, or threshold, beyond which, in an all-or-none fashion, a structural defect will occur. Table 38-5 lists some common multifactorial disorders and their recurrence risks. This type of multifactorial heritability is postulated to account for most isolated malformations.

TABLE 38-3 Selected teratogens and their effects

Teratogen	Anomalies	Comments
Phenytoin (Dilantin)	Growth deficiency	Similar facial features seen with exposure to carbamazepine, valproate, mysoline, phenobarbital.
	Wide anterior fontanelle	
	Hypertelorism	
	Cleft lip and palate	
	Hypoplastic distal phalanges	
Warfarin (Coumadin)	Small nails	Critical period between 6 and 9 week's gestation. One-third of exposed fetuses are affected.
	Nasal hypoplasia	
	Stippled epiphyses	
	Short fingers	
	Seizures	

Retinoic acid (Accutane)	Microtia or anotia Hypertelorism Micrognathia Conotruncal cardiac defects Hydrocephalus Microcephaly Cortical, cerebellar dysplasia	If exposed more than 15 days after conception, one-third have embryopathy.
Rubella	Growth deficiency Microcephaly Deafness Cataracts Microphthalmia Chorioretinitis Cardiac septal defects Patent ductus arteriosus Peripheral pulmonic stenosis	Fifty-percent chance of effects if exposed in first trimester, but risk extends into second trimester. May have late, persistent infectious sequelae, e.g., diabetes mellitus.
Varicella	Mental deficiency Seizures Cortical atrophy/microcephaly Growth deficiency Limb hypoplasia/club foot Cutaneous scars	One to two percent with effects when exposed between 8 and 20 week's gestation; wide spectrum of severity.
Maternal phenylketonuria	Mental retardation (73% to 92%) Hypertonia Low birth weight (52%) Microcephaly (73%) Cardiac defects (15%) Spontaneous abortion (30%)	Even when "on diet," phenylalanine levels may rise above 4 to 10 mg/dL, the apparent threshold for fetal effects. Percentages cited here are for levels >.16 mg/dL. Normal is <.2.

TABLE 38-4 Structural anomalies in fetal alcohol syndrome

Growth deficiency of prenatal onset
Mental retardation
Microcephaly
Short palpebral fissures
Maxillary hypoplasia
Cervical vertebral malformations (10%-20%)
Short nose
Smooth philtrum
Thin upper lip
Ventricular septal defect, atrial septal defect
Small distal phalanges
Small fifth fingernails

The neural tube defects (NTDs) result from failed neural tube folding before 28 days' gestational age and comprise a spectrum of malformations ranging from anencephaly at one extreme to simple meningocele at the other. A number of genetic and environmental (e.g., ethanol, valproic acid) causes are well delineated. Seventy percent to 80% of NTDs have traditionally been considered to be isolated phenomena with recurrence risks of the usual order of magnitude for multifactorial disorders: 3% to 5%. Over the past decade, although, epidemiologic studies have demonstrated that seventy percent of isolated NTDs can be avoided by adequate maternal intake of folic acid in the periconceptual period (24). Numerous public health and professional organizations recommend that all women of childbearing age take 0.4 mg of folic acid per day. Women who have previously borne an affected child should take folic acid at an increased dosage, 4.0 mg/d, beginning 1 month prior to conception and continuing through at least the third month of gestation (25).

TABLE 38-5 MULTIFACTORIAL DISORDERS

Disorder	Empiric Recurrence Risk
Cleft lip with or without cleft palate	4%–5%
Cleft palate	2%–6%
Ventricular septal defect	3%–4%
Pyloric stenosis	3%
Hirschsprung anomaly	3%–5%
Clubfoot	2%–8%
Congenital hip dysplasia	3%–4%
Neural tube defects	3%–5%
Atrial septal defect (secundum)	2%–3%

Chromosomal Abnormalities

Since 1956, when Tjio and Levan demonstrated that the normal diploid number of human chromosomes (46), seemingly innumerable permutations of abnormal chromosome number and structure have been described. Many of these are unique, but others are recurrent and produce readily recognized phenotypes. Most trisomies, such as trisomy 16, the most common trisomy in humans, are uniformly lethal in the prenatal period. Other rearrangements, such as most balanced translocations, have no phenotypic consequences unless a breakpoint disrupts a gene. Aneuploidy that adds or deletes enough genetic material to be cytogenetically visible commonly causes multiple congenital anomalies in several developmental fields.

Trisomy 21

Down Syndrome is the most common chromosomal aberration recognized at birth, with an incidence of about 1 per 700 live births. Only one of four conceptions that result in trisomy 21 is viable (27). The phenotype is quite variable, but distinctive facies (Fig. 38-3) and some degree of mental retardation are always present. Gestalt recognition of Down syndrome usually is uncomplicated, but diagnosis may be difficult if the infant is seriously ill or has atypical findings. Conversely, between 13 and 18 percent of children referred to a clinical geneticist because of suspected Down syndrome actually have another diagnosis (28).

An individual infant with Down syndrome will almost certainly lack one or several "classic" findings, such as a wide gap between the first and second toes. Keep in mind that a single feature, such as the simian crease, falls well short of being pathognomonic, but the overall constellation of major and minor anomalies suggests the diagnosis. Tables 38-6 and 38-7 list the major and minor anomalies, respectively, that have been observed in children with Down syndrome. Although major heart defects are present in about half of Down syndrome infants, a heart murmur and other signs of cardiovascular pathology may be quite subtle in the immediate newborn period. Atrioventricular canal can be particularly tricky to diagnose by auscultation. An echocardiogram is recommended for all newborns with suspected or confirmed Down syndrome, ideally prior to discharge, certainly by 1 month of age. If for any reason the cardiac ultrasound is delayed or unavailable before hospital discharge, an electrocardiogram should be obtained. Leftward deviation of the QRS axis to between zero and — 90 degrees is characteristic of an endocardial cushion defect.

For 90% of newborns with Down syndrome, nondisjunction during maternal meiosis results in the formation of a gamete with two copies of chromosome 21 (27). The well-recognized relationship between trisomy 21 and maternal age (Table 38-8) has yet to be well-explained. Although risk increases with age, most Down syndrome infants are born to younger mothers because their birth rate is much greater than that of older mothers.

Translocation of

P.901

chromosome 21 to another acrocentric chromosome occurs in 1 of 30 Down syndrome neonates, and other mechanisms of abnormal gametogenesis can also give rise to an extra copy of this chromosome. Accordingly, these possibilities must be evaluated via karyotyping, to provide accurate genetic counseling. Any chromosomal pattern other than trisomy 21 mandates analysis of parental karyotypes. For example, if an isochromosome 21 is present in the infant, parental chromosomal analysis may disclose that a parent carries the same isochromosome. Recurrence risk for that parent is then 100%. Straightforward trisomy 21 in the infant is not associated with chromosomal abnormalities of either parent and their testing is unnecessary. Recurrence risks are then 1% plus the age-related maternal risk.

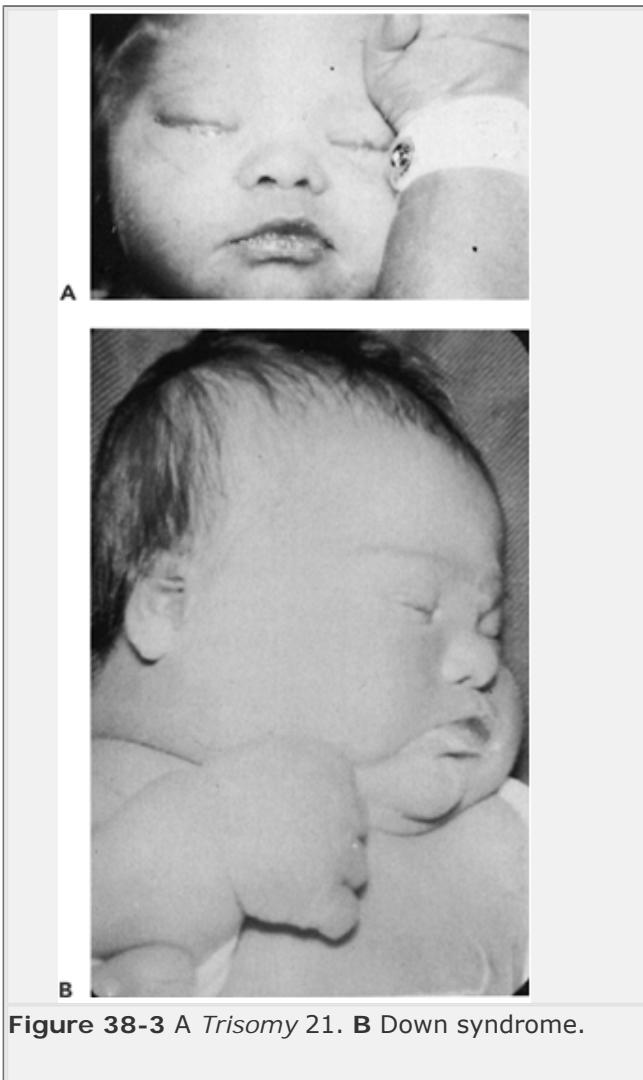

Figure 38-3 A *Trisomy 21*. B Down syndrome.

Improvement in routine health care and advances in cardiac surgery have improved both the quality and longevity of life for individuals with Down syndrome. Median life expectancy is now 58.6 years (29). The American Academy of Pediatrics has published helpful health supervision guidelines that address the needs of Down syndrome children and their parents from birth to adulthood (30).

TABLE 38-6 Major anomalies at birth indown syndrome		
Cardiac: all types		40%

Trisomy 18

Described by Edwards and associates (31) in 1960, trisomy 18 affects 1 of 5,000 newborns. Girls outnumber boys at a 4:1 ratio, and a maternal age effect is well established: *de novo* nondisjunction during meiosis accounts for 90%. One-tenth represent mosaicism, and various translocations and isochromosomal anomalies occasionally are seen. Life expectancy is markedly reduced, with nearly 90% mortality in the first year and

frequent demise in the neonatal period (32). The congenital anomalies in trisomy 18 neonates usually are multiple, severe, and associated with considerable

morbidity. Severe psychomotor retardation always is present. Fig. 38-4 demonstrates typical facial features.

From ref. 27.

Considerable overlap with trisomy 13 syndrome may result in frequent diagnostic uncertainty in the newborn

period, pending cytogenetic analysis. Table 38-9 lists some features that are common to both conditions, and Table 38-10 includes those findings that are more common to trisomy 18. Careful communication with the cytogenetic laboratory will ensure that chromosomal data are available as soon as possible, a helpful adjunct for decision-making when the clinical management options include expectant care and minimal intervention. In selected instances, there may be considerable benefit from rapid analysis via FISH probes for chromosome 13 and 18 markers. Bear in mind, however, that, on occasion, these modalities may not detect trisomic states that involve translocations or partial duplication and that full chromosomal analysis is superior and definitive. These results usually are available 48 to 72 hours after the laboratory receives the specimen.

Trisomy 13

This is the third most common autosomal trisomy recognized at birth, affecting 1 of 12,000 newborns, and initially was delineated in 1960 by Patau and associates (33). Three-fourths are straightforward trisomy 13; a maternal age effect is apparent. Twenty percent are caused by translocations, mostly Robertsonian, in which the long arm of the acrocentric chromosome 13 becomes attached via the centromere to another acrocentric chromosome, commonly chromosome 14. A small percentage of these translocations are familial, so parental karyotyping is

P.903

essential for adequate recurrence risk counseling. Mosaicism is seen in 5%. For both trisomy 13 and trisomy 18, the median age of death is 10 days and 91% die within the first year. As with trisomy 18, cognitive and motor development is profoundly affected. Table 38-11 lists some of the anomalies that tend to be encountered more commonly in trisomy 13. Figure 38-5 shows typical facies.

Cystic kidneys
Cryptorchidism
Overlapping, flexed fingers
Prominent heels

The Support Organization for Trisomy 18, 13, and Related Disorders (34) is a consumer-oriented, lay group that serves as an excellent resource for parents, professionals, and other interested parties regarding trisomies 13 and 18 in particular.

Abnormalities of the Sex Chromosomes

With the exception of Turner syndrome, sex chromosome aneuploidies tend to be phenotypically bland in newborn children. Klinefelter syndrome, 47, XXY, is associated with a few, occasional congenital anomalies, such as cryptorchidism and hypospadias. Variants with more than one Y or more than two X chromosomes tend to have greater mental deficiency and more malformations, both minor and major.

TABLE 38-10 FINDINGS MORE COMMON TO TRISOMY 18

Prominent occiput
Narrow palpebral fissures
Small mouth
Short sternum
Widely spaced nipples
Cardiac: polyvalvular disease
Prominent clitoris

Iris coloboma
Prominent nasal bridge
Cleft lip
Cleft palate
Short neck
Hypoplastic nipples
Cardiac: dextrocardia
Polydactyly (postaxial)
Apnea

Turner syndrome is caused by complete or partial absence of one X chromosome and occurs in 1 of 2,500 newborn girls. One half have a 45, X karyotype; a large

number of other X chromosome anomalies, ranging from various isochromosome X patterns to simple deletions, ring chromosomes, and mosaics, account for the remainder. Almost all conceptuses with Turner syndrome are spontaneously aborted but, of those that are live born, only one-third are recognized in the newborn period. Clinical findings may include prominent ears, low posterior hairline, webbed neck, broad chest with widely

spaced nipples, and puffiness of the dorsa of the hands and feet (Fig. 38-6). Although short stature is common in older girls, mean birth length is 47 cm, just within two standard deviations of the population mean. Ovarian dysgenesis (greater than 90%), renal anomalies (40% to 60%, horseshoe kidney in particular), and cardiac malformations (10%-20%, especially coarctation of the aorta) will require directed investigations once this diagnosis is suspected (35). An AAP health supervision guideline (36) summarizes the age-specific evaluations for girls with Turner syndrome. For neonates, recommendations include careful examination for hip dysplasia, hearing screening, pediatric cardiology consultation, comparison of systolic blood pressures in the arms and legs, renal ultrasonography, and consultation with pediatric endocrinology.

Partial Aneusomies

Deletions, duplications, and translocations of any segment, small or large, of any chromosome are possible. The resulting partial monosomy, partial trisomy, or combination of the two often causes multiple major and minor anomalies, intrauterine growth retardation, and a dysmorphic facial appearance. The deleted or duplicated segment may be interstitial, involving the midsection of one of the arms of a chromosome, or terminal. As a general rule, the larger the deletion or duplication, the more severe the somatic and functional effects. For example, deletion of the short arm of chromosome 5 (sometimes designated 5p- or 5p minus) is one of the most common autosomal deletion syndromes, with an incidence of 1 in 20,000 births. Also called cri-du-chat syndrome because of the high-pitched cry of affected infants, 5p- results in a distinctive phenotype: microcephaly; round facies; hypertelorism; broad nasal bridge, epicanthal folds; posteriorly rotated, malformed ears; preauricular skin tags, and small chin (Fig. 38-7). Various other malformations may be present, including cleft lip with or without cleft palate, heart defects, and megacolon. Hypotonia and mental retardation are typical. The severity of cri-du-chat syndrome can be correlated roughly with the location and extent of the deletion: absence of band 5p15.2 is associated with severe mental retardation; deletion of band 5p15.3 causes the typical cat cry (37). Other common partial aneusomies are summarized in Table 38-12.

Figure 38-6 A, B Turner syndrome.

Many chromosomal rearrangements occur de novo as spontaneous events in a single egg or sperm. These are unlikely to recur. Some, however, are the consequence of a balanced translocation or other rearrangement, such as pericentric inversion, in one parent. Generally, balanced translocations do not cause problems because most of the human genome consists of long stretches of DNA between genes. Breaks and rejoinings in these noncoding regions will have neutral consequences. If the break falls within

P.905

a gene, some phenotypic effects may ensue. Careful analysis of balanced translocations has, in fact, provided the critical link for mapping and cloning several important genes.

Figure 38-7 Cri-du-chat syndrome (5p-).

TABLE 38-12 Selected chromosomal anomaly syndromes

TABLE 38-12 Selected chromosomal anomaly syndromes	

Karyotype	Features
4p-	Poor growth, microcephaly, prominent glabella, hypertelorism, downturned corners of mouth, micrognathia, cleft lip/palate, cryptorchidism, heart defects, profound developmental retardation. May involve only a small region, to include 4p16, requiring high-resolution banding or FISH for confirmation. Also known as the Wolf-Hirschhorn syndrome.
Dup 9p	Poor growth, macrocephaly, hypertelorism, downslanting palpebral fissures, prominent nose, downturned corners of mouth, cupped ears, short fingers and toes, developmental retardation.
Del 11p13	Mental deficiency, poor growth and microcephaly, aniridia, cataracts, blindness, cryptorchidism, hypospadias, Wilms tumor (50%). The interstitial deletion encompasses a tumor-suppressor gene and provides the de facto "first hit" in tumorigenesis.
13q-	Growth deficiency, mental deficiency, microcephaly, prominent nasal bridge, hypertelorism, microphthalmia, colobomata, bilateral retinoblastoma, micrognathia, anomalous auricles, hypoplastic thumbs, congenital heart disease, genitourinary anomalies. Band q14 is the locus of the RB gene, a tumor-suppressor gene implicated in retinoblastoma.
18p-	Mild growth deficiency and microcephaly, psychomotor retardation, ptosis, epicanthal folds, hypertelorism, wide mouth, protruding ears, small hands and feet, pectus excavatum.
18q-	Short-stature hypotonia, variable mental deficiency, conductive deafness, auricular anomalies, long hands, tapering digits, cardiac defects.
Dup 22q	Highly variable, also known as cat-eye syndrome, after the bilateral inferotemporal colobomata of the irides, which also may involve the choroid and retina. Mild developmental delays, normal growth, slight hypertelorism, downslanting palpebral fissures, preauricular tags or pits, cardiac defects, anal atresia, renal agenesis. Forty-seven chromosomes are present: the "extra" chromosome is composed of one or two chromosome 22 fragments, joined by their acrocentric short arms, creating trisomy or tetrasomy 22 q. FISH provides confirmation of the nature of the small "marker" chromosome. Parental karyotypes are necessary because a mildly affected parent also may have the marker.

Not uncommonly, an unbalanced translocation in a newborn with multiple congenital anomalies is the consequence of a balanced translocation in a parent. During formation of eggs or sperm at meiosis, balanced rearrangements often yield gametes that have significant deletions, duplications, or more complex anomalies, with serious consequences for the offspring. Unbalanced translocations, in which there is both a duplicated chromosomal segment and a deletion, produce phenotypes that are unique, because they are a blending of a partial monosomy and a partial trisomy. Chromosomal studies on both mother and father then are critical for providing adequate recurrence risk counseling.

Microdeletion Syndromes

An increasing number of dysmorphic syndromes are proving to be caused by fairly subtle interstitial or terminal chromosomal deletions. These are sometimes detectable via chromosome studies, especially if high-resolution or prometaphase analysis is employed, but more often the deleted region is submicroscopic and must be specifically investigated via specialized cytogenetic and molecular techniques, most commonly FISH. Although these microdeletions seem almost trivially small, they amount to a loss of several thousand of base pairs of DNA, usually resulting in haploinsufficiency of several contiguous genes. In some instances, microdeletions may be transmitted from parent to child as an autosomal dominant trait, but most occur de novo, with unaffected parents, as a consequence of imprecise alignment of homologous chromosomes and unequal crossing over during meiosis. Another technique, comparative genomic hybridization (38), can also delineate small deletions. Table 38-13 lists several common microdeletion syndromes, their loci, and general features.

22q11.2 Deletion Syndrome has emerged over the last several years as the most commonly diagnosed microdeletion syndrome. Also known as Shprintzen syndrome, velo-cardio-facial syndrome (VCFS), DiGeorge syndrome (DGS), or conotruncal anomaly face syndrome, this condition may be manifest by congenital heart defects, especially those affecting the conotruncal structures (tetralogy of Fallot, conal ventricular septal defect,

persistent truncus arteriosus, or interrupted aortic arch), and palate abnormalities, ranging from complete cleft palate as a result of the Pierre Robin sequence to submucous clefting or velo-pharyngeal insufficiency. Hypocalcemia as a result of parathyroid dysplasia, thymic hypoplasia with diminished T-cell production, developmental delays and mental retardation, renal malformations, subnormal growth, and a characteristic craniofacial appearance may be apparent in many affected individuals. Minor ear malformations, a bulbous nasal tip, malar hypoplasia, and long facies are frequently encountered in children and adults; however, these typical facial features may not be present in newborns, especially African-American infants (39). Consequently, the concurrence of cardiovascular and palatal anomalies should prompt FISH studies for the 22q11 submicroscopic deletion. Because other chromosomal defects can resemble

22q11 deletion syndrome, cytogenetic testing should routinely be submitted simultaneously. In about 15% of individuals with the VCFS/ DGS phenotype, 22q11.2 FISH is normal; in some, atypical or other cytogenetic deletions can be identified. Should testing be considered for infants with apparently isolated palatal clefting or conotruncal anomalies? Many authorities advocate a low threshold for testing. Our appreciation of the incidence of 22q11.2 deletion syndrome continues to grow, FISH analysis is sensitive and specific, and our considerable insights into the natural history of this condition allow for practical and beneficial management (40).

TABLE 38-13 Microdeletion syndromes

Chromosome	Locus	Syndrome	Clinical Features
1p36			Hypotonia, growth retardation, developmental delays, deep-set eyes, pointed chin, seizures, cardiomyopathy, deafness
4p16		Wolf-Hirschhorn	Hypotonia, microcephaly, hypertelorism, prominent glabella, severe mental deficiency
5p16		Cri du chat	Low birth weight, cat-like cry, microcephaly, downslanting palpebral fissures
7p13		Grieg cephalopolysyndactyly	Polydactyly, syndactyly, frontal bossing.
7q11.23		Williams	Supravalvular aortic stenosis, hyperacusis, stellate irides, prominent lips, mild mental retardation
8q24		Langer-Giedion	Multiple exostoses, bulbous nose, protruding ears, loose skin in infancy
11q13		WAGR	Wilms tumor, Aniridia, Genital anomalies, growth Retardation
13q14.11		Retinoblastoma	Retinoblastoma, growth deficiency, microcephaly, prominent nasal bridge, hypoplastic thumbs, cardiac defects
15q12		Prader-Willi	Paternal deletion in 70%, maternal 15q disomy in 30%, hypotonia, hypogonadism, poor growth in infancy, hyperphagia and obesity in childhood, behavioral difficulties
15q12		Angelman	Maternal deletion in 60%, paternal disomy in 5%, severe mental retardation, seizures, ataxic gait, microcephaly, paroxysmal laughter
16p13.3		ATR-16	Alpha thalassemia, mild mental retardation
16p13.3		Rubinstein-Taybi	CBP gene deletion in 25%, growth deficiency, mental retardation, small mouth, beaked nose, broad thumbs and toes
17p13		Miller-Dieker	Lissencephaly, high forehead with vertical furrowing while crying
17p11.2		Smith-Magenis	Brachycephaly, broad nasal bridge, short philtrum, prominent jaw, broad hands

20p11.23	Alagille	Deep-set eyes, broad forehead, chronic cholestasis, vertebral defects, peripheral pulmonary artery stenosis
22q11.2	DiGeorge, Shprintzen,	Aortic arch anomalies, parathyroid and Velo-cardio-facial thymic deficiency leading to hypocalcemia and diminished cellular immunity, cleft palate, prominent nose with narrow alar base, conotruncal cardiac defects, tapering fingers

Single Gene Disorders

Achondroplasia

The most common skeletal dysplasia recognized at birth, achondroplasia is an autosomal dominant condition characterized by short limbs, frontal bossing, a large head, midface

P.907

hypoplasia, and distinctive radiographic findings. In the newborn period, a thoracolumbar gibbus, or sharp kyphotic angulation of the vertebrae, may be present, followed in early childhood by lumbar lordosis. Midface hypoplasia, a low nasal root, and relative prognathism (Fig. 38-8) are apparent at birth and become more pronounced in childhood. The limb shortening is of the rhizomelic type, involving the humeri and femurs more than the distal extremities. There may be limitation of elbow extension, yet other joints may be relatively hyperextensible. The fingers often display a trident pattern, with a splay or gap between the third and fourth digits. Mild hypotonia is common. The enlarged head circumference is associated with mild ventriculomegaly in some cases, and in older children and adults a narrow foramen magnum has, on occasion, caused symptomatic cervicomedullary compression. Cognitive development is normal.

Figure 38-8 Achondroplasia.

Achondroplasia is caused by specific mutations of the fibroblast growth factor receptor-3 gene (FGFR3) on chromosome 4p16.3. Heterozygosity for a point mutation at nucleotide 1138, converting a glycine residue to either an arginine or cysteine, is responsible for 99% of cases (41).

Smith-Lemli-Opitz Syndrome

For this inborn error of metabolism, a deficiency of 7-dehydrocholesterol reductase results in a distinctive pattern of multiple congenital anomalies (42). Like most other enzyme deficiencies, this SLOS is inherited in an autosomal recessive fashion. The reductase, which maps to chromosome 7q32.1, is responsible for the last step in cholesterol synthesis. Consequently, serum cholesterol tends to be low, although in 10% it falls within normal limits, and the immediate precursor, 7-dehydrocholesterol, is markedly elevated. A variable spectrum of anomalies may be seen, including microcephaly, various central nervous system structural defects, hypotonia, growth deficiency, and distinctive facies with a high, square forehead, ptosis, a short nose, anteverted nares, and micrognathia (Fig. 38-9). Peripheral and central neural myelination is reduced. About three-fourths of

genotypic XY males have genital anomalies—cryptorchidism, ambiguous genitalia, even complete sex reversal. Polydactyly and syndactyly between the second and third toes is very common. More severely affected individuals may have visceral defects, such as renal cysts or agenesis, cardiac anomalies, pancreatic hyperplasia, hepatic dysfunction, cataracts, severe growth retardation, postaxial polydactyly, and may be stillborn or die in the neonatal period.

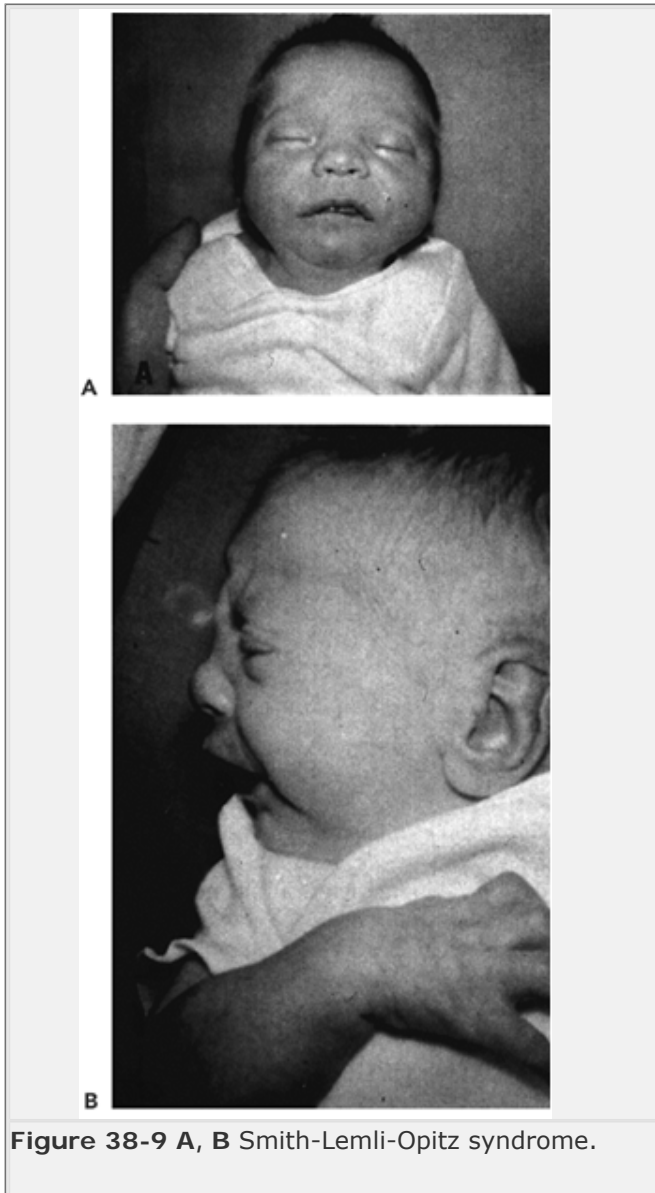

Figure 38-9 A, B Smith-Lemli-Opitz syndrome.

Chondrodysplasia Punctata, Rhizomelic Type

Rhizomelic chondrodysplasia punctata, an autosomal recessive inborn error of peroxisome metabolism as a result of mutations of the peroxin 7 (PEX7) gene on chromosome 6q22-24, is manifest as a distinctive skeletal dysplasia with mental retardation and poor long-term survival

P.908

(43). Birth length is reduced and the proximal limbs are shortened. Additionally, there is microcephaly, full cheeks, a depressed nasal bridge, cataracts, ichthyosis, coronal clefts of the vertebral bodies, and congenital heart disease (Fig. 38-10). In the neonatal period, punctate calcific stippling of the epiphyses is readily apparent on lateral radio- graphs of the knee. Severe psychomotor retardation is the rule, and death usually occurs in the first year of life. Serum phytanic acid is increased and plasmalogen biosynthesis is deficient. Ultrastructural studies of hepatocytes demonstrate that peroxisomes are absent or markedly abnormal.

Figure 38-10 A, B Rhizomelic chondrodysplasia punctata.

Treacher Collins Syndrome

Also known as mandibulofacial dysostosis, this autosomal dominant condition was first described in the mid-1800s. Clinical features vary within and between families but typically include a narrow face with downslanting palpebral fissures, zygomatic underdevelopment, a small chin, and an extension of scalp hair onto the cheek (Fig. 38-11). The lower eyelids are notched at the outer third; medially the eyelashes are sparse or absent. The ears often are crumpled and small. One-third lack the external auditory canal and/or have ossicular anomalies of the middle ear that cause conductive hearing loss. Ear tags and preauricular fistulae are common. The mouth is wide, and overt or occult palatal clefts are common. Intelligence is usually normal. In the early 1990s, several investigators localized the gene to chromosome 5q32-33.2 using linkage analysis and FISH. In 1996, the gene, designated *TCOF1*, was positionally cloned (44). The gene product, named "treacle" (British for "molasses"), is truncated in most *TCOF1* patients as a result of the introduction of a premature termination codon via various deletions, insertions, and splicing alterations.

Apert Syndrome

This autosomal dominant craniosynostosis syndrome is readily recognized by the combination of an unusual head shape and characteristic limb anomalies. Premature fusion of coronal sutures bilaterally leads to acrobrachycephaly—a short yet tall cranial shape—with a full forehead, flat occiput, flat midface, shallow orbits, and downslanting palpebral fissures. There is a mitten-like syndactyly of the fingers and toes, both cutaneous and osseous, and broad thumbs (Fig. 38-12). Other anomalies may involve the cardiac, gastrointestinal, central nervous, and genitourinary systems. Most infants with Apert syndrome are born to unaffected parents: in a single germ cell, a new mutation occurs in the fibroblast growth factor receptor-2 (*FGFR2*) gene on chromosome 10q25-26. Other *FGFR2* mutations cause several other dominant craniosynostosis syndromes, such as Crouzon syndrome and Pfeiffer syndrome (45).

Malformation Sequences

A malformation sequence represents the ultimate consequence of a precise cascade of fetal events. Initiated by one primary event, which is often a mechanical or vascular disruption of a specific developmental field, a sequence may stand alone as a recognizable entity or may be a component

of a larger picture, associated with a chromosomal defect, microdeletion, or single-gene disorder. The Pierre Robin sequence, for example, is recognized as a cleft of the posterior palate, often in the shape of a "U," in a child with a markedly retruded, small mandible. At 5 to 9 weeks' gestation, the malpositioned jaw allows the tongue to interfere with the medial apposition of the posterior palatal shelves as they migrate toward the

midline, thereby mechanically prohibiting their fusion. The newborn can quickly develop significant airway obstruction and will require very close observation and occasional surgical intervention. The Robin sequence may be isolated but, compared to other orofacial clefts, has a relatively high association with chromosomal anomalies and syndromic diagnoses, such as trisomy 18, 22q11 deletion Beckwith-Wiedemann syndrome, Miller-Dieker syndrome, fetal alcohol syndrome, and many others.

Figure 38-11 Treacher Collins-Franceschetti syndrome.

Figure 38-12 Apert syndrome.

Other Mechanisms

Uniparental disomy involves the inheritance of both copies of a particular chromosome or chromosome segment from only one parent and has been observed in cystic fibrosis, Russell-Silver syndrome, Prader-Willi syndrome, and Angelman syndrome, among others. Imprinting refers to how a gene may function differently, depending on whether it is inherited from the mother or the father, and is often mediated via methylation of DNA sequences that regulate gene expression.

Beckwith-Wiedemann syndrome (BWS) is a complex condition that may be caused by several mechanisms affecting a multigenic region on the short arm of chromosome 11, including mutations of the CDKN1C gene, abnormal methylation, paternal uniparental disomy, and chromosome 11p15 duplications. Diagnosis of BWS, however, remains clinical: frequent features include somatic overgrowth, macroglossia, omphalocele, visceromegaly, and dysplasia of the renal medulla. Transitory, symptomatic hypoglycemia is present in 30%, and a number of neoplasms, including Wilms tumor, adrenal cortical carcinoma, and hepatoblastoma, are common, especially in individuals with hemihypertrophy, which affects about 13% of patients. Glabellar nevus flammeus, linear grooves of the ear lobes, and posterior helical ear pits are valuable diagnostic signs (Fig. 38-

13). About 85% of cases are sporadic, 15% familial. About 1% to 2% have either a small, interstitial duplication of chromosome 11 involving band p15.5 or an inversion or translocation in this region; invariably the duplicated region is paternal in origin. Other individuals derive both 11p15.5 regions from their father. They have the normal number of chromosomes—that is, they are disomic for this region—but have inherited both segments from only one parent, i.e., uniparental disomy. These data also suggest that BWS is caused by a dosage effect related to a gene or genes that are differentially expressed in maternally and paternally derived alleles, i.e., imprinting. Recently, two genes, *KCNQ1OT1* and *H19*, have been found to have abnormal methylation in 2/3 cases of BWS, and direct DNA analysis of the *CDKN1C* gene, which is available on a research basis, can uncover mutations many individuals. The recurrence risk depends on the nature of the genetic mutation. For instance, if an 11p15 inversion is inherited from the mother, the recurrence risk is 50%, but paternal uniparental disomy has a

P.910

very low chance of recurrence. Some genotype-phenotype associations have been delineated. Individuals with cytogenetic abnormalities may have some degree of mental retardation; uniparental disomy and *H19* hypermethylation are associated with an increased risk for Wilms tumor (46).

Figure 38-13 Beckwith-Wiedemann syndrome.

Disorders of Unknown Etiology

Cornelia de Lange syndrome is a sporadic condition of unknown etiology that can be recognized by the facial gestalt. The eyebrows are crescent shaped, neatly defined, and often meet in the midline (synophrys); the anterior hairline is low; the nose is short and the nostrils upturned; and the lips are thin with down turned corners, like that of a carp (Fig. 38-14). Microcephaly and mental retardation are common but not invariable. Growth is deficient prenatally and postnatally. About one-fourth have upper limb anomalies, which can range from proximally placed thumbs to severe reduction defects. Empiric recurrence risk is estimated to be 2% to 5%. Duplication of the long arm of chromosome 3 causes a very similar malformation pattern (phenocopy) and must be excluded.

GENETIC COUNSELING

Throughout human history, various astrologers, wise men, shamans, village elders, high priestesses, court jesters, and mothers in law have paid close attention to birth defects. Curiosity has naturally inspired us to theorize, to attempt to find meaning and significance, and then to communicate the “truth” about a congenital anomaly to parents, relatives, communities, and rulers. As an omen or prophecy, the malformation of a newborn has been inferred to be the visitation of a god, of celestial forces, of bad seed or bad morals, sure to portend either a bright future or ruin to the bearer of bad fruit. From these basic impulses to understand and to predict has grown the modern discipline of genetic counseling.

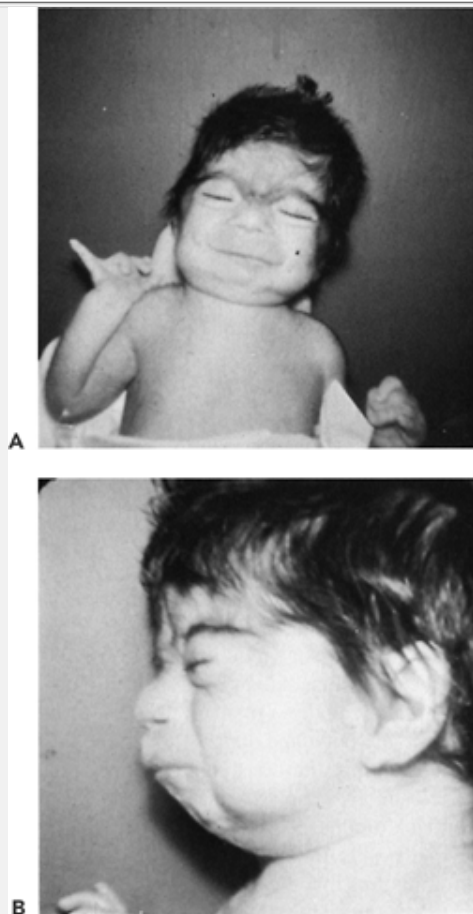

Figure 38-14 A, B: Cornelia de Lange syndrome.

The term “counseling” has the unfortunate connotation of giving authoritative advice, a fairly formal process in which information and directive statements flow in one direction, from counselor to consultand. Genetic counseling seeks to eschew these misconceptions. It is a process of communication between a genetic counselor or counseling team and an individual, couple, or family about what exactly has caused a genetic problem, how they might understand it, and what options they have for the future—in which they can find additional educational resources, support groups, research studies, what modifications to the usual health maintenance activities might be able to prevent potential problems, whether a similar problem could affect other family members, how one could detect this prenatally or after birth, the risks and benefits of doing so, and the options for prenatal management. Informally, many clinicians perform these activities as an integral component of routine care giving. Formally, however, genetic

P.911

counseling is a complex and comprehensive activity that has blossomed as a discipline in its own right. It is learned didactically and practically via postgraduate programs in medical genetics and genetic counseling, with board certification (and recertification) incumbent on thoroughly documented case workups, close supervision by experienced preceptors, and successful performance on rigorous, standardized examinations. There are 27 American Board of Genetic Counseling (ABGC) accredited programs in the United States and Canada; nearly 2500 individuals have received ABCG certification since 1993. Additionally, physicians who have completed formal postgraduate training in clinical genetics, via fellowship or, in the past decade, through residency training, and who obtain board certification through the ABMG are also qualified to provide genetic counseling.

The goals of genetic counseling have evolved over the past several decades. The provision of advice regarding reproductive choice and behavior, with an eye toward reducing the amount of genetic disease in future generations, has been superseded by other aims. The genetic counselor fundamentally seeks to provide information with clarity, sensitivity, and support to enable the person seeking information, the consultand, to understand well and decide capably. Emphasis is placed on the psychological and cultural aspects of this interactive process, and support and follow-up are key elements. Genetic counseling requires that the diagnosis be established with as much precision as possible, that an accurate and full pedigree be obtained, and that up-to-date information regarding the diagnosis be researched. Recurrence risk calculations may be simple and straightforward, or they may require more sophisticated tools, such as Bayesian analysis. Bayes' theorem, created more than 200 years ago, allows the laws of probability to be applied to a specific clinical scenario and

quantifies the risk of recurrence by incorporating multiple observations into a complex formula (47). These data, the natural history of the disorder in question, management options, and the full spectrum of reproductive options are discussed in detail with the consultant, often with explicit attention to the significance these have for that individual, the psychological and practical burden perceived in the context of the social structure, finances, and personal experience. Principles of genetic counseling also include a commitment to strive for a nondirective approach, truth telling, avoidance of paternalism, respect for autonomy and dignity, and anticipation of ongoing psychological needs and issues. A concerted effort is made to identify and facilitate outside sources of information and support, such as from clergy, genetic support groups, and social services.

Difficult Decisions

Some infants are born with anomalies that are irreparable and incompatible with life. For these newborns, the decision to limit intervention, although deeply saddening, is clear. Bilateral renal agenesis and anencephaly are salient examples—no amount of intervention will help; solace and support are the only options. Other newborns, whose malformations are profound, but who may respond to heroic therapy, demand greater courage on the part of parents and clinicians—courage to analyze carefully in the face of chaos, in the context of a health care system whose bias is to act, simply because action is possible, and without much time in which to reach a decision. A clinical genetics consultation that incorporates rapid dysmorphic analysis and directed, confirmatory testing will usually clarify the key issues of this decision making process.

The central importance of an accurate diagnosis is difficult to overstate. For a neonate with multiple major anomalies, the neurologic prognosis cannot always be predicted solely on the basis of the severity of the obvious malformations. For instance, in the case of VACTERL association, the tracheo-esophageal fistula and anal atresia will require urgent, life-saving surgery, the vertebral abnormalities can seem grimly bizarre, and the overall picture may appear dismal. However, these children typically have normal cognitive development, our surgical and rehabilitation medicine colleagues have much to offer, and prognosis may be quite good. On the other hand, some infants with trisomy 13 or trisomy 18 have remarkable few major anomalies—parents may even have strong doubts about the diagnosis—but the neuro-developmental progress will be minimal.

The dignity of the child compels the caregiver to have as clear a vision of the future as possible, to deal with decisions such as whether or not to intubate, transplant an organ, etc. The infant with thanatophoric dysplasia may well live, with extraordinary care, to several years of age, as has been reported in a few children, and one in ten infants with trisomy 18 lives to the first birthday, albeit with significant psychomotor retardation. However, these facts are a starting point for an individualized analysis, shared between family and physician, and not the foundation of policy to either routinely offer maximal intervention or insist that care be denied.

The parents of some profoundly disabled children perceive them as interactive and capable of both receiving and giving affection. For these families, the rationale to limit medical support, because the long-term prognosis is not good, is specious. They counter that they find richness and reward in their child, which they feel is reciprocated, and that any judgment regarding "quality of life" is theirs, and theirs alone, to make. Of course, the parents of a newborn with, for instance, trisomy 13 have had only the limited experience of the pregnancy to develop an appreciation for their baby's human worth. If they have had prenatal genetic testing and counseling, they may have been aware of this diagnosis for more than 5 months, have made a conscious decision to not terminate the pregnancy, and have become well-read and quite sophisticated regarding options for intervention and support. These parents will be seeking a neonatal and pediatric team with whom they can be partners, not adversaries. If there is disagreement regarding prognosis or intervention, medical or surgical, the clinician may do worse than fall back on basic principles—complete ascertainment of facts,

P.912

diagnostic precision, and solid understanding of the natural history. One cannot underestimate the power of careful and frequent communication with the family, with the dual aims of appreciating the family's points of view and of presenting, with clarity, the medical point of view.

Chapter 39

Endocrine Disorders of the Newborn

Mary M. Lee

Thomas Moshang Jr.

From the moment of conception, physiologic endocrine processes are actively involved in growth and development of the human fetus. Disturbances in the interplay of these complex hormonal processes during intrauterine life can cause somatic or biochemical alterations in the fetus and newborn infant. Clinical disorders of endocrine function in the neonate therefore, can reflect an altered physiologic state in the fetus, the mother, or the fetal-maternal unit. Moreover, the occurrence of these perturbations of endocrine function at varying stages of fetal development results in diverse clinical manifestations. Knowledge of the ontogeny of the endocrine glands and their physiologic function during fetal development facilitates understanding disorders of endocrine function in the newborn.

DISORDERS OF SEXUAL DIFFERENTIATION

Normal Sexual Differentiation

The normal regulation of sexual differentiation is broadly illustrated in Fig. 39-1. All embryos are initially undifferentiated with a bipotential gonad and the anlagen for both male and female reproductive tracts and genitalia (1). Differentiation of the gonads as testes or ovaries dictates the subsequent development of the internal and external genitalia. The gonad forms when germ cells migrate from the dorsal endoderm of the yolk sac to populate the genital ridges. At the fifth to sixth week of gestation, these primitive bipotential gonads consist of both cortical (ovarian) and medullary (testicular) components. The genital ridge is composed of three cell types: (a) germ cells destined to become prespermatogonia in the male or oogonia in the female, (b) supporting epithelial cells destined to become Sertoli cells (male) or granulosa cells (female) and (c) mesenchymal cells destined to become the steroid-producing Leydig cells (male) or theca cells (female). Development of the

supporting cells as Sertoli or follicular are a critical determinant in whether the germ cells differentiate as spermatogonia or oogonia. Of the genes that are critical for gonadal development, mutations in two have been clearly associated with gonadal dysgenesis. Mutations of the Wilms tumor gene (2) (WT1), are associated with three related syndromes (the WAGR contiguous gene syndrome, and Denys-Drash and Frasier) that affect renal function and gonadal development and mutations in the transcription factor, steroidogenic factor 1 (3) (SF-1), cause agenesis of the adrenals and gonads.

Sexually dimorphic differentiation of the gonads and reproductive system commences when the testis-determining gene is first expressed. In 1959, Ford and colleagues determined that the Y chromosome was necessary for male development (4); in 1966, the critical region for testis determination was localized to the short arm of the Y chromosome (5); and in 1990, the primary testis-determining gene was definitively identified at Yp11.3 by positional cloning in patients with sex reversal (6). This gene, termed SRY (sex-determining region of the Y chromosome), is a member of the Sox family of transcription factors that all contain a high mobility group (HMG) DNA-binding motif (6). Activation of SRY initiates differentiation of the bipotential gonad as a testis. Loss of function mutations in SRY or a delay in its onset of expression can cause XY sex reversal with gonadal dysgenesis, although a gain of function mutation in SRY causes XX sex reversal associated with incomplete testicular development.

SOX9, a presumptive target for SRY, is a related HMG box gene that induces the supporting cells of the gonadal ridge to differentiate as Sertoli cells (7). Inactivating mutations of SOX9 cause the skeletal anomalies of campomelic dysplasia that is associated with variable penetrance of 46, XY sex reversal and testicular dysgenesis (8). A role for additional downstream genes in testicular determination is supported by the absence of identifiable SRY or SOX9 mutations in

P.915

some cases of sex reversal and the association of sex reversal and dysgenetic gonads with other autosomal deletions.

Figure 39-1 Schematic of the sex differentiation pathway. The urogenital ridge and gonad are initially undifferentiated. In male embryos, the induction of SRY expression initiates testis determination. The testicular hormones, MIS/AMH and androgens stimulate male phenotypic development of the internal and external genitalia. In female embryos, the absence of SRY in concert with the expression of genes that inhibit testicular determination enables the gonad to develop as an ovary. In the absence of androgens and MIS/AMH, the internal and external genitalia differentiate as female.

At least two genes, Wnt-4, a locally secreted signaling glycoprotein, and Dax-1, a nuclear hormone receptor in the DSS region of the X-chromosome, are critical for ovarian development, perhaps by suppressing testicular genes. A duplication of either of these genes interferes with normal testicular development to cause a dosage sensitive form of 46, XY sex reversal (3,9).

Sexually dimorphic differentiation of the wolffian (male anlagen) and mullerian (female anlagen) internal genital tracts depends on the hormonal milieu established by the somatic cells. If SRY is expressed, the primary sex cords develop into testes and the somatic cells differentiate as Sertoli and Leydig cells. The Sertoli cells secrete Mullerian inhibiting substance (MIS), a 140-kd glycoprotein in the TGF- β family of proteins. MIS causes degeneration of the mullerian ducts by inducing apoptotic cell death of the ductal epithelial cells.

The Leydig cells secrete testosterone, which stimulates the wolffian ducts to differentiate into the vas deferens, seminal vesicle, and epididymis and virilizes the external genitalia.

Differentiation of the external genitalia requires the activation of testosterone by 5 α -reductase-2 to its more active metabolite, dihydrotestosterone (DHT). DHT stimulates fusion of the urethral folds and the labioscrotal swellings to form the corpus spongiosa and scrotum. DHT also stimulates growth of the genital tubercle and prostate. Sexually dimorphic differentiation of the internal ducts and the external genitalia is complete by 12 weeks of gestation. Subsequently, during the latter part of gestation, the testes descend into the scrotum and the phallus enlarges as testosterone production increases under the stimulus of pituitary gonadotropins.

In 46, XX embryos, the primary sex cords become follicles by 10 weeks gestation and the germ cells differentiate to oogonia. Both X chromosomes are needed for maintenance of the ovary. In the absence of one X chromosome,

P.916

as in Turner syndrome, the ovaries form initially, but regress before birth. In females, fetal ovaries do not secrete MIS, thus the mullerian ducts differentiate to form the uterus, fallopian tubes and upper vagina. The absence of testosterone and DHT production by the fetal ovary cause the wolffian ducts to degenerate and enables the external genitalia to differentiate as female.

DISORDERS OF CHROMOSOMAL SEX

A number of sex chromosome aberrations have been reported (see Chapter 38): some are embryonic lethal (e.g., 45, YO), others cause minimal somatic or hormonal manifestations in the newborn (e.g., 47, XXY), and a few perturb gonadal and genital development (45, X/46, XY, 45, XO). In contrast to the autosomes, extra genetic material from the X chromosome can be tolerated with minor untoward effects as a result of inactivation of the second and additional X chromosomes. Although ovarian formation and function are intact in patients with X polyploidy, early menopause may occur (10). In contrast, a Y chromosome is generally necessary for testicular development, although rare cases of sex-reversed 46, XX males with normal testicular function and male genitalia are reported (11).

The classic sex chromosomal anomalies occur relatively frequently as determined by newborn screening. In the New Haven Study, 47, XXY occurred once in 545 males, 47, XYY occurred once in 728 males, 47, XXX occurred once in 727 females, and 45, XO occurred once in 2181 female newborns (12). The incidence of 45, XO is higher than this, but leads to increased fetal demise and is found in 1 in 15 spontaneous abortions (13). The diagnosis of Turner syndrome, however, is made with greater frequency than the other sex chromosomal aberrations because of the associated somatic abnormalities.

Turner Syndrome

The classic and most common chromosomal abnormality is total loss of one X chromosome. Over 50% of girls with Turner syndrome have a 45, XO karyotype, 17% have mosaicism with an isochromosome 46, X, i(Xq), 8% are chimeras with 45, XO/46, XX, and the remainder have other forms of mosaicism with loss of X material (14). The presence of a mosaic 46, XX cell line has little bearing on stature or somatic abnormalities, but does influence gonadal development. Goldberg and associates reported spontaneous female sexual development in 3 of 25 patients with mosaic karyotypes, but in none in those with 45, XO (15). The Turner phenotype in the newborn is secondary to lymphangiectasia and lymphedema. The webbed neck is most often seen as redundant

folds about the posterior neck. The lymphedema involves the dorsa of the hands and feet. A host of associated somatic defects have been described in this syndrome (14,16), most of which become more evident with increasing age. The most common are triangular facies with low-set ears, high-arched palate, low hairline, shield-like chest with widespread and hypoplastic areolae, and cubitus valgus. Coarctation of the aorta is the typical cardiovascular abnormality; however the more benign condition of bicuspid aortic valves occurs more frequently. Miscellaneous renal malformations are observed. Skin manifestations include hemangiomas, cutis laxa, pigmented nevi, dysplastic nails, and tendency to keloid formation. Skeletal abnormalities include "beaking" of the medial tibial condyle, drumstick-shaped distal phalanges, vertebral anomalies, and short metacarpals (17). Dermatoglyphic abnormalities include palmar simian creases, distal axial triradius, and an increased number of digital ulnar whorls. Declining growth can manifest in young children and is the most consistent characteristic in the older child. After diagnosis, screening for associated disorders such as cardiac and renal defects is needed (16). Therapy is focused on the specific developmental anomaly, such as coarctation of the aorta, and on providing education about potential associated problems, such as recurrent otitis media, chronic lymphocytic thyroiditis, and idiopathic hypertension. The incidence of mental retardation is slightly increased with specific X chromosome rearrangements. In most children with Turner syndrome however, cognition is normal with good verbal skills and selected spatial deficits.

A major concern for girls with Turner syndrome is extreme short stature with a mean adult height of 148 cm. Recombinant growth hormone increases final height and is approved for treatment of short stature in Turner syndrome. The combination of early use of growth hormone (before 5 years of age) and low dose estrogen replacement at an appropriate age is thought to give the best outcome in terms of height and psychosexual development (18). Estrogen/progesterone therapy at the appropriate age is indicated for the treatment of sexual infantilism. Questions regarding fertility may arise even in the newborn period because primary gonadal failure occurs in more than 90% of individuals

with Turner syndrome. Women with Turner syndrome, however, have successfully carried offspring to term using donor oocytes, at a rate similar to couples with other causes of infertility (19).

The presence of Y material in the karyotype raises concerns about testicular elements that are at risk for malignant transformation. In patients with mosaicism that includes Y material, gonadectomy is therefore recommended, both to eliminate the risk for gonadoblastoma and to avoid the virilizing effects of hormonally active residual testicular elements (20).

DISORDERS OF GONADAL DETERMINATION

Disorders of gonadal determination can occur in association with autosomal or sex chromosomal anomalies and/or loss of function mutations or deletions of SRY and

P.917

SOX-9. Mutations have also been identified in other genes essential for gonadal formation such as WT-1 and SF-1. The clinical phenotype of these single gene mutations varies from complete gonadal dysgenesis to lesser degrees of testicular damage. Teratogens such as radiation, viruses, and drugs have also been implicated in *in utero* gonadal damage. Differentiation and development of the internal ducts and external genitalia in these infants depend on the timing and extent of insult to the developing gonad.

Complete Gonadal Dysgenesis

Complete dysgenesis of the genital ridges results in normal female genitalia with no associated somatic findings, thus the diagnosis is often not suspected during infancy. Infants with 46, XY complete gonadal dysgenesis may be identified as a result of genitalia that are discordant with the prenatal karyotype. Affected girls tend to be tall with eunuchoid proportions and often present with primary amenorrhea and sexual infantilism. An autosomal recessive form of 46, XX gonadal dysgenesis is associated with sensory neural deafness (21). The majority of 46, XY gonadal dysgenesis is sporadic but familial forms can be sex-limited autosomal recessive, X-linked, or autosomal dominant in inheritance (22)

Partial Gonadal Dysgenesis

Incomplete loss of function of genes essential for testicular differentiation, or exposure to teratogens that damage the developing testis cause partial gonadal dysgenesis. Testicular loss after 9-10 weeks of gestation will not interfere with involution of the mullerian structures because the critical time for exposure to MIS is at 7 to 10 weeks, but will perturb mid-line fusion and development of the external genitalia, which is dependent on on-going testosterone production by the testes. Thus the external genitalia are female or severely undervirilized, but the gonads, uterus and fallopian tubes are absent and the wolffian structures are incompletely developed.

True Hermaphroditism

In true hermaphroditism, both ovarian and testicular elements are present. Findings may consist of an ovary on one side and a testis on the contralateral side, an ovary or a testis and a contralateral ovotestis, or two ovotestes (23). Most patients with true hermaphroditism have ambiguous external genitalia, although differentiation of the internal duct structures and external genitalia depend on the amount of functioning testicular tissue. In those reared as female, the testicular component of the gonad may secrete androgens at puberty to cause unwanted virilization, thus gonadectomy should be performed early. Although some patients have sex chromosome abnormalities, 46, XX is the most common karyotype, followed by 46, XY. The pathogenesis of true hermaphroditism is not well understood, but is not consistently linked to alterations in SRY expression.

DISORDERS OF PHENOTYPIC SEX

Disorders of phenotypic sex result when the anatomic development of the external genitalia does not correspond to the chromosomal and gonadal sex. The external genitalia may be truly ambiguous—that is, the sex of the infant cannot be ascertained by physical examination. Alternatively, the phenotype may be normal male or female, but inappropriate for the genotype. These conditions may be secondary to genetic defects affecting hormonal synthesis or action, problems in timing or regulation

or hormonal secretion, defects in receptor binding or signaling defects, or teratogens or maternal hormones that perturb reproductive tract development. A genotypic (46, XY) male with testes and inadequate virilization falls in the category of male pseudohermaphroditism. A virilized genotypic (46, XX) female with ovaries is considered to have female pseudohermaphroditism.

Female Pseudohermaphroditism

The female fetus can be virilized by fetal adrenal androgens or maternal androgens transferred across the placenta. Exposure to androgens prior to week 12 of gestation results in fusion of the urogenital sinus and genital folds. Exposure to androgens after week 12 of gestation or after birth causes milder manifestations of clitoral enlargement, labial hyperpigmentation, and posterior labial fusion.

Congenital Adrenal Hyperplasia

The major cause of virilization in a female is congenital adrenal hyperplasia (CAH) as a result of steroidogenic enzyme defects in cortisol biosynthesis. The more common inherited enzymatic deficiencies of adrenal biosynthesis (21-hydroxylase, 11-hydroxylase, and 3 β -hydroxysteroid dehydrogenase defects) all virilize the female. The gonads are ovaries, thus internal genital duct development is female—the wolffian ducts regress and the mullerian structures are normally formed. The excess adrenal androgens, however, promote fusion of the labia and the urogenital sinus, and phallic enlargement. Rarely, the virilization is severe enough to cause complete external masculinization. The 21-hydroxylase and 3 β -hydroxysteroid dehydrogenase forms of CAH are complicated by associated mineralocorticoid deficiency that may present as a salt-losing adrenal crisis. The enzymatic defects causing CAH are more fully discussed in the section on adrenal disorders.

Drug-Induced Female Pseudohermaphroditism

A number of female newborns have been virilized by progestational agents used to prevent spontaneous abortion or other medications with androgenic potency (24). When these drugs are used during the first trimester, the labioscrotal folds are fused with formation of a urogenital

sinus and clitoromegaly. When fetuses are exposed after the first trimester, they develop only clitoral enlargement, without labioscrotal fusion. In contrast to untreated infants with CAH, there is neither progressive virilization nor continued acceleration of growth and skeletal maturation after birth. No medical intervention is needed as androgens are not elevated but surgical correction might be warranted. These children will feminize normally at puberty and achieve normal fertility.

Virilizing Disorders in the Mother

Virilization of a female fetus by an androgen-producing maternal tumor is rare. These tumors almost always are caused by an ovarian lesion—arrhenoblastomas, Krukenberg tumors, luteomas, lipid or stromal cell tumors, although adrenal adenomas are also reported (25). The tumors cause clitoromegaly, acne, deepening of the voice, decreased lactation and hirsutism in the mothers and are associated with elevated serum androgens and elevated excretion of urinary 17-ketosteroids (26).

Aromatase Deficiency

Rare genetic defects in the fetal or placental aromatase gene impair aromatization of maternal and placental androgens to estrogens and cause in utero elevations of androgens (27). Both fetal and maternal virilization can occur.

Idiopathic Female Pseudohermaphroditism

Idiopathic virilization may be caused by nonhormonal factors as exposure to androgens cannot be documented. This can occur in isolation or in conjunction with congenital anomalies of the gastrointestinal (GI) and urinary tracts that include imperforate anus, renal agenesis, urinary tract obstructions, urethrovaginal fistulas, and/or defective müllerian duct formation.

Male Pseudohermaphroditism

Incomplete masculinization of the male fetus can be as a result of a myriad of causes that disrupt either androgen action or the response of target tissues to androgens during sexual differentiation. The differential diagnosis of male pseudohermaphroditism is extensive, including enzymatic defects of testosterone synthesis, unresponsiveness to testosterone action (androgen-resistance syndromes), hypothalamic or pituitary dysfunction, and vascular or teratogenic insult to the testis.

Defects in Testosterone Biosynthesis

Male fetuses are undervirilized when in utero testosterone production is reduced as a result of a genetic mutation in one of the testosterone synthetic enzymes (28). The phenotype varies according to the specific gene affected. Defects in 17 α -hydroxylase/lyase and 17 β -hydroxysteroid dehydrogenase primarily affect testosterone production although defects in enzymes needed for both testosterone and cortisol synthesis cause a form of CAH associated with incomplete masculinization. Steroidogenic acute regulatory protein (StAR) and 3 β -hydroxysteroid dehydrogenase mediate early steps in cortisol and aldosterone synthesis. Mutations in either of these genes can result in a severe salt-losing syndrome and insufficient masculinization of the genitalia. The full details of these disorders, including diagnosis and treatment, are outlined in the section on adrenal hyperplasia.

Syndromes of Androgen Resistance

This is a group of disorders characterized by undervirilized genitalia with normal mullerian duct regression and normal testosterone synthesis (29). The term androgen resistance encompasses androgen receptor or postreceptor defects (androgen insensitivity syndrome [AIS]) and 5 α -reductase deficiency in which the conversion of testosterone to its more active metabolite, DHT is affected. In both conditions, MIS is produced normally by the fetal testis and causes involution of the mullerian structures. In AIS, although testosterone is produced, the defect resides

in the receptor or its signaling, thus target tissue response is compromised. Consequently, all aspects of male development mediated by androgens, including development of the wolffian structures and external genitalia are affected.

In contrast, in 5 α -reductase deficiency, sufficient testosterone is produced for differentiation of the wolffian structures, but not for complete virilization of the external genitalia, which requires DHT (30). DHT is needed for mid-line fusion and phallic growth, thus patients with 5 α -reductase deficiency typically have a blind vaginal pouch, a small phallic structure with chordee, a hooded prepuce, and perineoscrotal hypospadias. At puberty, the increase in secretion of testosterone and induction in expression of 5 α -reductase and the androgen receptor in genital tissues stimulate growth of pubic hair, penile enlargement, and descent of the testes. 5 α -reductase deficiency is suspected in 46, XY patients with perineoscrotal hypospadias and an elevated testosterone to DHT ratio of more than 35 under basal conditions and more than 74 after human chorionic gonadotropin (hCG) stimulation. The diagnosis is confirmed by finding reduced 5 α -reductase activity in fibroblasts from genital skin.

Complete AIS (CAIS), an X-linked condition, was previously referred to as the testicular feminization syndrome (31). Affected patients have a 46, XY karyotype, normal female external genitalia with a blind vaginal pouch, absent wolffian and mullerian structures, and abdominal or inguinal testes. Unlike patients with 5 α -reductase deficiency, virilization does not occur at puberty but peripheral conversion of the high testosterone concentrations to estradiol stimulates good breast development and estrogenization of the vaginal mucosa. Most patients have little pubic hair and some have total absence of sexual hair. In

P.919

all other respects, including height, habitus, voice, breast development, and gender identity, these individuals are feminine. The diagnosis is made in infancy or childhood as a result of female genitals that are discrepant with an 46, XY karyotype, or to the discovery of testicular tissue during hernia repair. Adolescent patients frequently present with

primary amenorrhea. Genetic mutations of the androgen receptor are identified in only two thirds of individuals with suspected AIS. The gonads in CAIS have a 9% risk for malignant transformation to neoplasia, thus should be removed surgically.

A wide spectrum of phenotypes is observed in individuals with incomplete forms of androgen insensitivity. Partial or mild AIS (PAIS) can range from a female phenotype with clitoromegaly and posterior labial fusion to a male phenotype with infertility and sparse pubic hair. Sex assignment may be difficult in patients with PAIS. In some cases, assessment of responsiveness of the phallus to andro- gens is helpful.

OTHER CONDITIONS INVOLVING GENITOURINARY DEVELOPMENT

Male or Female Genital Phenotype

Inconsistent with Genotype

A problem ensues at birth when the phenotype is inconsistent with the chromosomal sex determined by prenatal cytogenetic analysis. A repeat karyotype after birth may reveal an error in the prenatal cytogenetic analysis. A number of intersex conditions, however, can present at birth with external genitalia that are normal in appearance but discordant with chromosomal sex (Table 39-1). In general, these children should be raised according to the phenotypic sex.

Hypospadias and Cryptorchidism

Isolated hypospadias occurs in 0.8% of newborn infants and isolated cryptorchidism is present in approximately 5% of full-term and up to 15% of premature infants. Generally, neither condition by itself is associated with an endocrine abnormality. The incidence of intersex conditions however, is greater if the hypospadias is severe (on the shaft or perineum), or if the testes are nonpalpable. If cryptorchidism and hypospadias are both present, 25% of infants have a disorder of intersex.

TABLE 39-1 ETIOLOGY OF MALE OR FEMALE GENITAL PHENOTYPE INCONSISTENT WITH THE GENOTYPE

Disorder	Genotype	Phenotype	Etiology
Pure gonadal dysgenesis	XY	Female	mutations in SRY, SOX9 WT1, SF-1
46, XX Males	XX	Male	SRY translocation
46, XY Females	XY	Female	SRY deletion
Congenital lipoid hyperplasia	XY	Female	CAH (StAR)
17,20-Lyase deficiency	XY	Female	CAH (17- β HSD)
17-Hydroxylase deficiency	XY	Female	CAH (p450c17)
Androgen resistance syndrome	XY	Female	mutation in AR

Micropenis

Isolated micropenis with otherwise normally formed genitalia generally is not considered as ambiguous genitalia. This condition is associated with insufficient testosterone secretion during the third trimester. The

evaluation of micropenis is discussed under hypopituitarism, the most common treatable cause of this condition.

EVALUATION

The evaluation of a newborn with ambiguous genitalia should be managed expediently by a team of experienced providers. Parents should be reassured that incomplete or excessive differentiation of the genitals occurred as part of a continuum in the developmental process and that the appropriate sex will be determined within several days. It is our general philosophy not to discuss pending studies in detail because there are occasions for gender assignment that are inconsistent with either chromosomal or gonadal sex and presentation of all data available enables a more cohesive explanation. As in any diagnostic problem, the approach to the child with ambiguous genitalia should begin with a thorough history, a careful physical examination, and appropriate laboratory and radiologic testing. Table 39-2 outlines the different causes of sexual ambiguity.

A history of drug ingestion, particularly in the first trimester, or recent androgenic changes in the mother might suggest the cause of female pseudohermaphroditism. First trimester infections or exposure to teratogens might suggest gonadal dysgenesis. A family history of an unexplained neonatal death or siblings with virilization or precocious puberty, might suggest the diagnosis of CAH although a history of female relatives with sexual infantilism suggests X-linked causes such as AIS. A thorough physical examination is important, but on no account should a diagnosis be based on the physical

P.920

findings. The presence or absence of palpable gonads helps to differentiate the major categories of intersex conditions. In general, gonads lacking testicular elements will not descend below the inguinal region. Thus, a palpable gonad excludes the diagnosis of female pseudohermaphroditism in which the gonads are ovaries by definition. Measurement of the length and diameter of the penis is valuable both for prognostic information and also as a baseline if treatment is given to

enlarge the penis. The urethral opening should be identified and the existence or absence of a vagina should be determined. The degree of fusion of the labial-scrotal folds and the presence of associated urinary or GI tract anomalies should be assessed.

Teratogenic insult

Idiopathic

Isolated

Associated with midline congenital anomalies

The physical examination can help direct the laboratory and radiologic investigation. Certain tests are obtained as soon as it is apparent that there is sexual ambiguity, although others may be required at a later stage to make an accurate diagnosis (Table 39-3). For example, serum 17-hydroxyprogesterone and electrolytes are useful initial screening tests for congenital adrenal hyperplasia but other steroid precursors and genetic studies may help establish the specific diagnosis. In the newborn period, testosterone, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) should be drawn to assess the hypothalamic-pituitary-gonadal axis. Serum testosterone can be elevated from either gonadal or adrenal production and should be interpreted in the context of the examination and other laboratory studies. Measurement of MIS may help determine the presence of testicular tissue (32). It should be stressed that sex assignment does not require that all studies leading to a final diagnosis be completed (e.g., the exact type of congenital adrenal hyperplasia may be important for genetic counseling and future prenatal diagnosis, but not for sex assignment). The karyotype can help determine whether the infant is a virilized female or an inadequately virilized male. This, however, should not be used as the primary criteria for sex assignment as other factors such as gonadal function, sensitivity to androgens, future sexual function and potential for fertility or pregnancy (even if by *in vitro* fertilization) are also critical.

Pelvic ultrasound to evaluate the internal genital structures and gonads should be performed by an experienced radiologist. Ultrasonography may identify nonpalpable gonads, and may be able to define the echogenic pattern as either ovarian or testicular tissue (33). The presence of a uterus indicates a lack of MIS action and probable absence of functioning testicular tissue in early gestation, and usually indicates that the child should be raised as a female. Conversely, the absence of mullerian structures implies the presence of functioning testicular tissue that secreted MIS at 7 to 9 weeks of gestation. This is consistent with sex-determining region Y (SRY) expression and suggestive of an XY karyotype, but is not a major determinant for male sex assignment. The karyotype, phallic size and degree of hypospadias, internal genital structures, gonadal pathology, and etiology of the intersex condition are all part of the equation in gender determination.

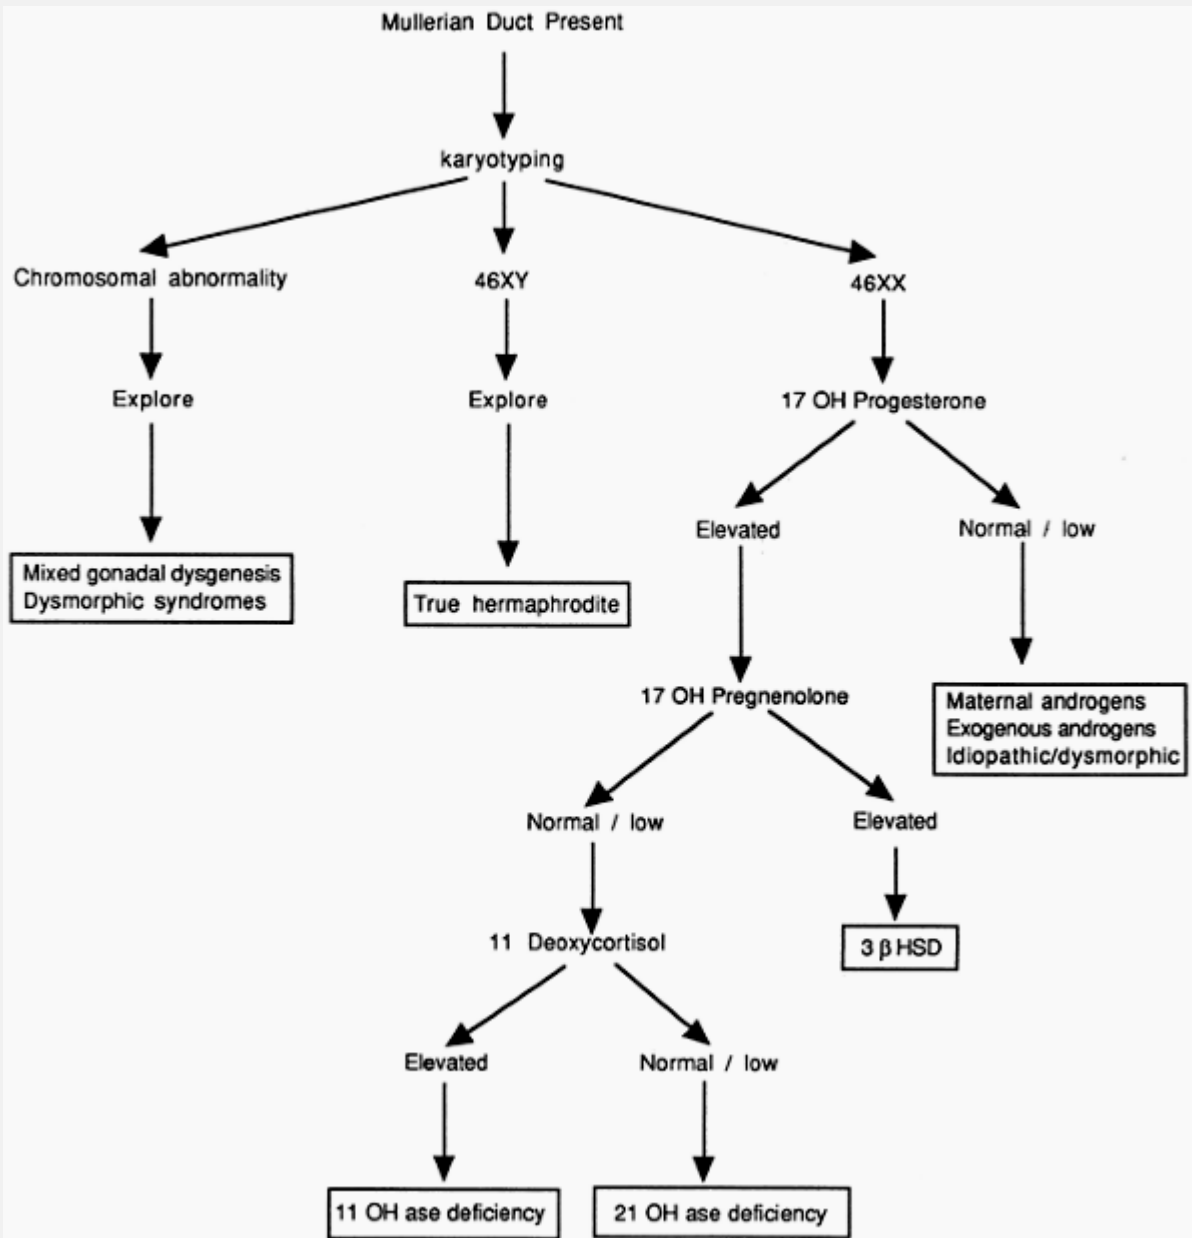

Figure 39-2 An algorithm for evaluating sexual ambiguity in infants with mullerian structures.

To evaluate further the specific etiology of the sexual ambiguity, secondary studies may be necessary. The algorithms in Figs. 39-2 and 39-3, which are based on the initial ultrasound findings, delineate the steps that may be necessary to make a definitive diagnosis. These algorithms do not include patients with normal male or female phenotypes that are discordant with the genotype. Surgical exploration frequently will be required in cases of true hermaphroditism or partial gonadal dysgenesis but may be done at a later time. It should be stressed that the final histopathologic diagnosis is not necessary for sex assignment.

After the evaluation is complete, including consultations from an endocrinologist and an urologist, the appropriate sex assignment is determined by a consensus of opinion from the team that might also include a geneticist, a psychiatrist or psychologist, the pediatrician, and clergy or other support personnel. Parental input is also considered in the decision, especially in cases in which the appropriate sex assignment is uncertain. Gender identity, and future sexual function and fertility are major determining factors. The attending physician should discuss the condition fully with the parents, including expectations for future sexual function and fertility and whether any hormonal medications or surgery are recommended.

Gender assignment for most infants with ambiguous genitalia is straightforward when chromosomal sex and gonadal sex correlate with the internal structures. The external genitalia may require reconstructive surgery to improve function and cosmetic appearance. The timing of surgery has become controversial and highly politicized as a result of heightened concerns about ethical issues of informed consent by the child, the possibility of gender dysphoria and sex reassignment, and the risk for postsurgical loss of genital sensation. With little long-term data to support early vs. late reconstructive surgery, it may be prudent to postpone surgery until gender identity is clear and

P.922

to have the full participation of the family (and child) in the decision. Hormonal therapy may be required to induce secondary sexual maturation, but is usually not needed during the neonatal period. Rarely,

as in cases of partial androgen resistance syndromes, true hermaphroditism, or mixed gonadal dysgenesis, gender assignment contrary to chromosomal or gonadal sex must be considered. In these cases, careful consideration must be given to the likelihood of gender role and sexual function as an adult (34).

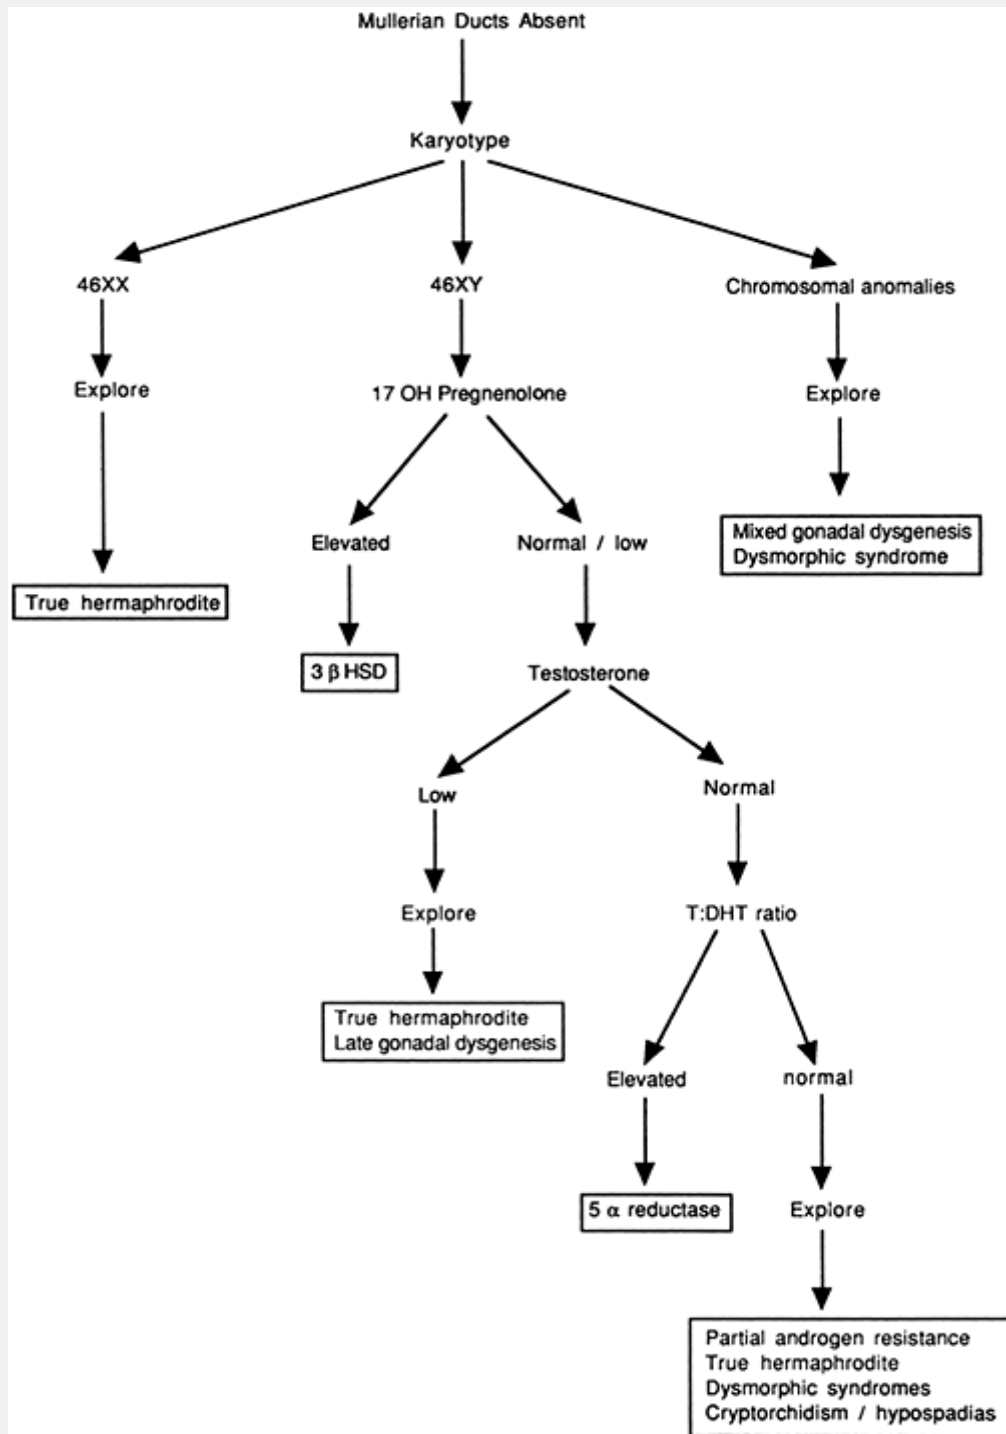

Figure 39-3 An algorithm for evaluating sexual ambiguity in infants without mullerian structures.

Severe micropenis or agenesis previously warranted a female sex assignment despite the presence of testes or a normal 46, XY karyotype, but this approach is now under reappraisal. Recent reports of dissatisfaction with a female sex assignment in some 46, XY individuals with cloacal exstrophy or other nonhormonally mediated causes of aphantasia reinforce the need to explore new paradigms for sex assignment. These paradigms will need to include other factors that affect adult gender identity such

P.923

as the role of prenatal hormones on central nervous system (CNS) sex differentiation.

DISORDERS OF THE HYPOTHALAMUS AND PITUITARY

Development of the Hypothalamic-Pituitary

Axis

The hypothalamus arises by proliferation of neuroblasts in the intermediate zone of the diencephalic wall and formation of the supraoptic and periventricular nuclei. The anterior pituitary, or adenohypophysis, arises embryonically from an invagination of the oral ectodermal cavity called the Rathke pouch. This diverticulum arises at 3 weeks of gestation, and by 5 weeks has migrated upward to its final position and separated completely from the oral cavity. Concordantly, the posterior pituitary, or neurohypophysis, is formed from a downward invagination of the floor of the diencephalon. Neural fibers migrate from the hypothalamus down to the posterior pituitary to form the neurohypophyseal tract. The hypothalamus regulates the pituitary by secreting both stimulatory and inhibitory hormones. The stimulatory hormones include growth hormone-releasing hormone (GHRH), thyrotropin-releasing hormone (TRH), corticotropin-releasing hormone (CRH), and gonadotropin-releasing hormone (GnRH). The main inhibitory hormones are somatostatin, which inhibits growth hormone release and prolactin inhibitory factor, which inhibits prolactin release. In response

to these hypothalamic hormones, the anterior pituitary secretes prolactin, growth hormone (GH), thyroid-stimulating hormone (TSH), adrenocorticotrophic hormone (ACTH), LH, and FSH. The posterior pituitary secretes vasopressin and oxytocin. The hypothalamic and pituitary glands are functional after week 12 of gestation.

TABLE 39-4 ETIOLOGY OF DISORDERS OF THE HYPOTHALAMIC-PITUITARY AXIS

- Toxoplasmosis

Tumor

- Hypothalamic hamartoblastoma (i.e., Pallister Hall syndrome)
- Rathke pouch cyst
- Craniopharyngioma
- Glioblastoma

Isolated or combined familial or idiopathic pituitary hormone deficiency

- Autosomal recessive or X-linked recessive familial panhypopituitarism

Most disorders of the hypothalamic-pituitary axis in the newborn period, except for the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), are those of insufficiency related to malformations,

trauma, infection or genetically inherited disorders, as outlined in Table 39-4. This differs from older children and adults who may have either functionally active tumors that secrete pituitary hormones or infiltrative disease or tumors that interfere with normal pituitary function.

DISORDERS OF THE ANTERIOR PITUITARY

Anterior pituitary dysfunction is difficult to detect in the newborn. The predominant features of anterior pituitary insufficiency are hypoglycemia, micropenis and, occasionally, cholestatic jaundice. The hypoglycemia may be quite severe and comparable to that seen in infants with congenital hyperinsulinism. The infants may even have a brisk glycemic response to glucagon causing further confusion (35). The cholestatic jaundice is initially unconjugated, then becomes predominantly conjugated, and will often only resolve after hormone replacement. There may be combined deficiency of multiple pituitary hormones or isolated deficiency of a single hormone. The molecular basis of multiple hormone deficiency is established for a number of genetic defects and was reviewed recently by Parks and associates (36). Evidence for the importance of the POU family of pituitary transcription factors in establishing pituitary lineages came from identifying the roles of Pit-1 in the Snell dwarf mouse (37), Prop-1 in the Ames dwarf mouse (38) and P-Lim knockout mice (39). In humans P-Lim is associated with deficiencies of all anterior pituitary hormones except ACTH in conjunction with retinal colobomas. Pit-1 mutations cause pituitary gland hypoplasia and deficiencies of GH, TSH, and prolactin. Prop-1 (Prophet of Pit-1) is essential for Pit-1 expression, and therefore has an identical clinical picture. Hypopituitarism in conjunction with optic nerve hypoplasia and absence of the septum pellucidum comprise the syndrome of Septo-optic dysplasia (SOD). Pituitary function can vary from intact to panhypopituitarism including diabetes insipidus. Mutations in a homeodomain protein, HESX-1, have been found in some patients with SOD associated with mild panhypopituitarism or isolated GH deficiency (40). SOD is often suggested by wandering nystagmus in the newborn, reflective of optic nerve hypoplasia and blindness.

Growth Hormone Deficiency

Growth hormone deficiency in the neonate may present as hypoglycemia, micropenis, or both. Micropenis is defined as penile size less than 2.5 cm stretched length in the term

P.924

infant. Congenital deficiency of growth hormone does not cause intrauterine growth retardation and often does not affect linear growth until 6 to 9 months of age. Intrauterine growth is primarily determined by maternal factors, including nutritional status, placental function, and gestational infection or drugs. During early postnatal life, thyroid hormone, insulin, and nutrition are more important growth determinants than growth hormone. A family history of short stature is pertinent because familial autosomal dominant inheritance of growth hormone deficiency is well recognized.

Gonadotropin Deficiency

Gonadotropin deficiency can occur as either isolated hypogonadotropic hypogonadism or combined multiple pituitary hormone deficiency. Although infants with combined deficiencies present with micropenis, those with isolated gonadotropin deficiency may not be recognized at birth. The genitalia can be normal male in Kallmans syndrome (hypogonadotropic hypogonadism and anosmia), a syndrome caused by mutations in the KAL gene encoding anosmin-1. Female infants are asymptomatic at birth and may not be identified until puberty fails to occur. Other causes of micropenis associated with gonadotropin deficiency include syndromic conditions, such as Noonan syndrome and Prader-Willi syndrome.

Adrenocorticotrophic Hormone Deficiency

Adrenocorticotrophic hormone deficiency rarely presents as an acute adrenal crisis; the cortisol insufficiency is typically mild and may cause hypoglycemia or hyponatremia without hyperkalemia, and occasionally, prolonged direct hyperbilirubinemia. Isolated ACTH deficiency is extremely rare but has been linked to the CRH gene locus (41). The combination of both growth hormone and ACTH deficiency may cause

hypoketotic hypoglycemia of such severity that it is difficult to differentiate from congenital hyperinsulinism (35).

Thyroid-Stimulating Hormone Deficiency

Thyroid-stimulating hormone deficiency is essentially asymptomatic in the newborn. On newborn screening tests, the serum thyroxine (T₄) concentration is low or low normal with the TSH in the normal range. This finding may be misinterpreted as the euthyroid sick syndrome (see Disorders of the Thyroid) in a stressed neonate. Furthermore, secondary hypothyroidism may be missed if primary TSH screening is used. TSH deficiency is usually associated with other pituitary deficiencies and rarely occurs in isolation. In an infant with any of the CNS abnormalities outlined in Table 39-4, secondary hypothyroidism should be considered and may be missed with routine newborn screening procedures.

Diagnosis

The diagnosis of hypothalamic and pituitary deficiency may require stimulation testing if random values are nondiagnostic. Growth hormone is tonically elevated in the first few days of life, thus a random growth hormone greater than 10 ng/mL suggests adequate growth hormone secretion. If a random value is low, growth hormone provocative testing is needed to confirm deficiency. In normal newborn infants, growth hormone values increase to greater than 25 ng/mL with stimulation testing. ACTH deficiency causing adrenal insufficiency is unlikely if a random cortisol is greater than 20 mcg/dL, because serum cortisol is low in newborns, without diurnal variation. In general, ACTH or CRH stimulation testing is necessary to test the hypothalamic-pituitary-adrenal axis. Random sex steroids, FSH, and LH may be diagnostic at 1 to 3 months of age when the hypothalamic-pituitary-gonadal axis is active transiently, otherwise gonadotropin-releasing hormone stimulation testing is needed to assess LH and FSH secretion.

In those infants suspected of anterior pituitary deficiency, ultrasonography through the open fontanelle may discern mid-line malformations of the brain, although magnetic resonance imaging or computed tomography scanning is more sensitive. If septo-optic dysplasia is a consideration, ophthalmologic examination should be performed.

Treatment

Anterior pituitary deficiency may not be detected clinically during the neonatal period if the hypoglycemia is mild, the micropenis, obviously not a clinical feature in hypopituitary females, is marginal, and jaundice is not severe. Treatment considerations, therefore, are based on the severity of symptoms. The child who is severely hypoglycemic will require immediate growth hormone and glucocorticoid replacement albeit at relatively modest doses. Recombinant growth hormone is injected subcutaneously, at a dose of 0.04 mg/kg daily. Glucocorticoid replacement with 8 to 10 mg/m² of oral hydrocortisone per day is often sufficient. This dose should be at least tripled for acute illness. If the testes are nonpalpable, MIS determination will ascertain their presence (32). An MIS value in the normal male range for age verifies the presence of testes. In male infants with micropenis, testosterone enanthate at a dose of 25 mg every month can be administered to stimulate penile growth. If the penile response is inadequate after a three month course, this can be repeated.

DISORDERS OF THE POSTERIOR PITUITARY

Vasopressin or antidiuretic hormone (ADH) and oxytocin are the two major posterior pituitary endocrine hormones. Oxytocin has no known function in the neonate although

P.925

ADH helps to regulate intravascular volume and osmolality. ADH is synthesized in the supraoptic and periventricular nuclei of the hypothalamus by 12 weeks of gestation. It is bound to neurophysin and is transported along the neurons of the neurohypophyseal tract to the posterior pituitary, where it is stored and released as necessary. ADH increases the permeability of the collecting tubules of the kidney to water and urea. Its secretion is stimulated by hyperosmolar states and volume depletion and inhibited predominantly by volume overload. The two main disorders of ADH secretion are diabetes insipidus and the syndrome of inappropriate SIADH.

Diabetes Insipidus

Diabetes insipidus (DI) in the newborn may be as a result of central ADH insufficiency or renal unresponsiveness to ADH (nephrogenic DI). This section will discuss only central DI.

DI in the neonate may present with failure to thrive, irritability, fever, vomiting, hypernatremia, and a history of polyhydramnios. Polyuria is difficult to appreciate in newborn infants because healthy newborn infants can void up to 20 times a day (42). However, sustained urine outputs greater than 60% of fluid input, and single-void volumes of greater than 6 mL/kg suggest DI. In a child with hyperosmolar serum, the diagnosis is confirmed by finding inappropriately dilute urine that becomes more concentrated after vasopressin administration. Failure to respond to vasopressin is suggestive of renal DI. Water deprivation tests should not be done in newborns as acute dehydration and hypernatremia may cause permanent CNS injury.

A list of causes of central DI is given in Table 39-5. Secondary DI is more common than primary in the neonatal period and should be strongly suspected in infants with certain malformations.

TABLE 39-5 ETIOLOGY OF CENTRAL DIABETES INSIPIDUS

Histiocytosis X
Granulomatous disease
Germ cell tumors (in older children)

Treatment

Treatment of DI requires strict management of fluid balance. Infants with DI require enormous quantities of free water; it is not unusual to provide several times the usual maintenance quantities of water as 5% glucose intravenously, although providing nutrition and electrolytes by the oral route. Desmopressin is a long-acting analogue of vasopressin. A number of different formulations are available; oral or subcutaneous may be easiest in infants. Sublingual administration can be helpful in patients with cleft lip and palate. Sublingual or subcutaneous dosing starts at 1 to 2 mcg once or twice daily and oral doses are about 10- to 20-fold higher. The dose and dose interval must be carefully titrated in each child by monitoring fluid intake, urine output, serum electrolytes and osmolality, and state of hydration. Management should include a "breakthrough" period of diuresis daily to avoid fluid overload although providing sufficient milk intake to meet caloric needs. Rapid shifts in the serum

sodium caused by excessive fluid input or urine output should be avoided. An alternative approach, which minimizes the risk of water overload, is to use a diluted formula without administering any vasopressin. This treatment is based on the principle that hunger rather than thirst is the driving force behind fluid intake in the neonate. Providing the total daily caloric intake as one-third strength formula will usually result in stable fluid balance. This approach requires two to three hourly feeding even during the night, thus sleep may be disrupted. Moreover the volume of fluid needed can compromise growth in some infants. For emergency treatment of severe dehydration, intravenous aqueous pitressin infusion, instead of desmopressin, is recommended as the short half life of pitressin allows precise control of fluid balance.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

The secretion of ADH is normally higher in premature infants (43) but can be further increased in sick premature infants for the reasons outlined in Table 39-6. A common mechanism in many pathologic cases is intravascular volume depletion, which is detected by stretch receptors in the left atrium. Thus, the elevated ADH levels are appropriate for the volume status, but inappropriate for the osmolar status. SIADH, by definition, occurs in a volume replete or overloaded state when there is dilutional hyponatremia associated with inappropriately concentrated urine with continued sodium loss (urine sodium >20-30 mEq/L). This occurs in the absence of volume depletion, renal failure, or adrenal insufficiency. True SIADH is uncommon in neonates (44), and should be differentiated from hyponatremia caused by ADH levels that are appropriately elevated in response to volume depletion. It is vitally important to limit water and sodium intake and prevent hyponatremia in SIADH, but equally important to adequately treat the volume depletion states associated with appropriately increased ADH secretion.

TABLE 39-6 CAUSES OF ELEVATED LEVELS OF ANTIDIURETIC HORMONE IN THE NEWBORN

Birth asphyxia
Acute deterioration of hyaline membrane disease and bronchopulmonary dysplasia
Respiratory syncytial virus infection
Pneumothorax
Pulmonary interstitial emphysema
Artificial ventilation
Acute blood loss
Periventricular hemorrhage
Surgery
Pain
Syndrome of inappropriate ADH secretion

ADH, antidiuretic hormone.

P.926

Hyponatremia occurs commonly in newborn premature infants who have a higher fractional excretion of sodium than term infants. The most common nonphysiological cause of hyponatremia is renal sodium wasting as a result of diuretics. The differential diagnosis of hyponatremia in the newborn includes prerenal failure, renal failure, adrenal insufficiency and SIADH. The SIADH, if it occurs, is associated more commonly with sepsis and central nervous system infection in older infants, but perhaps in critically ill neonates as well. Unlike volume depletion states, SIADH is treated by fluid restriction. If volume depletion is evident, combined with polyuria, urinary sodium loss, and hyponatremia, salt wasting should be suspected.

DISORDERS OF THE ADRENAL GLAND

Development and Function of the Adrenal Gland

The adrenal gland consists of a cortex and medulla, which each function independently and secrete two different classes of hormones. The fetal adrenal cortex is of mesodermal origin, whereas the chromaffin cells of the adrenal medulla are of neuroectodermal origin. Diseases of the adrenal medulla during the neonatal period are extremely rare, thus this section will focus on disorders of the adrenal cortex.

The anlage of the adrenal cortex arises as two large masses on either side of the aorta, at the level of the first thoracic nerve, immediately adjacent to the medullary cells that have migrated from the neural crest. Fetal adrenal cortical cells can be identified by 4 weeks gestation. By 7 weeks of gestation, the medullary cells begin to migrate to the interior of the adrenal cortex. The coelomic epithelium envelops the original cortical cells and remains as an outer shell. The fetal adrenal gland is steroidogenically active and large during gestation, but involutes during the latter half of pregnancy and especially after birth, suggesting a role in the maintenance of pregnancy. The adult adrenal cortex slowly develops from the outer shell although the fetal zone undergoes involution. DAX-1, a gene on the X chromosome, is essential for development of the definitive zone of the adrenal cortex (3). Mutations in this gene are responsible for congenital adrenal hypoplasia.

The trophic hormonal control of the fetal adrenal is not clear. In anencephalic fetuses, the fetal adrenal appears to develop normally during the first 12 weeks of gestation, then involutes. In patients with enzymatic defects of cortisol biosynthesis however, the hyperplasia and increased activity of the adrenal glands during the first 12 weeks of gestation suggests that ACTH must play some role during that time. The adrenal cortex secretes three main types of steroid hormones, glucocorticoids, mineralocorticoids, and androgens. The glucocorticoids, of which cortisol (hydrocortisone) is the most important, exert their major physiologic effects on carbohydrate, protein, and fat metabolism.

The mineralocorticoids, desoxycorticosterone and aldosterone, maintain salt and water balance by promoting sodium retention in exchange for hydrogen and potassium in the distal convoluted tubules of the kidney. The adrenal androgens, dehydroepiandrosterone (DHEA), δ 4-androstenedione, and 11β -hydroxyandrostenedione, are anabolic and responsible for the development of sexual hair in girls at puberty. The slightly higher levels of adrenal androgens during the neonatal period may be secondary to the relative deficiency of 3β -hydroxysteroid dehydrogenase in the fetal zone of the fetal adrenal cortex, which is reflected in the higher concentrations of δ 5 steroids (e.g., DHEA, 17-OH pregnenolone) especially in premature infants.

The production of adrenocortical steroids is controlled by a hypothalamic-pituitary-adrenal homeostatic mechanism. Hypothalamic CRH stimulates release of pituitary ACTH, which in turn, stimulates cortisol biosynthesis. Increased levels of cortisol exert down-regulation of the axis, probably at the level of the hypothalamus.

Aldosterone secretion is controlled by the renin-angiotensin system rather than ACTH. Acute changes in pressure receptors control the release of renin from the juxtaglomerular cells of the kidney. Circulating renin, in turn, increases angiotensin II, which acts on the zona glomerulosa of the adrenal cortex to stimulate aldosterone secretion and vascular contractility. The increased blood volume and higher pressures within the arterial receptors exert negative-feedback inhibition of the renin-angiotensin system. Secondary mechanisms such as a low sodium or high potassium intake also increase aldosterone excretion. ACTH will cause a transient, albeit unsustained, increase in aldosterone excretion, and aldosterone secretion will be diminished in the absence of ACTH. Finally, cortisol itself may have a permissive role in aldosterone action at the tissue level.

P.927

ADRENAL INSUFFICIENCY

The disorders of the adrenal cortex during the neonatal period consist almost entirely of those conditions that cause adrenal insufficiency. The

inborn errors of steroid biosynthesis (CAH) can cause excessive production of various steroids, but Cushing syndrome or cortisol excess is rare during the neonatal period. Cushing syndrome may occur secondary to exogenous steroids such as dexamethasone, but Cushing disease has not been described in the very young infant. Adrenal cortical tumors occur in older infants but have not been reported in the neonate. Adrenal insufficiency can result from hypopituitarism, adrenal hemorrhage and other adrenal injury, ACTH receptor abnormalities, inherited degenerative disorders, or inborn errors of steroid biosynthesis.

Adrenocorticotrophic Hormone Insufficiency

In a number of neonatal deaths associated with shock and peripheral vascular collapse in conjunction with severe hyponatremia and hyperkalemia, the adrenal glands were noted to be hypoplastic at autopsy. Because some of these cases were reported in infants with anencephaly or with partial or total pituitary aplasia, the lack of ACTH was thought to be responsible for the failure of development of the definitive zone after birth. The possibility, however, of another critical trophic factor is suggested by the findings in patients with congenital hypopituitarism. These patients have decreased cortisol production, but normal mineralocorticoid function and rarely develop hyperkalemia. They develop hypoglycemia, poor feeding, and failure to thrive, but can, in general, maintain water and electrolyte balance and respond to sodium deprivation with an increase in aldosterone excretion.

Familial isolated glucocorticoid insufficiency. This is an autosomal recessive disorder that can present during the neonatal period or later in childhood with shock, hyperpigmentation, hypoglycemia, and failure to thrive. These patients have cortisol insufficiency and cannot increase serum cortisol or urinary 17-hydroxysteroid excretion in response to ACTH stimulation. They can, however, respond to sodium deprivation with increased aldosterone excretion and decreased sodium excretion. Some pedigrees have a defect in the melanocortin-2 receptor (ACTH receptor) although others may have postreceptor defects (45). In one family with five affected siblings, two had intact glucocorticoid function during early infancy and developed glucocorticoid deficiency at a later

age, suggesting an inherited degenerative process of the adrenal glands as the pathogenetic basis in this family (46).

Damage

Adrenal insufficiency can occur during the newborn period as a result of damage to the relatively large and hyperemic adrenal glands. Trauma in association with a difficult delivery, particularly breech delivery; hemorrhagic diseases; or infectious processes can damage the adrenal glands. Minor hemorrhage or unilateral damage may not cause adrenal insufficiency, and may present subsequently as calcification of the adrenal glands detected on an abdominal radiograph obtained for other purposes. All patients with shock in association with hyponatremia should be suspect for adrenal insufficiency. The highly sensitive ACTH determinations, using monoclonal antibodies and immunoradiometric assays, can detect elevated levels of plasma ACTH that are diagnostic of primary adrenal insufficiency.

Congenital Adrenal Hyperplasia

CAH is a genetic disorder involving a deficiency of one of several enzymes required for normal steroid biosynthesis. Deficient cortisol synthesis secondary to an enzymatic deficiency causes increased ACTH production, which in turn, stimulates a compensatory hypertrophy of the adrenal cortex and increase in steroidogenesis. This partially compensates for the block in the biosynthetic pathway, but also leads to the increased production and accumulation of precursor steroids preceding the enzymatic defect. Although ACTH chiefly regulates the glucocorticoid pathway, the synthesis of mineralocorticoids and androgens are variably affected depending on the specific enzyme involved.

The principal biochemical reactions in the conversion of cholesterol into active adrenocortical steroids require a series of hydroxylations (Fig. 39-4) that are mediated by cytochrome P450 oxidases. The initial step requires that the StAR protein form contact sites between the outer and inner membranes of mitochondria to transport cholesterol into the mitochondria and start the steroidogenic process. Five enzymes are necessary for the synthesis of cortisol: P450scc, P450c17, P450c21,

P450c11, and 3 β -hydroxysteroid dehydrogenase enzymes (47). The genes for all of these enzymes have been cloned and defects in any of them can cause insufficient glucocorticoid production and CAH. The clinical manifestations of this syndrome correspond to the particular enzyme affected and are summarized in Table 39-7.

Virilization

Virilization of the female is secondary to the elevated adrenal androgens caused by those enzymatic defects subsequent to 17-hydroxylation. In most cases, the labioscrotal folds are partially fused with clitoral enlargement, which may be bound down by chordee. Occasionally, virilization may be so severe that a phallic urethra develops. In male infants, virilization is generally not apparent during the neonatal period, and, the diagnosis in the milder nonsalt-losing forms of this disorder, can be undetected for several years. Boys can present later with secondary sexual changes, increased somatic growth, and well-developed musculature. The classic, and most prevalent virilizing form of CAH is a defect in cytochrome P450c21 (21-hydroxylase deficiency), accounting for almost 90% of recognized cases (48).

P.928

Mutations in P450c11 and 3 β -hydroxysteroid dehydrogenase also cause female virilization.

Incomplete Masculinization

Failure of complete masculine development occurs in those forms of adrenal hyperplasia in which the androgen pathway is affected.

Incomplete masculinization in the male, which requires fetal testosterone production, suggests that the enzymatic defects occur in both the adrenal gland and the testis (28). In the 3 β -hydroxysteroid dehydrogenase defect, secreted steroids consist almost entirely of compounds with δ 5-3 α -hydroxy configuration (49). Fetal testosterone production by the testis is also impaired, causing incomplete masculinization in the male (50). The marked elevation of δ 5-3 β -hydroxyadrenal androgens, especially DHEA, however, is converted peripherally to active androgens that virilize the female infant.

Elevation

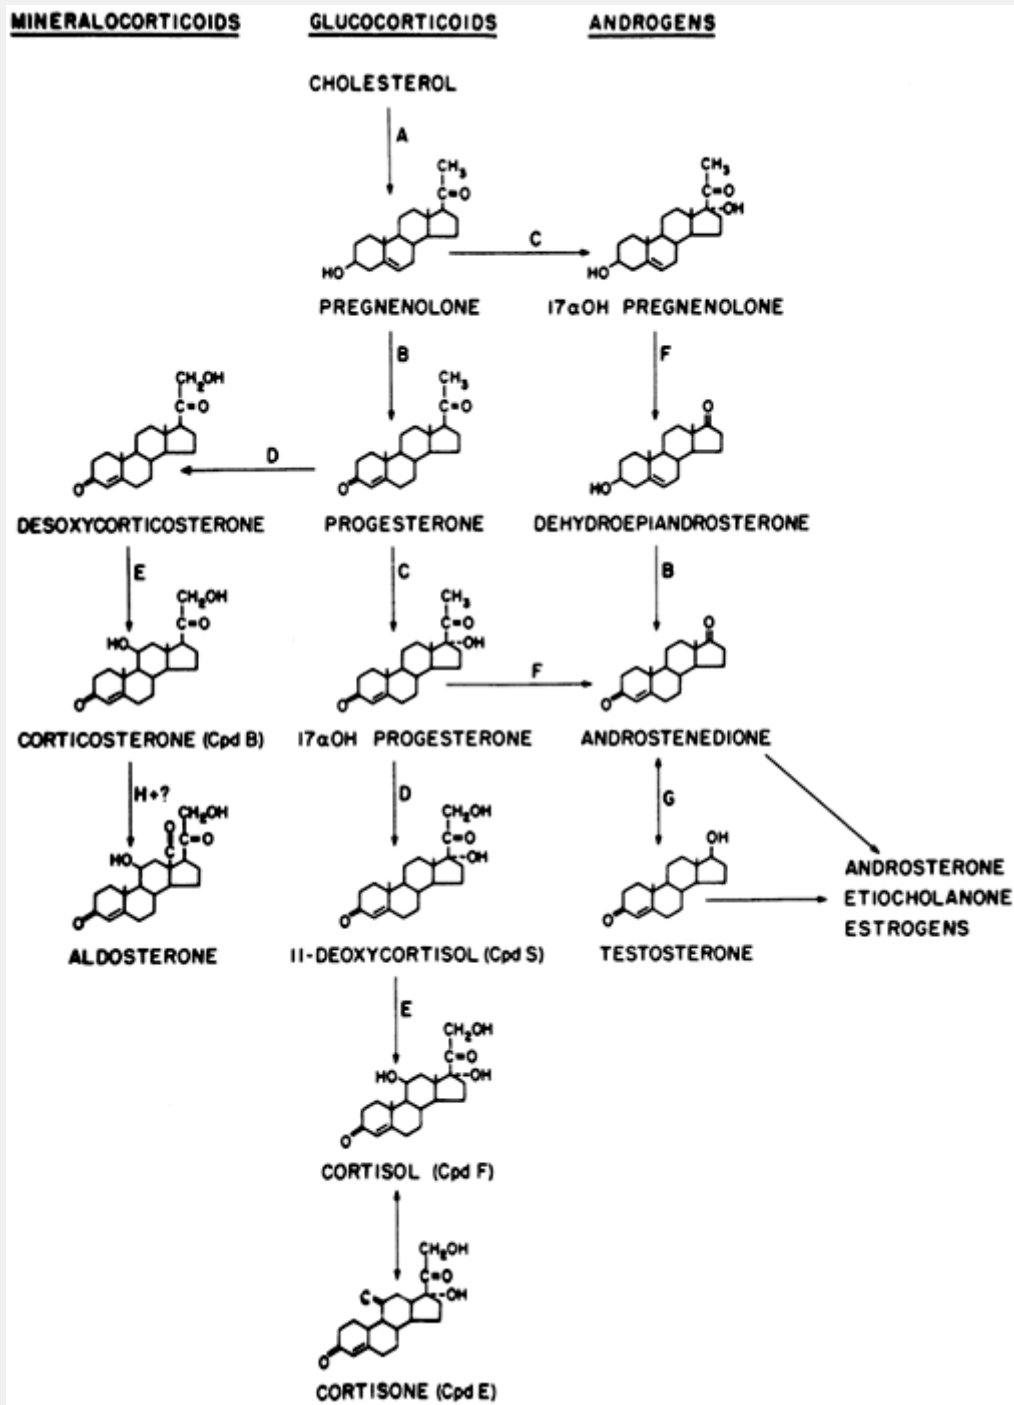

Figure 39-4 The biosynthetic pathway of adrenal steroid. The classic enzyme terminology is represented by the alphabetical letters with the appropriate cytochrome P450 oxidases in parentheses. A, 20,22-desmolase (P450scc); B, 3 β -hydroxysteroid dehydrogenase; C, 17 α -hydroxylase (P450c17); D, 21-hydroxylase (P450c21); E, 11-hydroxylase (P450c11); F, 17,20-lyase (P450c17); G, 17-keto reductase; H+, 18-hydroxylase + 18-oxidase (P450c11).

P.929

of serum 17-hydroxypregnenolone is diagnostic of 3 β -hydroxysteroid dehydrogenase deficiency, although 17-hydroxyprogesterone concentrations also are markedly elevated (50).

TABLE 39-7 CLINICAL AND BIOCHEMICAL FINDINGS OF THE COMMON VARIANTS OF CONGENITAL ADRENAL HYPERPLASIA

Phenotype				
Enzyme Deficiency (Classic)	46XX	46XY	Other Clinical Manifestations	Predominant Steroids
Congenital lipoid hyperplasia	Female	Female	Salt-wasting crisis	Low level-all steroids No response to ACTH
3 β -Hydroxysteroid dehydrogenase deficiency	Virilized	Hypospadias	Salt-wasting crisis	Dehydroepiandrosterone 17-OH pregnenolone Increased Δ^5 - Δ^4 ratio of steroids
21-Hydroxylase deficiency Late virilization in female Salt-wasting crisis	Virilized	Male	Pseudoprecocious puberty in male	17-OH progesterone Androstenedione Testosterone
11 α -Hydroxylase deficiency Hypertension	Virilized	Male	Pseudoprecocious puberty in male	11-Deoxycortisol 11-Deoxycorticosterone Androstenedione Low renin
17 α -Hydroxylase deficiency	Female	Female	Sexual infantilism Hypertension	Corticosterone 11-Deoxycorticosterone (Low renin)

ACTH, adrenocorticotrophic hormone.

Hypertension

Hypertension has been associated with enzymatic blocks resulting in excessive secretion of mineralocorticoids. A defect of cytochrome P450c11 (11-hydroxylase deficiency) causes an accumulation of desoxycorticosterone, a potent mineralocorticoid, and 11-deoxycortisol (47). The P450c17 defect (17 α -hydroxylase deficiency) blocks 17-hydroxylation of progesterone, interfering with cortisol and androgen biosynthesis, and shunting steroid production to the mineralocorticoid pathway (51). Genital development in females is unaffected but males are undervirilized. The hypertension resulting from excess mineralocorticoid production, however, is an inconstant feature and it is not known if hypertension is present during the newborn period. Whether the hypertension is related to the duration of excessive secretion of mineralocorticoid, the severity of the defect, or variations in sodium intake is also unclear.

Salt Loss

Mineralocorticoid insufficiency and severe sodium loss are seen in the salt-losing form of 21-hydroxylase deficiency, and 3 β -hydroxysteroid dehydrogenase deficiency. The electrolytes initially are normal, but, within the first week of life, serum sodium will slowly decrease with a concomitant rise in serum potassium. These infants may manifest acute adrenal crisis with shock, peripheral collapse, and dehydration, by a week of age.

The underlying metabolic defects for two clinical variants of the 21-hydroxylase enzyme defect are now understood. Bongiovanni and Eberlein postulated that both are the result of the same enzymatic defect (52). In the salt-loser, there is almost complete 21-hydroxylase deficiency, whereas in the simple form, there is sufficient 21-hydroxylase to permit aldosterone synthesis. A single gene mediates the hydroxylation of both progesterone and 17-hydroxyprogesterone. Different mutations of the P450c21 gene account for the heterogeneity of 21-hydroxylase deficiency disorders, including the nonclassic late-onset variant, although there is phenotypic variability with the same genotype (47,48).

A few instances of aldosterone deficiency caused by a specific defect of 18-dehydrogenase, the last enzymatic process in aldosterone synthesis, have been described (53,54). There is salt and water loss, without the other clinical consequences of congenital adrenal hyperplasia. These disorders are secondary to mutations of the P450c11 enzyme.

Congenital Lipoid Hyperplasia

Previously, this disorder was thought to be as a result of a deficiency of the enzyme, 20,22 desmolase (P450scc) that mediates the conversion of cholesterol to pregnenolone. The etiology is now recognized as a genetic defect of the StAR protein, a mitochondrial protein needed for transport of cholesterol across the mitochondrial membrane. StAR is needed for acute steroidogenesis, thus in some individuals, glucocorticoid production is initially preserved, but the accumulation of cholesterol esters causes continuing destruction of the adrenal and onset of adrenal insufficiency at older ages (55). Male and females both have female appearing external genitalia, hyponatremia,

P.930

hyperkalemia and dehydration. However, the age at presentation varies from the newborn period to several months of age and later. No steroids are produced and the adrenal glands are markedly enlarged, filled with cholesterol esters.

Prenatal Diagnosis and Treatment of

Congenital Adrenal Hyperplasia

CAH, 21-hydroxylase deficiency, can be diagnosed prenatally using molecular techniques. Once the diagnosis of 21-hydroxylase deficiency has been established in a propositus, molecular analysis of the P450c21 gene should be done in the propositus and the parents. The parents should have ACTH stimulation testing to confirm biochemically that they are genetic heterozygotes for 21-hydroxylase deficiency. The management of the pregnancy, the techniques used for diagnosis, the treatment of the female fetus with 21-hydroxylase deficiency, and the problems with these techniques have been reviewed (56,57). In brief,

the mother is started on dexamethasone early in the first trimester and, subsequently, chorionic villus sampling or amniocentesis is performed to determine the sex and genetic studies. If molecular and genetic techniques confirm the diagnosis and the fetus is female, dexamethasone treatment is continued to term. Long-term consequences of prenatal steroids remain unknown and therapy can be associated with cushingoid symptoms in the mother, thus prenatal management and therapy should be monitored closely and performed at centers with expertise.

Diagnosis of Adrenal Insufficiency

The diagnosis of acute adrenal insufficiency is difficult to make in the newborn. There must be a high index of suspicion in any acutely ill infant with shock, peripheral collapse, and a rapid and weak pulse, and in any infant with poor feeding, failure to thrive, intermittent pyrexia, or even hypoglycemia and convulsions. A subtle sign of congenital adrenal hypoplasia is hyperpigmentation, especially in the extensor creases and genitalia; however, this sign is seldom recognized until the diagnosis has been made. Decreased serum sodium and chloride and increased serum potassium levels are suggestive of mineralocorticoid deficiency. Isolated hyponatremia does not exclude glucocorticoid insufficiency, and should be viewed as a possible sign of adrenal insufficiency. Certainly, ambiguous external genitalia at birth always should suggest the possibility of CAH.

Serum cortisol levels are low in all newborns, especially in premature infants and lack diurnal variation, therefore random cortisol determinations usually are not diagnostic. In clinical situations highly suggestive of adrenal insufficiency, it is recommended that a rapid, 1-hour low dose ACTH stimulation test be performed and that pharmacologic doses of glucocorticoids be administered, along with fluid and electrolyte resuscitation, after testing. Plasma concentrations of ACTH are elevated in those infants with primary adrenal insufficiency, including CAH. A plasma sample for ACTH determination should be obtained before ACTH testing.

Delineation of the specific enzyme defect in CAH can be determined by measuring serum concentrations of the various steroidal precursors (see

Table 39-7). Cord blood concentrations of 17-hydroxyprogesterone are normally elevated to the range of 900 to 5,000 ng/dL. Serum values rapidly decrease by the second or third day of life to less than 100 ng/dL in newborns (58), but can increase to greater than 200 ng/dL at 1 to 2 months of age in male infants. Newborn values above 1,000 ng/dl are of concern although 17-hydroxyprogesterone values are higher in stressed newborns, especially preterm sick newborns, in whom they can be greater than 600 ng/dL (59). These values, however remain significantly lower than those in patients with 21-hydroxylase deficiency, which are often markedly above 2,000 ng/dL. Serum 17-hydroxyprogesterone is used for newborn screening for CAH using a filter paper technique (60). It is important to recognize that elevated serum concentrations of 17-hydroxyprogesterone are not diagnostic of the 21-hydroxylase defect. Serum 17-hydroxyprogesterone can be mildly elevated in the 11-hydroxylase defect and can be markedly elevated in the 3 β -hydroxysteroid dehydrogenase defect secondary to peripheral conversion of 17-hydroxypregnenolone to 17-hydroxyprogesterone (50). Serum values of 17-hydroxypregnenolone are especially elevated in the premature infant, and values up to 2,000 ng/dL are normal (59).

Treatment of Adrenal Insufficiency

The immediate need of a critically ill infant in adrenal crisis is for cortisol. If possible, cortisol should be withheld until the diagnosis can be established, either by ACTH testing or by obtaining serum for determination of the appropriate steroids and ACTH. However, if a newborn infant is in shock and in extremis, glucocorticoids should be immediately given as a lifesaving measure. In the usual situation, salt and water alone will relieve the clinical crisis. Intravenous isotonic saline in 5% glucose water should be infused at a rate of 100 to 120 mL/kg during the first 24 hours. If the infant is in severe shock, the use of plasma or 5% albumin, 10 to 20 mL/kg to restore intravascular volume, and cortisol, is often necessary. Hydrocortisone hemisuccinate or phosphate, 1.5 to 2 mg/kg, should be given intravenously immediately. Constant infusion of hydrocortisone hemisuccinate or phosphate (50 mg/m²/day) should be continued. Hydrocortisone hemisuccinate, 2 mg/kg,

can be given intramuscularly if intravenous access is a problem. The infant with severe shock may require a vasopressor, although vasopressor drugs may not be efficacious until hydrocortisone is administered.

Hydrocortisone or cortisone acetate, 10 to 12 mg/m²/day, is the mainstay for long-term treatment of patients with adrenal insufficiency. For acute illness, stress doses of hydrocortisone should be given parenterally at triple the maintenance dose.

P.931

Often a mineralocorticoid is a necessary adjunct for the chronic treatment of adrenal insufficiency. The dose of the oral mineralocorticoid, 9 α -fludrocortisone (Florine) is 0.05 to 0.1 mg/day, which is sufficient for most forms of adrenal insufficiency. In the salt-losing forms of congenital adrenal hyperplasia, occasionally higher doses of fludrocortisone are necessary. Even the compensated (nonsalt-losing) variant may benefit from low dose mineralocorticoid.

Iatrogenic Adrenal Insufficiency

During the neonatal period, pharmacologic doses of glucocorticoids are often needed for adjunctive treatment of a number of diseases, such as bronchopulmonary dysplasia. The dose and duration of glucocorticoid therapy that will cause iatrogenic adrenal insufficiency is not known, particularly in infants. High-dose glucocorticoid therapy for a brief duration (<1 week) probably will not cause adrenal insufficiency, therefore a slow taper is not needed unless the clinical course of the primary condition deteriorates. Treatment longer than 14 days may result in at least transient adrenal insufficiency. After a prolonged course, the dose of glucocorticoids can be decreased by one-half every several days until a physiologic replacement dose (10 mg of hydrocortisone/m²/day orally) is achieved. The dose can then be lowered more gradually, by 20% every 4 or 5 days.

Adrenal function may be suppressed for some time after prolonged pharmacologic glucocorticoid therapy. Again, there are no studies correlating dose, duration of pharmacologic treatment, and time needed

for recovery of adrenal function after high-dose glucocorticoid therapy in infants. There are anecdotal reports of adrenal crisis occurring during stress more than 6 months after discontinuation of pharmacologic glucocorticoid therapy. Although it is possible to evaluate periodically the adrenal response to exogenous ACTH to determine when iatrogenic adrenal insufficiency has resolved, alternatively, pharmacologic doses of glucocorticoids can be used empirically during situations of stress for at least a year after discontinuation of prolonged high-dose glucocorticoid therapy. A minimal dose of glucocorticoid to be used during stress situations is 30 mg of hydrocortisone/m²/ day, orally.

DISORDERS OF THE THYROID

Development and Function of the Thyroid

The fetal thyroid begins as a thickening of epithelium at the base of the tongue that migrates down the trachea, leaving the thyroglossal duct as an embryonic remnant. During its caudal migration, the thyroid assumes a more bilobate shape. The developing thyroid is able to concentrate iodide by 12 weeks of gestation, and to organify iodide and synthesize thyroxine (T₄) and triiodothyronine (T₃) by 14 weeks of gestation. Free T₄ and, more so, T₃ can cross the placenta in either direction. It is probable that the gradient is from mother to fetus during the first 12 weeks and then the gradient in transfer of thyroid hormones is from fetus to mother except in the hypothyroid fetus (61,62). There is no placental transfer of maternal or fetal TSH, although thyroid-stimulating immunoglobulins (TSI) will cross the placenta. The hypothalamic-pituitary feedback mechanisms are operative by the latter part of gestation. The hypothalamus secretes a tripeptide, TRH, which stimulates pituitary secretion of TSH. TSH, in turn, stimulates thyroid hormone production by regulating every step of thyroid hormone biosynthesis and release, from iodide accumulation to proteolysis of thyroglobulin. The thyroid hormones exercise negative feedback control of TSH response to TRH at the pituitary level but also inhibits at the hypothalamic level. The biosynthesis of thyroid hormones is illustrated in Fig. 39-5. Circulating plasma iodide is concentrated by the thyroid gland, then oxidized by a thyroid peroxidase and bound to tyrosine to form

monoiodotyrosine (MIT) and diiodotyrosine (DIT). The iodotyrosines are held by peptide linkage to thyroglobulin and coupled to form T3 and T4. T3 and T4 are then cleaved from thyroglobulin by thyroid proteases and secreted into the circulatory system. A large percentage of circulating T3 arises by deiodination of T4 by diiodinases 1, 2, and 3. Diodinase 1 (D1) and Diodinase 2 (D2) are differentially localized in the pituitary and peripheral tissues. At the pituitary level, D2 partially regulates TSH production by modulating T3 concentrations. Diodinase 3 (D3) converts T4 to reverse T3 and T2, biologically inactive iodothyronines. Within the thyroid, iodotyrosines and iodothyronines are deiodinated by dehalogenase enzymes and remain within the intrathyroidal iodide pool to be reused. The iodide released from peripheral deiodination enters the circulatory system to be reconcentrated by the thyroid gland or excreted by the kidneys. The iodothyronines are transported in the plasma by proteins. Thyroxine-binding globulin (TBG), an α -globulin, is the major carrier of T4, but binds T3 to a lesser extent. Thyroxine also is bound by T4-binding prealbumin and by albumin. At the cellular level, the unbound, free T3 and T4 are biologically active. Genetic disorders, acquired conditions, or drugs that quantitatively change the concentration of TBG will alter circulating total T4 without affecting the physiologic thyroid status.

THYROID FUNCTION TESTS

Thyroid function tests in infants are elevated compared to values in older children. This is secondary to the cold-stimulated surge of TSH and TRH in the immediate postnatal period and the higher TBG concentrations secondary to maternal estrogen effect. Total T4 ranges from 7.3 to 22.9 mcg/dL during the first month of life, with mean values greater than 10 mcg/dL (Tables 39-8 and 39-9). Thyroid function tests normally are lower in premature and sick newborns

P.932

than in healthy term newborn infants (Table 39-10), as a result of lower concentrations of TBG (64,65).

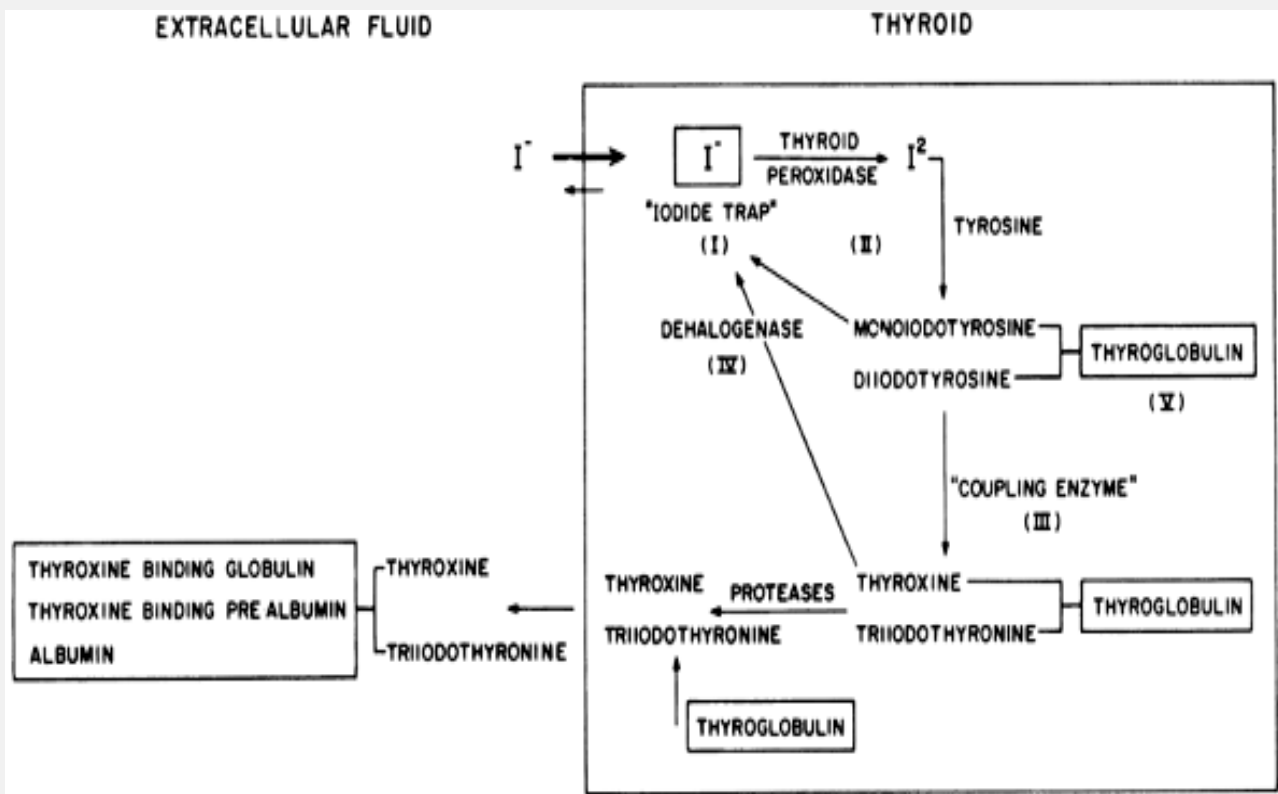

Figure 39-5 Thyroid hormone synthesis. The roman numerals represent described enzymatic defects of thyroxine synthesis.

Congenital Hypothyroidism

The causes of congenital hypothyroidism are many and include genetic and sporadic disorders of embryogenesis, inborn errors of T4 biosynthesis, and environmental factors. Congenital hypothyroidism can be classified into the following subgroups:

- agenesis (athyrotic cretinism) or dysgenesis of the thyroid gland (thyroid hypoplasia, thyroid ectopia)
- endemic goitrous hypothyroidism
- inborn errors of T4 synthesis (familial goitrous cretinism)
- drug-induced hypothyroidism
- thyroid hormone resistance
- thyroid unresponsiveness to TSH
- secondary hypothyroidism (pituitary hypothyroidism)
- tertiary hypothyroidism (hypothalamic hypothyroidism).

TABLE 39-8 RANGE OF MEAN VALUES FOR THYROID AND THYROID-STIMULATING HORMONES DURING THE NEONATAL PERIOD IN FULL-TERM INFANTS

	T₄ (μg/dL)	T₃ (ng/dL)	TBG (mg/dL)	TSH (μU/mL)
Cord blood	10.9 (7–13)	48 (12–90)	5.4 (1.2–9.6)	9.5 (2.4–20)
2 h of age	22.1	217		86
24–72 h of age	17.2 (12.4–21.9)	125 (89–256)	5.4	7.3(<2.5–16.3)
2 wk of age	12.9 (8.2–16.6)	250	5 (1–9)	
6 wk of age	10.3 (7.9–14.4)	163 (114–189)	4.8 (2–7.6)	2.5 (<2.5–6.3)

T₃, triiodothyronine; T₄, thyroxine; TBG, thyroxine-binding globulin; TSH, thyroid-stimulating hormone.

Agenesis or Dysgenesis of the Thyroid Gland

Disordered embryogenesis of the thyroid gland is the most frequent cause of congenital hypothyroidism in the United States. Although congenital endemic goitrous hypothyroidism may have been more prevalent throughout the world at one time, the frequency of this disorder has declined with the introduction of iodine into endemic areas. Genetic mutations in thyroid transcription factors have been identified in familial forms of thyroid agenesis, although athyrosis generally is a sporadic disorder (66). Thyroid antibodies have been detected with increased incidence among mothers of children with hypothyroidism and may cause either transient or persistent congenital hypothyroidism (67). Most mothers with thyroid antibodies have unaffected children, however, and, conversely, most mothers of children with congenital hypothyroidism do not have thyroid antibodies. Thyroid hypoplasia has been reported in children with congenital toxoplasmosis,

P.933

but in utero infectious disorders have not been implicated commonly as a cause of thyroid dysgenesis.

TABLE 39-9 THE UPPER LIMIT OF NORMAL FOR MEASUREMENTS OF THYROID-STIMULATING HORMONE IN THE FIRST 5 DAYS OF LIFE^a

Age at Collection (d)	Standard TSH Cutoff		Age-adjusted TSH Cutoff

Endemic Goitrous Hypothyroidism

Although endemic goiter is one of the widespread nutritional diseases in the world, the introduction of iodine into various foods, including infant formulas, has markedly decreased the incidence of endemic goitrous hypothyroidism. The dietary requirements for iodine vary, but 40 to 100 mcg/day is sufficient for most children. In areas with endemic goiters, factors other than iodine (e.g., enzymatic defects, other genetic factors, and other dietary factors such as goitrogens), probably contribute to goiter formation. Such factors are suggested by the evidence that females are more commonly afflicted than males, that not everyone within the endemic area is afflicted despite similar iodine intake, and the variable incidence of endemic cretinism in different areas. In the Alps, deaf-mutism is a common finding in association with endemic cretinism, suggesting possibly an associated enzymatic defect of organification of iodide. When cretinism occurs in conjunction with an endemic goiter, the signs and symptoms are similar to the dysgenetic form of cretinism except for the presence of a goiter and an elevated radioactive iodine uptake.

TABLE 39-10 MEAN VALUES FOR THYROID AND THYROID-STIMULATING HORMONES IN CORD BLOOD OF FULL-TERM AND PREMATURE INFANTS

	T ₄ (μg/dL)	T ₃ (ng/dL)	TSH (μU/mL)
Term	10.9	48	9.5
35 wk of gestation	9.5	29	12.7
32 wk of gestation	7.6	15	

T₃, triiodothyronine; T₄, thyroxine; TSH, thyroid-stimulating hormone.

Inborn Errors of Thyroxine Synthesis

The inherited disorders of T₄ synthesis involve deficiencies in one or more of the enzymes necessary for hormonogenesis or release of thyroid hormones, resulting in hypothyroidism (69). A compensatory increase in TSH production produces hyperplasia and enlargement of the thyroid gland, creating the clinical picture of familial goitrous cretinism.

Iodide Trap Defect

The thyroid gland has the ability to concentrate iodide, so that the intrathyroidal iodide concentration may be 40-fold greater than in serum. In this rare inherited defect of T₄ synthesis, this ability is lost. As would be anticipated, the 24-hour radioactive iodine uptake is negligible. Thyroid scans do not demonstrate the presence of thyroid tissue, although there may be some uptake, but the gland is detected by ultrasonography. Several other organs, including the salivary glands, share the ability to concentrate iodide, and this defect can be

distinguished from athyrosis because the salivary iodide concentration also is low and there usually is a goiter that can be detected by ultrasonography. This defect essentially reflects iodine deficiency, and can be compensated using high doses of iodide, although treatment with thyroxine is easier and probably more effective.

Organification or Peroxidase Defect

A defect in the organification of iodide is one of the more frequent disorders of hormonogenesis. In this defect, the thyroid has an increased uptake of iodide but is unable to oxidize it or combine it with tyrosine. This leads to the accumulation of free iodide in the gland that can be discharged or released with administration of anions such as perchlorate or thiocyanate, although iodine bound to tyrosine or thyronines cannot be discharged. These findings have led to a simple test for the organification defect. The patient is given a tracer amount of radioactive iodine, which is rapidly concentrated into the gland in a patient with the organification

P.934

defect. When the radioactivity over the gland has stabilized, a potassium perchlorate or thiocyanate given orally (0.5-1 g) will displace the unorganified iodine, causing a rapid discharge of the radioactive iodine from the thyroid gland.

A variant of this form of familial goiter secondary to a defect in organification is associated with neurosensory hearing loss (or Pendred syndrome). The clinical picture differs from the full organification defect, in that patients with the Pendred syndrome often have only small goiters and the perchlorate discharge is incomplete.

Coupling Defect

Coupling of MIT and DIT into T₄ and T₃ is a complex intermediate step involving several processes, and should not be considered a defined single enzymatic deficiency. The inability of the thyroid gland to couple MIT and DIT into T₄ and T₃ leads to the accumulation of large amounts of MIT and DIT in the gland, with the small amounts of T₄ and T₃ synthesized being immediately released into the circulation. Radioactive

iodine uptake by the thyroid gland is rapid and high. Definitive diagnosis requires thyroid biopsy and chromatographic analysis of the iodotyrosines and iodothyronines. Chromatographic analysis of thyroid gland tissue detects large amounts of MIT and DIT with only trace quantities of T4 and T3.

Dehalogenase Defect

The deiodination of the iodotyrosines and iodothyronines occurs within the thyroid and in the liver, kidneys, and other organs. The inherited inability of the thyroid to deiodinate MIT and DIT causes leakage of these precursors from the gland and depletion of iodide stores. This loss of iodide causes decreased hormone synthesis, resulting in a compensatory rise in TSH, thyroid hyperplasia, and increased synthesis of MIT, DIT, and iodothyronines. The goitrous hypothyroidism in this defect is not caused by a biosynthetic block but by iodine deficiency, which can be treated with large amounts of iodine. However, equally efficacious and easier is to use thyroid hormone replacement therapy. Radioactive iodine is rapidly accumulated and turned over. Because this defect is extrathyroidal and intrathyroidal, radioactive MIT and DIT appears unchanged in the urine.

Abnormal Thyroglobulin

Thyroglobulin is synthesized exclusively within the thyroid. The defects of thyroglobulin formation incorporate a group of disorders, including errors of thyroglobulin synthesis, and decreased synthesis. Deficient protease activity for thyroglobulin degradation also has been postulated to result in deficiency of thyroid hormone release. These disorders are characterized by abnormal circulating and intrathyroidal iodoproteins. These peptides sometimes have been described as albumin-like, and have been identified as the iodoalbumin thyroalbumin, in which the major iodinated compounds appear to be monoiodohistadines and diiodohistadines (70,71). The thyroglobulin abnormality is thought to cause iodination of inappropriate proteins, mainly albumin, with a subsequent low yield of T4. A compensatory increase in TSH secretion causes thyroid hyperplasia and a rapid turnover of T4 or albumin.

Proteolysis of the iodohistadinethyroalbumin results in a high secretion of iodohistadine, which can be detected in the urine.

Drug-induced Neonatal Goiter

Many drugs have been demonstrated to be goitrogenic. In the newborn infant, the most commonly implicated drugs are iodides and thiourea derivatives used for treatment of maternal thyrotoxicosis. The use of these drugs not only has caused goiter in the newborn but also has been associated with scattered reports of hypothyroidism (72). Although the correlation between the dose of the drug and the occurrence of goiter is poor, prolonged administration of thiourea drugs to the mother increases the risk of fetal goiter. One recommendation for minimizing this risk is to lower the dose of thiourea drugs during the last trimester and add thyroid hormone concurrently (73). In infants of hyperthyroid mothers, it is necessary to distinguish the drug-induced goiter from the TSI-induced goiter. A low T4 suggests that the goiter is secondary to the drug, whereas a high T4 is more compatible with a TSI-induced goiter and maternal antibody mediated neonatal hyperthyroidism. A mixed picture can also occur with an initially low T4 that increases within a few days as serum concentrations of the drug decline sufficiently. The stimulating effects of TSI antibodies, which have a much longer half-life, can manifest as thyrotoxicosis at a few days to a week of age (discussed under congenital thyrotoxicosis). Treatment usually is not necessary for the infant with a drug-induced goiter unless the goiter is asphyxiating or, more rarely, the infant is hypothyroid. Thyroid hormone will cause the goiter to subside.

Concerns have been raised regarding the appropriate use of antithyroid agents in the lactating mother. Propyl-thiouracil (PTU) is the preferred drug (74), but if alternatives are needed because of adverse drug reactions, carbimazole and methimazole are only transmitted at low levels in breast milk and also appear to be safe (75,76). Nonetheless, thyroid function should be monitored in the infant.

RESISTANCE TO THYROID HORMONES

Refetoff and associates reported a family with deaf-mutism, stippled epiphyses, delayed bone age and goiter that appeared clinically

euthyroid (77). Serum T4 was elevated but thyroid hormone-binding proteins and hormone biosynthesis were normal. This family had the variant of thyroid hormone resistance characterized by generalized tissue unresponsiveness to thyroid hormone. Other patients with primarily central resistance of the hypothalamus and pituitary gland to thyroid hormone are mildly hyperthyroid during infancy and childhood (78). Mutations in the

P.935

α isoform of the thyroid hormone receptor have been identified in a number of families with both peripheral and central resistance to thyroid hormones (79).

UNRESPONSIVENESS TO THYROID-STIMULATING HORMONE

Stanbury and associates reported a severely retarded 8-year-old boy with a normal thyroid gland, a low PBI, normal radioactive iodine uptake, and high endogenous levels of biologically active TSH (80). Exogenous TSH neither stimulated the thyroid gland *in vivo* nor increased glucose metabolism by thyroid slices *in vitro*. Thyroid-stimulating hormone unresponsiveness of the thyroid gland was postulated by these investigators as an explanation for this clinical syndrome. Mutations in the TSH receptor have now been identified as the cause of TSH resistance (79). Patients can be either euthyroid or present with congenital hypothyroidism.

SECONDARY AND TERTIARY HYPOTHYROIDISM

Central hypothyroidism is caused by the failure of secretion of TSH and TRH from the pituitary and hypothalamus, respectively. Newborn infants with these disorders may be missed in newborn screening programs, which rely on primary TSH screening or those directed to primary hypothyroidism, by screening for both low T4 and elevated TSH levels. All patients with the midline abnormalities outlined in Table 41-4 should be suspected of possible secondary or tertiary hypothyroidism.

Therefore, they should have more complete thyroid studies (including a free T4 determined by dialysis and ultra sensitive TSH level) because of the risk that they might be missed by the newborn screening test.

Isolated TSH deficiency is rare and identification of central hypothyroidism should lead to evaluation of other pituitary functions.

SYMPTOMS OF HYPOTHYROIDISM

Symptoms of agenesis of the thyroid gland are readily detectable by 6 weeks of age; however, some infants will have clinical manifestations at birth or during the immediate neonatal period (81). Infants with ectopic or residual thyroid tissue or inborn errors of T4 synthesis often will produce enough thyroid hormone to delay the onset of clinical symptoms and are typically asymptomatic when identified by newborn screening.

The signs during the early neonatal period are subtle and include prolonged neonatal jaundice, mottling of the skin, poor suck, poor feeding, lethargy, umbilical hernia, bradycardia, constipation, and intermittent cyanosis. Occasionally infants with congenital hypothyroidism can demonstrate severe respiratory distress. Later, the more classic symptoms of cretinism appear. The progressive myxedema causes coarsening of the facies, with puffy eyelids, flattened nasal bridge, and enlarged tongue. The cry is hoarse secondary to myxedema of the larynx and epiglottis. Lethargy, hypotonia, constipation, poor feeding, poor weight gain, dry hair, and pallor become more notable with time.

There is considerable evidence for the essential role of the thyroid hormones in the growth and development of the central nervous system (82). The final outcome of mental development in children with congenital hypothyroidism depends on the severity and duration of thyroid insufficiency and the time of initiation of therapy and dose of hormone administered. The prognosis appears to be worse if signs of hypothyroidism are clinically evident at diagnosis. Thus, a delay in treatment until three months of age is associated with a poorer cognitive outcome than those treated earlier (83). Klein and associates found no differences in IQ testing or other psychometric parameters in children with congenital hypothyroidism treated before 1 month of age as

compared to matched normal controls (84). Others have found developmental delay even in those infants treated within 1 month of age who had severe hypothyroidism as defined by a thyroxine concentration less than 2 mcg/dL and retarded bone maturation (85). In general although, the prognosis for cognitive outcome is good in those children with congenital hypothyroidism are started on adequate doses of thyroid hormone within the first month of life.

DIAGNOSIS

The incidence of congenital hypothyroidism has been estimated to be 1 in 4,000 births. In view of the desirability of early diagnosis and treatment, newborn screening using filter paper spots is standard in the United States (86). Previously, it was a common approach is to use an initial T4 screen. If the T4 is in the lowest 10% of the samples being tested or below a specific value, a repeat T4 and a TSH are determined on the same sample. If the repeat T4 is still low (<10 mcg/dL) or the TSH is elevated, confirmatory tests are requested. More recently, many of the states are using an approach to detect primary hypothyroidism, screening for elevation of TSH. This latter approach provides better detection of primary hypothyroidism, eliminating the infants who are premature, euthyroid sick or have thyroxine binding protein deficiency. The potential problems with newborn screening for congenital hypothyroidism have been reviewed (87). Following a positive screen, a serum sample should be obtained for more specific thyroid functions. The diagnosis should be confirmed by serum free T4, TSH, and thyroid hormone binding index.

In those states still using T4 as a primary screen, almost 34% of low T4 values detected by newborn screening are not the result of true hypothyroidism, but represent diminished levels of TBG in patients with TBG deficiency or prematurity. In those cases suggestive of deficient thyroid hormone

P.936

binding, a direct measurement of TBG should be determined and a test such as the T3 resin uptake to evaluate for problems of thyroxine binding

other than TBG deficiency. A low T4 and a normal TSH may represent secondary or tertiary hypothyroidism or TBG deficiency. Thyroxine-binding globulin deficiency is an X-linked disorder and occurs in 1 in 2,000 screening studies of boys. Low T4 levels also are found normally in premature infants and severely ill newborn infants, and are not necessarily indicative of hypothyroidism (see Euthyroid Sick Syndrome). A T4 greater than 7 mcg/dL is regarded as normal in premature or sick infants (65,86). Note the need to avoid using specimens obtained in the first 24 to 48 hours after birth because of the normal surge of TSH (see Tables 39-8 and 39-9). Radiographic skeletal age is often useful, because 50% of full-term infants with congenital hypothyroidism will not have the osseous centers normally present at birth. It is important to perform a thyroid scan or ultrasound on all patients with congenital hypothyroidism to identify those patients with inborn errors of T4 synthesis so that appropriate genetic counseling may be given.

TABLE 39-11 INCIDENCE OF VARIOUS FORMS OF CONGENITAL HYPOTHYROIDISM

Disorder	Incidence
Congenital thyroid agenesis or dysgenesis	1:4000
Inborn errors of thyroxine synthesis	1:30,000
Hypothalamic-hypopituitary hypothyroidism	1:66,000 ^a

^aHypothalamic-hypopituitary hypothyroidism incidence is based on newborn screening studies so may be underdetected.

The incidence figures for various forms of congenital hypothyroidism, as determined by the newborn screening studies, are listed in Table 39-11.

It is probable that the hypothalamic-hypopituitary forms of hypothyroidism have been underestimated by the newborn screening studies, because many of the TSH-deficient patients have normal serum T4 concentrations at birth. Also, the syndromes of T4 resistance and thyroid resistance to TSH can be missed by the newborn screening method. Probably the most common cause of undetected congenital hypothyroidism is omitting the screening study. This is more likely to occur in intensive care situations, because of the magnitude of other ongoing problems.

TREATMENT AND PROGNOSIS

The dose of thyroid hormone prescribed should be sufficient to achieve high euthyroid levels of serum T4 within 2 weeks of starting therapy. During the newborn period, the starting dose of l-thyroxine is 10-12 mcg/kg/day, which usually equals 37.5 mcg/day for most full-term infants. Serum T4 normalizes before the serum TSH, therefore serum T4 should be used to guide therapy during the first 4 weeks to avoid overdosing with L-thyroxine. After 4 to 6 weeks of therapy, however, TSH level is the best measure for monitoring treatment. If the TSH remains elevated, the dose of l-thyroxine should be increased.

Recently controversy has arisen over the issue of transient hypothyroxinemia in preterm infants and neurological outcome. A retrospective analysis of T4 levels in premature infants suggested that severe transient hypothyroxinemia during the immediate neonatal period was associated with problems in neurologic and mental development at two years of age (88). None of the infants were subsequently diagnosed as having permanent hypothyroidism. Despite adjusting for many variables it is still not clear whether those children with the impaired neurologic and mental outcome had lower thyroxine levels causing the worse outcome or because these children were sicker which resulted in the worse outcome and lower thyroxine levels. Perhaps the answer lies in a paper, which showed that thyroid replacement in a randomized double blind, placebo controlled study of 200 infants, less than 30 weeks gestation did not improve developmental outcome (89).

No firm recommendations may be made at this time and further studies are awaited.

EUTHYROID SICK SYNDROME

The euthyroid sick syndrome is a reflection of adaptive physiologic processes that occur during acute and chronic illness. Thyroid hormones increase basal metabolism, cardiac output, and oxygen consumption. Reduced production of thyroid hormones, especially T₃, which reduces oxygen consumption and basal metabolic rate, is beneficial for certain illnesses (e.g., catabolic or hypoxic conditions). In animal studies, hypophysectomized rats survive longer during oxygen deprivation than intact animals. The euthyroid sick syndrome has been noted in both premature and full-term sick newborn infants.

The euthyroid sick syndrome is characterized by a low normal T₄ concentration, an extraordinarily low T₃ concentration, and a normal TSH level. The latter two findings distinguish the euthyroid sick syndrome from primary and secondary hypothyroidism. T₃ levels generally are in the low normal range in both primary and secondary hypothyroidism, with TSH levels markedly elevated in primary hypothyroidism. Unlike older infants and children, reverse T₃ is not useful in the diagnosis of euthyroid sick syndrome, because it is elevated normally in the newborn infant. Euthyroid sick syndrome does not require any treatment other than correction of the primary disease.

CONSUMPTIVE HYPOTHYROIDISM SECONDARY TO GIANT HEMANGIOMA

Infants with large hemangioma may develop hypothyroidism, which is not present at birth, and therefore is not detected by newborn screening studies (90). The location of the hemangioma may be in the liver and ectodermally.

P.937

The infants develop hypothyroidism as the hemangioma grows during early infancy (within a few months to a year), which is detrimental to brain development if undetected. The cause of the hypothyroidism is as a

result of markedly increased activity of the type D3 iodothyronine deiodinase that rapidly converts T4 to reverse T3 and T3 to T2. Both reverse T3 and T2 are biologically inactive, resulting in insufficient T4 and T3 for metabolic needs and increased TSH. This "consumption" of T4 and T3 ameliorates with involution of the giant hemangioma, which sometimes need to be surgically excised. The hypothyroidism must be treated with significant doses of synthetic thyroxine to overcome the rapid inactivation of T4.

CONGENITAL THYROTOXICOSIS

Thyrotoxicosis in the neonatal period is relatively uncommon. Affected infants almost always are born of mothers who have either active or a previous history of Graves disease. Neonatal thyrotoxicosis may also present in infants born to mothers with Hashimoto thyroiditis. Fewer than 5% of infants born to mothers with Graves disease will have thyrotoxicosis in the newborn period. Neonatal thyrotoxicosis is caused by the placental transfer of maternal thyroid stimulating immunoglobulins, which can be demonstrated in over 90% of studied cases (91).

Neonatal thyrotoxicosis is manifested by poor weight gain or excessive weight loss, goiter, irritability, tachycardia, flushing, and exophthalmos. A number of these infants tend to be small for gestational age. The infant of a thyrotoxic mother with a high normal T4 should be followed closely. A low or suppressed TSH is further evidence of neonatal thyrotoxicosis. The onset of symptoms usually occurs within the first week of life, but may be delayed until the second week, particularly if the mother has been on antithyroid drugs that can also cross the placenta. Arrhythmias, such as paroxysmal atrial tachycardia, cardiac failure, and rarely death have been reported with severe thyrotoxicosis (92). In several reported cases, there has been a rapid advance in skeletal maturation, with advanced bone age and premature closure of the cranial sutures (93,94). Neonatal thyrotoxicosis is a self-limiting condition and abates as the levels of TSI antibodies decrease, thus the prognosis is good. Most infants are asymptomatic by 2 months of age and most cases will have resolved by 9 months.

Major therapeutic concerns in neonatal thyrotoxicosis are tracheal obstruction secondary to goitrous encroachment, and cardiac failure. Subtotal thyroidectomy is rarely required to relieve tracheal obstruction. Iodide (one drop every 8 hours of saturated solution of potassium iodide), along with a β -adrenergic blocking agent such as propranolol hydrochloride, can be used to control the thyrotoxicosis. Iodide has the advantage of interfering not only with T4 synthesis but also with the release of thyroid hormones. In the most severe cases, digitalis, sedation, or glucocorticoids may be necessary to prevent cardiovascular collapse.

Chapter 40

Gastrointestinal Disease

Jon A. Vanderhoof

Terence L. Zach

Thomas E. Adrian

Although most pediatric gastroenterologists are uncomfortable with primary care of the sick premature infant, they often are valuable consultants to the neonatologist. In evaluating a complex gastrointestinal (GI) or hepatobiliary problem, a gastroenterologist often uses an organ system-specific developmental pathophysiologic approach. In looking at a problem from a somewhat different perspective than the neonatologist, the opinion of the consultant may augment the analysis of the primary physician. It remains the responsibility of the neonatologist to put the consultant's view into perspective as it relates to the other complex problems of the sick infant.

The gastroenterologist also may offer his or her skills in invasive procedures to aid in the diagnosis of GI and liver disease. Upper and lower GI endoscopy, liver biopsy, rectal suction biopsy, esophageal, antroduodenal, and anorectal motility studies, and even endoscopic retrograde cholangiopancreatography can be performed in term infants and, depending on the skill and training of the gastroenterologist, in premature infants as well. Small diameter neonatal endoscopes are now available which facilitate obtaining small bowel biopsies from the distal duodenum and jejunum.

In some institutions, gastroenterologists with special expertise in nutrition provide assistance in nutritional support of parenteral nutrition-dependent or malnourished infants. Their role becomes especially important in infants with GI or liver disease who may require long-term follow-up, such as the infant with progressive liver disease, or home on parenteral nutrition, such as the infant with short bowel syndrome.

DEVELOPMENT OF THE GASTROINTESTINAL TRACT

Subsequent to the development of the individual organs of the GI tract, specialized features of the system begin to become apparent, mostly in the second and third trimesters (1). At approximately 14 weeks of gestation, differentiation of the pancreatic endocrine and exocrine tissues begins, and crypts and villi begin to form in the small intestine. A few weeks later, the colon, initially

populated with villi similar to those in the small intestine, begins to develop its more characteristic surface, with gradual loss of villi. As these morphologic changes occur, numerous functional processes begin, some of which mature early *in utero*, some only at birth, and some during the first year of life.

Carbohydrate Absorption

The functional maturation of the digestive process is complex (2). There are marked differences in maturation of the digestive and absorptive processes of different nutrients (Table 40-1). In the neonate, most dietary carbohydrate is presented in the form of lactose, the predominant carbohydrate in virtually all mammalian milk. Lactose and other disaccharides are digested by enzymes located on the brush border membrane in mature enterocytes; those located on the distal and midportions of the small intestinal villi. Component monosaccharides are released after hydrolysis by disaccharidases. Lactase hydrolyzes lactose to glucose and galactose, and both subsequently are transported by active carrier-mediated transport. Other disaccharidases include maltase, which hydrolyzes maltose to two glucose units, glucoamylase, which hydrolyzes glucose oligosaccharides to glucose monomers, and sucrase, which hydrolyzes sucrose to fructose and glucose. Sucrase is actually a double enzyme, the other part of the molecule being isomaltase, which hydrolyzes α -1-6 bonds of α -limit dextrans. Disaccharidase activities are highest in the proximal and midjejunum and decrease distally.

Lactase activity develops later in gestation than the other disaccharidases. Lactase activity is low until the final weeks of gestation. Although other disaccharidase levels can be detected somewhat earlier in gestation and reach nearly adult levels between 26 and 34 weeks of gestational age, lactase levels are only 30% of full-term levels by that point in gestation. Because of the delayed maturation of lactase, specialized infant formulas for preterm infants have been designed, with a significant percentage of carbohydrate presented as sucrose or glucose polymers rather than lactose. Alternatively, the addition of lactase to formulas for

P.941

preterm infants may enhance weight gain (3). The predominant enzyme for digestion of starches and glucose polymers is pancreatic amylase, which is nearly absent during the first 4 to 6 months of life and gradually matures during the latter half of the first year. An alternative pathway therefore must exist for the digestion of these glucose polymers (4,5).

**TABLE 40-1 DIGESTIVE AND ABSORPTIVE FUNCTION IN INFANTS
RELATIVE TO ADULTS**

Process	Premature Infant	Full-term Infant	Adult
Salivary enzymes	Normal	Normal	Normal
Gastric acid production	∅	∅ to normal	Normal
Bile acid secretion	∅∅	∅	∅
Pancreatic enzyme production	∅∅	∅	Normal
Lactase production	∅	Normal	Normal
Sucrase and isomaltase production	Normal	Normal	Normal

Salivary glands produce an amylase that may be important in the digestion of complex carbohydrates in the newborn. This enzyme is detectable at 20 weeks of gestation and is present in significant quantities in premature infants. As with pancreatic amylase, however, the ability of the newborn to secrete salivary amylase is substantially reduced and matures throughout the first year of life. Salivary amylase is inactivated by gastric acid, but probably retains some activity in the stomach of premature infants. Glucoamylase is a brush border enzyme capable of digesting glucose units from the nonreducing ends of starch and dextrin. Glucoamylase is present in neonates and infants at 50% to 100% of adult levels.

Finally, it is probable that some malabsorbed carbohydrate is digested in the colon through the colon salvage pathway. Colonic anaerobic bacteria are capable of metabolizing carbohydrates to produce short-chain fatty acids that then are absorbed through the colonic mucosa. Considering the relative pancreatic insufficiency and lactase deficiency in the newborn infant, the colon salvage pathway may be an important mechanism by which infants absorb carbohydrates.

Fat Absorption

Fat absorption is a complex process, primarily because fat is insoluble in the aqueous environment of the small intestinal lumen (6). Solubilization, therefore, is an important part of the fat assimilation process. The first phase of fat absorption is that of enzymatic digestion or lipolysis. Because most dietary fat is present in the form of triglycerides, otherwise known as triacylglycerols, these first must be hydrolyzed by pancreatic lipase.

Phospholipids are hydrolyzed concurrently by pancreatic phospholipase. Colipase, a cofactor secreted by the pancreas, also is required, facilitating the action of lipase by binding to bile salt-lipid surfaces and improving the interaction of lipase with triglyceride. The efficiency of this process is augmented by the release of

cholecystokinin (CCK) from the duodenal epithelium, which occurs in response to the presence of lipid and protein in the duodenum. Cholecystokinin stimulates pancreatic secretion, gallbladder contraction, and simultaneous relaxation of the sphincter of Oddi, to mix large quantities of bile acids and digestive juices with lipids. Pancreatic lipase levels are reduced in preterm infants and intrauterine growth-retarded infants, significantly impairing lipolysis (7). Lingual lipase, secreted from the salivary glands, may facilitate lipolysis in the premature infant and partially compensate for the infant's relative pancreatic insufficiency (8). Nonetheless, fat absorption is significantly impaired in newborn infants and, to a greater extent, in premature infants, due at least in part to pancreatic insufficiency.

Closely linked with the process of enzymatic digestion of fats is micellar solubilization by bile acids (9). Bile acid molecules are complex structures with both hydrophobic and hydrophilic ends. Bile acids interface with lipids to render them water soluble by positioning the hydrophobic portion in close proximity to the lipid globules although allowing the hydrophilic portion to remain free to interact with the aqueous environment. Lipids then become enclosed in disc-shaped water-soluble micelles that contain fatty acids, monoglycerides, phospholipids, cholesterol, and fat-soluble vitamins.

Solubilization is particularly important because of the presence of the intestine's unstirred water layer. This stagnant layer of water overlies the microvillus membrane of the intestinal epithelial cells and is the primary barrier to lipid transport. The actual thickness of the unstirred water layer is complex and difficult to measure, but the layer is significantly reduced by the constant agitation of the fluid in the GI tract as a result of gut motility and villus contraction. Because of the convolutions in the small intestine caused by the presence of villi and microvilli, the total surface area available to interface between the intestinal surface and the unstirred layer is much greater than the interface between the unstirred water layer and the aqueous intraluminal environment. Penetration through the unstirred layer by the disc-shaped micelles is the rate-limiting step for lipid absorption. Disease processes that increase the unstirred layer thickness will markedly inhibit fat absorption in much the same manner as disease states that render the supply of bile acids inadequate for micellar solubilization. Bile acids commonly are deficient in cholestatic liver diseases, such as neonatal hepatitis or biliary atresia, and in rare cases of congenital bile acid deficiency. Bile acids are deconjugated rapidly and reabsorbed in the presence of small intestinal bacterial overgrowth. Bile acid deficiency therefore may occur in patients with disorders that cause intestinal stasis and bacterial overgrowth, such as short bowel syndrome. In disorders of mucosal injury, the unstirred layer thickness may be increased, making penetration of the fat-containing micelles difficult and further exacerbating fat malabsorption.

Bile acids are extremely important in the fat absorption process. In the absence of bile acids, only about one-third of dietary triglycerides, a very small percentage of fatty acids, and virtually no cholesterol or fat-soluble vitamins are absorbed. Medium-chain triglycerides may be better absorbed because of their enhanced water solubility, which allows penetration of the unstirred water layer without micellar solubilization. In both preterm and term infants, bile acid synthesis is limited and the bile salt pool size is low (10). Moreover, preterm infants may have an ineffective bile salt transport process in the distal ileum, resulting in impaired enterohepatic circulation of bile salts (11). Consequently, the bile acid concentration may be less than adequate for the formation of micelles and solubilization of fat. Thus, penetration of the unstirred layer is less efficient in the term infant and further impaired in the preterm infant compared to adults.

After lipids are enclosed in the bile acid micelle and reach the lipid bilayer membrane of the small intestinal mucosal cell, absorption into the cell occurs by passive diffusion. Because of the convolutions of the GI tract, a large surface area exists for lipid assimilation. In the absence of disease, this process progresses in the term and preterm infant relatively uninhibited. In disorders in which the absorptive surface area is reduced or damaged, however, such as short bowel syndrome or any form of diffuse enterocolitis, fat, carbohydrate, and, to a limited degree, protein are malabsorbed.

Within the enterocyte, monoglycerides and esterified fatty acids are immediately resynthesized to triglycerides. These triglycerides, along with apoproteins, phospholipids, free cholesterol, some diglycerides, and esterified cholesterol, are stabilized within chylomicrons. The outer structure of the chylomicron then fuses with the basolateral membrane and is extruded into the lamina propria, in which it is carried by the lacteals and lymphatic channels and deposited into the blood stream.

Protein Absorption

The assimilation of protein begins in the stomach through the action of hydrochloric acid and pepsin. The maturational aspects of this process have been the subject of substantial study and some controversy. Conflicting data exist regarding the status of acid secretion in the newborn infant. Newborn infants appear to be capable of secreting acid, although the process is somewhat immature (12). In premature infants, it is probable that the process is impaired to a greater extent (13). Pepsinogen, the proenzyme for pepsin, which facilitates protein digestion in the stomach, is secreted in preterm infants, but in much lower concentrations than in term infants (14).

The gastric aspects of protein digestion are relatively inconsequential, compared to the much more complete process in the small intestine. Enterokinase, produced in the duodenal mucosa, activates the pancreatic proteolytic enzyme trypsinogen,

converting it to trypsin, which then activates essentially all of the other enzymes involved in protein digestion. Enterokinase levels have been demonstrated in human fetuses as early as 21 weeks of gestation (15). Enterokinase expression is diminished during fetal development, however, and is only 10% of adult levels in the term newborn. Additionally, pancreatic and duodenal proteolytic enzymes are present in preterm and term infants in lower concentrations than in older children and in adults. These enzymes initiate hydrolysis of proteins, and the hydrolysis process is completed by brush border and cytosolic peptidases. Protein is absorbed in the form of amino acids and dipeptides through active transport processes that appear to be well developed by 28 weeks of gestational age. Despite the relative immaturity of multiple phases of the protein assimilation process, both preterm and term infants are quite capable of absorbing adequate quantities of dietary protein. In small infants, the protein malabsorption resulting from mucosal injury is probably far less consequential than the malabsorption of the other major macronutrients.

Micronutrient Absorption

Absorption of micronutrients matures at varying rates in infancy. Water is absorbed passively in response to sodium and other electrolytes, as it is in older children and adults (16). Experimental evidence suggests that the intestinal epithelium may be more secretory during early infancy, and the increased susceptibility of infants to diarrheal disorders probably is at least partially related to this process.

Mineral absorption depends on the form in which the mineral is presented to the infant. Iron, for example, is absorbed extremely well from breast milk. Even the preterm infant is capable of absorbing nearly 50% of the iron in breast milk, whereas only a small percentage of iron is absorbed from cow-milk formulas, necessitating iron supplementation. Calcium and phosphorous also are well absorbed from breast milk (17,18). Magnesium, copper, and, to a lesser extent, zinc are well absorbed by both term and preterm infants (19). In general, minerals are absorbed somewhat better from breast milk than from cow milk. Most vitamins appear to be absorbed adequately in both term and preterm infants, although fat-soluble vitamin deficiency is common in disorders affecting fat absorption, especially disorders causing bile acid deficiency.

Gut Motility

Although nutrient assimilation is heavily dependent on the development of digestive and absorptive function, actual feeding depends greatly on the maturation of gut motility (20,21,22). Neuroblasts migrate in a cranial-to-caudal direction between weeks 5 and 12 of gestation. There is gradual maturation of gut motility throughout the fetal period and the first several years of postnatal life. In

the fetus, normal propulsive motility in the gut probably does not appear until approximately 30 weeks of age. Interdigestive phenomena, known as migrating motor

P.943

complexes, can be demonstrated by approximately 33 weeks of gestation. Motor activity in the neonatal gut differs significantly from that in adults, in that the propagation rate of the migrating motor complex is substantially slower in neonates, and the complex is not abolished by feeding as in older children.

Sucking and swallowing reflexes begin early during fetal development, but the maturation of the process is not completed until after birth. The fetus is able to swallow amniotic fluid as early as 11 to 12 weeks of gestation. Actual sucking probably does not occur until approximately 18 to 24 weeks. This type of sucking is termed nonnutritive sucking, differentiating it from the more effective nutritive sucking mechanism that develops by 34 to 35 weeks of gestation. The onset of nutritive sucking closely parallels a rapid increase in growth of the fetal stomach (23) and the acquisition of mature patterns of gastric antral and small intestinal motility.

By the time a term infant is born, sucking movements are followed in an orderly progression by swallowing, esophageal peristalsis, relaxation of the lower esophageal sphincter, and relaxation of the gastric fundus. The first stage of swallowing is an involuntary reflex in both the term and preterm infant. Early introduction of oral feeds may accelerate the time from gavage to full nipple feeding (24).

Some data suggest that nonnutritive sucking may play an important role in weight gain in preterm infants. The mechanism of this effect may be related to maturational changes in the infant GI tract, and sucking may facilitate gastric emptying and other GI functions, primarily through stimulation of secretion of GI regulatory peptides.

Maturation of GI motility may have important implications for a number of conditions. Gastroesophageal reflux is common in both term and preterm infants, and probably relates to diminished lower esophageal sphincter function or inappropriate relaxation of the lower esophageal sphincter, often in association with delayed gastric emptying. The maturation of both lower esophageal sphincter function and gastric emptying has been studied extensively, with somewhat equivocal results. Depending on the technique used to measure sphincter function, the lower esophageal sphincter tone has been shown to be either low or normal in both preterm and term infants (25). Hyper-tonic carbohydrate solutions appear to delay gastric emptying in infants, much as they do in adults.

GASTROINTESTINAL HORMONES AND ENTERIC

NEUROPEPTIDES

GI peptide hormones appear to play an important role in the structural and functional development of the gut, and in the control of alimentary functions. The function of a vast endocrine system is integrated with that of the enteric nervous system, which itself uses other regulatory peptides as local messengers.

Endocrine cells producing gastrin, somatostatin, motilin, and glucose-dependent insulintropic peptide (GIP) are detectable in the fetus at 8 weeks of gestation, with gastrin- and somatostatin-producing cells being most numerous (26). By 14 weeks, all of the endocrine cell types are present in the intestinal mucosa, although the anatomic distribution is more widespread than that seen in the adult (26). By the end of the second trimester, the distribution of gut endocrine cells resembles that of the adult (26). Peptidergic nerves are first demonstrable in the myenteric plexus at about 12 weeks of gestation, correlating with the known developmental pattern of enteric nerve plexuses (26). These enteric nerves then migrate through to the submucous plexus. By the third trimester, all of the regulatory peptide systems are well developed (27). At birth, the molecular forms of the GI regulatory peptides and their distribution in the gut are similar to those of the adult (27).

Surges of gut hormones appear to be responsible for the marked growth and functional change that occur in the alimentary tract in early neonatal life. Substantial changes in GI hormone secretion are seen during this period, triggered by the switch from intravenous to enteral feeding (28).

Gastrin is an important regulator of gastric secretion and is trophic to the gastric mucosa. At birth, cord blood levels of gastrin are already four to five times higher than those in the adult, and prefeed basal levels remain elevated for several weeks (29,30). Furthermore, gastrin levels increase in response to the first milk feed (31). After 3 to 4 weeks of life, basal gastrin levels decline, a change accompanied by development of marked elevation of levels following feeding (29,32). Gastric acid is detectable in the stomach at birth and reaches a peak in the first day or two of life (30,33). Thereafter, acid output decreases for a period of about 1 month despite the hypergastrinemia and rapid growth of the stomach. It has been suggested that the lack of responsiveness to gastrin could be as a result of a lack of receptors in the oxyntic gland mucosa. Perhaps a more likely explanation, however, is that secretion is suppressed by an inhibitor, such as peptide YY (PYY) or neurotensin, thus enabling gastrin to stimulate growth of the gastric mucosa without hyperstimulation of acid secretion (34,35).

Basal levels of the duodenal hormone, secretin, are higher at birth than in adults, and, during the first 3 weeks of life, a more marked postprandial response develops than is seen in the adult (36). Because secretin is considered to be a major factor in triggering the neutralization of acid chyme entering the duodenum, the increase in circulating secretin levels may be of considerable importance in

mucosal protection during this period. It is notable that the postnatal surge of secretin, unlike that of the other alimentary hormones, occurs even in the absence of feeding, indicating the importance of this mucosal cytoprotective function (32).

Cholecystokinin, released from the upper small intestine, stimulates pancreatic enzyme secretion and contracts the gallbladder. Additionally, CCK has marked trophic effects on the pancreas and appears to be responsible for regeneration after resection or acute pancreatitis (37). The

P.944

observed postnatal surge of plasma CCK concentrations, therefore, may be of importance in stimulating growth of this organ (38). Interestingly, CCK levels decrease during kangaroo care in the NICU setting, in contrast to the increase seen with nasogastric tube feeding (39).

Also released from the small intestine, motilin is a hormonal peptide with powerful motor functions. These motor functions include acceleration of gastric emptying and stimulation of the interdigestive myoelectric complexes (MMC) during the interprandial period. The motilin receptor-mediated induction of phase III of the MMC occurs by 32 weeks of gestational age. Motilin concentrations are low in cord blood, but preprandial basal concentrations show a massive postnatal surge that peaks at around 2 weeks of postnatal life (32). This peak is enhanced, but delayed, in preterm neonates. It is likely that this increase in circulating motilin concentrations is responsible for the known increase in motor activity of the gut that occurs during the neonatal period. Interdigestive motor complexes appear normal at birth in the term infant, but interdigestive cycles are incomplete in preterm neonates (40). Premature babies exhibit abnormal motor activity, with periods of motor quiescence and nonpropagating contractions. Thus, motor activity is more immature in preterm infants than in term infants (40). The relationship between maturation of the migrating motor complexes and the late postnatal surge of motilin in preterm neonates is not clear.

The jejunal hormone, GIP, is thought to be largely responsible for the postprandial increase in circulating insulin levels (41). Basal GIP concentrations are low at birth and increase gradually throughout the first month of life, together with the development of a marked postfeeding GIP response similar to that seen in the adult after ingestion of a mixed meal (32,42). The development of the GIP response to feeding in neonates is mirrored by the postprandial insulin response, which increases through the first month of life to maintain glucose homeostasis (42).

Neurotensin is an ileal peptide that has inhibitory effects on gastric secretion and motility. Plasma neurotensin concentrations are higher in the neonate than in the adult, and an enhanced postprandial response develops in the first month of life (43). Both reduction of gastric secretion and slowing of the rate of gastric emptying will decrease the rate at which acid chyme enters the duodenum and,

therefore, will result in a more steady absorption of nutrients from the gut. Thus, neurotensin may be important in the adaptation of the neonate to enteral nutrition. PYY is an important hormone from the distal intestine that inhibits gastric emptying and slows small bowel transit (44). PYY also inhibits gastric and small bowel secretion, leading to an increase in net absorption (34). Concentrations of PYY are elevated in cord blood and rise postnatally to a peak within the first 2 weeks postpartum (35). At their peak, plasma PYY concentrations are about 50 times higher than fasting levels in normal adults (35). There is evidence to suggest that gastric emptying and intestinal transit are rapid during the first week of life, both in term and preterm infants. The triggering mechanism for the changes that then take place is unknown, but it is likely that factors such as PYY play a role (44). Additionally, the very potent inhibitory effect of PYY on gastric secretion may account for the prevention of hypersecretion of acid during the early neonatal period, despite the marked hypergastrinemia (34). A truncated form of PYY (PYY7-36 amide) is produced by proteolytic cleavage of the 36 amino acid peptide. A recent study demonstrated that this truncated form of PYY potently inhibits food intake.

Enteroglucagon is one of three biologically active peptides produced by posttranslational processing of the glucagon gene product in the small and large intestine. Glucagon-like peptides I and II (GLP-I and GLP-II) are the two other peptides secreted in parallel with enteroglucagon, which can serve as a marker for production of all three. GLP-I has incretin effects and physiologically enhances insulin secretion in response to ingested nutrients in the same manner as GIP and is also a satiety hormone. GLP-II, on the other hand, is a trophic peptide that increases growth of the small intestinal mucosa (45,46). Plasma enteroglucagon concentrations show a very marked postnatal surge, which peaks within the first week and is associated with the development of a marked postprandial response (29,32). Because an increased rate of small intestinal growth occurs in the early neonatal period, it is likely that GLP-II is important in neonatal alimentary maturation. The resulting mucosal growth increases the absorptive area for the uptake of nutrients from the gut lumen.

Temporally, the postnatal surges of gut hormones parallel the changes in GI function that accompany the introduction of enteral feeding in the infant. It is therefore of considerable interest that these surges are not seen in infants who have never received enteral feeding nor with nonnutritive suckling (32,47). Concentrations of all gut hormones, with the exception of secretin, remain low in infants receiving only parenteral nutrition (32,47).

Precise mechanisms control the secretion of each gut hormone, and the amount of a particular peptide liberated by a meal is adequate to stimulate the appropriate digestive response (48). For example, a meal rich in long-chain triglycerides will evoke a large CCK response, not seen with medium-chain fats (49). The high circulating levels of CCK in turn stimulate pancreatic enzyme secretion and, by

gallbladder contraction, release of the bile salts necessary for digestion of the long-chain fat. Medium-chain triglycerides, on the other hand, are rapidly hydrolyzed by lingual and gastric lipases; they are water soluble, do not require micelle formation, and are absorbed rapidly. Thus, bile salts and pancreatic enzymes are not required for digestion of medium-chain triglycerides, and a large CCK response is not seen when they are ingested (49). The gut endocrine system, with its sparse distribution of overlapping cell types, is designed to produce an integrated digestive response to the discontinuous stimulation of ingested food (48). Because the type of food presented can influence the integrated hormonal response, it is apparent that differences in nutrition in early neonatal life may result in

P.945

changes in the growth and functional development of the neonatal alimentary tract.

Although the fetus makes little demand on its GI tract, the situation changes dramatically at birth, when demand for nutrients necessitates the rapid maturation of the alimentary tract. This development of the GI tract is characterized by the integrated maturation of its many functions. The observation, however, that premature infants make a satisfactory transition from intravenous nutrition through the placenta to extrauterine enteral feeding suggests that external influences can exert a substantial influence. The massive postnatal surges in circulating levels of hormones, which have trophic and secretory and motor functions, is compelling circumstantial evidence of a profound gut endocrine influence on alimentary development (32). This is supported further by the observation that these hormonal surges are not seen in sick infants who are on parenteral nutrition and have not been fed orally (47). It is likely that failure of secretion of trophic gut hormones is responsible for the hypoplastic gut and pancreas that accompany parenteral nutrition. Appropriate enteral stimuli or hormone replacement eventually may alleviate this problem. Indeed, early minimal enteral feeding, sufficient to stimulate hormonal surges appears to have beneficial effects without any abdominal complications.

ABNORMALITIES OF THE GASTROINTESTINAL TRACT

To avoid repetition, an attempt has been made to confine the abnormalities described in this section to those that might require consultation by a pediatric gastroenterologist. Some overlap with general surgery has been allowed, however, to avoid extensive cross-referencing (see Chapter 44).

Abdominal Wall Defects

Major defects of the abdominal wall, omphalocele and gastroschisis, occur in

approximately 1 of 6,000 live births (50,51,52). In either case, a portion of the infant's GI tract remains outside the abdominal cavity at birth. Omphalocele is a failure of the extraembryonic intestine to reenter the abdominal cavity through the umbilicus, a developmental anomaly that occurs between weeks 10 and 12 of gestational age. The defect includes the umbilicus, and the viscera typically are covered with a peritoneal sac. Occasionally, the sac may rupture, making the disorder difficult to distinguish clinically from gastroschisis.

Omphalocele can be an isolated defect; however, omphalocele is often associated with other congenital anomalies or syndromes. Genetic evaluation of patients with omphalocele may provide information regarding causation or recurrence risk. Periconceptual multivitamin use may reduce the risk of nonsyndromic omphalocele (53).

Gastroschisis is an actual defect in the abdominal wall that occurs lateral to the umbilicus. The infant with gastroschisis has a normal umbilical cord not involved in the defect. The defect usually occurs to the right of the umbilical cord. Both omphalocele and gastroschisis may occur in the presence of other intestinal anomalies. Malrotation is present in association with omphalocele. Although intestinal atresias more commonly are found in gastroschisis, atresias may be associated with either anomaly. Abdominal wall defects frequently are diagnosed prenatally by fetal ultrasound (54). The preferred route of delivery remains controversial and may depend on the size of the defect (55). Vaginal delivery may be acceptable for small defects, and cesarean section may be preferred in cases with large defects (56).

Gastroschisis or omphalocele requires immediate pediatric surgical consultation. Fluid losses and hypothermia are of primary immediate concern, especially in the case of gastroschisis because no membrane covers the bowel. Large fluid and heat losses are common, and intravenous fluid replacement should be initiated immediately. The defect should be wrapped, using warm, sterile, moist saline gauze or a sterile transparent plastic bag. Care must be taken to prevent twisting and infarction of the bowel. A nasogastric tube should be inserted to minimize intestinal distention.

Postoperative management includes sedation and mechanical ventilation for at least 48 to 72 hours because of increased intraabdominal pressure. Careful monitoring of fluids and electrolytes is essential. High fluid intake is required (57). During the postoperative period, gut motility is slow to return, especially in the case of gastroschisis. Patients with gastroschisis may demonstrate sluggish motility for up to 8 months, and a protracted course of parenteral nutrition commonly is required. Delayed onset of necrotizing enterocolitis (NEC) is not uncommon and should be suspected if bloody stools are observed.

Disorders of the Esophagus

Gastroesophageal Reflux

Gastroesophageal reflux is the most common esophageal disorder in the neonatal period (58). Gastric contents normally are retained within the stomach through the action of the lower esophageal sphincter, a zone of high pressure in the distal esophagus that remains tonically contracted except during deglutition (59). The anatomy of the stomach and esophagus, and their relationship to the diaphragm and related structures, may play a secondary role in retaining gastric contents within the stomach. Although considerable controversy exists, there is evidence to suggest that the lower esophageal sphincter may be fully functional in the normal full-term infant. Some evidence suggests that sphincter pressure may be decreased, either continuously or intermittently, in infants with gastroesophageal reflux, facilitating reflux of gastric contents into the esophagus. There is considerable controversy over the incidence of reflux in the premature infant. Reflux appears relatively more common, but some data suggest that the lower esophageal sphincter

P.946

may be competent. Delayed gastric emptying and other motility problems also may play a role in reflux in premature infants.

In adults and older children, chronic esophagitis as a result of reflux of acid into the distal esophagus is the major concern with gastroesophageal reflux. During the neonatal period, however, esophagitis rarely occurs. Reflux typically presents with continual regurgitation and spitting up or vomiting of small quantities of formula after eating. The association between reflux and apnea of prematurity remains controversial (60,61). Recurrent aspiration during reflux episodes may occasionally result in pneumonitis or exacerbation of preexisting neonatal pulmonary disease. If enough formula is regurgitated, the infant may fail to thrive. In neonates, reflux also may be associated with delayed gastric emptying. Delayed gastric antral distention occurs in some very premature infants in the early postnatal period (62). Such delays in antral distention could contribute to gastroesophageal reflux and feeding intolerance commonly seen in premature infants less than 32 weeks' gestation. As in older children, reflux is encountered more frequently in infants with neurologic abnormalities.

Gastroesophageal reflux may exist as a primary disorder as a result of lower esophageal sphincter incompetence or intermittent relaxation, or it may be a manifestation of another disorder. First of all, it must be realized that gastroesophageal reflux may occur physiologically in all infants, although not with the frequency and severity of pathologic reflux. Any disorder that limits gastric emptying or causes a partial proximal small intestinal obstruction, such as annular pancreas or pyloric stenosis, will result in some gastroesophageal reflux. Small bowel disorders, including milk protein enterocolitis or infectious enteritis, will cause vomiting and regurgitation—in essence, gastroesophageal reflux. Finally, a

variety of systemic disorders, including certain inborn errors of metabolism, chronic infection, chronic renal disease, and increased intracranial pressure, may result in chronic emesis similar to gastroesophageal reflux. Drugs, such as xanthines, which may be given because of apnea or lung disease, decrease lower esophageal sphincter pressure and may exacerbate or even cause reflux.

Several diagnostic studies are available to diagnose gastroesophageal reflux in infants; however, these studies as a rule do not separate primary from secondary causes. For example, an infant with milk protein enterocolitis or pyloric stenosis will have a positive test result for gastroesophageal reflux by any of the available studies. The most widely available test for reflux is an upper GI series, which is preferable to a barium swallow, because the latter only examines esophageal motility. The stomach must be filled with barium to assess the patient accurately for reflux. Unfortunately, assessing a child for gastroesophageal reflux radiographically lacks sensitivity because of the short time interval during which the child is observed, and it lacks specificity because of the likelihood of physiologic reflux occurring during performance of an upper GI series. Therefore, the primary role of an upper GI series is to exclude gastric outlet lesions such as pyloric stenosis, or proximal small bowel partial obstructions such as duodenal webs or annular pancreas.

Twenty-four-hour potential of hydrogen (pH) monitoring is the most widely accepted means of assessing gastroesophageal reflux (63). The pH probe is placed approximately 2 cm proximal to the lower esophageal sphincter, and distal esophageal pH is recorded over a 24-hour period. The infant must be bolus-fed during the study, to ensure adequate gastric distention to simulate the physiologic state. Considerable controversy exists over appropriate feeding for children during 24-hour pH monitoring. The inconsistency of acid secretion in small infants makes the procedure much less reliable during the neonatal period, and, consequently, simultaneous measurement of intragastric pH often is helpful in determining the validity of the study.

A ^{99}Tc scintiscan may be used to screen for gastroesophageal reflux, although this technique is not considered as reliable as 24-hour pH monitoring. The technique is useful, however, for measuring gastric emptying delay, which may coexist with gastroesophageal reflux in a number of infants. Endoscopy with biopsy is a useful technique for detecting reflux in older infants; however, endoscopic biopsies are less useful during the neonatal period because pathologic reflux has not had sufficient time to cause esophageal mucosal injury. In older children, the presence of intraepithelial eosinophils suggests reflux, but this sign cannot be relied on in neonates, and biopsy specimens frequently are normal. Contrary to earlier belief, eosinophils are now recognized as being strongly associated with allergic disease of the gut, especially if present in the esophagus in large numbers. Most such cases however appear later in childhood.

Treatment of gastroesophageal reflux is based on the severity of symptoms. If the

child is thriving well and the major complaint is frequent regurgitation and spitting, the infant may be placed prone on an incline at approximately 30 degrees with the head higher than the feet. It has been demonstrated that children positioned in this manner will reflux less frequently. Although it may take several weeks for symptoms to resolve, the risk of esophagitis is lessened and reflux tends to resolve more quickly. If the volume of reflux is severe and the infant is chronically irritable, has evidence of esophagitis, or is failing to thrive, then inhibition of gastric acid secretion with agents such as antacids or histamine-2 (H₂)-receptor antagonists may be necessary. Cimetidine and ranitidine are available in liquid preparations, and they both work well. Data suggest that aluminum antacids may elevate serum aluminum levels in small infants (64). Proton pump antagonists such as omeprazole are even more potent suppressors of acid secretory activity than H₂-receptor antagonists. Suppression of gastric acidity may actually be harmful as it increases gastric colonization which could lead to increased risk of sepsis and pneumonia (65). Bethanechol, a parasympathomimetic agent, has been demonstrated to increase lower esophageal sphincter resting tone and improve weight gain in infants with failure to thrive secondary to gastroesophageal

P.947

reflux (66). Unfortunately, bethanechol may have associated central nervous system side effects, such as irritability and sleeplessness. Metoclopramide also has been used to treat gastroesophageal reflux in infants. The effectiveness of metoclopramide is controversial, and it probably is most helpful when delayed gastric emptying coexists with reflux. Some clinicians thicken infants' formula with cereal. Although this may reduce spitting, it usually does not reduce reflux or its complications and results in nutrient imbalance in the infant's carefully formulated diet. Infant formulas containing rice starch as part of the carbohydrate component have been shown to have a modest beneficial effect in gastroesophageal reflux in infants. They have a distinct advantage over addition of rice cereal in that they maintain an appropriate macronutrient balance.

Gastroesophageal reflux may be treated successfully at any age with surgical fundoplication in approximately 95% of cases. The most common surgical procedures include the Nissen fundoplication, in which the stomach is wrapped and sutured 360 degrees around the distal esophagus, and the Thal fundoplication, which consists of a 270-degree wrap. Complications, including gaseous distention of the stomach and dumping syndrome, may be less common with the Thal procedure. Many surgeons now perform fundoplications laparoscopically. Indications for an operation for gastroesophageal reflux include recurrent aspiration pneumonia, failure to thrive secondary to severe vomiting unresponsive to in-hospital medical management, or apparent life-threatening apnea events associated with gastroesophageal reflux (67). Such procedures may be performed laparoscopically by competently trained pediatric surgeons.

Differential diagnosis of the typical neonate with chronic recurrent vomiting includes, in addition to gastroesophageal reflux, two major categories of disease. The first is upper GI anomalies, including pyloric stenosis. Virtually all of these can be eliminated by upper GI contrast studies; pyloric stenosis can be excluded adequately by ultrasonography in the hands of an experienced pediatric ultrasonographer. The second major diagnostic category is formula protein intolerance. Infants with formula protein intolerance commonly vomit, especially those with significant small bowel mucosal disease. Such infants often are irritable and usually have loose, Hematest-positive (Ames, Elkhart, IN) stools. Proctoscopic examinations of the rectum usually demonstrate colitis. This disorder is discussed in detail later in this chapter.

Esophageal Anomalies

The other major category of esophageal disease that presents in the neonatal period is tracheoesophageal fistula or esophageal atresia (68). These anomalies occur in approximately 1 in 4,000 live births. In addition to a prenatal history of polyhydramnios, increased salivation with coughing, choking, and cyanosis shortly after birth should raise the suspicion of tracheoesophageal fistula-esophageal atresia. The most common variety is that of atresia with the distal esophageal pouch connected to the trachea through a fistula. Such infants frequently have a stomach distended with air and respiratory symptoms as a result of tracheal aspiration of refluxed gastric acid. Immediate pediatric surgical consultation is required (see Chapter 44).

After surgery, gastroesophageal reflux is a virtual certainty. Patients with tracheoesophageal fistula or esophageal atresia have incompetent lower esophageal sphincter function and aperistaltic contractions in the midesophagus. Although swallowing usually proceeds without much difficulty, gastroesophageal reflux with chronic esophagitis and occasionally stricture formation are frequent long-term complications. Subsequent esophageal dilatations and fundoplication may be necessary.

Disorders of the Stomach and Duodenum

Congenital Anomalies

Congenital anomalies of the upper GI tract frequently present with vomiting. The most common is pyloric stenosis, which occurs in approximately 1 in every 500 live births (69,70). The disease is most common in Caucasian males. A positive family history often is present. Pyloric stenosis usually presents with nonbilious projectile vomiting during the third to fourth week of life. The disorder often is insidious in onset. After emesis, infants are hungry and will attempt to eat to compensate for malnutrition. It is now clear that pyloric stenosis is caused by the

selective inadequate development of inhibitory neurons in the myenteric plexus of the pyloric region that utilize vasoactive intestinal polypeptide and nitric oxide as neurotransmitters to relax the sphincter. Eventually, nutrition deteriorates and infants become dehydrated and alkalotic secondary to chronic vomiting of the acidic gastric contents. Unconjugated hyperbilirubinemia is present in a small percentage. Patients with pyloric stenosis have normal or firm stools, in contrast to infants with formula protein intolerance, who usually have loose stools with evidence of malabsorption, inflammation, or both. Serum electrolytes reveal potassium and chloride deficiency and metabolic alkalosis. Prior to the availability of modern imaging techniques, the failure of a silver salt added to the infant's urine to produce a white precipitate of silver chloride was a means of differentiating pyloric stenosis from salt-losing adrenal hyperplasia. Physical examination demonstrates visible peristalsis in the epigastric region. Careful palpation of the abdomen while feeding may reveal a pyloric olive. The olive can be felt best when the stomach is empty, particularly just after vomiting. Diagnosis usually is confirmed by an upper GI series or ultrasonography, or both in the case of ambiguity, before proceeding with surgical intervention (71).

Before operative correction of the pyloric stenosis, infants should be rehydrated intravenously and the electrolyte imbalance and alkalosis corrected. Surgical correction consists of longitudinal incision of the hypertrophied muscle (i.e., pyloromyotomy). After the operation is completed, the patient usually can be fed within 6 to

P.948

12 hours. Rarely, if there has been prolonged gastric distention as a result of delayed diagnosis, time to full refeeding may be prolonged. Pyloric stenosis has been noted to recur in rare cases. Nonoperative medical management of pyloric stenosis, consisting of anticholinergic drugs and small frequent feedings, occasionally may be helpful. This therapy, sometimes used in Europe, is rarely used in North America because of the excellent results of surgical intervention.

Other rare gastric anomalies also may present in the neonatal period. Various forms of gastric atresia or hypoplasia have been described, most of which present with vomiting at or shortly after birth. Congenital microgastria may occur in association with a variety of other anomalies, including limb abnormalities, asplenia, megaesophagus, situs inversus, midgut malrotation, and cardiac anomalies. After major reconstructive surgery of the stomach, prognosis may be quite good.

Acid Peptic Disease

Acid peptic disease may be seen in newborn infants (72,73,74). Ulcers in children occur most commonly in the neonatal period or during the second decade of life. In newborn infants, ulcers, whether gastric or duodenal, usually present with

hematemesis. Occasionally, blood loss may be substantial, manifested by symptoms of hypovolemia and shock. Differential diagnosis of hematemesis in the newborn includes swallowed maternal blood, or blood ingested from a cracked nipple through breast-feeding. Detection of swallowed maternal blood can be determined by assaying for adult hemoglobin in the gastric contents with the Apt test.

Diagnosis of peptic ulcer disease in the neonate requires endoscopy. Radiographic studies rarely are useful because the lesions are quite superficial and difficult to image radiographically. Endoscopy can be performed easily in a newborn infant by a skilled pediatric endoscopist using appropriate equipment. The smallest pediatric upper GI endoscopes can be used safely in term infants under conscious sedation. The minimum size of the infant in whom endoscopy can be performed safely varies with the skill of the endoscopist, but endoscopy often also can be performed safely in larger premature babies. A bronchoscope can be used in smaller infants, although the examination usually is unsatisfactory. Neonatal upper GI endoscopes are now available which facilitate diagnosis significantly. Although ulcerations may be identified anywhere in the stomach and the duodenum, multiple superficial gastric lesions are most common in newborn infants. Ulcers may be primary, or they may be secondary, as in the case of drugs known to irritate the upper GI tract, such as steroids or theophylline. Treatment with antacids, or preferably H₁-receptor antagonists such as cimetidine or ranitidine, for a period of 2 to 6 weeks results in complete healing of the lesion. Secondary ulcers may be treated in a similar fashion. In this instance, continuation of the offending agent requires careful assessment of the risk-to-benefit ratio, because lesions will heal more rapidly if the agents are discontinued. Neonatal infection with *Helicobacter pylori* is a rare phenomenon (75).

Spontaneous gastric perforation is a rare occurrence in the newborn. It occurs most commonly during the first 5 days of life, especially in infants subjected to severe stress or hypoxia (76). The constellation of symptoms typically includes a sudden deterioration in clinical status between the second and fifth day of life, characterized by refusal to eat, vomiting, abdominal distention, and respiratory distress. Free intraperitoneal air (usually a large volume) and fluid are demonstrable on plain radiographs of the abdomen. Immediate surgical consultation should be sought.

Disorders of the Small Intestine

Congenital Anomalies

Of the various small intestinal disorders that present in the neonatal period, congenital anomalies that produce obstruction are likely to present earliest. Patients present with bilious vomiting, abdominal distention, and occasionally

obstipation. Bilious vomiting indicates obstruction distal to the ampulla of Vater. Bilious vomiting associated with the passage of blood through the rectum suggests vascular compromise of the small intestine, necessitating immediate surgical intervention.

Malrotation or nonrotation of the gut is an anatomic defect produced by incomplete rotation and fixation of the embryonic intestine after return from its extraabdominal location at about week 10 of gestation (77). During development, the intestine rotates 270 degrees around the axis of the superior mesenteric artery to place the cecum in the right lower quadrant. When the cecum fails to rotate completely, the mesenteric attachment of the small intestine is limited to that supporting the superior mesenteric artery and vein. This permits the bowel to twist on itself and produces a midgut volvulus. In the malrotated colon, adhesive bands, otherwise known as Ladd bands, stretch anteriorly from the right peritoneal gutter over the duodenum, in which they can produce obstruction. Rotational anomalies may be associated with other intestinal anomalies, usually duodenal stenosis or atresia or other small intestinal atresias. Cardiac, esophageal, urinary, and anal anomalies also may be present. Rotational abnormalities should be considered in the differential diagnosis of a high intestinal obstruction identified radiographically. Unfortunately, the diagnosis often is missed by plain abdominal radiographs because air may be present in several loops of bowel distal to the obstruction. Rotational abnormalities are identified more easily with an upper GI series, or barium enema. The radiographic hallmark of malrotation is the identification of the cecum in the upper abdomen or to the left of the midline. Symptomatic rotational abnormalities require urgent surgical exploration, because a volvulus may result in loss of the entire midgut within hours of presentation as a result of vascular occlusion. Intestinal dysmotility is common following operative repair of a malrotation with or without an associated volvulus (78).

P.949

Jejunal or ileal atresias range from membranous obstructions to complete atresia. Atresias can be single or multiple (79,80). An apple peel or Christmas tree deformity of the superior mesenteric artery results in an extensive jejunal atresia followed by multiple ileal atresias that are vascularly supplied by a branch of the ileocolic artery. Unlike duodenal atresia, relatively few anomalies are associated with ileal atresia. Cystic fibrosis, however, is present in approximately 20% of infants with jejunoileal atresia.

Small intestinal atresias in the neonatal period present with bilious vomiting. The degree of abdominal distention varies with the site of the atresia. If the atresia is distal, vomiting may be delayed for up to 24 hours after birth. Depending on the location of the atresia, varying numbers of dilated loops of bowel with air-fluid levels may be present on abdominal radiographs. Because it is difficult to differentiate small intestine from colon on plain abdominal radiographs in

newborns, a contrast enema should be performed to exclude colonic lesions and obstructions. Contrast enemas also are helpful in excluding disorders such as meconium plug syndrome or associated rotational abnormalities.

Meconium Ileus

Meconium ileus occurs almost exclusively in patients with cystic fibrosis. It is caused by abnormally viscid mucus glycoprotein in meconium (81). Approximately 10% to 20% of patients with cystic fibrosis have meconium ileus as the first sign of their disease. Pathologically, the lumen of the distal small intestine is obstructed by an accumulation of abnormal meconium. Infants present with bilious vomiting and abdominal distention during the first 2 days of life. A palpable sausage-like mass may be present, and rectal examination may identify hard, dry, gray-tan meconium. Abdominal radiographs demonstrate some evidence of complete obstruction, but the radiologic hallmark is the soap-bubble appearance of trapped air within the tenacious meconium in the distal small bowel. A water-soluble contrast enema occasionally is therapeutic in disrupting the meconium obstruction. Care should be taken to avoid dehydration, because contrast substances are hypertonic and can result in massive pooling of fluid within the bowel lumen. Surgical intervention is required if the contrast enema is unsuccessful. When the diagnosis of meconium ileus is made, patients should be thoroughly evaluated for cystic fibrosis.

Other disorders related to meconium may be seen in the neonatal period. Meconium peritonitis may occur when intrauterine bowel perforation, secondary to obstruction, has resulted in leakage of sterile meconium into the peritoneal cavity. Common causes include atresia, volvulus, stenosis, cystic fibrosis, meconium ileus, and Hirschsprung's disease. Small flecks of intraabdominal calcification may be identified radiographically. Ascites occasionally occurs, but may resolve spontaneously unless secondary infection develops. In severe cases, meconium peritonitis can result in adhesions that require surgical intervention.

Necrotizing Enterocolitis

The most serious GI disorder occurring in neonates is NEC (79,80). Because NEC appears predominantly in sick, low-birth-weight infants, the incidence has increased in recent years as the mortality rate for the very-low-birth-weight infant has decreased. It has been estimated that 90% of cases occur in premature infants and that NEC may develop in 1% to 10% of infants hospitalized in neonatal intensive care units (84). Significant intercenter differences in the prevalence of NEC have been reported (79). The mortality rates vary from 10% to 50%. The age of onset of NEC is related to birth weight and gestational age. Smaller, more immature infants (less than 28 weeks of gestation) tend to have NEC at an older age than larger, more mature (greater than 31 weeks of age)

infants (85). Thus, the more premature the infant, the longer the duration of risk. A diagnosis of NEC in a premature infant significantly increases the patient's length of stay and imposes added financial burden (86).

The etiology of NEC is not fully known (87). Multiple factors appear to be involved, including hypoxia, acidosis, and hypotension, which may lead to ischemic damage of the mucosal barrier of the small intestine (88). Secondary bacterial invasion of the mucosa may be involved in the pathogenesis of pneumatosis intestinalis. Moreover, NEC has been observed to occur in epidemics in neonatal intensive care units, further supporting the role of microbial agents in pathogenesis. A number of conditions may predispose the larger infant to development of NEC, including cyanotic congenital heart disease, obstructive lesions of the systemic cardiac outflow (e.g., hypoplastic left heart, coarctation of the aorta), polycythemia, umbilical catheters, exchange transfusions, perinatal asphyxia, maternal pre-eclampsia, and maternal use of cocaine. Infants with patent ductus arteriosus also seem to be at greater risk. In this case, oxygenated blood is shunted from the intestine. All of these factors suggest that mucosal injury and ischemia are important in the development of NEC. The role of inflammatory mediators, such as tumor necrosis factor- α and platelet-activating factor, oxygen free radicals, and local nitric oxide synthesis also have received attention (89,90,91,92).

Rapid onset of enteral feeding may be a risk factor for NEC, because of changes in enteric blood flow and oxygen requirements during feeding (93,94). Early introduction of small volumes of enteral feeding appears to significantly reduce the risk of necrotizing enterocolitis when compared to aggressive advancement of enteral feeding in at risk preterm infants. NEC occasionally is reported in infants who have never been enterally fed. Several factors related to enteral feeding have been studied, and a number of theories have been proposed on how enteral feedings might precipitate NEC. Hyperosmolar formulas have been implicated in the production of NEC, but these formulas differed

P.950

from standard formulas in other ways as well. Additionally, most hyperosmolar formulas have been reformulated to minimize this risk. Formula feedings seem to predispose to NEC more than breast-feeding, suggesting that breast milk factors, including growth factors, antibodies, and cellular immune factors, might be protective. It also is likely that formula within the GI tract may provide a substrate for bacterial proliferation. The role of bacterial invasion in this disease has been well recognized, but is likely to be a secondary event after compromise of the intestinal mucosal barrier. *Enterobacter sakazakii*, a rare infection in premature infants which is occasionally associated with the feeding of powdered formula has been seen in some infants with necrotizing enterocolitis but a causal relationship has not been established (95).

The shunting of blood away from the intestine in a fashion similar to the diving reflex in aquatic mammals has been postulated as a potential mechanism for

producing the initial gut ischemia. This reflex might occur in response to a hypoxic episode and has been studied extensively in animal models.

The association of NEC with prematurity implicates immaturity of the intestinal mucosal barrier. A number of factors that affect the mucosal barrier are immature in premature infants, including acid output, intestinal motility, and enzyme production. Immaturity of the microvillus membrane itself, and differences in the mucus secreted by the small intestine, may play a significant role. The mucosal immune system is immature, and less secretory IgA is produced. Some interest has arisen in the possible role of oral immunoglobulin administration for prophylaxis against NEC (96).

The reported GI hormone abnormalities in NEC patients are difficult to interpret because of the spectrum of ages at which the disease develops, the randomness of blood sample timing, and the variation in quantity of enteral feedings. Concentrations of GIP, neurotensin, and enteroglucagon in infants with NEC are lower than those normally fed infants of comparable age, but gastrin, motilin, and pancreatic polypeptide (PP) levels appear to be normal (97).

Clinical presentations vary widely. Abdominal distention usually is one of the earliest and most consistent clinical signs. Other symptoms include bloody stools, apnea, bradycardia, lethargy, shock, and retention of gastric contents as a result of poor gastric emptying. Thrombocytopenia, neutropenia, and metabolic acidosis may develop during bowel ischemia. Not every patient has every sign, however, and clinical presentation may vary markedly. Diagnosis is confirmed by radiographic demonstration of pneumatosis intestinalis or portal hepatic venous air. Nonspecific radiographic findings include thickening of the bowel wall, dilated loops of bowel, and ascites. The presence of reducing substances in the stool, as a result of carbohydrate malabsorption, may be an early finding in NEC, as may increased α 1-antitrypsin levels, which indicate protein-losing enteropathy.

Suspicion of NEC dictates that all enteral feedings should be discontinued. An orogastric tube is placed routinely to relieve distention of the alimentary tract. Intravenous access must be secured to provide fluid, electrolytes, and nutrition, because the patient will not be fed enterally for an extended period of time. Intravenous antibiotics are administered to provide coverage for enteric organisms. Inclusion of specific antianaerobic agents does not appear to be helpful (98). The duration of oral intake restriction depends on the clinical status. Patients who merely have poor feeding with increased residuals, and the presence of minimal radiographic findings, may be fed within 48 to 72 hours. In the presence of pneumatosis intestinalis and marked abdominal distention, 2 weeks of parenteral nutrition may be required before judicious gradual reintroduction of enteral feedings is considered.

Throughout the course of the disease, frequent radiographic evaluation of the abdomen for evidence of intestinal perforation is required. Apnea, bradycardia,

abdominal wall discoloration or edema, or a sudden increase in intraabdominal girth should give rise to the suspicion of bowel perforation. Frequent laboratory evaluations include a complete blood count and platelet count to look for thrombocytopenia and neutropenia, both of which suggest deterioration. In infants with severe inflammation of the small intestine, large volumes of fluid and electrolytes or blood products may be required to maintain perfusion and blood pressure. This is especially true in infants in whom severe metabolic acidosis develops secondary to poor perfusion. Ventilatory support usually is necessary. Exploratory laparotomy with resection of dead bowel has been the traditional surgical approach to patients with evidence of perforation or gangrenous bowel. Peritoneal drainage prior to laparotomy may be of benefit in extremely low birth weight infants or hemodynamically unstable patients (99).

Infants who require surgical intervention are at risk for postoperative complications and complications associated with total parenteral nutrition (TPN). The most common complications after surgery for NEC are sepsis, intestinal strictures, short bowel syndrome, and wound infections (100). Intraabdominal abscesses are relatively rare. In a number of infants, the mucosal inflammatory process may progress to transmural necrosis that may, if it does not lead to perforation, result in fibroblast proliferation, granulation tissue, and stricture formation. Some clinicians routinely study the GI tract radiographically after NEC has been treated medically. It is not uncommon to find asymptomatic ileal stenosis or colonic stenosis in such patients. If symptoms of partial obstruction, such as abdominal distention, failure to thrive, or poor feeding develop in infants who have recovered from a bout of NEC, contrast studies are indicated; however, it should be noted that ileal stenosis may not be detected by these studies.

Localized Intestinal Perforation

Localized intestinal perforation has recently been recognized as a clinical entity distinct from NEC (101). Localized intestinal perforations are similar to NEC in that they

P.951

occur almost exclusively in premature infants. In contrast, patients with localized intestinal perforations are less likely to have symptoms of a severe illness, such as metabolic acidosis or leukopenia, than patients with NEC (101). Patients with localized intestinal perforations are more likely to survive to discharge than patients with NEC.

The etiology of localized intestinal perforation is not known. Interruption of regional blood flow to the bowel has been hypothesized. Patients with localized perforation are more likely to have received higher dosages of indo-methacin or had an umbilical artery catheter in place shortly before the perforation than patients with NEC (101,102).

Short Bowel Syndrome

Short bowel syndrome is defined as a malabsorptive state that occurs after bowel resection. Infants with short bowel syndrome fall into two categories: those with congenital anomalies (e.g., gastroschisis, apple peel anomaly of the superior mesenteric artery, intestinal atresia) and anatomically normal patients who undergo bowel resection for NEC. The latter group tends to have fewer complications and a better prognosis, when equal lengths of residual small intestine remain.

After massive resection of the small intestine, the remaining small bowel undergoes an adaptation process characterized by epithelial hyperplasia (103). Within 1 to 2 days after resection, enterocytes begin replicating in the crypts. Gradual morphologic changes occur in the small intestine, including a marked lengthening of villi that results in increased mucosal surface area. This is followed by an increase in absorptive capacity that eventually enables many to survive without parenteral nutrition. The adaptation process is gradual, however, and may require weeks to years.

The major gut hormone changes seen after ileal resection are marked increases in plasma levels of PYY, entero-glucagon, and motilin (103,104). Increases of entero-glucagon (which reflect parallel changes in the enterotropic hormone, GLP-II and of PYY, which inhibits gastric acid secretion and small intestinal secretion, enhances absorption and delays gastric emptying and intestinal transit, are appropriate responses in this condition. Preservation, or even enhancement, of the PYY response would be valuable in diminishing the rapid transit and diarrhea associated with this condition. Studies in experimental animals have revealed that improvements in transit and fluid absorption are temporally related to the increase in PYY response that occurs after bowel resection (105,106).

Hypergastrinemia also accompanies intestinal resection and is responsible for the increased gastric secretion seen postoperatively. The increase of gastrin levels is triggered by the reduction in small intestinal inhibitory factors and usually subsides after a few weeks, when intestinal adaptation has taken place. Mucosal hyperplasia does not occur in the absence of enteral nutrition. In fact, mucosal atrophy may result if the patient is nourished only parenterally (107). Enteral nutrition stimulates intestinal adaptation by several mechanisms (108). Highly unsaturated long-chain fats stimulate intestinal adaptation to a greater extent than protein or carbohydrate; the mechanism by which this occurs is poorly understood. Nonetheless, careful attention to the provision of adequate enteral nutrition is important.

Management of the short bowel syndrome is a multistage process (109). During the early postoperative period, use of parenteral nutrition and careful attention to fluid and electrolyte abnormalities are essential. High-volume ostomy losses must

be replaced with a solution of comparable electrolyte content to obviate the need for frequent changes in electrolyte concentration in parenteral nutrition solutions.

The presence of an ostomy may create additional problems. These vary somewhat, depending on whether the ostomy is in the ileum, from which the volume output is likely to be much greater, or in the colon, in which case stool consistency may vary markedly based on whether the ostomy was placed proximally or distally. If available, the services of an enterostomal therapist, with special training in rehabilitation of infants and children with ostomies, will assist the parents in understanding the implications of the ostomy. In general, as would be expected, caring for an infant with a small intestinal ostomy requires meticulous monitoring of fluid and electrolyte balance which implies equally meticulous planning if home care is considered. The ostomy should be placed away from sites such as the iliac crest, costal margin, or umbilicus, so that ostomy appliances will fit easily.

Most ostomy devices consist of an adhesive, nonallergenic wafer device with a flange that allows the transparent drainage pouch to be secured to it over the stoma. The pouch can be removed easily for draining by snapping it off the wafer, or it can be emptied through a drainage port at the bottom of the bag. When leakage occurs beneath the wafer, the device should be removed, and careful skin care around the ostomy is necessary. The skin should be washed gently with a soft cloth moistened with mild soap and tepid water. The skin should be dried thoroughly after cleansing. Many protective ointments and powders are available to apply around the stoma area to prevent skin breakdown. If skin irritation is present, tincture of benzoin or steroid preparations available in spray form may be used. The pouches often are reusable and may be washed with mild soap and water and soaked in a deodorant solution to control odor problems. Appropriate teaching will prevent many of the other problems encountered by ostomy patients, such as skin excoriation, minor stoma bleeding, stoma prolapse, and odor. Additional ostomy problems include prolapse and stenosis. The latter should be suspected in the presence of abdominal distention and vomiting. In either situation, the surgeon should be notified.

When enteral feeds are started, a slow continuous infusion of an extensively hydrolyzed protein formula generally works best. Formulations such as Alimentum (Ross Laboratories, Columbus, OH) or Pregestimil (Mead Johnson

P.952

Laboratories, Evansville, IN), which contain significant quantities of long-chain fats, are ideal. These lactose-free preparations with hydrolyzed protein are absorbed rapidly, yet provide adequate stimulation of intestinal adaptation. Stool losses must be monitored carefully. If there is significant concern about allergic disease, an amino acid based formula such Neocate, (Scientific Hospital Supplies, Liverpool UK) may be advantageous. A marked increase in fluid losses or significant evidence of carbohydrate malabsorption manifested by a low stool pH

or positive stool-reducing substances are contraindications for further increasing the enteral infusion. Enteral infusions are increased as tolerated, and parenteral nutrition is decreased in a gradual isocaloric fashion. Patients then can be weaned to intermittent parenteral nutrition and prepared for home parenteral nutrition therapy (110). Intermittent parenteral nutrition allows provision of parenteral nutrients at night, primarily for the convenience of caregivers. Parenteral nutrition initially is discontinued only for short periods of time, usually 4 to 6 hours, each day. In small infants, this usually is delayed until the patient can tolerate approximately 20% of calorie intake enterally to avoid hypoglycemia when he or she is not receiving parenteral nutrition. The duration of parenteral nutrition can be decreased gradually until all parenteral nutrition infuses over 10 to 12 hours at night. It is wise to taper the parenteral nutrition rates up and down when placing a patient on or off of parenteral nutrition, to prevent fluctuation in serum glucose levels.

Home parenteral nutrition has markedly reduced the cost of long-term management of short bowel syndrome patients and has decreased family stresses and nosocomial infections (111). It has become a standard therapy in patients with short bowel syndrome, and prolonged hospitalizations rarely are necessary. To minimize complications, careful training of home nursing personnel is essential, and coordination of activity between physician and nursing staff must be tightly controlled.

Continuous enteral infusions are used in patients with short bowel syndrome for several reasons. The percentage of calories absorbed from the continuous infusion is greater than that possible with bolus feedings, because transport carrier proteins are continually saturated. Continuous infusion provides constant stimulation of mucosal adaptation and reduces the need for parenteral calories, decreasing the risk of parenteral nutrition liver disease. Children should be fed small quantities of formula orally to learn to suck and swallow. Eventually, solids can be fed around the nasogastric tube. These manipulations often will speed the transition from continuous enteral to oral feeding later in the course of therapy.

Numerous chronic complications arise in the treatment of short bowel syndrome, including bacterial overgrowth, nutritional deficiency states, watery diarrhea, parenteral nutrition liver disease, and catheter-related problems. Bacterial overgrowth is defined as increased bacterial content in the small intestine (112). Complications from bacterial overgrowth include increased malabsorption, δ -lactic acidosis, and colitis-like or ileitis-like syndrome. Normal small bowel bacterial counts vary from 10^3 /mL proximally to much greater numbers in the ileum. Normal antegrade peristalsis and gastric and mucosal immune factors prevent excess bacterial proliferation. In short bowel syndrome, because of disruption of normal anatomy and motility, overgrowth is likely and bacterial counts usually exceed 10^5 /mL. Bacterial overgrowth should be suspected whenever motility is slowed, the bowel is dilated, or the ileocecal valve is absent. Organisms typically

include facultative bacteria and anaerobes. Bacteria deconjugate bile salts, causing them to be reabsorbed, depleting the bile salt pool, impairing micelle solubilization, and resulting in steatorrhea and malabsorption of fat-soluble vitamins. More important, bacterial overgrowth causes mucosal inflammation, exacerbating malabsorption of all nutrients. Protein-losing enteropathy and loss of immunoglobulins may occur. Bacteria may compete with the host for nutrients, such as vitamin B12.

Screening for bacterial overgrowth can be done with a fasting breath hydrogen or glucose breath hydrogen test, or by detecting the presence of indican in the urine. Measurement of breath hydrogen is a simple test in infants and children, although collection of samples in the neonate requires special care. A fasting breath hydrogen level greater than 42 ppm is seen only in small bowel bacterial overgrowth (113). A breath hydrogen level greater than 20 ppm after the administration of 2 g/kg of oral glucose, with measurement at 15-minute intervals after ingestion, suggests bacterial overgrowth. Measurement of indican in the urine is a simple screening test for bacterial overgrowth, because bacteria convert dietary tryptophan to indican. Unfortunately, indicanuria may occur in other conditions, and the technique lacks sensitivity (114). Bacterial overgrowth can be diagnosed definitively by culture of aspirates from the small intestine, although this technique is difficult to interpret as contamination and culture techniques may frequently overestimate or underestimate the extent of overgrowth. Small intestinal biopsies demonstrating inflammatory changes suggest bacterial overgrowth.

Accumulation of d-lactate in the blood stream results in neurologic symptoms varying from frank disorientation to coma (115). Bacterial overgrowth may cause colitis-like or ileitis-like syndrome with large ulcerations characteristic of Crohn's disease, but without granulomas (116). Broad-spectrum oral antibiotics (e.g., metronidazole, trimethoprim-sulfamethoxazole (TMP-SMZ), gentamicin) and antiinflammatory agents often are beneficial. Broad-spectrum antimicrobial coverage should be directed at the organisms present, usually anaerobes. Antimotility agents may improve nutrient contact with the mucosa by lengthening transit time, but tend to exacerbate bacterial overgrowth and should be used with caution. Recently, use of probiotic bacteria has been proposed for the treatment of certain patients with small bowel bacterial overgrowth (117). However, the overall experience with probiotic therapy in bacterial overgrowth has been somewhat disappointing.

Secretory diarrhea may be a problem in some children with short bowel syndrome. This may be related to hypergastrinemia, which often occurs after resection. Because the tight junctions in the ileum are less permeable than the jejunum, the ileum plays a major role in fluid and electrolyte conservation, and ileal resections are more likely to result in major fluid and electrolyte losses than

jejunal resections. Because most infants with NEC have ileal disease, this is a major problem in neonates after bowel resection. Ileal resection also results in malabsorption of bile acids, because the ileum is the primary site for bile acid reabsorption. Malabsorption of bile acids into the colon may cause fluid secretion and watery diarrhea, which may respond to a bile acid-binding resin such as cholestyramine. Unfortunately, cholestyramine may further deplete the bile acid pool, exacerbating steatorrhea.

Nutritional deficiency states may occur after parenteral nutrition is discontinued, including deficiencies of fat-soluble vitamins A, D, and E, and the minerals iron, zinc, calcium, and magnesium.

Parenteral nutrition hepatobiliary tract disease is the major complication that may result in death in infants with short bowel syndrome (111). The mechanism by which the liver injury occurs is unknown. In most instances, enteral administration of a significant percentage of calories, usually between 20% and 30% of total requirements, reduces the risk of parenteral nutrition liver disease.

Cholelithiasis develops in approximately 20% of infants receiving parenteral nutrition for short bowel syndrome because of malabsorption of bile acids, altered bilirubin metabolism, and gallbladder stasis. Cholangitis may occur in the presence of partial obstruction. Early cholecystectomy should be considered if patients are symptomatic with elevated direct bilirubin and liver enzymes.

Catheter-related infections and thrombosis are common in infants requiring long-term parenteral nutrition (118). In our experience, catheter-related infections rarely are as a result of intestinal bacterial overgrowth and most commonly are related to catheter care technique. Diligent parental instruction in catheter care and in the signs and symptoms of sepsis is extremely important.

During later stages of therapy, additional surgery may be indicated (119). One of the first questions usually concerns whether to close a stoma that was formed at the time of initial surgery. If the colon remains, and especially if ileum exists as well, reconnecting an ostomy may substantially conserve fluid and electrolytes, but also may result in perianal disease. In infants with dilated segments of proximal bowel, resecting a tight anastomosis or tapering the bowel to improve flow of luminal contents often reduces bacterial overgrowth. A number of procedures have been designed to slow transit time, including reverse segments of bowel, one-way valves, or colon interposition, but none is considered reliably effective, and all may increase bacterial overgrowth.

A procedure to increase the length of the bowel has been devised that involves transecting the bowel longitudinally, preserving the blood supply to both sides of the bowel, and creating a segment about twice the length and one-half of the diameter. This allows reducing the diameter of the bowel without any loss of mucosal surface area. Because it does not actually increase the mucosal surface area, it is indicated primarily to reduce bacterial overgrowth without losing

absorptive surface in infants with dilated bowel. Our experience has been quite rewarding with this procedure, with 12 of 14 recent patients demonstrating significant improvement and several becoming independent of parenteral nutrition after surgery (120). More simplified techniques of intestinal lengthening have recently been described. In general, these procedures should not be performed in neonates, because they are likely to be successful only after significant bowel dilation has occurred.

Intestinal transplantation has now become a reality. Well over 100 patients now have been transplanted at a number of centers in the United States and Europe (121). Patients with short bowel syndrome with evidence of parenteral nutrition-induced liver dysfunction should be referred early for intestinal transplantation. Recent evidence suggests that isolated intestinal transplantation prior to the development of irreversible parenteral nutrition-induced liver disease may be an attractive alternative to the combined liver/bowel transplantation, which has traditionally been utilized for such patients. However, long-term survival 5 years following intestinal transplantation has only been in the range of 50%.

It is possible for infants to survive without transplantation or permanent parenteral nutrition with surprisingly short segments of bowel (122,123). As a general rule, patients with greater than 25 cm of normal bowel at the time of neonatal resection who have an ileocecal valve, or with greater than normal 40 cm of normal bowel at the time of neonatal resection who have no ileocecal valve, have a reasonable chance of eventually becoming independent of parenteral nutrition. The ileocecal valve appears to play a major role in determining the long-term prognosis, primarily because of its ability to exclude colonic bacteria from entering the small bowel and perhaps also because of its ability to delay transit through the small intestine.

Mucosal Injury Disorders

Because of the limited small intestinal reserve in small infants, small intestinal disease perhaps is most catastrophic in infancy. In small intestinal injury, all nutrients are malabsorbed. Most symptoms, however, are related to carbohydrate malabsorption because of the osmotic diarrhea produced when these malabsorbed molecules are broken down further by intestinal bacteria into smaller and smaller osmotically active particles. The osmotic gradient overrides the ability of the ileum and colon to reabsorb fluid effectively, and watery diarrhea ensues.

Measurement of stool pH and reducing substances is an ideal means to screen for small bowel mucosal disease in infancy. When carbohydrates are malabsorbed and broken down into organic acids by colonic bacteria, the stool pH drops below 5.5. Stool pH can be measured easily with

litmus paper, simply by inserting the paper into the stool. Measurement of

	Bacterial	Viral
Clinitest	-	±
pH	≥5.5	£5.5
Hematest	+++	-
Leukocytes	+++	-

-, negative; ±, negative or positive, +++, strongly positive.

Chronic diarrhea in infants with acquired immunodeficiency syndrome (AIDS) presents a very difficult management problem. Diarrhea in older children may result from opportunistic infections, tumors, including Kaposi's sarcoma and lymphoma, and direct HIV infection of the gut. Opportunistic organisms include viral agents (e.g., cytomegalovirus, rotavirus, herpes simplex, coxsackievirus, adenovirus), bacterial pathogens (e.g., *Salmonella* sp, *Campylobacter*-like organisms, *Listeria* sp, *Mycobacterium avium-intracellulare*, *Plesiomonas shigelloides*), fungal pathogens (e.g., *Candida* sp, *Aspergillus* sp), and parasitic pathogens (e.g., cryptosporidium, *Strongyloides* sp, *Giardia* sp, amoebas, *Isoospora belli*). A broad spectrum of endoscopic and histologic findings is possible because of the diverse nature of the disease. Extensive viral and bacterial cultures and examinations for ova and parasites are warranted in infants and children with AIDS.

Treatment consists of therapy directed at any specific infectious pathogen identified, coupled with use of parenteral and enteral nutrition. As in almost all chronic enteropathies, primary attention should be given to continuous enteral infusion with an elemental diet or protein hydrolysate formula. If malabsorption develops in the patient, as indicated by stools testing positive for reducing substances or manifesting a pH below 5.5, supplemental parenteral nutrition is needed to provide the remainder of caloric and other nutritional needs. The presence of a significant secretory component of the diarrhea may make treatment difficult, complicate the use of continuous enteral infusion, and require careful attention to intake and output of fluid and electrolytes to maintain biochemical homeostasis.

Hormonal Changes in Diarrhea

Infective diarrhea in infants is associated with a massive increase in circulating concentrations of motilin, entero-glucagon, and PYY (124,125). These abnormalities resolve once the patients are better. The gut endocrine system in

infants, however, responds in a manner different from that of adults. In infants with diarrhea, plasma motilin concentrations exceed those that are known to accelerate gastric emptying and increase small bowel motility (125). Motilin is therefore likely to be involved in the motor abnormalities associated with this condition. A hormonally triggered increase in transit rate may constitute a defense mechanisms to rid the bowel of pathogens and secreted toxins. The extremely high enteroglucagon levels in neonatal infective diarrhea appear to be related to the extent of mucosal injury and its repair (126). Measurement of selected gut hormones may give information on the extent of mucosal damage or the presence of ongoing pathologic change.

Formula Protein Intolerance

One of the most common causes of chronic diarrhea in small infants is formula protein-induced enterocolitis

P.955

(127,128). Small bowel involvement (i.e., enteritis), colon involvement (i.e., colitis), or concomitant small bowel and colon involvement are possible with this disorder. Protein-induced mucosal injury has been reported with cow-milk protein, soy protein, breast milk, and even beef protein. A number of infants who are intolerant of protein hydro-lysate formulas, have responded well to an amino acid-based infant formula, Neocate (129).

Infants typically present before 3 months of age with bright red blood in the stool, which may be normal or loose in consistency depending on the extent of inflammation. Sigmoidoscopic examination may reveal gross friability or may appear normal until the mucosa is wiped with a cotton swab, at which time the mucosa readily bleeds. Rectal biopsy confirms inflammation, with the combination of polymorphonuclear leukocytes and eosinophils in the lamina propria. Stools may test positive for occult blood and may contain leukocytes. If the inflammation extends into the small intestine, carbohydrate malabsorption may occur, infants will have watery diarrhea, and stools will be acidic (pH less than 5.5) and test positive for reducing substances. Small intestinal biopsy will demonstrate varying degrees of mucosal injury, with shortening and blunting of the villi, inflammatory infiltrates, and an increase in mitotic activity in the crypts. Disaccharidase levels in the mucosal biopsies often are reduced.

Other symptoms that may occur as a result of formula protein-induced enterocolitis are vomiting and irritability. Infants with formula protein intolerance commonly vomit, especially those with small intestinal disease. It often is difficult to differentiate this disorder from gastroesophageal reflux, because both groups may present with irritability; however, babies with formula protein sensitivity commonly have loose stools and abnormal sigmoidoscopic examinations. This is an important distinction because the treatment is vastly different. Irritability, not

dissimilar from infantile colic, may occur in infants with formula protein intolerance. In infantile colic, the irritability classically occurs at a specific time of the day and responds symptomatically to repetitive stimuli. Infants with irritability secondary to formula protein intolerance usually are inconsolably irritable, often feed poorly, have loose stools, spit up, and have abnormal sigmoidoscopic examinations or other evidence of small intestinal or colonic inflammation. A careful history and physical examination and appropriate laboratory studies can be quite specific in differentiating the two disorders.

Infants who manifest signs and symptoms of formula protein intolerance should be placed on a protein hydrolysate formula such as Nutramigen, Pregestimil, or Alimentum, because a high percentage also will be intolerant of soy formula. A small percentage of infants who do not respond to these formulas may improve on an amino acid formulation such as Neocate.

Most infants with formula protein intolerance will outgrow their sensitivity by 1 year of age. Powell (130) has described a specific challenge procedure to confirm the diagnosis of cow-milk protein intolerance. Patients should not have received the suspected antigen for at least 2 weeks before testing and should be asymptomatic. A standard dose (100 mL of cow milk or soy formula) is administered and the child is monitored carefully for reaction. Stool specimens are analyzed for occult blood, leukocytes, and reducing sugars, and a leukocyte count is obtained 6 to 8 hours later. The test result is considered positive if diarrhea develops within 24 hours, leukocytes or blood appear in stools, or the leukocyte count rises by more than 4,000 cells/mL over baseline. Approximately 20% of the infants have a delayed reaction. If the child originally had evidence of severe milk protein sensitivity, it is wise to hospitalize the infant, start with small volumes (5 to 10 mL) of formula, and gradually increase the volume to avoid severe mucosal injury, anaphylaxis, and shock. Skin testing rarely is useful in children with formula protein intolerance who have predominantly GI symptoms.

Intractable Diarrhea of Infancy

A state of persistent diarrhea and malabsorption despite the institution of a protein hydrolysate formula and in the absence of infectious pathogens is referred to as intractable or protracted diarrhea of infancy (131). These patients demonstrate a variety of histologic abnormalities on small intestinal biopsy, including blunting or flattening of the villi, increased mononuclear cells with occasional polymorphonuclear infiltrates, cuboidalization of the surface epithelium, and a mild-to-moderate increase in mitotic activity in the crypts. Histologic lesions vary substantially, however, and correlate poorly with ultimate prognosis (132). Such infants have chronic weight loss and progressive malnutrition unless appropriate therapy is instituted. Initial therapy involves slow institution of a continuous enteral infusion of a diluted extensively hydrolyzed protein formula such as Pregestimil or Alimentum (133). The rate is rapidly advanced to

approximately 150 mL/kg/d or more, provided the child is not on supplemental parenteral nutrition. The concentration of the formula then is advanced sequentially over 3 to 4 days, until the patient is tolerating full caloric requirements and gaining weight. During this time, stool pH and reducing substances are monitored, and evidence of carbohydrate malabsorption suggests failure of enteral feedings. If this occurs, a period of parenteral nutrition is indicated, usually through a central venous catheter, with gradual reintroduction of enteral feedings by continuous infusion. In treating such infants, it is important to avoid using formulas that contain intact milk or soy protein, because the likelihood of protein sensitivity in such infants is high and further mucosal injury may result. Lengthy periods of parenteral or continuous enteral infusion may be necessary, but the ultimate prognosis is good.

In addition to intractable (i.e., protracted) diarrhea associated with formula protein intolerance, other rare syndromes have been reported to result in mucosal injury and chronic diarrhea. One is congenital microvillus atrophy or microvillus inclusion disease, a disorder with

P.956

hypoplastic atrophy of the villi and shortening or depletion of microvilli (134). This disorder requires electron microscopic diagnosis and has a very poor prognosis. A similar disorder has been recognized electron microscopically and has been associated with "tufting" of the microvilli, hence, the term "tufting enteropathy" (135). A number of patients also have been described with an intractable diarrhea-like syndrome in association with a mild immune defect, stiff unmanageable hair, and peculiar facies (136). All of these conditions are quite rare. Severe protracted diarrhea also may be associated with autoimmune enteropathy; however, this disorder usually presents outside the immediate neonatal period (137). Mucosal lesions are severe and the prognosis is poor. Infants with this disorder often have multiorgan autoantibodies, including gut epithelium, and frequently have pancreatic involvement with hyperglycemia or hypoglycemia.

Disorders of the Colon

Congenital Anomalies

There is substantial overlap in small bowel and colonic disease in neonates. Many of the congenital anomalies involve both the small and large intestines, and certain mucosal injury disorders, including formula protein enterocolitis and NEC, can involve both the small intestine and colon. There are some disorders that primarily affect the colon. Most are congenital and involve anatomic obstructions, such as atresias, or dysmotility, such as Hirschsprung's disease.

Anatomic Lesions

Colonic stenosis or atresia is a rare event, often associated with other skeletal anomalies. Colonic duplication also is a rare entity, which may present with delayed symptoms of obstruction. Duplications usually are cystic, gradually enlarging masses, located posterior to the rectum, which may be confused with tumors (138).

Motility Disorders

More frequent are the disorders that present with delayed passage of meconium secondary to dysmotility. Meconium plug syndrome is one such entity, in which inspissated meconium in the distal colon results in obstruction and dilatation proximally. Delayed passage of meconium is the presenting symptom, and barium enema examination reveals a large plug of meconium that often is evacuated after the barium enema. Normal feeding and stooling usually follows removal of the obstruction, but 20% to 30% of patients with meconium plug syndrome have Hirschsprung's disease. If symptoms recur after removal of the meconium plug, rectal suction biopsy is indicated.

Delayed passage of meconium also may occur with the neonatal small left colon syndrome. Radiographic examination of these infants demonstrates normal-to-dilated proximal colon with constricted or smaller distal colon, with the constricted area usually beginning around the splenic flexure. The line of demarcation is much more abrupt than is seen in neonatal Hirschsprung's disease. The disorder is more common in infants of diabetic mothers (139). It usually resolves spontaneously, although placement of a colostomy may be necessary until normal motility returns. Colonic motility eventually will return, usually within 2 to 12 weeks, and the colostomy may be closed at that time.

Hirschsprung's disease, or congenital aganglionic megacolon, occurs in approximately 1 in 5,000 live births, more commonly in males than in females (140). The risk of recurrence in families is reported to be as high as 10%; higher in infants with total aganglionosis. The frequency is ten times higher in infants with trisomy 21. The disease is caused by a congenital absence of the ganglion cells in both the submucous and myenteric plexuses. Ganglion cells regulate normal colonic peristaltic activity. The absence of ganglion cells results in an inability of the bowel to undergo coordinated relaxation. Impaired migration of neural crest cells into the distal colon is thought to be the mechanism through which Hirschsprung's disease develops, although there is some controversy about this. The disorder almost always involves the distal rectum, but the extent varies substantially. There also is controversy regarding whether or not skip areas can occur. A few such cases have been reported, but they appear to be extremely rare. In most instances, involvement does not extend proximal to the sigmoid colon. In very rare instances, the involvement may extend beyond the colon into

the small intestine. The further the lesion extends, the more difficult the medical management becomes.

Most cases of Hirschsprung's disease are not diagnosed in the neonatal period. When they are, the most common clinical presentation is delayed passage of meconium, with passage of the first stool beyond 24 hours of age. This presentation probably is common but often overlooked. Infants also may appear irritable, with poor feeding and failure to thrive, which, unfortunately, is the typical presentation of a wide variety of small bowel and colonic disorders.

Some infants with Hirschsprung's disease may present with a life-threatening complication—acute enterocolitis (141). Toxic megacolon is common. Although enterocolitis may occur in the newborn period, it more commonly presents at 2 to 3 months of age. Mortality remains around 50%. The disorder presents with sudden or gradual onset of diarrhea, followed by bloody stools and eventually the clinical appearance of sepsis. The clinical overlap between infectious enterocolitis or formula protein-induced enterocolitis is such that Hirschsprung's enterocolitis also must be considered in the differential diagnosis of these more common entities. Patients who present with bloody diarrhea in infancy and have negative stool cultures, and who do not respond quickly to protein hydrolysate formula, need to have a rectal biopsy performed. If Hirschsprung's disease is suspected, surgical consultation should be obtained immediately, and attempts should be made

P.957

to decompress the colon with a rectal tube or rectal irrigation. Controversy continues in the surgical literature regarding what is the best operation for Hirschsprung's disease (142).

Diagnosis of Hirschsprung's disease usually rests with rectal suction biopsy. A small biopsy tube is inserted into the rectum and a small piece of tissue is removed from a point 2 cm proximal to the mucocutaneous junction. If the biopsy is obtained higher, patients with low-segment Hirschsprung's disease may be missed. If the biopsy is taken more distally, it will be obtained in the hypoganglionic zone, an area in which ganglion cells are normally sparse, resulting in a false-positive biopsy for Hirschsprung's disease. The biopsy must be deep enough to contain sufficient submucosa to identify ganglion cells. Superficial biopsies are inadequate to diagnose Hirschsprung's disease. Because ganglion cells are sparse, the biopsy must be serially sectioned, and 60 to 80 sections of tissue examined. Ganglion cells in newborns are somewhat immature and difficult to identify. Thus, a rectal suction biopsy is a reliable diagnostic tool, provided the biopsy is obtained from an appropriate location and depth and an experienced gastroenterologist or pathologist interprets the biopsy. If results are equivocal, a full-thickness biopsy may be performed to establish the diagnosis.

Diagnosis also can be made by inflating a balloon in the distal rectum and

measuring relaxation of the internal anal sphincter, a process impaired in Hirschsprung's disease. Although this technique is performed less commonly, those who are skillful in its use believe it is as reliable as rectal biopsy. In contrast, barium enema examination in the newborn is highly unreliable in the diagnosis of Hirschsprung's disease because the transition zone has yet to develop. Therefore, proximal colonic dilation usually is not apparent in the neonate, and the clinician must look for irregular contractions in the rectosigmoid as the primary hallmark of Hirschsprung's disease.

Treatment begins with placement of a decompressing colostomy proximal to the transition zone between ganglionic and aganglionic bowel. Definitive surgery usually is done at 8 to 12 months of age. A number of different operations have been devised in which the aganglionic bowel is removed and the ganglionic bowel attached into the distal rectum. Surgical treatment generally is successful in restoring long-term fecal continence (143).

Patients with total colonic Hirschsprung's disease present major difficulties in postoperative fluid and electrolyte balance. Infants frequently require prolonged courses of parenteral nutrition. Parents should be warned about the protracted nature of the disease, and infants should be observed closely for fluid, electrolyte, and nutritional problems.

Several other intestinal motility disorders present in the neonatal period. Transient hypomotility occurs in some premature infants and is characterized by markedly delayed gastric emptying and absent or diminished small bowel motility. In most instances, these abnormalities gradually resolve with time; support with parenteral nutrition coupled with intermittent attempts at feeding is all that is indicated. Alterations in calcium and magnesium metabolism such as parathyroid dysfunction or hypothyroidism can cause diminished motility, and these disorders should be excluded in infants with apparent motility disorders. Occasionally, infants with chronic idiopathic intestinal pseudoobstruction syndrome can present during infancy. This term applies to a number of neuropathic and myopathic disorders that result in chronic progressive GI hypomotility. A variety of histologic lesions have been described, and the prognosis for improvement is poor. Occasionally, the disorder also may involve the urinary tract, with associated megacystis and megaureter (144).

Pancreatic Disorders

Cystic Fibrosis

Disorders of the pancreas uncommonly present during the neonatal period. The most common is cystic fibrosis, which occurs in approximately 1 in 1,600 Caucasian live births (145). This autosomal recessive disorder usually presents later in childhood with failure to thrive or chronic pulmonary disease, but may

present with meconium ileus in the neonatal period. After the obstruction has been relieved, therapy consists of compensating for the pancreatic insufficiency through use of extensively hydrolyzed protein formulas such as Pregestimil or Alimentum, which contain -medium-chain triglycerides as part of their lipid component. Medium-chain triglycerides do not require digestion by pancreatic enzymes for absorption and, consequently, may facilitate nutrient assimilation in infants with pancreatic insufficiency. Despite the use of elemental formulas, replacement pancreatic enzyme therapy from birth is necessary to aid the digestion of endogenously secreted proteins.

In children with pancreatic insufficiency as a result of cystic fibrosis, the release of the pancreatic hormone polypeptide (PP) is almost totally abolished. Fasting PP levels are low and the normal response to milk feeding is absent (146). Plasma insulin and GIP responses are reduced significantly in cystic fibrosis patients compared to control subjects, even though the early glucose rise is greater in the former group (141). Reduced GIP secretion in response to feeding may exacerbate the glucose intolerance that accompanies pancreatic destruction. Although plasma enteroglucagon concentrations are elevated in cystic fibrosis, levels of other hormones such as gastrin, secretin, motilin, and glucagon are quite normal (146).

The second most common cause of pancreatic insufficiency in infancy is Shwachman syndrome, an autosomal recessive disorder characterized by pancreatic insufficiency and bone marrow dysfunction with cyclic neutropenia (145,148). This rare disorder should be considered in infants with steatorrhea and neutropenia. Extremely rare isolated defects in pancreatic enzyme secretion, including trypsinogen and lipase, also have been reported.

P.958

Liver Disease

Development

The liver is a complex organ serving multiple metabolic functions. From a digestive standpoint, its primary function is that of an exocrine organ producing bile for the emulsification of fats. Postnatally, the liver receives its blood from two separate sources, approximately 25% from the hepatic artery and 75% from the portal vein. The portal vein drains the splanchnic bed and allows the liver the opportunity to regulate and metabolize substances absorbed by the intestine and hormones produced in the GI tract.

Bile is composed primarily of water. The concentration of solids in the bile are increased threefold by the gallbladder. The fetal liver is capable of synthesizing bile acids from cholesterol slowly, and the rate of synthesis increases

progressively throughout gestation. The major bile salt in newborns is taurocholate. Conjugation of bile salts with glycine in preference to taurine gradually increases, and, by adulthood, most bile salts are conjugated with glycine. The bile acid pool is very small in the preterm infant, but gradually increases in the newborn and matures throughout infancy. This relatively small bile acid pool results in reduced bile salt secretion and, in addition to the relative pancreatic insufficiency, plays a role in the less efficient absorption of fat in the newborn infant. Bile acids are reabsorbed in the ileum through an active transport mechanism. There is some passive transport of bile acids in the jejunum and colon as well. In the fetus, taurocholate is absorbed passively and active ileal transport appears after birth.

Cholestatic Liver Disease

Most liver diseases in the neonatal period present with cholestasis, or conjugated hyperbilirubinemia (149,150). Although elevation of the amino transferase (i.e., transaminase) enzymes is considered the hallmark of hepatocellular injury in older children and adults, neonates may have significant hepatocellular injury even in the presence of normal amino transferase levels. There are many causes of prolonged conjugated hyperbilirubinemia in the neonatal period. These can be subdivided into general categories, including the following: infectious disorders; toxic insults such as parenteral nutrition and sepsis; metabolic disorders; anatomic disorders, including congenital hepatic fibrosis and choledochal cyst; and idiopathic infantile cholangiopathies, including primarily biliary atresia and neonatal hepatitis (151).

Neonatal Hepatitis and Biliary Atresia

After extensive evaluation of the infant with cholestasis, a diagnosis of either extrahepatic biliary atresia or idiopathic neonatal hepatitis is made in 70% to 80% of cases (152, 153). Current thinking suggests that neonatal hepatitis and biliary atresia form a continuum of a pathophysiologic process directed at various levels of the hepatobiliary tract. Inflammation in the bile duct epithelium may result in sclerosis and obliteration of the bile ducts and manifest itself as extrahepatic biliary atresia. Primary hepatocellular inflammation is more likely to result in neonatal hepatitis. Reovirus type III has been found in a number of infants with both idiopathic neonatal hepatitis and biliary atresia. This virus has been implicated as a causative agent in both disorders, although there is evidence that raises questions about this hypothesis (154,155,156).

Idiopathic neonatal hepatitis is slightly more common than biliary atresia. Both sporadic and familial varieties exist. Neonatal hepatitis, unlike biliary atresia, is more common in low-birth-weight infants. Jaundice develops during the first week of life in most cases. A wide variety of clinical presentations may occur, from

severe failure to thrive or fulminant hepatic failure to asymptomatic jaundice. Acholic stools are uncommon, but may occur if cholestasis is severe. Physical examination reveals a firm, enlarged liver and occasionally splenomegaly. The presence of other signs of congenital infection may point toward a more specific diagnosis. Liver biopsy may be helpful in making the diagnosis, but the histologic findings are relatively nonspecific. In most cases, neonatal hepatitis can be differentiated successfully from biliary atresia by percutaneous liver biopsy. Clinical management is directed toward nutritional support and medical management of clinical complications such as ascites or pruritus. The prognosis is variable, with one-half of the cases resolving with little or no sequelae. Life-threatening chronic liver disease may necessitate liver transplantation.

Extrahepatic biliary atresia accounts for about one-third of cases of neonatal cholestasis. Familial cases are uncommon, as are cases in premature infants. Patients typically present with jaundice during the first or second week of life. Acholic stools are more common than in neonatal hepatitis. The liver is firm and enlarged, and splenomegaly may be present, as in neonatal hepatitis. Infants often appear clinically well, although progressive liver injury results in nutritional deficiencies, failure to thrive, and ascites.

Differentiation between neonatal hepatitis and biliary atresia has been the subject of controversy over the years. Serum amino transferase (i.e., transaminase) levels are notoriously unreliable indicators of neonatal liver disease and may be normal even in some patients with neonatal hepatitis. Extremely elevated γ -glutamyltransferase levels are suggestive of the marked bile ductular proliferation found in biliary atresia (157). Liver biopsy demonstrates inflammatory obliteration of the extrahepatic biliary tree, with bile stasis and bile ductular proliferation in the liver. Histologic features may overlap with neonatal hepatitis, particularly early in the course of the disease, making it difficult to differentiate. Histologic transition from neonatal hepatitis to biliary atresia has been reported and may be a relatively common phenomenon. The duodenal intubation and aspiration test is a simple, rapid, inexpensive

P.959

method to check for patency of the extrahepatic biliary tree. Collection of 12 2-hour aliquots of duodenal drainage from a feeding tube placed in the duodenum over a 24-hour period suggests biliary atresia if no yellow fluid is present. Aspiration of bile-stained fluid from the duodenum suggests patency of the extrahepatic biliary tract. This test is sensitive and specific for the evaluation of infantile cholestasis (158). The test has reliability comparable to, or better than, radionuclide imaging with scans, which may give abnormal results in neonatal hepatitis during periods of severe cholestasis. Reliability of the radionuclide studies may be improved by measurement of duodenal fluid counts collected by a simple string test, in which infants swallow a string that absorbs fluid from the small intestine that later can be analyzed (159). The combination of liver biopsy

and imaging study or duodenal drainage usually is used to determine whether the patient is more likely to have biliary atresia or neonatal hepatitis. If bile drainage cannot be confirmed or the typical histologic picture of neonatal hepatitis is not apparent on liver biopsy, then surgical exploration and intraoperative cholangiography usually is performed to establish a final diagnosis.

If the patient has biliary atresia, a hepatoportoenterostomy with Roux-en-Y enteroanastomosis (i.e., Kasai procedure) is performed to attempt bile drainage. The Kasai procedure rarely alters the long-term outcome of biliary atresia (160, but may delay the necessity of liver transplantation. Some advocate not performing a Kasai procedure. Most, however, believe that performing the procedure does not worsen the prognosis at transplant and may allow the child to live longer so that a more suitable liver donor may be located before transplantation. For those infants with progressive liver disease after the Kasai procedure, every attempt must be made to optimize their condition before transplantation. Deficient absorption must be corrected by vitamin supplementation (i.e., A, D, E, and K) require supplementation. Salt and protein restriction may become necessary, as liver failure progresses.

Hepatic transplantation is the definitive treatment for biliary atresia and results in long-term survival in 70% to 85% of infants.

Other Causes of Cholestasis

Rare causes of cholestasis must be excluded before confirming the diagnosis of neonatal hepatitis or biliary atresia (Table 40-3) (151). Infectious diseases such as cytomegalovirus, hepatitis B, HIV, rubella, herpes, toxoplasmosis, and syphilis should be excluded by standard serologic or culture techniques. Metabolic disorders to be considered include tyrosinemia, galactosemia, and hereditary fructose intolerance. Obtaining urine for reducing substances to exclude galactosemia and hereditary fructose intolerance, and succinyl acetone to exclude tyrosinemia should be done immediately. Anatomic disorders such as choledochal cysts can be diagnosed by ultrasonography. Other causes such as TPN cholestasis or sepsis should be considered, based on the clinical presentation.

TABLE 40-3 STEPS IN EVALUATING NEONATAL CHOLESTASIS

1. Determine that hyperbilirubinemia is predominantly direct
2. Exclude metabolic and infectious causes of cholestasis
3. Perform ultrasound to exclude anatomic lesions
4. Obtain percutaneous liver biopsy and hepatobiliary scan or duodenal drainage study
5. Explore whether studies suggest biliary atresia and perform Kasai procedure if indicated

Occasionally, liver biopsy will demonstrate a marked reduction in the number of intrahepatic bile ducts, revealing a disorder known as paucity of the intrahepatic bile ducts or intrahepatic biliary hypoplasia. Some of these patients fall into the category of Alagille syndrome, also known as syndromic paucity or arteriohepatic dysplasia (161). These patients exhibit unusual facial characteristics, ocular abnormalities including posterior embryotoxon (i.e., prominent Schwalbe line), pulmonic stenosis, and vertebral arch defects, including anterior vertebral arch fusion with butterfly vertebrae. Careful cardiac examination, examination of the eyes by an ophthalmologist, and radiographic examination of the lumbosacral spine should be obtained in patients with suspected Alagille syndrome who have a paucity of intralobular bile ducts. Prognosis for long-term survival in syndromic patients is relatively good.

There are patients with nonsyndromic paucity who have liver biopsy findings similar to those with Alagille syndrome. In general, these patients have a much poorer prognosis than those with syndromic paucity. Life-threatening cirrhosis develops in many, and these patients may require hepatic transplantation. As in biliary atresia, liver transplantation has markedly changed the prognosis for these patients.

A number of infectious disorders, both viral and bacterial, may present during the neonatal period, and a specific diagnosis should be sought in such instances. Hepatitis B typically is found in infants whose mothers were infected during the third trimester. As many as 60% to 90% of infants born to hepatitis B surface antigen-positive mothers may be infected. Transmission from mother to infant most commonly occurs at the time of delivery. Mothers who are hepatitis B antigen-positive are at extremely high risk to transmit hepatitis B virus to their infants. Additionally, mothers who are chronic carriers of hepatitis B surface antigen also may infect their infants. Most hepatitis B in infancy is asymptomatic. Abnormal liver tests develop at approximately 6 to 8 weeks of age and may persist for up to 1 year. Nearly 50% of these children remain hepatitis B surface

antigen-positive and are at risk for developing hepatocellular carcinoma. Such children should be screened annually with α -fetoprotein levels for evidence of liver cancer, unless their hepatitis B surface antigen determinations revert to negative.

Maternal screening for hepatitis B surface antigen

P.960

is essential to prevent perinatal transmission of hepatitis B. Neonates born to mothers who are hepatitis B antigen-positive should receive hepatitis B hyperimmune globulin, 0.5 mL intramuscularly at the time of birth, and hepatitis B vaccine within 12 hours of birth. Booster immunizations with hepatitis B vaccine are recommended at 1 and 6 months of age (162).

Several other viruses may produce hepatitis during the neonatal period. Hepatitis A may develop in infants of mothers with active icteric hepatitis A at the time of delivery. Hepatitis C commonly is transmitted through blood contact and produces a clinical spectrum similar to hepatitis B. Serologic tests and viral RNA assays are available to detect hepatitis C. Infants with hepatitis B or C run substantial risks for chronic liver disease. Recent experience has been gained with the use of α -interferon in the treatment of chronic hepatitis B and C, and with lamivudine in hepatitis B. Preliminary results look promising, but more experience is needed. Other viruses, such as Epstein-Barr virus, cytomegalovirus, HIV, rubella, herpes simplex, coxsackievirus, and adenoviruses may cause a wide spectrum of neonatal liver disease (163). In most instances, infection with these viruses results in spontaneous resolution without chronic injury.

Bacteria also may produce neonatal liver injury, because invasion of the liver may occur. Specific hepatic infection may result from certain bacterial diseases such as syphilis and listeriosis, and the parasitic disorder toxoplasmosis.

A number of metabolic diseases may present with neonatal cholestasis. The most common is α 1-antitrypsin deficiency. α 1-Antitrypsin is the major protease inhibitor in the hepatocyte. Deficiency of α 1-antitrypsin occurs in a number of inheritable phenotypes. These Pi or protease inhibitor phenotypes can be determined. Type ZZ produces the most complete deficiency state and most cases of liver disease. It is estimated that 10% to 20% of type ZZ patients develop liver disease (164). Isolated cases of type MZ and MS also have been reported with liver injury (165). The ZZ phenotype is inherited through an autosomal recessive mechanism and occurs in 1 in 2,000 live births. Patients can be identified by the measurement of a very low α 1-antitrypsin level in the blood. Diagnosis is confirmed by the determination of the ZZ phenotype, plus the classic histologic findings of periodic-acid-Schiff-positive, diastase-resistant granules on liver biopsy.

Liver disease may develop in patients with cystic fibrosis, although very few of these present during the neonatal period. Measurement of sweat chloride and specific mutational analysis to exclude cystic fibrosis should be part of the evaluation of neonatal liver disease.

Three metabolic diseases present with rather fulminant neonatal liver disease. (See also Chapter 41.) These include galactosemia, hereditary fructose intolerance, and tyrosinemia. These disorders should be expected when coagulation abnormalities appear inappropriately severe relative to the apparent degree of liver disease. Fructose intolerance does not present in the neonatal period unless the infant is on a sucrose-containing formula (sucrose is metabolized to glucose and fructose). Patients with galactosemia have positive urinary reducing substances if they are being fed lactose at the time of screening. Patients with hereditary fructose intolerance also may test positive. Patients with tyrosinemia can be screened by measuring succinyl acetone content in the urine. Plasma and urine amino acids will demonstrate marked elevations of tyrosine, although this may be a nonspecific finding in any infant with neonatal liver disease. Patients with galactosemia respond to a galactose-free diet, and liver injury usually resolves spontaneously. Neonatal sepsis, particularly gram negative sepsis, is a frequent occurrence in these infants, and precautions should be taken. Patients with tyrosinemia commonly undergo progressive liver and renal dysfunction and are candidates for emergent liver transplantation once the diagnosis is made.

Several lipid storage diseases produce neonatal liver disease. Niemann-Pick disease, Wolman disease, cholesterol-ester storage disease, and Gaucher disease are included in this group. Most present with an insidious onset later in life.

A number of disorders exist in which paroxysmal dysfunction occurs. The most common is Zellweger syndrome, the cerebrohepatorenal syndrome. These patients present with cholestasis, hepatomegaly, hypotonia, and dysmorphic features, and may be diagnosed by demonstration of very-long-chain fatty acids in the serum.

Defects in the urea cycle may present with hyperammonemia during the first 2 days of life. A sepsis-like picture with vomiting, lethargy, seizures, and coma suggests this diagnosis. The most common form is ornithine transcarbamylase deficiency. Serum ammonia levels are very high, provided the infant is being fed protein. Diagnosis depends on plasma and urinary amino acid levels, and liver biopsy must be assayed for specific enzymes (see Chapter 41). Protein intake should be restricted and liver transplantation should be considered. Transient hyperammonemia of the newborn also has been reported with spontaneous resolution and no long-term neurologic sequelae. Permanent resolution of the hyperammonemia usually occurs by 2 weeks of age.

Another cause of acute liver failure in the neonate is neonatal hemochromatosis or neonatal iron storage disease (166,167). This rare, apparently inherited disorder of iron storage and metabolism may present with acute and rather fulminant liver failure characterized by severe cholestasis and coagulopathy. A variety of histologic findings have been observed in the livers of these patients, but they consistently have increased iron deposition in the liver and in other organs.

Salivary gland biopsy may be used to establish the diagnosis. The disorder is rapidly progressive and often fatal unless transplantation can be performed early. Recently, antioxidant cocktails have been advocated for such patients, and some success has been reported (168).

Cholestasis may occur in any patient on chronic parenteral nutrition, but it is far more common in sick premature infants who receive parenteral nutrition for long periods

P.961

of time (169,170). The mechanism by which the liver injury occurs is unknown and perhaps multifactorial (171). Several risk factors have been identified, however, including recurrent infections, prematurity, and lack of enteral feeding. Certain components of parenteral solutions have been implicated in causing liver injury. Excessive caloric administration may play a role. Certain amino acids may be more hepatotoxic, although many of these data are derived from animal studies. Higher doses of protein may result in a more rapid rise in bilirubin, but does not appear to alter ultimate risk of development of liver disease. Available intravenous lipid preparations do not appear to cause cholestasis and may, in fact, be beneficial in this regard.

The reason premature infants are more susceptible to liver disease while on parenteral nutrition probably is related to developmental immaturity of several hepatobiliary processes. These infants have reduced and altered bile acid synthesis, decreased bile acid pool size, and, therefore, decreased intraluminal bile acids. Gallbladder function also is impaired. Bile acid reabsorption from the small bowel is underdeveloped. The premature liver also is less capable of detoxifying potentially toxic secondary bile acids.

Lack of enteral feeding definitely predisposes to parenteral nutrition cholestasis. GI hormones that stimulate bile flow depend on enteral feeding for their release. Reduced gut motility in the unused bowel may contribute to bacterial proliferation and the resultant production of toxic secondary bile acids. Infection, especially GI, and GI surgery may potentiate the liver injury through related mechanisms. Limited amounts of enteral feeding, as tolerated, may be very beneficial in preventing liver injury in the parenteral nutrition-dependent infant.

Diagnosis of parenteral nutrition liver disease depends on exclusion of other causes of cholestasis in the parenteral nutrition-dependent patient. Separation of this disorder from other causes of cholestasis is difficult using standard laboratory tests. Histologic study is nonspecific, but may be helpful in making the diagnosis (172). The disease often is reversible once parenteral nutrition is discontinued. It occasionally may progress to cirrhosis, and hepatocellular carcinoma has been reported.

Treatment is accomplished best by discontinuing parenteral nutrition. If this cannot be accomplished, the following steps should be taken:

- Reevaluate solutions to ensure they are appropriately formulated and balanced.
- Use low-dose enteral feedings as tolerated to stimulate bile flow and gut motility.
- Cycle the parenteral nutrition so that it is given over only part of the day.
- Use amino acid solutions specially formulated for infants.

Other potential therapies, yet unproven, include cholergics such as Phenobarbital or ursodeoxycholic acid, hormone stimulation of bile flow, and bowel prokinetic agents. Success with combined intestinal-liver transplants suggests that this procedure may play an important role in infants with end-stage parenteral nutrition liver disease (173).

Chapter 41

Inherited Metabolic Disorders

Barbara K. Burton

Major advances in the recognition and treatment of inborn errors of metabolism have made it more essential than ever that the neonatologist be familiar with the clinical presentation of these disorders. Many of the diseases in this group are associated with symptoms in the neonatal period, and many affected infants find their way into neonatal intensive care units. The likelihood of establishing a diagnosis often is directly related to the level of awareness of the neonatologist responsible for the infant's care. Although many of the individual inborn errors of metabolism occur infrequently, collectively, they are not rare. There is no doubt that a significant number of children with these disorders are undiagnosed. Every geneticist has had the experience of diagnosing an inborn error of metabolism in a child and discovering that the parents have had one or more other children who died in early infancy of vague or undetermined causes. In such cases, it is reasonable to assume that the other children were similarly affected but undiagnosed. Autopsy findings in such cases are often nonspecific and unrevealing unless special biochemical studies are done. Infection often is suspected as the cause of death, and sepsis is a common accompaniment of inherited metabolic disorders.

The significance of the precise diagnosis of metabolic disease cannot be overemphasized. Increasingly, these disorders are lending themselves to successful medical management. If treatment means the prevention of significant mental retardation or death, even when the numbers are small, the diagnosis is clearly worth pursuing. However, the success of most treatment regimens depends on the earliest possible institution of therapy, stressing the importance of early clinical diagnosis. Even when no effective therapy exists or an infant cannot be salvaged, diagnosis is critical for purposes of genetic counseling.

Inborn errors of metabolism are all genetically transmitted, typically in an autosomal recessive or X-linked recessive fashion, and there is usually a substantial risk of recurrence. Prenatal diagnosis is available for many conditions in this group. Awareness of the diagnosis before birth of an at-risk infant can lead to earlier therapy and an improved prognosis.

This chapter defines the constellation of findings in the newborn that should alert the clinician to the possibility of inherited metabolic disease. The discussion is confined to the disorders for which manifestations are observed in the first few months of life and does not include the many disorders (e.g., most lysosomal storage diseases) that typically present in later infancy or childhood. The laboratory tools used to evaluate infants suspected of having inherited metabolic disease are discussed. Treatment of important groups of metabolic disorders are addressed, focusing on the stabilization and acute management of patients with these conditions.

A list of the major inborn errors of metabolism that have been described clinically in early infancy is shown in Table 41-1. This table cannot be considered complete because it includes only the disorders for which manifestations in the first few months of life have been documented in the literature. It is likely that disorders typically occurring later in childhood occasionally may present as early as the first month of life. New disorders causing neonatal disease undoubtedly will continue to be described. A single literature reference is listed for each disorder in the table, and detailed information about most of the disorders listed can be found in recent editions of reference textbooks 1 (1,2).

CLINICAL MANIFESTATIONS OF INBORN ERRORS OF METABOLISM

Acute Metabolic Encephalopathy

Several groups of inherited metabolic disorders, most notably the organic acidemias, urea cycle defects, and certain disorders of amino acid metabolism, typically present with acute life-threatening symptoms in the neonatal period. Because they are associated with protein intolerance, symptoms usually begin after feedings have been instituted.

P.966

P.967

Affected infants are typically full term and usually appear normal at birth. The interval between birth and clinical

symptoms ranges from hours to weeks. The initial findings are usually those of lethargy and poor feeding, as seen in almost any sick infant. Although sepsis is often the first consideration in infants who present in this way, these symptoms in a full-term infant with no specific risk factors strongly suggest a metabolic disorder. Infants with inborn errors of metabolism may rather quickly become debilitated and septic; therefore, it is important that the presence of sepsis not preclude consideration of other possibilities. The lethargy associated with these conditions is an early symptom of a metabolic encephalopathy that may progress to coma. Other signs of central nervous system (CNS) dysfunction, such as seizures and abnormal muscle tone, may also exist. Evidence of cerebral edema may be observed, and intracranial hemorrhage occasionally occurs (3).

TABLE 41-1 INBORN ERRORS OF METABOLISM THAT PRESENT IN EARLY INFANCY

Disorder	Reference
Disorders of Carbohydrate Metabolism	
Galactosemia (i.e., galactose-1-phosphate uridyl transferase deficiency)	39
Hereditary fructose intolerance (i.e., fructose-1-phosphate aldolase deficiency)	40
Fructose-1,6-bisphosphatase deficiency	41
Glycogen storage disease type I (i.e., von Gierke disease, glucose-6-phosphate deficiency)	42
Glycogen storage disease type II (i.e., Pompe disease, alpha-glucosidase deficiency)	43
Glycogen storage disease type III (i.e., limit dextrinosis, debrancher deficiency)	42
Glycogen storage disease type IV (i.e., amylopectinosis, brancher deficiency)	44
Disorders of Amino Acid Metabolism	
Maple syrup urine disease	45
Homocystinuria	46
Nonketotic hyperglycinemia	47
Phenylketonuria	48
Hereditary tyrosinemia	49
Hyperornithinemia-hyperammonemia-homocitrullinuria syndrome	50
Lysinuric protein intolerance	51
Methylene tetrahydrofolate reductase deficiency	52
Pyridoxine dependency with seizures (i.e., presumed glutamic acid decarboxylase deficiency)	53
Organic Acidemias	
Methylmalonic acidemia	54
Methylmalonic acidemia with homocystinuria	55
Propionic acidemia	56
Isovaleric acidemia	57
3-Methyl crotonyl CoA carboxylase deficiency	58
Holocarboxylase synthetase deficiency (i.e., early-onset multiple carboxylase deficiency)	59
Biotinidase deficiency (i.e., late-onset multiple carboxylase deficiency)	60
Glutaric acidemia type I	61
Glutaric acidemia type II (i.e., multiple acyl CoA dehydrogenase deficiency, severe)	62
Ethylmalonic-adipic aciduria (i.e., later-onset glutaric acidemia type II, multiple acyl CoA dehydrogenase deficiencies, mild)	63
3-Hydroxy-3-methylglutaric acidemia	64
2-Methylacetoacetyl-CoA thiolase deficiency	65
Mevalonic aciduria	66
Pyroglutamic aciduria	67
3-Hydroxyisobutyric aciduria	68
3-Methylglutaconic aciduria	69
2-Methylbutyryl CoA dehydrogenase deficiency	70
Urea Cycle Disorders	
Carbamyl phosphate synthetase deficiency	71
Ornithine transcarbamylase deficiency	71
Citrullinemia	71
Argininosuccinic aciduria	71

Arginase deficiency	72
<i>N</i> -Acetylglutamate synthetase deficiency	73
Fatty Acid Oxidation Defects	
Short-chain acyl CoA dehydrogenase deficiency	74
Medium-chain acyl CoA dehydrogenase deficiency	75
Very-long-chain acyl CoA dehydrogenase deficiency	76
Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency	77
Carnitine-acylcarnitine translocase deficiency	78
Carnitine transporter deficiency (i.e., primary systemic carnitine deficiency)	79
Carnitine palmitoyl transferase II deficiency	80
Isobutyryl-CoA dehydrogenase deficiency	81
Lactic Acidemias	
Pyruvate dehydrogenase deficiency	32
Pyruvate carboxylase deficiency	82
Phosphoenolpyruvate carboxykinase deficiency	83
Mitochondrial encephalomyopathies	84
Transport Disorders	
Cystic fibrosis	85
Infantile free sialic acid storage disease	86
Hartnup disease	87
Lysosomal Storage Disorders	
GM ₁ gangliosidosis type I (i.e., generalized gangliosidosis, beta-galactosidase deficiency)	88
Gaucher disease type II (i.e., glucocerebrosidase deficiency)	89
Niemann-Pick disease types A and B (i.e., sphingomyelinase deficiency)	90
Niemann-Pick disease type C	91
Mannosidosis (i.e., <i>α</i> -mannosidase deficiency)	92
Fucosidosis (i.e., <i>α</i> -fucosidase deficiency)	93
Farber disease (i.e., acid ceramidase deficiency)	94
Wolman disease (i.e., acid lipase deficiency)	95
Krabbe disease (i.e., galactocerebrosidase deficiency)	96
Mucopolysaccharidosis type VI (i.e., Maroteaux-Lamy syndrome, arylsulfatase B deficiency)	97
Mucopolysaccharidosis type VII (i.e., beta-glucuronidase deficiency)	98
Mucopolipidosis type II (i.e., I-cell disease)	99
Mucopolipidosis type IV	100
Multiple sulfatase deficiency	101
Sialidosis type II (i.e., neuraminidase deficiency)	102
Peroxisomal Disorders	
Zellweger syndrome	103
Neonatal adrenoleukodystrophy	103
Rhizomelic chondrodysplasia punctata	103
Disorders of Metal Metabolism	
Menke kinky hair disease	104
Molybdenum cofactor deficiency	105
Sulfite oxidase deficiency	106
Neonatal hemochromatosis	107
Other Disorder	
Congenital adrenal hyperplasia	108
Carbohydrate deficient glycoprotein syndrome	109
Hereditary orotic aciduria	110
Hypophosphatasia	111
Crigler-Najjar syndrome	112
A ₁ -antitrypsin deficiency	113

Canavan disease (i.e., aspartoacylase deficiency)	114
Steroid sulfatase deficiency	115
Senger syndrome	116
Smith-Lemli-Opitz syndrome	32
Lowe syndrome	117

An infant with an inborn error of metabolism who presents more abruptly or in whom the lethargy and poor feeding go unnoticed may first come to attention because of

P.968

apnea or respiratory distress. The apnea is typically central in origin and a symptom of the metabolic encephalopathy, but tachypnea may be a symptom of an underlying metabolic acidosis, as occurs in the organic acidemias. Infants with urea cycle defects and evolving hyperammonemic coma initially exhibit central hyperventilation, which leads to respiratory alkalosis. Indeed, the finding of respiratory alkalosis in an infant with lethargy is virtually pathognomonic of hyperammonemic encephalopathy.

TABLE 41-2 LABORATORY STUDIES FOR AN INFANT SUSPECTED OF HAVING AN INBORN ERROR OF METABOLISM

Complete blood count with differential
Urinalysis
Blood gases
Electrolytes
Blood glucose
Plasma ammonia
Urine reducing substances
Urine ketones if acidosis or hypoglycemia is present
Plasma and urine amino acids, quantitative
Urine organic acids
Plasma lactate

Vomiting is a striking feature of many of the inborn errors of metabolism associated with protein intolerance, although it is less common in the newborn than in the older infant. If persistent vomiting occurs in the neonatal period, it usually signals significant underlying disease. Inborn errors of metabolism should always be considered in the differential diagnosis. It is common for an infant to be diagnosed as having a metabolic disorder after having undergone surgery for suspected pyloric stenosis (4). Formula intolerance frequently is suspected, and many affected infants have numerous formula changes before a diagnosis finally is established.

The basic laboratory studies that should be obtained for an infant who has acute life-threatening symptoms consistent with an inborn error of metabolism are listed in Table 41-2.

HYPERAMMONEMIA

Among the most important laboratory findings associated with inborn errors of metabolism presenting with an acute encephalopathy is hyperammonemia. A plasma ammonia level should be obtained for any infant with unexplained vomiting, lethargy, or other evidence of an encephalopathy. Significant hyperammonemia is observed in a limited number of conditions. Inborn errors of metabolism, including urea cycle defects and many of the organic acidemias, are at the top of the list. Also in the differential diagnosis is a condition referred to as transient hyperammonemia of the newborn (THAN) (5). Ammonia levels in these conditions frequently exceed 1,000 $\mu\text{mol/L}$. The finding of marked hyperammonemia provides an important clue to diagnosis and indicates the need for urgent treatment to reduce the ammonia level. The degree of neurologic impairment and developmental delay subsequently observed in infants with urea cycle defects depends on the duration of the neonatal hyperammonemic coma (6).

A flow chart for the differentiation of conditions producing significant hyperammonemia in the newborn is shown in Fig. 41-1. The timing of the onset of symptoms may provide an important clue. Infants with urea cycle defects typically do not become symptomatic until after 24 hours of age. Patients with some of the organic acidemias, such as glutaric acidemia type II, or with pyruvate carboxylase deficiency may exhibit symptomatic hyperammonemia during the first 24 hours. Symptoms in the first 24 hours are characteristic of THAN, a

condition that is poorly understood but apparently not genetically determined. The typical patient with this disorder is a large premature infant (mean gestational age of 36 weeks) who has symptomatic pulmonary disease, often from birth, and severe hyperammonemia. Survivors do not have recurrent episodes of hyperammonemia and may or may not exhibit neurologic sequelae, depending on the extent of the neonatal insult. There are some affected infants who survive with normal intelligence despite extraordinarily high ammonia levels (5). The disorder has become extremely rare in recent years for unknown reasons.

Infants who develop severe hyperammonemia after 24 hours of age usually have a urea cycle defect or an organic acidemia; infants with organic acidemias typically exhibit a metabolic acidosis and ketonuria as well. Urine organic acids should always be obtained, regardless of whether or not acidosis is present. Metabolic acidosis is not a feature of the urea cycle defects. Plasma amino acid analysis is helpful in the differentiation of the specific defects in this group. Characteristic amino acid abnormalities provide a definitive diagnosis of citrullinemia and argininosuccinic aciduria. Although no diagnostic amino acid elevations are observed in carbamyl phosphate synthetase deficiency or ornithine transcarbamylase deficiency, a low or undetectable level of plasma citrulline is observed in both of these conditions. This finding is helpful in differentiating these two conditions from THAN, in which the plasma citrulline level is normal. However, plasma citrulline is not accurately measured in all laboratories performing amino acid analysis, probably because it is important in few other clinical settings. In clinical situations in which this is a critical diagnostic test, samples should be sent to laboratories with expertise in the differentiation of urea cycle defects. Carbamyl phosphate synthetase deficiency and ornithine transcarbamylase deficiency may be differentiated by measuring urine orotic acid, which is low in the former and elevated in the latter. The pattern of inheritance of the two may also help to differentiate them; ornithine transcarbamylase deficiency, an X-linked disorder, rarely produces severe hyperammonemia in a female infant, whereas carbamyl phosphate synthetase deficiency, an autosomal recessive disorder, occurs with equal frequency in the two genders.

Although the clinical and laboratory evaluation outlined should lead to a specific tentative diagnosis for virtually

P.969

all patients, liver biopsy may be indicated for enzymatic confirmation of the diagnoses of carbamyl phosphate synthetase and ornithine transcarbamylase deficiencies, because these diagnoses dictate rigid lifelong therapy or consideration of hepatic transplantation. Acute treatment should be based on the presumptive diagnosis, with biopsy considered only after the infant is stabilized.

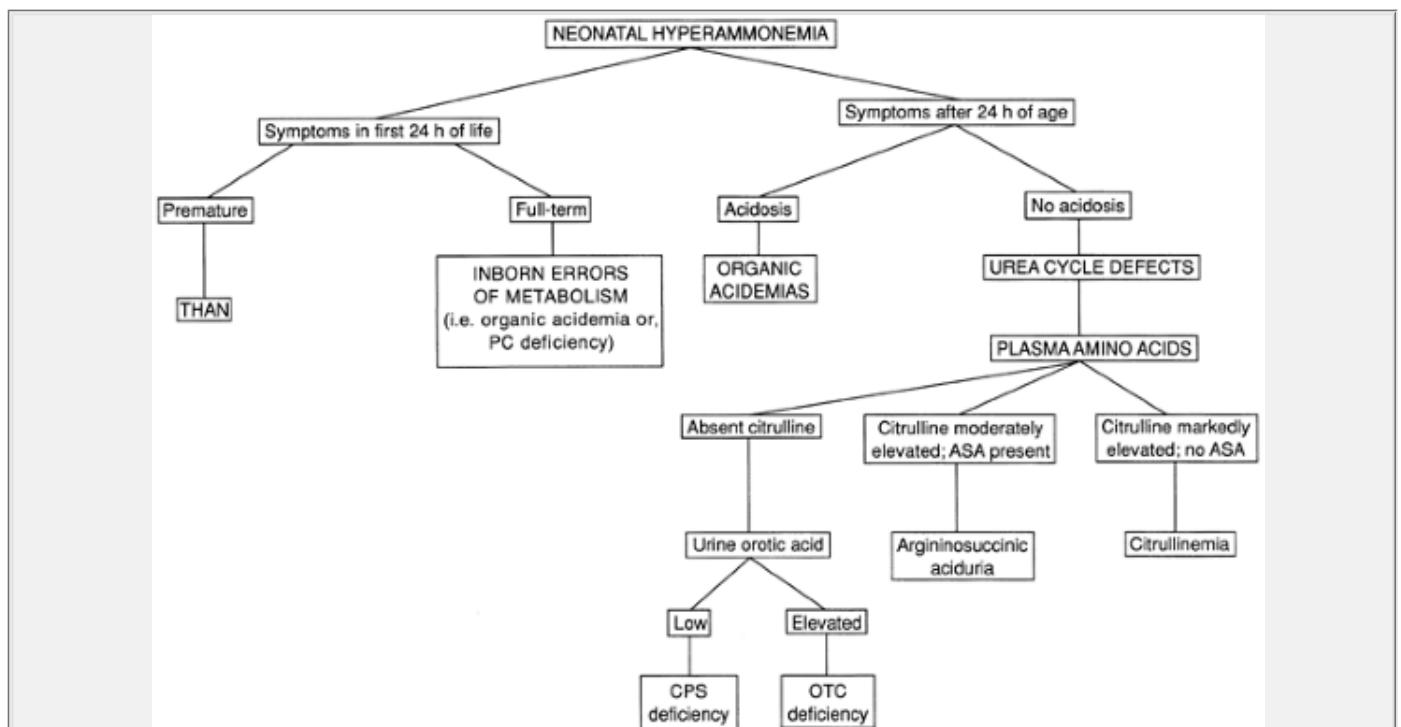

Figure 41-1 Differentiating between conditions that produce severe neonatal hyperammonemia. ASA, argininosuccinic acid; CPS, carbamyl phosphate synthetase; OTC, ornithine transcarbamylase; PC, pyruvate carboxylase; THAN, transient hyperammonemia of the newborn.

Less significant elevations of plasma ammonia than those associated with inborn errors of metabolism and THAN can be observed in a variety of other conditions associated with liver dysfunction, including sepsis, generalized

herpes simplex infection, and perinatal asphyxia. Liver function studies should be obtained in evaluating the significance of moderate elevations of plasma ammonia. However, even in cases of severe hepatic necrosis, it is rare for ammonia levels to exceed 500 $\mu\text{mol/L}$ (7). Mild transient hyperammonemia with ammonia levels as high as twice normal is relatively common in the newborn, especially in the premature infant, and is usually asymptomatic. It appears to be of no clinical significance, and there are no long-term neurologic sequelae (8).

METABOLIC ACIDOSIS

The second important laboratory feature of many of the inborn errors of metabolism during acute episodes of illness is metabolic acidosis with an increased anion gap, readily demonstrable by measurement of arterial blood gases or serum electrolytes and bicarbonate. A flow chart for the evaluation of infants with this finding is shown in Fig. 41-2. An increased anion gap (greater than 16) is observed in many inborn errors of metabolism and in most other conditions producing metabolic acidosis in the neonate. The differential diagnosis of metabolic acidosis with a normal anion gap essentially is limited to two conditions, diarrhea and renal tubular acidosis. Among the inborn errors, the largest group typically associated with overwhelming metabolic acidosis in infancy is the group of organic acidemias, including methylmalonic acidemia, propionic acidemia, and isovaleric acidemia. The list of disorders in this group has expanded dramatically as new disorders have been defined through the use of organic acid analysis.

In addition to specific organic acid intermediates, plasma lactate often is elevated in organic acidemias as a result of secondary interference with coenzyme A (CoA) metabolism. Neutropenia and thrombocytopenia commonly are observed and further underscore the clinical similarity of these disorders to neonatal sepsis. Hyperammonemia, sometimes as dramatic as that associated with urea cycle defects, is seen commonly but not uniformly in critically ill neonates with organic acidemias.

The metabolic acidosis associated with organic acidemias and certain other inborn errors of metabolism may have

P.970

significant adverse impact on many different organ systems, which may lead to the erroneous diagnosis of a wide variety of seemingly unrelated disorders. I had the experience of caring for an infant with isovaleric acidemia who presented at 10 days of age with respiratory distress, severe metabolic acidosis, a dilated heart, and poor cardiac output. The infant was suspected of having the hypoplastic left heart syndrome or other severe congenital heart disease. Cardiac catheterization was performed, even though members of the nursing staff had observed that the infant had a strong unpleasant odor, reminiscent of sweaty feet. Personnel in the catheterization laboratory also noticed that the blood had a strong peculiar odor, but it was not until 18 hours later, long after significant heart disease had been ruled out, that the diagnosis of metabolic disease was first considered. Despite attempts at therapy with dialysis and other measures, the child succumbed to the disease. In this case, the metabolic acidosis led to poor function of the myocardium and not the reverse.

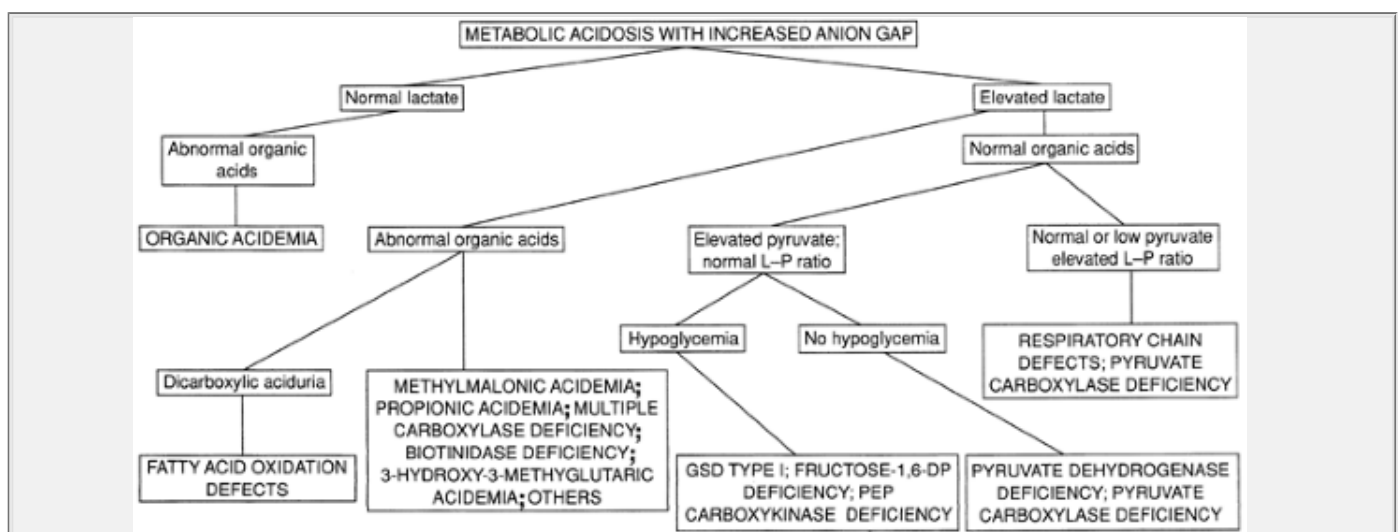

Figure 41-2 Evaluating metabolic acidosis in the young infant. fructose-1,6-DP, fructose-1,6-bisphosphatase; GSD, glycogen storage disease; L/P, lactate/pyruvate.

Another child subsequently found to have methylmalonic acidemia was admitted through the emergency room

with severe metabolic acidosis and a tight, distended abdomen with evidence of multiple air-fluid levels on X-ray films. The history revealed that the child had fed poorly since birth and had repeated episodes of vomiting despite several formula changes. Intestinal obstruction was suspected, and the child was taken to the operating room, in which most of the small intestine was found to be infarcted, presumably secondary to the acidosis and poor tissue perfusion. No anatomic abnormalities were found. Postoperatively, metabolic disease was considered, and the diagnosis of a vitamin B12-responsive form of methylmalonic acidemia was made. The infant died of complications of the disease even though the early diagnosis and treatment of this disorder, before the terminal episode, should have been associated with a good prognosis.

Defects in pyruvate metabolism or in the respiratory chain may lead to primary lactic acidosis presenting as severe metabolic acidosis in infancy (9,10). Unlike most of the other conditions presenting acutely in the newborn, the clinical features of these disorders are unrelated to protein intake. Disorders in this group should be considered in patients with lactic acidosis who have normal or nondiagnostic urine organic acids. Differentiation of the various disorders in this group can be facilitated by measuring plasma pyruvate and calculating the lactate/pyruvate ratio. A normal ratio (less than 25) suggests a defect in pyruvate dehydrogenase (PDH) or in gluconeogenesis, and an elevated ratio (greater than 25) suggests pyruvate carboxylase deficiency or a mitochondrial respiratory chain defect.

Not all infants with life-threatening metabolic disease have metabolic acidosis or hyperammonemia. For example, patients with nonketotic hyperglycinemia typically present in the neonatal period with evidence of severe and progressive CNS dysfunction, but do not exhibit metabolic acidosis or hyperammonemia (11). Even patients with galactosemia rarely may present with symptoms of acute CNS toxicity, which may progress to cerebral edema, when galactose-1-phosphate levels rise precipitously. Therefore, a series of laboratory studies designed to screen for inborn errors of metabolism should be obtained for any infant with clinical findings suggesting an inborn error of metabolism, even if metabolic acidosis and hyperammonemia are not present. These studies are listed in Table 41-2. Most are self-explanatory. Although not available in many hospital laboratories, amino acid and organic acid analysis can be obtained in any part of the country through reference

P.971

laboratories or through referral of samples to medical center genetics units. It is important to insist that any reference laboratory used for this purpose provide prompt test results and reference ranges and provide interpretation of abnormal results.

TABLE 41-3 DISORDERS ASSOCIATED WITH NONGLUCOSE REDUCING SUBSTANCES IN URINE	
Disorder	Compound
Galactosemia	Galactose
Hereditary fructose intolerance	Fructose
Hereditary tyrosinemia	p-Hydroxy-phenylpyruvic acid
Galactokinase deficiency	Galactose
Essential fructosuria	Fructose
Pentosuria	Xylulose
Severe liver disease with secondary galactose intolerance	Galactose

Urine testing for reducing substances should be performed using Benedict reagent (Clintest tablets, Miles, Elkhart, IN). If the result is positive, the urine should be tested for glucose by dipstick. A nonglucose reducing substance in the urine is probably galactose, but there are other possibilities (Table 41-3).

Several disorders associated with an acute metabolic encephalopathy in the neonate deserve special mention because they typically are not associated with hyperammonemia or metabolic acidosis. One of these is nonketotic hyperglycinemia, a condition that typically results in severe and progressive CNS dysfunction, including obtundation, seizures, and altered muscle tone. Routine laboratory studies all yield normal findings. The first diagnostic clue is usually the finding of elevated glycine on plasma amino acid analysis. The diagnosis is confirmed by measurement of cerebrospinal fluid (CSF) glycine and demonstration of an elevated CSF to plasma glycine ratio. Although therapy of infants with nonketotic hyperglycinemia has been attempted with dietary protein restriction, sodium benzoate, and a variety of other drugs, the results have been disappointing. Most

infants with this disorder die or exhibit significant neurologic impairment.

TABLE 41-4 MAJOR INBORN ERRORS OF METABOLISM PRESENTING IN THE NEONATE AS AN ACUTE ENCEPHALOPATHY

Disorders	Characteristic Laboratory Findings
Organic acidemias (includes MMA, PA, IVA, MCD and many less common conditions)	Metabolic acidosis with increased anion gap; elevated plasma and urine ketones; variably elevated plasma ammonia and lactate; abnormal urine organic acids
Urea cycle defects	Respiratory alkalosis, no metabolic acidosis; markedly elevated plasma ammonia; elevated urine orotic acid in OTCD; abnormal plasma amino acids
Maple syrup urine disease	Metabolic acidosis with increased anion gap; elevated plasma and urine ketones; abnormal plasma amino acids
Non-ketotic hyperglycinemia	No acid-base or electrolyte abnormalities; normal ammonia; abnormal plasma amino acids
Molybdenum cofactor deficiency	No acid-base or electrolyte abnormalities; normal ammonia; normal amino and organic acids; low serum uric acid; elevated sulfites in urine

IVA, isovaleric acidemia; MCD, multiple carboxylase deficiency; MMA, methylmalonic acidemia; OTCD, ornithine transcarbamylase deficiency; PA, propionic acidemia.

A second disorder that produces a progressive encephalopathy with no clues on routine laboratory studies is molybdenum cofactor deficiency. The neurologic findings in the affected infant are virtually indistinguishable from those associated with hypoxic-ischemic encephalopathy. Surviving infants exhibit similar neurologic sequelae including cerebral palsy, mental retardation, and seizures. The diagnosis may be suggested by the finding of hypouricemia or, beyond the neonatal period, by ectopia lentis noted on ophthalmologic examination. If it is suspected, urine should be screened for the presence of sulfites, a finding attributable to a deficiency of the enzyme sulfite oxidase, which accompanies the disorder.

The inborn errors of metabolism most likely to be associated with an acute encephalopathy in the newborn are summarized in Table 41-4. The typical laboratory findings in each condition or group of conditions also are listed.

EMERGENCY TREATMENT OF THE INFANT WITH AN ACUTE METABOLIC ENCEPHALOPATHY

When an inborn error of metabolism, such as an organic acidemia or urea cycle defect, is suspected in a critically ill infant, immediate treatment should be initiated even if a definitive diagnosis may not yet be established. Within 48 to 72 hours, the results of amino acid and organic acid analyses should be available, allowing diagnostic confirmation in

P.972

most cases. Appropriate and aggressive treatment before the confirmation of a diagnosis may be life saving and may avert or reduce the neurologic sequelae of some of these disorders. The immediate treatment of infants with disorders in this group has two primary goals. The first is the removal of accumulated metabolites, such as organic acid intermediates or ammonia. At the first suspicion of a disorder associated with protein intolerance, protein intake in the form of breast milk, infant formula, or hyperalimentation should be discontinued immediately. In critically ill infants with hyperammonemia, arrangements should be made for hemodialysis. Although peritoneal dialysis, continuous arteriovenous hemoperfusion, and exchange transfusion all have been used in the past to lower plasma ammonia levels, all are substantially less effective than hemodialysis (12). In infants who are comatose, ventilator dependent, or exhibit evidence of cerebral edema, dialysis should be instituted immediately without waiting to see if there is a response to dietary manipulation, medication, or other less aggressive therapy. Maximal supportive care should be provided simultaneously. In patients suspected of having a urea cycle defect because of significant hyperammonemia without acidosis, an infusion of 6 cc/kg of

10% arginine hydrochloride (HC1) (0.6 g/kg) can be given intravenously over 90 minutes. In patients with citrullinemia and argininosuccinic aciduria, this often results in a precipitous drop in the plasma ammonia level. An intravenous arginine preparation is commercially available and should be readily accessible from any hospital pharmacy.

If an organic acidemia is suspected, vitamin B12 (1 mg) should be given intramuscularly in case the patient has a vitamin B12-responsive form of methylmalonic acidemia. Biotin (10 mg) should be given orally or by nasogastric tube, because some patients with multiple carboxylase deficiency are biotin responsive. If acidosis exists, intravenous bicarbonate should be administered liberally. Calculations of bicarbonate requirements appropriate for the treatment of other conditions rarely are adequate in these disorders because of ongoing production of organic acids or lactate. The acid-base status should be monitored frequently, with therapy adjusted accordingly.

After removing toxic metabolites, the second major goal of therapy in infants with inborn errors of metabolism should be to prevent catabolism. Ten percent glucose should be liberally administered intravenously, because it is important to provide as many calories as possible. Intravenous lipids can be given to infants with urea cycle defects and other disorders in which dietary fat plays no role. Protein should not be withheld indefinitely. If clinical improvement is observed and a final diagnosis has not been established, some amino acid intake should be provided after 2 to 3 days of complete protein restriction. Essential amino acids or total protein can be provided orally or intravenously at an initial dose of 0.5 g protein/kg body weight/24 hours. This should be increased incrementally to 1.0 g/kg/24 hours and held at that level until the diagnostic evaluation is complete and plans can be made for definitive long-term therapy. Therapy should be planned in conjunction with a geneticist or specialist in metabolic disease. Until then, supplemental calories and nutrients can be provided orally using protein-free diet powder (Product 80056, Mead Johnson, or Prophree, Ross Laboratories).

The chronic therapy of urea cycle defects and most of the organic acidemias involves restriction of dietary protein. Depending on the specific diagnosis, this may be accomplished by simple restriction of total protein intake in breast milk or standard infant formula or by use of special formulas designed for individual inborn errors of metabolism. Formulas have been developed for many of the more common metabolic disorders and are commercially available. These specialized formulas typically are deficient in one or several specific amino acids. Dietary treatment alone may be effective in management of some patients with organic acidemias and in several disorders of amino acid metabolism, such as maple syrup urine disease.

In several of the vitamin-responsive disorders, such as methylmalonic acidemia, multiple carboxylase deficiency, and homocystinuria, dietary protein restriction may be combined with specific cofactor therapy. In the organic acidemias and certain other disorders, L-carnitine, usually beginning with a dose of 100 mg/kg/d, may be given. Acyl-CoAs accumulating in these disorders combine with carnitine to produce acylcarnitine that are water soluble and excreted in the urine. Without treatment, many patients with these disorders develop a secondary carnitine deficiency. Treatment with exogenous carnitine prevents the development of symptoms of carnitine deficiency and provides a measure of protection against recurrent episodes of metabolic decompensation by providing an augmented mechanism for excretion of accumulated meta-bolites.

Patients with urea cycle defects require supplementation with oral arginine or, in some cases, citrulline, which is converted to arginine in the body. In normal persons, adequate amounts of arginine are synthesized via the urea cycle. Patients with a defect in urea synthesis have deficient arginine production and must depend on dietary supplementation. In the case of carbamyl phosphate synthetase and ornithine transcarbamylase deficiencies, the most severe of the urea cycle defects, drug therapy also is required. These disorders were formerly almost uniformly lethal in the neonatal period. The development of novel drugs that provide an alternate pathway for waste nitrogen excretion has allowed survival of many affected infants (13). Sodium benzoate and sodium phenylacetate were the agents originally used, but these have been replaced largely for oral use by sodium phenylbutyrate.

Despite rigorous therapy and intensive surveillance, patients with urea cycle defects remain at risk for intercurrent episodes of hyperammonemia, which may result in death or neurologic sequelae. The risk appears to be greatest for patients with carbamyl phosphate synthetase and ornithine transcarbamylase deficiency. Liver transplantation should be considered seriously for patients with these disorders, if they can be stabilized.

HYPOGLYCEMIA

Hypoglycemia and its associated symptoms occasionally may be seen in infants with disorders of protein

intolerance, but it more commonly is seen in disorders of carbohydrate metabolism or of fatty acid oxidation. Among the best known inborn errors of metabolism associated with hypoglycemia are the glycogen storage diseases, of which types I and III are the most likely to be associated with manifestations in the neonatal period. The hypoglycemia in these disorders is related to the inability of the liver to release glucose from glycogen, and it is most profound during periods of fasting. Hypoglycemia, hepatomegaly, and lactic acidosis are prominent features of these disorders. Hypoglycemia is not a feature of glycogen storage disease type II (Pompe disease) because cytoplasmic glycogen metabolism and release are normal in this disorder, in which glycogen accumulates within lysosomes as a result of the deficiency of the lysosomal enzyme α -1,4-glucosidase. The clinical manifestations of this disorder include macro-glossia, hypotonia, cardiomegaly with congestive heart failure, and hepatomegaly. Cardiomegaly is the most striking and may be apparent in the neonatal period. Congestive heart failure is the cause of death in most cases.

A disorder that presents clinically with findings virtually indistinguishable from the hepatic glycogen storage diseases types I and III is fructose-1,6-bisphosphatase deficiency, a disorder of gluconeogenesis. Several other disorders of gluconeogenesis have been described. The basic immediate treatment of all of these disorders is frequent feedings and glucose administration. The definitive diagnosis is made by liver biopsy and assay of appropriate hepatic enzymes. In some cases, enzymatic assays can be performed using lymphocytes or cultured skin fibroblasts.

A number of inherited defects in fatty acid oxidation have been identified in infants presenting with hypoglycemia. Although many of the disorders in this group typically present after 2 months of age, neonatal manifestations may be observed. These disorders are important because of their apparent frequency and because of the variability of the initial presentation. Affected infants have an impaired capacity to use stored fat for fuel during periods of fasting and readily deplete their glycogen stores. Despite the development of hypoglycemia, acetyl CoA production is diminished, and ketone production is impaired. The hypoglycemia occurring in these conditions typically is characterized as nonketotic, although small amounts of ketones may be produced. Hypoglycemia may occur as an isolated finding or may be accompanied by many of the other biochemical derangements typically associated with Reye's syndrome, such as hyperammonemia, metabolic acidosis, and elevated transaminases. Hepatomegaly may or may not be present. Any infant presenting with findings suggesting Reye's syndrome should be evaluated for fatty acid oxidation defects. As the incidence of true Reye's syndrome has decreased, most children presenting at any age with this constellation of findings have an inherited metabolic disorder.

The most common of the fatty acid oxidation defects is medium-chain acyl-CoA dehydrogenase deficiency, which is estimated to occur in 1 of 15,000 births, an incidence similar to that observed for phenylketonuria (PKU) (14, 15). It is among the most common inborn errors of metabolism. In addition to presenting as nonketotic hypoglycemia or a Reye's-like syndrome, it may present as sudden death or an acute life-threatening event. Many infants diagnosed as having medium-chain acyl-CoA dehydrogenase deficiency have a history of a sibling who died of sudden infant death syndrome (16). Fat accumulation in the liver or muscle of any infant who dies unexpectedly should strongly suggest the possibility of this or a related disorder of fatty acid oxidation. Very-long-chain fatty acyl-CoA dehydrogenase deficiency is associated with similar clinical findings, although there may be evidence of a significant cardiomyopathy. Infants with this defect may present with cardiac arrhythmias or unexplained cardiac arrest. Defects in the carnitine cycle or in carnitine uptake also may lead to a profound defect in fatty acid oxidation and result in sudden neonatal death.

The accumulation of fatty acyl-CoAs in patients with fatty acid oxidation defects leads to a secondary carnitine deficiency, probably as a result of excretion of excess acylcarnitine in the urine (17,18). Urine organic acid analysis and measurement of serum carnitine and analysis of the plasma acylcarnitine profile are the most helpful laboratory studies in the initial screening for defects in fatty acid oxidation. These studies are sufficient to establish the diagnosis of medium-chain acyl-CoA dehydrogenase deficiency, which is associated with the presence of a characteristic metabolite, octanoylcarnitine, on the acylcarnitine profile. Enzymatic assays may be necessary for the definitive diagnosis of some of the fatty acid oxidation defects. As is true for the defects in carbohydrate metabolism leading to hypoglycemia, treatment of the fatty acid oxidation defects involves avoidance of fasting and provision of adequate glucose. Restriction of dietary fat intake and supplemental l-carnitine therapy at a dose of 50 to 100 mg/kg/d is recommended. With appropriate therapy, patients with medium-chain acyl-CoA dehydrogenase deficiency appear to have an excellent prognosis. The prognosis for the other fatty acid oxidation defects is more variable.

JAUNDICE AND LIVER DYSFUNCTION

Jaundice or other evidence of liver dysfunction may be the presenting finding in a number of inherited metabolic disorders in the neonatal period. These are listed in Table 41-5, along with the laboratory studies useful in diagnosis. For most of the inborn errors of metabolism associated with jaundice, the elevated serum bilirubin is of the direct-reacting type. This generalization does not include those inborn errors of erythrocyte metabolism, such as

glucose-6-phosphate dehydrogenase deficiency or pyruvate kinase deficiency, which occasionally are responsible for hemo-lytic disease in the newborn. The best-known metabolic disease associated with jaundice is galactosemia, in which the deficiency of the enzyme galactose-1-phosphate uridylyl transferase results in an accumulation of galactose-1-phosphate and other metabolites, such as galactitol, which are thought to have a direct toxic effect on the liver and on other organs. Jaundice and liver dysfunction in this disorder are progressive and usually appear at the end of the first or during the second week of life, with vomiting, diarrhea, poor weight gain, and eventual cataract formation if the infant is receiving breast milk or a galactose-containing formula. Hypoglycemia may be observed. The disease may present initially with indirect hyperbilirubinemia resulting from hemolysis secondary to high levels of galactose-1-phosphate in erythrocytes. Alternatively, the effects of acute galactose toxicity on the brain rarely may cause the CNS symptoms to predominate and, in some cases, *Escherichia coli* sepsis is the presenting problem.

TABLE 41-5 INBORN ERRORS OF METABOLISM ASSOCIATED WITH NEONATAL LIVER DISEASE AND LABORATORY STUDIES USEFUL IN DIAGNOSIS

Disorder	Laboratory Studies
Galactosemia	Urine reducing substances; red blood cell galactose-1-phosphate uridylyl transferase
Hereditary tyrosinemia	Plasma quantitative amino acids; urine succinylacetone
α_1 -antitrypsin deficiency	Quantitative serum α_1 -antitrypsin; protease inhibitor (Pi) typing
Neonatal hemochromatosis	Serum ferritin; liver biopsy; buccal biopsy
Zellweger syndrome	Plasma very long chain fatty acids
Niemann-Pick disease type C	Skin biopsy for fibroblast culture; studies of cholesterol esterification and accumulation
Glycogen storage disease type IV (brancher deficiency)	Liver biopsy for histology and biochemical analysis or skin biopsy with assay of branching enzyme in cultured fibroblasts

If galactosemia is suspected, the urine should be tested simultaneously with Benedict reagent and with a glucose oxidase method. The glucose oxidase method is specific for glucose, and Benedict reagent can detect any reducing substance. A negative dipstick for glucose with a positive Benedict reaction means that a nonglucose reducing substance is present. With appropriate clinical findings, this is most likely to be galactose. Paper or thin-layer chromatography can be used to identify positively the reducing substance. If a child with galactosemia has been on intravenous fluids and recently has not been receiving galactose in the diet, galactose may not be present in the urine.

If the diagnosis of galactosemia is suspected, whether or not reducing substances are found in the urine, galactose-containing feedings should be discontinued immediately and replaced by soy formula or other lactose-free formula, pending the results of appropriate enzyme assays on erythrocytes to confirm the diagnosis. Untreated galactosemics, if they survive the neonatal period, have persistent liver disease, cataracts, and severe mental retardation. Many affected infants die of *E. coli* sepsis in the neonatal period, and the early onset of sepsis may alter the presentation of the disorder (19).

Treatment of the disorder by maintenance of strict dietary restriction of galactose, if started early, results in complete reversal of liver disease and enables many affected individuals to develop normal or near-normal intelligence. Unfortunately, there continues to be an increased incidence of mental retardation even among treated patients. Additionally, there are some late sequelae of the disorder that appear to be unaffected by current therapy. These include premature ovarian failure in females and a late-onset neurologic syndrome involving ataxia and tremors in both genders (20,21). Many states have newborn screening programs for galactosemia, but clinical manifestations of the disorder often appear before the results of screening studies are

available; therefore, it is critical that physicians remain alert to this possibility.

Another inborn error of metabolism that occasionally presents in the newborn period with jaundice, hepatomegaly, and the presence of reducing substances in the urine is hereditary fructose intolerance, which is characterized by episodes of profound hypoglycemia, vomiting, and metabolic acidosis. This disorder is seen uncommonly in the neonate, because most newborns are not exposed immediately to a fructose-containing diet unless they have been given a soy formula with sucrose as the carbohydrate source. In the uncommon event that an infant who has been receiving fructose should present with these findings, this diagnosis should be considered. Analysis of the urine reveals the presence of a nonglucose reducing substance that can be demonstrated by chromatography to be fructose. Treatment involves elimination of fructose from the diet and results in complete resolution of all clinical signs and symptoms. Confirmation of the diagnosis is by assay of the deficient enzyme fructose-1-phosphate aldolase in liver tissue, but this rarely is necessary.

P.975

α 1-Antitrypsin deficiency, a puzzling disorder that is among the most common of all inherited metabolic diseases, also may present with neonatal jaundice (22). The clinical manifestations of this disorder may be identical to those of traditional neonatal or giant cell hepatitis, and a determination of serum α 1-antitrypsin should be a part of the initial evaluation of all children presenting with this syndrome. Infants with deficient levels of α 1-antitrypsin on quantitative analysis should have protease inhibitor typing performed to confirm the diagnosis. There is no specific treatment for the liver disease associated with α 1-antitrypsin deficiency, but approximately one-half of all affected infants eventually exhibit complete resolution of the liver dysfunction. Others may progress to end-stage disease and require liver transplantation. A history of chronic pulmonary disease in adult family members may be obtained.

Hereditary tyrosinemia is another disorder that presents with liver disease in early infancy. The biochemical hallmarks of this disorder include marked elevations of plasma tyrosine and methionine and generalized aminoaciduria with a disproportionate increase in the excretion of tyrosine. However, these findings are relatively nonspecific and may be observed as a secondary phenomenon in other forms of liver disease. Hereditary tyrosinemia once was among the most difficult of inborn errors of metabolism to diagnose clinically. The finding of succinylacetone in the urine of patients with this disease has led to a helpful diagnostic test for the disorder (23). It also has become possible to establish the diagnosis definitively by demonstrating a deficiency of the enzyme fumarylacetoacetate fumarylhydrolase in lymphocytes and cultured skin fibroblasts of affected individuals (24).

Neonatal hemochromatosis, a recently described and poorly understood disorder, may be the most common cause of congenital cirrhosis. Its fulminating course distinguishes it from many of the other metabolic disorders associated with neonatal liver disease. In addition to being associated with severe liver failure from birth, the disorder is characterized by distinctive hepatic morphology and hepatic and extrahepatic parenchymal iron deposition. Serum ferritin and iron typically are elevated, whereas total transferrin is low, but these findings are not diagnostic. The definitive diagnosis is established by liver biopsy or autopsy. If liver biopsy is contraindicated because of a secondary coagulopathy, biopsy of the salivary glands or buccal mucosa is a useful alternative. Most affected infants succumb to the disorder during the early weeks of life. The only clearly effective mode of therapy is liver transplantation; intensive chelation therapy may be attempted but largely has been unsuccessful. At present, it is not clear whether iron storage is the primary defect or is secondary to fetal liver disease that may be causally heterogeneous. There are familial recurrences, so at least some cases appear to have a genetic basis, although the mode of inheritance is not well established.

Less common metabolic causes of neonatal liver dysfunction include Niemann-Pick disease type C and glycogen storage disease type IV. Infants with Niemann-Pick disease type C exhibit cholestatic jaundice, which typically resolves by several months of age. They then are clinically normal for a period of months to years before developing findings of a degenerative neurologic disorder. Infants with glycogen storage disease type IV accumulate an abnormal form of glycogen in the liver as a result of a deficiency of the glycogen branching enzyme. This leads to progressive cirrhosis and generalized hepatic dysfunction. Hypoglycemia is not a prominent feature, as it is in some other forms of glycogen storage disease.

Zellweger syndrome, formerly referred to as the cerebrohepatorenal syndrome, is another cause of neonatal jaundice and hepatic dysfunction, but it usually is recognizable clinically because of the associated hypotonia and dysmorphic features. It is the prototype of the peroxisome assembly disorders and is associated with generalized peroxisomal dysfunction.

In contrast to disorders in which there is an elevation of the direct-reacting bilirubin, a persistent elevation of

indirect bilirubin beyond the limits of physiologic jaundice, without evidence of hemolysis, suggests the diagnosis of the Crigler-Najjar syndrome. The hyperbilirubinemia in this disorder is related to a partial or complete deficiency of glucuronyl transferase, the liver enzyme responsible for the normal conjugation of bilirubin to bilirubin diglucuronide. There is no effective long-term therapy for all patients with this disorder, but the standard modalities of phototherapy and exchange transfusion may prevent the development of kernicterus in the neonatal period (25,26). Hepatic transplantation has been performed successfully in patients with this disorder. Patients with a partial deficiency of the enzyme may respond to phenobarbital therapy (26).

FINDINGS SUGGESTIVE OF A STORAGE DISEASE

Many of the well-known lipid storage diseases typically do not present in the neonatal period. Among those that occasionally may be associated with hepatosplenomegaly in the neonatal period are GM1-gangliosidosis type I, Gaucher disease, Niemann-Pick disease, and Wolman disease. The glycogen storage diseases that are associated with hepa-tomegaly in the newborn have previously been discussed in reference to hypoglycemia. Infants with the most common mucopolysaccharidoses, such as the Hurler and Hunter syndromes, uncommonly exhibit clinical abnormalities in the first month of life. Newborns with the typical features of these syndromes, such as coarse facial features, hepatosplenomegaly, skeletal abnormalities, and hernias, are more likely to have GM1-gangliosidosis or a mucopolysaccharidosis, such as I-cell disease. Beta-glucuronidase deficiency, also classified as mucopolysaccharidosis type VII, may present in the neonatal period with features virtually indistinguishable clinically from those seen later in the Hurler and Hunter syndromes. An infantile form of

P.976

sialidosis (i.e., neuraminidase deficiency) typically is associated with findings at birth. The clinical manifestations of several of these conditions may be so severe in utero that fetal hydrops develops.

If one of these disorders is suspected, urine screening tests for mucopolysaccharides and oligosaccharides should be performed. These can be helpful diagnostically, but negative results do not rule out the possibility of a storage disorder. False-positive mucopolysaccharide spot tests are commonly observed in neonates. The definitive diagnosis of most disorders of lipid or mucopolysaccharide metabolism is made by appropriate biochemical studies on leukocytes or cultured skin fibroblasts.

ABNORMAL ODOR

Abnormal body or urinary odor, more commonly observed by nurses or mothers rather than physicians, is an important but often overlooked clue to the diagnosis of several of the inborn errors of metabolism and may be the most specific clinical finding in these patients. It is best described for PKU, for which the urine was found to have a peculiar musty odor years before the biochemical basis of the disease was understood. In the acutely ill neonate with an abnormal odor, isovaleric acidemia, glutaric acidemia type II, and maple syrup urine disease are the most likely entities to be encountered. In maple syrup urine disease, the urine has a distinctive sweet odor, said to be reminiscent of maple syrup or burnt sugar. The odor associated with isovaleric acidemia and glutaric acidemia type II is pungent and unpleasant and similar to that of sweaty feet.

DYSMORPHIC FEATURES

There formerly appeared to be a clear distinction between inborn errors of metabolism and dysmorphic syndromes, both of which may be inherited in a similar fashion. Infants with inherited metabolic disease were thought to be phenotypically normal at birth, with no evidence of major or minor structural anomalies. It is becoming increasingly apparent that inherited metabolic disorders may be associated with consistent patterns of birth defects, suggesting that metabolic derangements in utero may disrupt the normal process of fetal development.

This phenomenon is illustrated clearly by the group of disorders associated with multiple defects in peroxisomal enzymes, including those involved in fatty acid oxidation and plasmalogen synthesis (27,28). These include Zellweger syndrome, neonatal adrenoleukodystrophy, and several variant conditions, all of which are associated with congenital hypotonia and dysmorphic features, such as epicanthal folds, Brushfield spots, large fontanelles, simian creases, and renal cysts. Patients with glutaric acidemia type II, one of the organic acidemias, have a characteristic phenotype, including a high forehead, hypertelorism, low-set ears, abdominal wall defects, palpably enlarged kidneys, hypospadias, and rocker bottom feet (29,30). An energy-deficient mechanism, referred to as fuel-mediated teratogenesis, similar to that postulated for maternal diabetes mellitus, has been suggested to explain these findings. Several of the other organic acidemias, such as mevalonic aciduria, and 3-

hydroxyisobutyric aciduria, have been associated with multiple dysmorphic features.

Some infants with pyruvate dehydrogenase (PDH) deficiency have dysmorphic facial features resembling those observed in the fetal alcohol syndrome (FAS) (31). The specific findings observed include a narrow forehead with frontal bossing, a broad nasal bridge, short nose with anteverted nostrils, and a long philtrum. The resemblance to FAS has been explained by suggesting that there is a common mechanism in the two disorders, involving a deficiency of PDH activity. It has been postulated that, in FAS, acetaldehyde from the maternal circulation inhibits fetal PDH, which leads to malformations.

The Smith-Lemli-Opitz syndrome is an autosomal recessive disorder associated with a wide range of malformations, including dysmorphic facies, cleft palate, congenital heart disease, hypospadias, polydactyly, and 2-3 syndactyly of the feet. Recent observations have revealed that this disorder is an inborn error of cholesterol biosynthesis. Affected infants have decreased levels of plasma cholesterol accompanied by markedly elevated levels of the cholesterol precursor 7-dehydrocholesterol (32).

Isolated malformations may be even more commonly associated with inherited metabolic disorders than are specific malformation patterns. Patients with nonketotic hyperglycinemia frequently have agenesis of the corpus callosum and may have gyral malformations related to defects in neuronal migration as well (33). Patients with PDH deficiency also may exhibit agenesis of the corpus callosum (34). It is not uncommon for patients with almost any of the inborn errors of metabolism to exhibit one or more dysmorphic features or anomalies that are nonspecific. The observation of dysmorphic features in an infant in no way should preclude consideration of an inherited metabolic disorder. In selected circumstances, it may heighten the clinical suspicion.

ABNORMAL EYE FINDINGS

Abnormal eye findings typically are associated with many of the inborn errors of metabolism, although they are not always found at the time of initial presentation. Cataracts classically are associated with galactosemia and other disorders of galactose metabolism, but also are observed in disorders such as Zellweger syndrome and Lowe syndrome. Dislocated lenses, seen in homocystinuria, molybdenum cofactor deficiency, and sulfite oxidase deficiency, may be found as early as the first month of life and are an important clue to diagnosis. Retinal degenerative changes are typical of the peroxisomal disorders, including Zellweger syndrome

P.977

and neonatal adrenoleukodystrophy, and are observed in several other conditions. Other abnormalities that may be associated with inborn errors of metabolism include corneal clouding and congenital glaucoma. A careful eye examination, preferably by an ophthalmologist, should be performed whenever an inherited metabolic disorder is suspected. A summary of some of the inherited metabolic disorders associated with specific ocular abnormalities is shown in Table 41-6

Eye Finding	Associated Disorders
Cataracts	Galactosemia Homocystinuria Lowe syndrome Zellweger syndrome Rhizomelic chondrodysplasia punctata Senger syndrome Hypophosphatasia
Ectopia lentis	Homocystinuria Molybdenum cofactor deficiency Sulfite oxidase deficiency
Cherry red spot	Niemann-Pick disease types A and B Gaucher disease type II GM ₂ gangliosidosis (Tay-Sachs; Sandhoff) Sialidosis type II Farber disease

Corneal clouding	Mucopolysaccharidoses
	Mucopolipidoses
	Lowe syndrome
	Homocystinuria
Pigmentary retinopathy	Zellweger syndrome
	Neonatal adrenoleukodystrophy
	Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency

SAMPLES TO OBTAIN FROM A DYING CHILD WITH A SUSPECTED INBORN ERROR OF METABOLISM

If death appears imminent in a child suspected of having an inborn error of metabolism, it is important to obtain the appropriate samples for postmortem analysis. This is critical for resolution of the cause of death and is essential for subsequent genetic counseling and prenatal diagnosis. The following samples should be collected and stored: urine, frozen; plasma, separated from whole blood and frozen; and a small snip of skin obtained using sterile technique and stored at room temperature or 37°C in tissue culture medium, if available, or sterile saline. The latter sample can be obtained by slipping a 25-gauge needle under the skin, lifting the skin, and snipping a 2- to 3-mm ellipse with a sterile scissors, which can be found in a suture removal tray. The skin should be cleansed with alcohol. If an autopsy is performed, a sample of unfixed liver tissue should be obtained as soon as possible after death and frozen at -20°C for subsequent biochemical studies. Additional tissue should be preserved for electron micro-scropy. If consent for autopsy is denied, consent for a postmortem needle biopsy of the liver should be requested. The liver tissue should be frozen in total or in part if histologic studies appear to be indicated. As soon as possible after death, the case should be reviewed with a metabolic specialist and plans made for the transport of samples to the appropriate laboratory.

NEWBORN SCREENING FOR INHERITED METABOLIC DISORDERS

All 50 states and the District of Columbia in the United States and many other countries have newborn screening programs in place for genetic disorders. However, there are significant state-to-state differences in the disorders that are included, the methods of screening, and follow-up. Therefore, physicians must become familiar with the newborn screening protocol in the state or country in which they are practicing. The recent development of the technology of tandem mass spectroscopy has led many states to reexamine their newborn screening practices and many are now moving toward implementation of expanded newborn screening using this technology. Tandem mass spectroscopy (MS/MS) allows for the performance of a complete acylcarnitine profile and amino acid profile on the filter paper blood specimen and is being used in an increasing number of states and countries to screen for organic acid and fatty acid oxidation disorders and an increased number of amino acid disorders, including maple syrup urine disease, homocystinuria, and hereditary tyrosinemia. Phenylketonuria is also detected through MS/MS, replacing testing methods previously used for this disorder which was routinely screened for in all states and the District of Columbia.

The only other disorder that is a routine component of newborn screening in all 50 states and the District of Columbia is congenital hypothyroidism. Hemoglobinopathies and galactosemia are included in the newborn screening panel of most states. Testing methods vary from state to state for each of these individual disorders. In the case of many metabolic disorders such as PKU, the levels of the abnormal metabolite do not begin to rise in the infant's circulation until the umbilical cord is cut and therefore testing is not recommended until the infant is at least 24 hours of age. In the case of infants discharged before 24 hours of age, most states recommend that a sample be obtained at discharge and subsequently repeated. In the case of sick infants who are not being fed, the initial newborn screening sample should not be withheld indefinitely but should be submitted at the recommended time, often 7 days, because screening for some other disorders, such as hypothyroidism, is not affected by the feeding history. For PKU screening and screening for some other disorders, however, another specimen should be submitted

P.978

after feedings are instituted. Confirmation of positive newborn screening test results is always necessary to establish a definitive diagnosis regardless of the type of screening method utilized. Even with tandem mass spectroscopy, false positive test results occur. Each state or country has developed a system for the evaluation of infants with positive results which may or may not include submission of repeat specimens to a central laboratory.

As newborn screening for metabolic disorders is expanded, an increasing number of inborn errors of metabolism will be diagnosed presymptomatically. This should not in any way discourage the neonatologist from considering the diagnosis of an inborn error of metabolism in an infant presenting with appropriate signs and symptoms. Many infants with conditions such as galactosemia, maple syrup urine disease and many of the organic acidemias will become symptomatic before the results of newborn screening tests are available. Additionally, there are many important inherited metabolic disorders, such as ornithine transcarbamylase deficiency that will not be detected by newborn screening, even with tandem mass spectroscopy. Therefore, it will be important to continue to have a high index of suspicion for metabolic disease in any infant who presents with findings suggestive of such a disorder.

MATERNAL METABOLIC DISORDERS

With advances in therapy for inborn errors of metabolism, it is now common for patients with many of these disorders to reach adult life with normal or near-normal intelligence and the desire to have families of their own. This has led to serious concerns about the potential adverse effects of maternal metabolic derangements on fetal growth and development. The real potential for adverse consequences is illustrated by the experience that has accumulated with maternal PKU. In the past, patients with PKU were severely retarded and did not reproduce. This changed completely with the initiation of newborn screening programs and early dietary management. Dietary therapy was once maintained until 5 to 6 years of age and then discontinued. Treatment now is continued indefinitely in most cases, because it has been demonstrated that some patients exhibit neurologic deterioration and loss of intelligence quotient (IQ) points after discontinuation of the diet. Nonetheless, many patients with PKU who are now adults have been off the diet for years and have high phenylalanine levels. After women with PKU began reproducing, it became clear that the maternal metabolic environment in this condition had extremely harmful effects on fetal development. A spectrum of findings referred to as "maternal PKU syndrome" is observed in a large percentage of exposed infants, most of whom do not themselves have PKU (35,36). More than 90% of exposed infants exhibit mental retardation, and microcephaly occurs in 72%, growth retardation in 40%, and congenital heart disease in 12%. Altered facial features, similar to those observed in FAS, may be observed. Mothers with hyperphenylalaninemia, a condition that is associated with lower phenylalanine levels than classical PKU and does not always require treatment, may also be at increased risk for fetal abnormalities.

There is evidence that dietary treatment of pregnant women before conception and throughout pregnancy, with careful control of phenylalanine levels, reduces the risk to the fetus (38). This is a difficult goal to achieve, however, because the phenylalanine-restricted diet is an onerous one to patients who have ever been on a normal diet, and some adult patients, despite early therapy, may have borderline intellectual functioning. There has been no evidence for an increased risk of birth defects or any other problems in infants born to fathers with PKU.

Pregnancies have been reported in mothers with a variety of other inherited metabolic disorders, including several forms of glycogen storage disease, propionic acidemia, isovaleric acidemia, homocystinuria, hereditary orotic aciduria, and several others, with no adverse outcomes clearly attributable to the maternal disorder. The collaborative experience with many disorders, however, is limited to single cases or small numbers of patients. It is probable that other maternal metabolic disorders will be identified that adversely affect fetal development.

Developmental Physiology

The kidneys play a central role in the physiologic transition from fetal to postnatal life. Whereas homeostasis *in utero* is maintained largely by the placenta, adaptation to the extra uterine environment requires that the kidneys assume the responsibility of regulating water and solute balance. Although the neonatal kidney traditionally has been characterized as dysfunctional, closer analysis indicates that this organ functions at a level that is appropriate to the physiologic needs of the growing infant, except in the very-low-birth-weight (VLBW) infant.

Embryology

The metanephros, the definitive mammalian kidney, first appears at 5 weeks postconceptional age and begins to produce urine by 10 weeks postconceptional age (1,2 and 3). The ureteric bud, an offshoot of the mesonephric duct, induces formation of nephrons within the metanephric blastema. The nephroblastic cells of the blastema, on contact with the ureteric bud, differentiate into the glomerulus, proximal convoluted tubule, loop of Henle, and distal convoluted tubule. The ureteric bud ultimately forms the ureter, pelvis, calyces, and collecting ducts of the metanephros.

The processes of induction, morphogenesis and differentiation of the metanephros occurs in a centrifugal pattern, proceeding from the center to the periphery (4,5 and 6). Thus, the first nephrons to develop are those residing in the juxtamedullary region, whereas the youngest are located in the nephrogenic zone just under the renal capsule.

The full complement of approximately 1 million nephrons per kidney in the human is achieved by about 35 weeks' gestational age (GA), or a body weight of about 2,300 g (6). When birth occurs before this age, the formation of new nephrons (nephronogenesis) continues until a full complement is achieved. Once complete, nephronogenesis is never resumed, even after extensive loss of renal tissue. Thus, the full-term infant is born with as many nephrons as he or she will ever have.

Physiologic, biochemical, and enzymatic maturation of newly formed nephrons may lag behind anatomic maturation by weeks or months. Thus, the immature kidney is characterized by structural and functional heterogeneity arising from the concurrent presence of nephrons in varied stages of differentiation.

Renal Physiology

Urine produced by the fetal metanephric kidneys contributes to the formation of amniotic fluid (3,6). Although renal function is not necessary for long-term

regulation of fetal water and electrolyte homeostasis, it is important for normal growth (7), lung development (8), and protection from acute changes in fetal vascular volume (9). The hourly rate of urine production in normal fetuses is about 5 mL at 20 weeks, 10 mL at 30 weeks, increasing to up to 50 mL at 40 weeks (3,10).

Renal Blood Flow

Low rates of fetal and neonatal renal blood flow (RBF) exist in a variety of animal species, whether normalized to body weight, surface area or kidney weight. RBF in the human fetus, estimated by Doppler ultrasonography, increases from 20 mL/min at 25 weeks GA to more than 60 mL/min at 40 weeks and reaches adult levels by 2 years of age (11,12). The effective renal plasma flow (RPF) has traditionally been calculated from the renal clearance of the organic acid para-aminohippurate (PAH), corrected for the fraction of PAH extracted by the kidney (12); the value for effective RPF divided by $(100 - \text{hematocrit} [\%])/100$ provides an estimate of RBF. The effective RPF increases rapidly between 30 and 40 weeks GA, reaching adult values by 24 months of postnatal life (12) (Fig. 42-1).

Because the renal extraction ratio for PAH varies with age, calculated values of effective RPF must be interpreted with caution in the fetus and neonate. The rate of extraction of PAH in the 1-week-old full-term newborn is only about 60%, reaching the adult value of 90% by 5 months (13). PAH clearance averages 148 mL/min/1.73 M² body surface

P.982

area (BSA) in full-term infants at 2 weeks of life, increasing to 200 mL/min/1.73 M² by 3 months (14). PAH clearance, corrected for BSA, reaches adult levels sometime between 1 and 2 years of age (12). The incomplete PAH extraction early in life appears to be as a result of relatively greater blood flow to juxtamedullary nephrons and efferent arteriovenous shunting in cortical nephrons, thereby allowing blood to bypass PAH-transporting segments of the nephron. Additionally, the organic acid secretory pathways in the proximal tubule are immature early in development (15). Thus, RBF and RPF will be underestimated by PAH clearance alone in neonates, particularly in premature infants, in the absence of determination of the PAH extraction ratio.

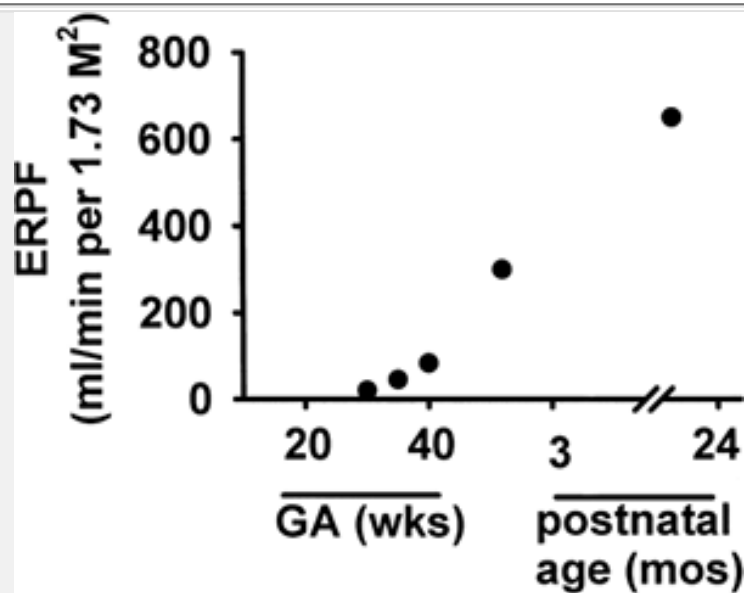

Figure 42-1 Developmental changes in effective renal plasma flow (ERPF), calculated from the renal clearance of para-aminohippurate (PAH) and corrected for the fraction of PAH extracted by the kidney. The ERPF, used to estimate RBF, increases rapidly between 30 and 40 weeks GA, reaching adult values by 24 months of postnatal life (From ref. 12, with permission).

RBF is determined by cardiac output and the ratio of renal to systemic vascular resistance. Developmental changes in both hemodynamic variables contribute to the postnatal increase in RBF. Adult kidneys (which comprise 0.5% of total body mass) receive approximately 20% to 25% of the total cardiac output, corresponding to a RBF of 4 mL/min/g kidney weight. In contrast, the pre-viable fetus receives only about 5% of the cardiac output, and the 1-week-old term infant receives about 9% (16).

The perinatal increase in RBF is gradual (13,17,18), consistent with the premise that clamping of the umbilical cord and the immediate imposition of functional demands at birth do not in themselves account for the postnatal increase in RBF. The maturational increase in RBF cannot be completely explained by increases in renal mass (19) or by nephronogenesis, which is complete well before maximal levels of RBF are achieved.

The intrarenal distribution of RBF in the newborn differs from that in the adult, reflecting the relative size, number, and maturity of glomeruli present in the different regions of the kidney at that stage of development. RBF in the newborn is distributed primarily to the inner cortex and medulla. Maturation is accompanied by a redistribution of blood flow toward the superficial cortex, so that the ratio of inner cortical to outer cortical blood flow becomes progressively smaller than in the fetus (18,20,21 and 22) (Fig. 42-2). At maturity, about 93% of RBF goes to the cortex, which constitutes about 75% of the renal mass, whereas only 7% is distributed to the renal medulla and perirenal fat.

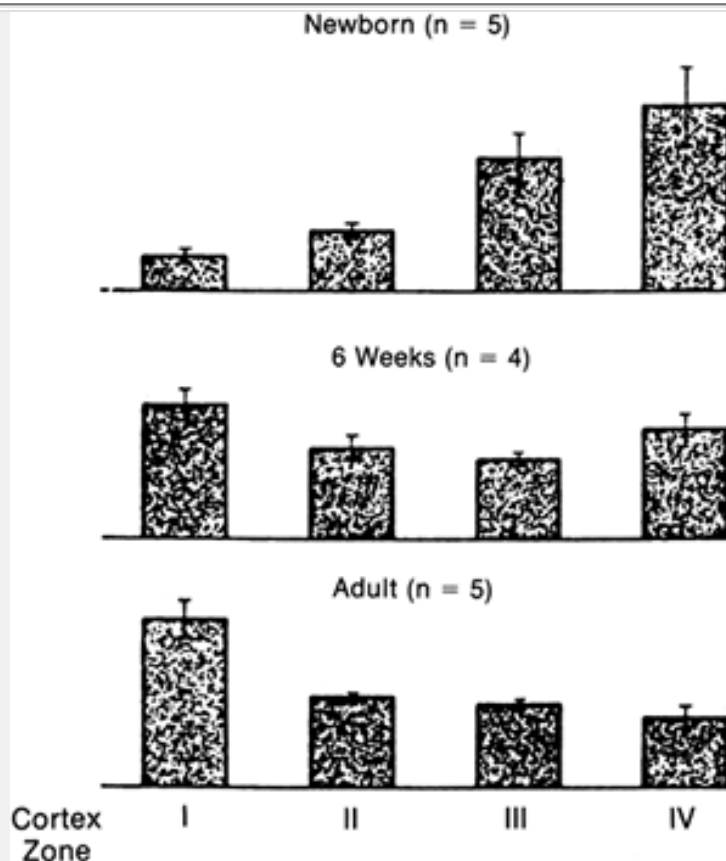

Figure 42-2 Postnatal changes in the intrarenal distribution of blood flow. Relative rates of blood flow per glomerulus in the four cortical zones of the canine kidney. Zone I represents the most superficial region, and zone IV represents the deepest. The total height of the bars in each age group is equal. At birth, the blood flow to the superficial cortex was lowest, with most blood flow perfusing the deep cortex. By 6 weeks of age, this pattern was reversed. Maturation is accompanied by an increase in blood flow to the outer cortex, due primarily to a decrease in renal vascular resistance (From ref. 17, with permission).

The primary factor responsible for the maturational increase and change in intrarenal distribution in RBF is a decrease in renal vascular resistance (RVR) (23), with the rise in cardiac output and mean arterial blood pressure (MAP) only partially accounting for these postnatal changes in renal hemodynamics (23,24 and 25,27). The balance of afferent and efferent arteriolar resistances ultimately determines the RVR, RBF, glomerular capillary pressure and glomerular filtration rate (GFR). The intrarenal vascular resistance, localized both at the afferent and efferent arterioles (26), is much higher in the newborn than in the adult (19,23). The postnatal fall in RVR occurs at a time when the systemic vascular resistance increases about 6-fold (23).

Anatomic factors also contribute to the developmental increase and redistribution of RBF. The intrarenal vascular system distal to the afferent arteriole in the neonate differs from that in the adult. Variability in the complexity of the glomerular capillary network exists early in postnatal life (28). Inner cortical glomeruli at this age generally have a smaller number of capillaries than the in adult, although

they appear similar in overall structure. Few efferent arterioles descend into the medulla; most connect directly to the venous system (arteriovenous shunting) (29), bypassing the proximal tubules (26).

A variety of vasoactive substances have been implicated in the developmental regulation of RBF and GFR. The most important factors are discussed below. Changes in the balance of the vasoconstrictor renin-angiotensin system (RAS) and renal sympathetic nervous systems, both of which are highly active in early development, and vasodilatory humoral factors, including nitric oxide (NO), are believed to mediate, at least in part, the developmental reduction in RVR and increase in RBF.

Renin-Angiotensin System

All components of the RAS are present in the fetal metanephric kidney (30,31,32,33,34) (Fig. 42-3). Renin, angiotensinogen and angiotensin-converting enzyme (ACE) are first detected in fetal metanephros by ~6 weeks gestation. The site of localization of renin within the kidney is developmental-stage specific. Whereas the majority of renin-containing cells are located in the juxtamedullary apparatus in both the newborn and adult, renin message and protein in the fetus are also present in the arcuate and interlobular arteries and glomeruli (35).

The RAS is very active in the fetus and newborn. The fetus produces renin as early as 17 weeks GA (36). Plasma renin activity (PRA) is inversely related to GA in the fetus and newborn, decreasing from 60 ng/mL/h at 30 weeks to about 10 to 20 ng/mL/h at term (37). PRA is 3-to-5 times higher in human infants (38,39,40,41,42,43 and 44) than in adults. Changes in PRA in the fetus in response to several stimuli (increase after volume depletion or hypoxia, and decrease after volume expansion or after administration of a β -adrenergic antagonist or of a prostaglandin synthetase inhibitor [PGSI]) are similar to those observed in adults.

The high levels of PRA in neonates are generally associated with circulating levels of angiotensin II (ANG II) and aldosterone that exceed those measured in the

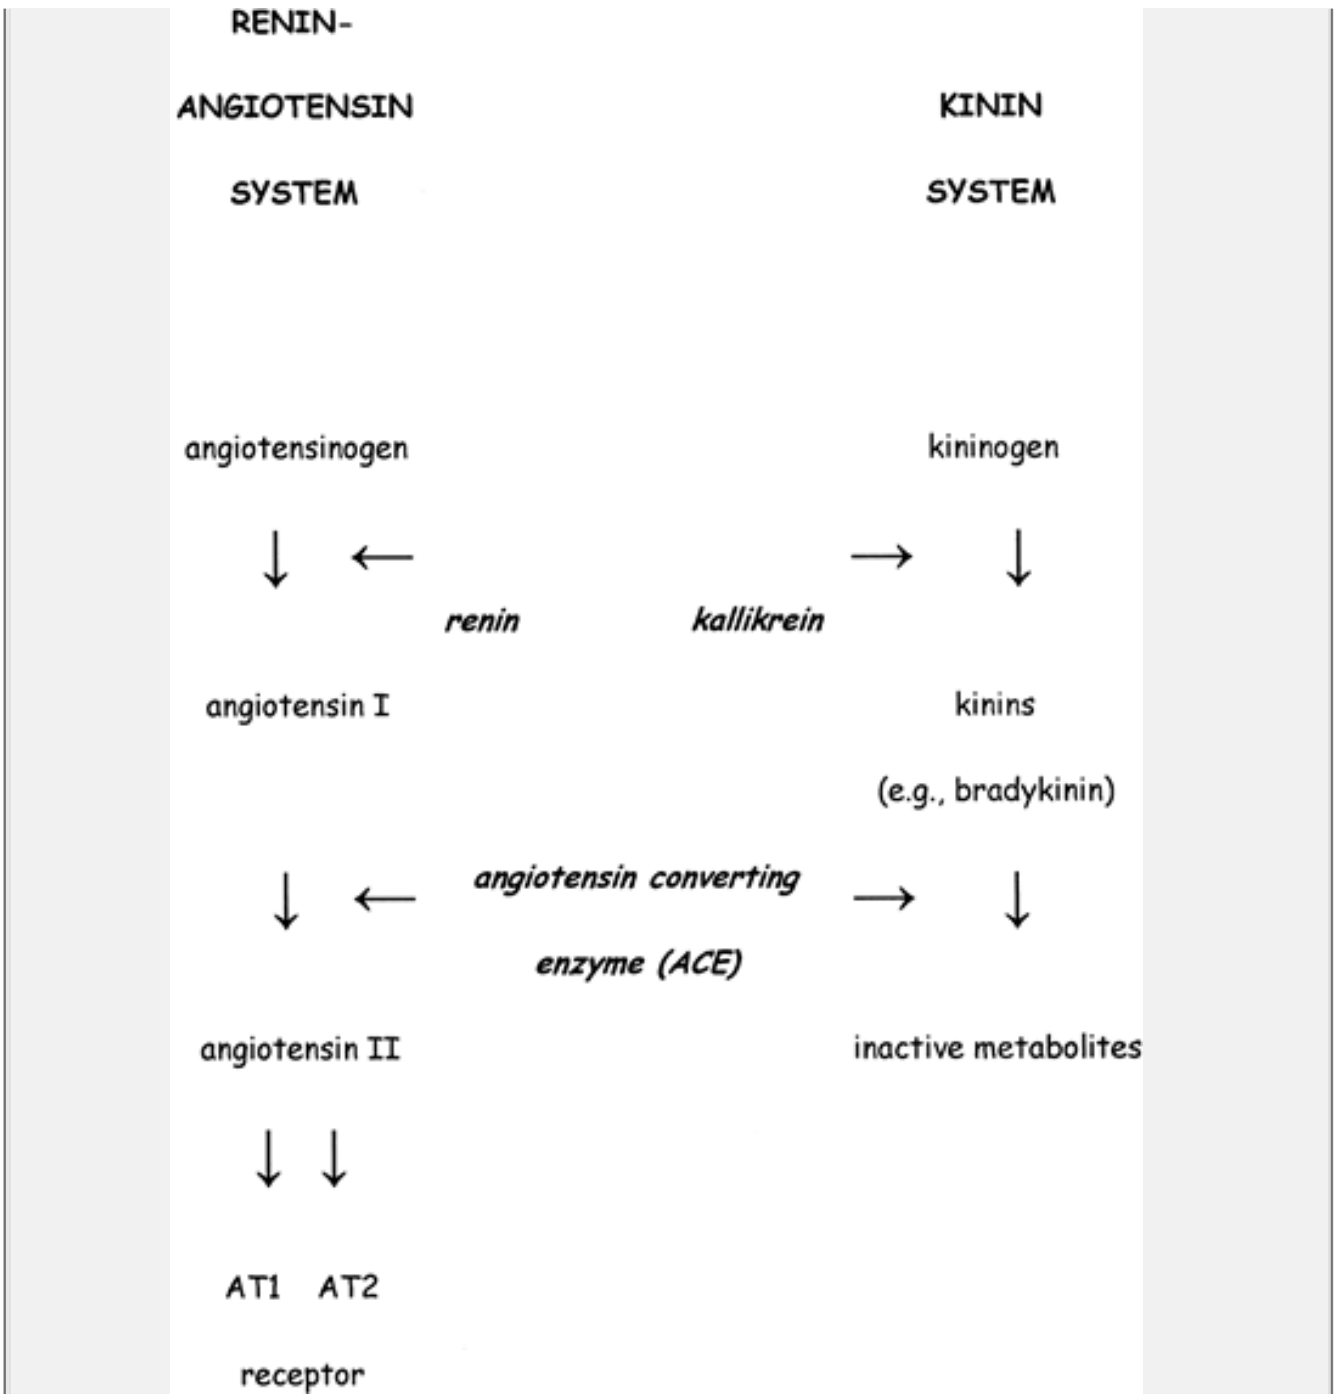

Figure 42-3 Relationship between the renin-angiotensin and kinin systems. See text for details.

adult (45,46,47,48,49 and 50). These high levels may reflect high rates of secretion or low metabolic clearance rates relative to body size. The reason for these high levels may be a relative end-organ unresponsiveness to aldosterone (51,52). Circulating levels of plasma ANG II decrease during postnatal life in parallel with PRA (53).

The observation that administration of ACE inhibitors during late gestation can result in anuria and oligohydramnios, renal tubular abnormalities, pulmonary hypoplasia, growth retardation, and increased fetal loss (54,55,56) underscores the pivotal role of the RAS in normal fetal growth and development. Genetic disruption of the genes encoding angiotensinogen (57), ACE (58), or ANG II type 1 re-ceptor is also associated with profound abnormalities in kidney morphology.

SThe significance of the RAS in the maintenance of renal hemodynamics in the perinatal period remains uncertain. However, as identified above, a number of observations suggest that this axis may be important under conditions of stress in the near-term fetus. An acute reduction in blood volume or onset of hypoxia in the fetus or neonate significantly increases renin and ANG II levels (10,59,60). ACE inhibition blocks the increase in RVR and reduction in RBF experienced by near-term fetuses in response to hemorrhage (61,62).

Kinins

Bradykinins are potent vasodilator peptides generated from the protein precursor kininogen by the proteolytic enzyme kallikrein (Fig. 42-3). The kinins are inactivated by kininase I, which is a carboxypeptidase, and the peptidyl dipeptide hydrolase kininase II, which is ACE. Thus, ACE inhibitors not only decrease ANG II production but also prevent the breakdown of kinins.

Premature infants have undetectable levels of urinary kinins (63); urinary excretion of kallikreins and kinins is lower in newborns than older children (64). The role of these substances in modulating the function of the immature kidney remains unclear.

Prostaglandins

Prostaglandins (PGs) contribute to the maintenance of RBF and GFR, especially during conditions of enhanced

P.984

vasoconstrictor activity. Complex interactions between PGs and the RAS and kinin systems exist, making it difficult to identify the specific effects of PGs on regulation of blood pressure, RBF, and electrolyte and water homeostasis. PG synthesis from arachidonic acid requires cyclooxygenase (COX), the inhibitory target of aspirin and various non-steroidal antiinflammatory drugs (65). Two isoforms of COX have been identified, each representing a different gene product and subject to

differential regulation. COX-1 has been proposed to participate in glomerulogenesis (66), whereas COX-2 regulates renal perfusion and glomerular hemodynamics (67). Differences in intrarenal COX-1 and -2 localization between the adult and fetal human kidney may account for the variable renal responses to PG inhibition observed between the two groups (66).

Urinary excretion of PGs is high in the fetus (68,69), presumably reflecting a high rate of renal synthesis. Urinary excretion of PGE₂ and prostacyclin metabolites in the premature infant is five times that noted at term and 20 times that measured in older children (70). Although rates of excretion decrease after birth, urinary PG excretion remains significantly higher in neonates than in children or adults (71,72).

PGs produced by the fetal and neonatal kidney may contribute to the regulation of renal perfusion and glomerular hemodynamics. Maternal administration of indomethacin, a nonselective COX inhibitor, reduces RBF in the fetus, and is associated with an increase in RVR and MAP (73). Intrauterine exposure of the human fetus to COX inhibitors can lead to a decrease in GFR with consequent reduction in fetal urine output and oligohydramnios (74,75,76,77). Postnatal administration of a PGSI to preterm infants (78,79) to close a patent ductus arteriosus (PDA) may also compromise renal function, leading to a reduction in RBF, GFR and urine volume.

Renal Nerves and the Adrenergic System

The renal vascular bed of the fetus is less reactive to renal nerve stimulation than that of the newborn and adult (80,81). In contrast to observations made in adult animals, several studies have demonstrated that renal nerve stimulation in the fetal and newborn kidney activates noradrenergic pathways, norepinephrine stimulates β ₂-adrenoceptors to produce renal vasodilation, and maturation of the renal adrenergic system is associated with downregulation of the renal β -adrenoceptor response (80,81 and 82).

Circulating catecholamine levels, particularly norepinephrine, are very high just before and immediately after birth (83), falling to adult values within a few days of life. The high plasma levels of catecholamines act directly to increase afferent arteriolar tone and indirectly, via stimulation of renin and ANG II release, to increase efferent resistance, possibly contributing to the maintenance of the high RVR characteristic of the neonatal kidney (84). The fetal and neonatal kidney demonstrates enhanced sensitivity to catecholamines compared to the adult, related in part to developmental differences in adrenergic receptor density (85,86).

Nitric Oxide

Endogenous NO is a major vasodilator in the developing kidney, contributing to the

maintenance of intrarenal vascular tone and serving to buffer the highly activated endogenous vasoconstrictor state (87,88). The sensitivity of renal hemodynamics in the fetal and neonatal kidney to inhibition of NO synthesis is significantly greater than that of the adult kidney.

Dopamine and Dopamine Receptors

The fetal and neonatal kidneys are less sensitive than their adult counterparts to the renal vasodilatory and the natriuretic effects of dopamine (89,90). Exogenous administration of dopamine, which results in an increase in RBF in the adult, has no effect in the young animal unless there also is an increase in systemic blood pressure and cardiac output (81,91,92). This blunted response is considered to reflect the limited generation of the vasodilatory second messenger cyclic adenosine monophosphate (cAMP) (89,91) and a low density of renal dopamine-1-like receptors in the neonatal kidney (93).

The pharmacological effects of dopamine are dose-dependent. Whereas the renal response to low concentrations of dopamine generally reflects dopaminergic receptor-mediated effects, high concentrations stimulate α -adrenergic receptors. Thus, the renal vasoconstriction observed following intrarenal dopamine infusion in fetal and neonatal animals (94,95) likely reflects dopamine binding to α -adrenoceptors, which are abundant by term (96,97).

Arginine Vasopressin

The plasma concentration of arginine vasopressin (AVP) in neonates increases abruptly after birth and is highest in infants whose mothers labored before vaginal delivery (98). Although AVP has the potential to contribute to the high RVR characteristic of the neonate through its action on vascular and glomerular V1 receptors, its role in regulating basal renal hemodynamics remains poorly defined. Infusion of synthetic AVP does not alter RBF and RVR in fetal sheep (99). However, AVP may play a role in certain stress-induced responses. For example, during hemorrhage, but not during hypoxemia, the marked decrease in RBF and increase in RVR correlate closely with the rise in plasma AVP (10,59,100).

Atrial Natriuretic Factor

ANF acts on the mature kidney to increase sodium excretion and GFR, antagonize renal vasoconstriction, and inhibit renin secretion (101). ANF release from atrial cardiocytes is stimulated in the fetus by an increase in intra-cardiac pressure and atrial distention (102,103,104 and 105), and levels fall in response to a decrease in central venous pressure, as during hemorrhage (106). The natriuretic and diuretic

response to systemically infused ANF in newborns is attenuated compared to adults (107,108,109,110 and 111). Whereas specific ANF receptors have been identified on near-term fetal glomerular membranes, the ANF binding capacity is age-dependent, increasing 7-fold between fetal and adult life (112). The blunted response of the immature subject to ANF has been attributed to ineffective production of the second messenger cyclic GMP (108,113), a rapid systemic clearance of ANF (107,108), and a greater ANF-induced reduction in RBF in fetuses and newborns than in adults (107).

Glomerular Filtration

Initiation of glomerular filtration in the human fetus occurs between 9 and 12 weeks of GA (114,115). It has been suggested that the functional demand placed on the neonatal kidney by cessation of placental function at birth stimulates GFR to increase. However, estimates of GFR correlate well with GA, a relationship that persists whether the fetus remains in utero or is born prematurely (116,117,118 and 119). Specifically, GFR averages approximately 8 to 10 mL/min/ 1.73 M² at 28 weeks of GA and increases only slightly before 34 weeks postmenstrual age, although body size and kidney weight increase appreciably during this time. After about 34 weeks postmenstrual age, at which time GFR averages 25 mL/min/1.73 M² regardless of postnatal age, GFR increases rapidly, often by threefold to fivefold within 1 week (116,118,120), coincident with completion of nephrogenesis (Fig. 42-4). Thus, an infant born prematurely at 28 weeks of GA shows little increase in GFR until the infant is about 6 weeks old, i.e., until a postmenstrual age of 34 weeks is attained and nephrogenesis has been completed (121). The GFR of neonates who are small for GA is similar to that of infants whose body weight is appropriate for the same GA.

Figure 42-4 Changes in glomerular filtration rate (mL/min), estimated by creatinine clearance, and nephrogenic activity in the kidney cortex (%) are plotted as a function of postconceptional age in the human infant. There is a temporal relationship between the accelerated rate of increase in glomerular filtration rate and completion of nephrogenesis after 34 weeks of gestation (From Arant BS. Neonatal adjustments to extrauterine life. In: Edelmann CM Jr, ed. *Pediatric kidney disease*. Boston: Little, Brown and Company, 1992:1021).

During the first 4 months of life, GFR increases rapidly relative to body size, kidney weight, and BSA (11). Thereafter, a slower rise is noted until adult values, determined on the basis of BSA, are reached by 2 years of age (11,122,123). The postnatal increase in GFR in premature infants may lag behind that observed in full-term newborns; at 9 months of age, the GFR of VLBW infants is approximately 70% of that measured in full-term infants of identical postnatal age (121).

Glomeruli are formed in the nephrogenic zone of the kidney. With maturation, these glomeruli migrate to deeper zones of the renal cortex. At birth, the more mature glomeruli in the juxtamedullary cortex, which are nearly as large as glomeruli in the adult kidney, have higher filtration rates than the most recently formed glomeruli in the superficial cortex, some of which may not begin filtration for some time. Thus, GFR, similar to RBF, matures centrifugally. As nephrons enlarge and forces that regulate filtration permit, GFR increases, with most of the surge as a result of enhanced perfusion of superficial nephrons (18,24,124) (Fig. 42-2), related temporally to the increase in total RBF and its centrifugal redistribution within the renal cortex.

The addition of newly functioning nephrons is insufficient, however, to account for the large increases in GFR observed during maturation. A substantial rise in single nephron GFR occurs (125). The process of urine formation starts with ultrafiltration of plasma through the glomerular capillary membrane. The rate of filtration depends on filtration characteristics of the membrane and on the net ultrafiltration pressure, represented by the difference between the mean glomerular transcapillary hydraulic, i.e., glomerular capillary minus the Bowman's space hydraulic pressures and mean colloid osmotic pressures over the length of the glomerular capillary, and the glomerular plasma flow. The capillary hydrostatic pressure promotes filtration, whereas both the colloid osmotic pressure within the capillary and the hydrostatic pressure in the Bowman's space oppose it. The postnatal increase in GFR may result from changes in all of these variables, in addition to the surface area available for filtration, and the permeability of the filtering membrane.

Autoregulation of Renal Blood Flow and Glomerular Filtration Rate

Autoregulation in the mature kidney allows for constancy of RBF and GFR as the MAP and renal perfusion pressure vary over a wide range, from about 80 to 150 mmHg. Autoregulation is accomplished primarily by changes in the RVR at the level of the afferent and efferent arterioles. Although systemic blood pressure in the fetus (i.e., 40-60 mmHg) and neonate is less than the lower limit of autoregulatory range defined for adults, experimental evidence suggests that the fetus and newborn are able to autoregulate RBF efficiently at their prevailing low arterial pressure,

P.986

albeit at a lower perfusion set point than in the adult (126,127 and 128). In support of this notion is the observation that a 16% increase in fetal arterial blood pressure elicited by AVP infusion does not alter RBF (129). The autoregulatory response is considered to be mediated in part by a myogenic response of the renal afferent arteriole (130,131), which constricts to limit any rise in glomerular hydrostatic pressure, and the tubuloglomerular feedback control mechanism (132,133) (see below). As MAP falls, the renal afferent arteriole dilates and the efferent arteriole constricts, the latter effect due, at least in part, to stimulation of renin release and ANG II generation (134,135). The balance of these two responses maintains glomerular capillary hydrostatic pressure and preserves RBF and GFR.

Tubuloglomerular Feedback

Tubuloglomerular feedback serves to maintain a constant rate of water and salt delivery to distal segments of the nephron in which reabsorption is regulated to maintain fluid balance. A stimulus (e.g., tubular flow rate, ion concentration) at the macula densa is transmitted to vascular structures of the nephron that control GFR to elicit a change of single nephron GFR. Tubuloglomerular feedback is maximally sensitive in a range that corresponds to normal values of single nephron GFR and tubular flow rate. As GFR increases with maturation, the maximal response and flow range of maximum sensitivity also increase, so that the relative sensitivity of the tubuloglomerular feedback mechanism is unaltered during growth (136,137). An intact RAS appears to be critical for this signaling pathway (157) and NO may play a modulatory role (138,139).

Tubular Function

The axial and polarized (apical vs. basolateral) distribution of transport proteins along sequential segments of the nephron allows the kidney to reabsorb the bulk of glomerular filtrate proximally and then, in more distal segments, adjust the solute and water content of the urine to maintain homeostasis. The fully differentiated kidney is generally a reabsorptive organ. However, transport of some ions and solutes by individual nephron segments is bi-directional. Thus,

sodium, bicarbonate, phosphate, amino acids, and glucose are reabsorbed, hydrogen ions are secreted, and potassium and organic acids are both reabsorbed and secreted. In general, the kidney of the full term, but not necessarily preterm, neonate is uniquely suited to meet the developmental stage-specific metabolic demands.

Sodium

Term infants are in a state of positive sodium balance, a requisite for somatic growth, particularly of bone. Although the sodium intake per unit of BSA is generally smaller in the newborn than in the adult, the magnitude of this positive balance remains relatively constant within a wide range of sodium intakes (140,141). The tendency of the neonatal kidney to retain sodium may become problematic under conditions of salt loading. Exogenous administration of a sodium load to an adult is followed by immediate expansion of the extracellular fluid (ECF) space. This signals the kidney to decrease tubular sodium reabsorption, resulting in increased excretion of sodium and a relatively rapid return of the ECF space to the baseline condition. Full-term newborn infants given a sodium load in excess of 12 mEq/kg/d experience a rise in serum sodium levels, abnormal increase in weight, and generalized edema (142). The limited capacity of the neonatal kidney to excrete a sodium load compared to its mature counterpart appears to be due more to factors related to tubular sodium reabsorption than to the low GFR (143).

The fractional excretion of sodium (FENa) is the ratio of the sodium clearance to the creatinine clearance, expressed as a percent. It is obtained from the following formula:

$$\text{FENa (\%)} = 100 \times \text{Una/Ucr} \times \text{Pcr/PNa}$$

in which UNa is the urinary concentration of sodium (mEq/L), Ucr is the urinary concentration of creatinine (mg/dL), PNa is the plasma sodium concentration (mEq/L), and Pcr is the plasma creatinine concentration (mg/dL). FENa, which may be as high as 20% during early fetal life, decreases progressively during gestation (144,145,146), so that the FENa in the full-term newborn generally averages about 0.2% (146,147). After the first few hours of postnatal life, the FENa and urinary sodium excretion decline rapidly, possibly secondary to contraction of the ECF volume (144). Premature infants of less than 30 weeks of GA continue to show elevated values of FENa, similar to those observed in the fetus, which may exceed 5% during the first few days of life (146,148,149). In these infants, excessive urinary sodium losses exceeding dietary sodium intake (e.g., breast milk, low-salt formula) often create a state of negative sodium balance and loss of body weight during the first 2 weeks of life (i.e., hyponatremia of prematurity). These infants may require at least 2 mEq/kg/d of supplemental sodium to maintain a normal sodium concentration and remain in positive balance (150,151).

Sodium is freely filtered at the glomerulus. The initial two-thirds of the proximal tubule of the suckling rat absorbs ~50% of the filtered load of sodium and water

(143,152,153 and 154), values only slightly less than those reported in the adult (152,153,155). Studies in several mammalian species ingesting a normal salt intake demonstrate parallel and proportionate increases in GFR and the reabsorptive capacity of the proximal tubule after birth, consistent with maintenance of glomerulotubular balance during postnatal development (125,156,157). Functional glomerulotubular imbalance may exist in the premature infant in whom the reabsorptive capacity of the proximal tubule lags behind the capacity for glomerular filtration (158,159).

The fractional reabsorption of sodium along the loop of Henle, expressed as a percentage of load, increases by about 20% during postnatal development (153), consistent with functional maturation of this nephron segment. Sodium is

P.987

absorbed in this segment through the furosemide- and bumetanide-sensitive Na-K-2Cl cotransporter located in the urinary membrane and is extruded from the cell at the basolateral membrane by the Na-K-ATPase transporter. In contrast, the fractional reabsorption of sodium along the distal tubule is greater in younger than in older animals, thereby explaining the sodium retention and blunted response to sodium loading characteristic of the young animal (143,160).

Clearance studies in human infants (151,152,153,154 and 155,158, 159,161,162,163,164,165 and 166) suggest that the percent of filtered sodium reabsorbed by the proximal tubule increases by about 5% between 28 and 34 wks GA, whereas the percent of distal sodium reabsorption increases by more than 15% during this same period. However, because the proximal tubule reabsorbs more than 70% of the filtered load of sodium, the small percentage increase in fractional reabsorption in this segment contributes to the postnatal increase in renal sodium retention as much as the larger percentage increase in the distal tubule.

Distal sodium reabsorption occurs in the cortical collecting duct (CCD) by apical sodium entry into principal cells through the amiloride-sensitive sodium channel ENaC and its extrusion at the basolateral membrane by the Na-K-ATPase. The avidity of the distal nephron for sodium reabsorption, may be related to the high levels of aldosterone that prevail in early postnatal life (44). Cellular effects of aldosterone within the fully differentiated distal nephron (specifically the CCD) include increases in the density of ENaC channels and stimulation of Na-K-ATPase activity (167,168 and 169). The net effect of these actions is the stimulation of sodium absorption.

Plasma aldosterone concentrations in the premature infant and newborn are high compared to those in the adult (50,170). However, clearance studies in premature infants (50,171) and investigations in neonatal laboratory animals (172,173) reveal a blunted responsiveness of the immature kidney to aldosterone. The density of aldosterone binding sites, receptor affinity, and degree of nuclear

binding of hormone-receptor appear to be similar in mature and immature rats (18), suggesting that the early hyposensitivity to aldosterone represents a postreceptor phenomenon. Premature infants can augment their renin secretion in response to negative sodium balance, but aldosterone production initially fails to respond adequately to this stimulation (174). The resulting relative hypoaldosteronism results in an inability to conserve sodium, manifested clinically by weight loss and hyponatremia.

Paradoxically, preterm infants of about 34 to 36 weeks GA excrete a sodium load more efficiently than do term newborns, but not as efficiently as adults (118,148,171). The sodium wasting characteristic of the preterm infant may be as a result of paucity of ENaC channels in the urinary membrane of the distal nephron (175).

Urinary sodium excretion during maturation is regulated not only by the RAS, but also by circulating catecholamines, renal sympathetic innervation, atrial natriuretic factor (ANF), PGs, dopamine, and glucocorticoids. Direct renal nerve stimulation in fetal and newborn sheep leads to sodium retention (176), a response qualitatively similar to that observed in adult animals and attributed to norepinephrine acting on α -adrenergic receptors (177). Studies in newborns indicate a relatively poor natriuretic response to ANF compared to their adult counterparts (108,178,179). Renal PGE₂, PGD₂, and PGI₂ reduce sodium and water absorption in the adult, promoting a natriuresis and diuresis, responses that are blocked by administration of indomethacin. In contrast, administration of this inhibitor to fetal sheep causes a natriuresis, despite a decrease in fetal RBF (73). Dopamine inhibits sodium reabsorption in the nephron by activation of D₁-like dopamine receptors. The natriuretic effect of dopamine is less pronounced in the fetal and neonatal kidney of many species, including man, compared to the adult as a result of blunted renal hemodynamic and tubular effects (171,173,180,181 and 182).

Circulating levels of glucocorticoids, including cortisol and corticosterone, surge in many species during or just before the period of weaning (183,184,185 and 186). Both endogenous gluco- and mineralocorticoids bind to the mineralocorticoid receptor with equal affinity (187). Although blood glucocorticoid concentrations are ~100-fold higher than aldosterone concentrations, the metabolism of cortisol into inactive derivatives by 11 β -hydroxysteroid dehydrogenase type 2 (11- β -HSD₂) protects the mineralocorticoid receptor from glucocorticoids (187). The presence of ENaC, mineralocorticoid receptor and low levels of 11- β -HSD₂ in the CCD suggest that glucocorticoids may act as sodium retaining steroids during early postnatal life (188,189).

Potassium

Potassium is transported actively across the placenta from mother to fetus (190). Indeed, fetal potassium is maintained at levels exceeding 5 mEq/L even in the face of maternal potassium deficiency (190,191).

Unlike adults, who are in zero balance, growing infants maintain a state of positive potassium balance (50,192). The relative conservation of potassium early in life generally is associated with higher plasma potassium values than in the adult (153,159,192,193). These levels average 5.2 mEq/L from birth to age 4 months, decreasing to 4.2 mEq/L by 3 years of age (193). The renal clearance of potassium in the infant is less than in the older child, even when corrected for GFR (193). Children and adults ingesting a regular diet containing sodium in excess of potassium excrete urine with a sodium-to-potassium ratio greater than 1, as expected. Although the sodium-to-potassium ratio of breast milk and commercial infant formulas averages 0.5, the urinary sodium-to-potassium ratio of the newborn also is greater than 1, consistent with significant potassium retention.

Infants, like adults, can excrete potassium at a rate that exceeds its glomerular filtration when given a potassium load, indicating the capacity for net tubular secretion (194); however, the rate of potassium excretion per unit

P.988

body weight in response to exogenous potassium loading is less in newborn than older animals (195). Clearance studies in saline-expanded dogs also provide indirect evidence for a diminished secretory and enhanced reabsorptive capacity of the immature distal nephron to potassium (196). In general, the limited potassium secretory capacity of the immature kidney becomes clinically relevant only under conditions of potassium excess. Under normal circumstances, potassium retention by the newborn kidney is appropriate and a requirement for growth.

Potassium is freely filtered at the glomerulus. Approximately 50% of the filtered load is reabsorbed along the proximal tubule in both newborns and adults (153). Up to 40% of the filtered load of potassium reaches the superficial distal tubule of the newborn, in contrast to about 10% in mature animals, providing evidence for functional immaturity of the loop of Henle (153,197).

Urinary potassium excretion is derived almost entirely from secretion in distal segments of the nephron, including the CCD. The low rates of potassium excretion characteristic of the newborn kidney are due, at least in part, to a low potassium secretory capacity of this segment (198). In contrast to the high rates of potassium secretion observed in adult CCDs, neonatal segments show no significant baseline potassium transport (199). An increase in tubular fluid flow rate does not stimulate potassium secretion in the neonatal CCD of the rabbit, as it does in the fully differentiated segment, until after weaning (199,200). Baseline and flow-stimulated potassium secretion appear to be limited early in life by a paucity of small-conductance (SK) (201) and calcium-activated maxi-K channels (200), respectively, in the urinary membrane of the CCD. The developmental expression of immunodetectable ROMK, the molecular correlate of the SK channel (202,203), and shortly thereafter, the maxi-K channel, immediately precedes the appearance of baseline and flow-stimulated potassium secretion in the CCD.

As stated above, fetal and neonatal kidneys are relatively insensitive to aldosterone. Chronic administration of exogenous aldosterone to fetal sheep increases sodium absorption and decreases PRA, yet fails to increase urinary potassium excretion (204). However, administration of the aldosterone antagonist spironolactone or sodium channel blocker amiloride, both without consistent effect on sodium excretion, inhibit renal potassium excretion in fetal sheep, suggesting that endogenous mineralocorticoids influence renal potassium excretion in utero (205).

Acid-Base

The acid-base status of the fetus is maintained by placental function and maternal mechanisms. The fetal kidney in the second one-half of pregnancy, however, is able to acidify the urine (206,207). Immediately after birth, the acid-base state of the full-term newborn is characterized by a metabolic acidosis (208); respiratory compensation generally occurs within 24 hours in the full-term infant (209).

The normal range for serum bicarbonate is lower for preterm infants (16 to 20 mmol/L) and full-term infants (19 to 21 mEq/L) than for children and adults (24 to 28 mmol/L). The lower levels of buffer base concentration in the blood of infants can be accounted for in part by the inability to completely excrete the byproducts of growth and metabolism (210,211). The load of endogenous acid generated by the metabolism of protein and deposition of calcium into the skeleton is larger in the infant than in the adult (212,213,214,215).

The concentration of bicarbonate in plasma is determined predominately by the renal bicarbonate threshold, which is lower in preterm and term infants than adults (194,216,217,218 and 219). The low bicarbonate threshold characteristic of the newborn is considered to reflect nephron heterogeneity and/or a low fractional reabsorption of bicarbonate in the immature kidney (50,220), the latter attributed in part to the relatively large proportion of total body water in the infant.

Postnatal maturation of the proximal tubular capacity for bicarbonate absorption has been proposed to be as a result of increases in activity of the sodium-hydrogen (Na/H) exchanger (NHE) and H⁺-ATPase localized to the urinary membrane of this segment (221,222). Experimental evidence further suggests that neonatal bicarbonate reabsorption is limited by low activity of carbonic anhydrase. Carbonic anhydrase facilitates renal acidification by catalyzing the interconversion of carbon dioxide and water to carbonic acid. The two major renal isoforms are cytosolic carbonic anhydrase II (95%) and membrane-bound carbonic anhydrase IV (5%). Carbonic anhydrase activity is present in the early human fetal kidney (223,224 and 225). The newborn kidneys of several experimental animals (226,227 and 228) exhibit less carbonic anhydrase activity than do mature kidneys. Postnatal increases in carbonic anhydrases II and IV likely contribute to the developmental increase in bicarbonate absorption observed in the maturing proximal tubule (226,229).

The renal response to acid loading increases with advancing gestational and postnatal ages. When compared to adult subjects given a comparable acid load, the infant exhibits a larger fall in blood potential of hydrogen (pH) and bicarbonate concentration, a smaller and slower fall in urine pH, and much smaller increase in urinary titratable acid and ammonium excretion per M2 (230,231,232 and 233). Premature infants born at 34 to 36 weeks of GA and studied 1 to 3 weeks after birth exhibit rates of excretion of net acid, titratable acid, and ammonium that are about 50% lower than term babies of similar postnatal age; net acid excretion increases to levels observed in term newborns only after 3 weeks of age (219,233). In response to acid loading with ammonium chloride, urinary pH values of less than 6 are rarely observed in premature infants until the second month of life (234). In contrast, by the end of the second postnatal week, urinary pH values of 5.0 or lower, comparable to those in the adult, are consistently observed in term infants (235,236).

The capacity of the neonatal kidney for the excretion of net acid is blunted, due in part to a limited excretion of urinary buffers, including phosphate and ammonium ions.

P.989

The rates of ammonia synthesis and excretion are low in the neonate (237) and, in response to acid loading, do not increase to mature values until 2 months of age (218, 235,238). Phosphate loading, administration of cow milk that is rich in protein and phosphate instead of breast milk, or high-protein feeding enhances the ability of the newborn to excrete titratable acids and ammonia (236,239).

The final site of urinary acidification is the renal collecting duct. Functional immaturity of this segment and the acid-base transporting intercalated cells therein may further limit the ability of the neonate to eliminate an acid load (240,241). Postnatal differentiation of intercalated cells has been shown to include changes in the morphology and function of these specialized cells with an increase in density.

Up to 10% of preterm infants develop a partially compensated hyperchloremic metabolic acidosis during weeks 1 to 3 of life, i.e., late metabolic acidosis (218), despite an otherwise healthy appearance. Typically, spontaneous remission occurs in the subsequent 2 weeks. These infants are characterized further by an apparent delay in postnatal weight gain despite ample dietary intake, suggesting a high rate of endogenous acid formation in infants whose dietary intake exceeds their anabolic capacity (212). Although infants provided supplemental sodium bicarbonate to maintain acid-base homeostasis showed greater increases in length than controls, there were no differences in weight gain between the two groups (217,242).

Calcium

The state of positive calcium balance characteristic of growing individuals is sustained by the coordinated interaction of bone, intestine and kidney. Urinary excretion of calcium varies inversely with GA in the first week of life and varies directly with urine flow and sodium excretion (243). High rates of calcium excretion may contribute in part to early neonatal hypocalcemia, which occurs in the first 24 to 48 hours of life (244). The urinary calcium-to-creatinine ratio in full-term infants ranges from 0.05 to 1.2 mg/mg during the first week of life, but may exceed 2 in premature neonates (243,245). In children more than 1 year of age, the ratio is approximately 0.2, and in adults, the ratio is less than 0.11 (246). The high fractional excretion of calcium in preterm infants may be related to maturational changes in the tubular handling of calcium. Approximately 50% of filtered calcium is reabsorbed along the superficial proximal tubule in mature rats, yet only 1% of filtered calcium is excreted (153), suggesting that, in the adult, almost one-half of the filtered calcium is reabsorbed at a site beyond the proximal tubule or in deep nephrons (153). The fractional reabsorption of calcium in the loop of Henle, like that for sodium, potassium, and chloride, is low in newborn rats, increasing significantly with advancing postnatal age (153,247). Absorption in both proximal tubule and thick ascending limb of the loop of Henle (TALH) is predominantly coupled to sodium absorption and is a passive process through the paracellular pathway. Calcium reabsorption within the distal nephron is active, transcellular and is regulated independently of sodium (248). Furosemide, methylxanthines, and dexamethasone increase urinary calcium excretion, thus increasing the risk for nephrocalcinosis and nephrolithiasis (249,250).

The principal hormones that regulate renal calcium excretion in the adult are parathyroid hormone (PTH), 1,25-dihydroxyvitamin D₃ and calcitonin (251). A reduction in the serum calcium concentration results in the secretion of PTH from the parathyroid glands, a response leading to the conservation of calcium by the kidney and the enhanced uptake of calcium by the intestine, which occurs indirectly through the PTH-induced synthesis of the active vitamin D metabolite 1,25-dihydroxyvitamin D. The net effect is to return the serum calcium back toward its normal baseline level. In mature animals and in adults, PTH decreases urinary calcium excretion by stimulating calcium reabsorption across the cortical TALH and collecting duct (252,253,254,255,256,257 and 258). PTH-responsive adenylate cyclase has been found in renal cortical homogenates from preterm rabbits (259) and in the TALH in 2-day-old puppies (260). It has been suggested that neonatal hypocalcemia may be as a result of end-organ unresponsiveness to PTH. In premature and full-term newborns, however, the administration of exogenous PTH increases urinary excretion of cAMP (261,262), results in a calcemic response, but affects calciuria and phosphaturia only minimally (263). Vitamin D stimulates calcium reabsorption in the distal tubule via binding to vitamin D receptors (VDRs). Renal production of 1,25-dihydroxyvitamin D increases rapidly after birth, provided that the concentration of the substrate, 25-hydroxyvitamin D, is adequate (264). VDR are present in cells of branching

ureteral buds by 15 days GA and at later developmental stages in glomerular and tubular cells (265).

Systemic calcium homeostasis is controlled in large part by the extracellular G protein-coupled calcium-sensing receptor (CaSR), located on parathyroid and kidney cells in which it senses the extracellular calcium concentration and in turn alters the rate of secretion of PTH and renal calcium (and sodium and chloride) reabsorption in the TALH and early distal nephron (266,267,268 and 269). There is little expression of CaSR in the fetal kidney (270). Steady state abundance of CaSR messenger ribonucleic acid (mRNA) and protein increase significantly during the first week of life, related principally to an increase in expression of the receptor in the TALH and, to a lesser extent, in the collecting duct (270).

Phosphate

In contrast to most other transport processes, the capacity of the kidney of the neonate to reabsorb phosphate is far greater than in the adult and progressively declines with advancing age (271,272). The fractional reabsorption of phosphate increases from 85% of the filtered load at 28 weeks GA to 99% at term, decreasing thereafter to approximately 85% between 3 and 20 months of age (273). The

P.990

high renal reabsorptive capacity for phosphate early in life allows the infant to retain a large portion of phosphate absorbed from the gut and sustain a state of positive balance (273), as is required for growth and development. Note that phosphate is a major constituent of bone, muscle, and membrane phospholipids and is critical for cellular processes involving ATP. Human neonates and older infants have a higher serum phosphate concentration than adults.

Studies in experimental animals also demonstrate enhanced renal tubular reabsorption of phosphate early in life (168,169). Younger subjects have a higher maximal net reabsorption of phosphate per unit glomerular filtrate than adults (274,275). The fractional reabsorption of phosphate in the newborn proximal tubule and distal nephron is higher than that in the adult (276,277). The high intrinsic rate of sodium phosphate transport measured in neonatal proximal tubules has been attributed to an abundance of a growth-related sodium-phosphate cotransporter protein in the luminal membrane (278), a high membrane fluidity of the immature nephron (279), a low intracellular phosphate concentration (174), and the hormonal milieu prevailing in the perinatal period (279,280). Nephron heterogeneity may also explain, in part, the limited urinary phosphate excretion observed in the rapidly growing animal. Because deep nephrons reabsorb more phosphate than cortical nephrons (281,282), and nephronogenesis begins in the juxtamedullary region, the kidney of the immature animal may contain a relatively greater number of functioning nephrons with a

high capacity for phosphate reabsorption.

Renal phosphate transport is regulated by a number of factors, including dietary intake, PTH, growth hormone, insulin-like growth factor 1, and glucocorticoids (283,284). The sensitivity of the renal response to these factors is developmental-stage specific. Growth hormone stimulates proximal tubular phosphate transport (283). The high reabsorptive capacity of the juvenile kidney for phosphate persists after parathyroidectomy (275,285). Serum levels of PTH are low immediately after birth, increasing substantially thereafter to levels in infancy exceeding those observed in later childhood (286,287). Although exogenous PTH administered to humans or experimental animals results in a blunted response in the immediate postnatal period (259,274), 1-wk-old full term infants exhibit a prompt phosphaturic response and an increase in urinary cAMP excretion after PTH administration (261,262 and 263).

Magnesium

Ninety-seven percent of the filtered magnesium is reabsorbed by the mature nephron, largely (~60%) in the TALH (288). Micropuncture analysis of magnesium transport in developing rats shows efficient renal tubular reabsorption of magnesium in this segment early in life (153). The proximal tubule of the adult animal reabsorbs only about 10% of the filtered magnesium, whereas that of the young rat reabsorbs about 60% of the filtered load (153). Postnatal maturation is associated with a decrease in the fractional reabsorption of magnesium in the proximal tubule (153). The avid retention of magnesium by the immature kidney likely contributes to the inverse relationship noted between plasma magnesium and somatic maturity in early postnatal life (289).

Magnesium reabsorption is regulated by a number of hormones, including PTH, calcitonin, glucagon, and AVP (290,291,292,293,294 and 295). Additionally, dietary magnesium restriction or loading stimulates or inhibits magnesium reabsorption, as appropriate, a response mediated by the CaSR in the cortical TALH and distal tubule (296,297). Loop diuretics such as furosemide inhibit magnesium absorption and increase magnesium excretion as a result of their inhibition of sodium chloride transport and modification of the transepithelial voltage in the TALH (298).

Glucose

Premature infants of less than 34 weeks of GA have a higher urinary glucose concentration, higher fractional excretion of glucose, and lower maximal reabsorption of glucose than full-term infants and older children (116). However, the maximal reabsorption of glucose factored by GFR, the fractional reabsorption of glucose, is similar in neonates and in adults (116,299,300). These results provide additional evidence for preservation of glomerulotubular balance, at least in term infants. The lower renal threshold for glucose in newborns compared to

their adult counterparts is believed to reflect a greater degree of nephron heterogeneity early rather than later in life (299).

The neonatal proximal tubule possesses both high- and low-affinity sodium-coupled glucose transporters that mediate reabsorption of filtered glucose; interestingly, only the low-affinity high-capacity system is present in adults (301,302 and 303). It is not clear when during maturation the high-affinity system disappears, but its presence early in life may enable the anatomically immature kidney to efficiently reabsorb sugar from the glomerular filtrate.

Organic Acids

Organic acids, including PAH (see RBF) and endogenously produced uric acid, are eliminated by filtration and proximal tubular secretion. Organic acids are transported from the peritubular circulation across the basolateral surface of the proximal tubule to the tubular fluid. The renal clearance of organic acids is low in the neonate, even when corrected for body size, and increases gradually with age (17,304,305). As discussed previously, the limitation in tubular excretion of weak acids may be due in part to the preponderance of blood flow to the juxtamedullary region, bypassing tubular secretory sites. Additional variables that may account for the limited clearance of organic acids include the low GFR, limited energy for transport, and restricted expression of organic anion transporter proteins (306).

P.991

Amino Acids

The renal reabsorption of many amino acids, including threonine, serine, proline, glycine, and alanine, is lower in newborn animals and humans than in adults, often resulting in aminoaciduria (307,308). This does not appear to be a generalized defect in amino acid reabsorption, because other filtered amino acids (e.g., methionine, isoleucine, leucine, tyrosine) are reabsorbed more completely. Specific transporters for acidic, basic, and neutral amino acids have been identified in the urinary membrane of proximal tubules in newborn kidneys (309,310,311 and 312). The transient limitation in net transtubular reabsorption of amino acids characteristic of the neonate may arise from intrinsic differences in activity and transport capacity of these discrete transport systems, and/or a lower rate of amino acid efflux out of the cell into the peritubular circulation in the neonate compared to the adult, a mechanism that also would account for the high intracellular concentrations of amino acids observed early in life (309).

Urinary Concentration and Dilution

The fetal metanephric kidney of a variety of species, including man, produces large volumes of hypotonic urine that contribute significantly to the volume and

composition of amniotic fluid (144,158,313,314 and 315). Yet, the fetal nephron is able to concentrate urine under conditions of stress, such as that induced by maternal water deprivation (316), hemorrhage (61), or infusion of AVP (317,318). However, the maximum urine osmolality that can be achieved is only about 20% of that in the adult (129,319).

Urinary Concentration

Urine voided at or shortly after birth generally is hypotonic with respect to plasma (313,320). The maximal urinary concentrating ability ($\sim 1,000$ - $1,200$ mOsm/kg) of children and adults is generally not attained by the neonate before 6 to 12 months of age (321,322). After fluid deprivation for 12 to 24 hours, the maximal urine osmolality achieved in premature and full-term newborns is 600 to 800 mOsm/kg, respectively (321,322). A few 1- to 2-month-old infants may be able to generate a urine osmolality as high as 1,000 mOsm/kg (323,324).

Urinary concentration requires a corticomedullary osmotic gradient, the pituitary release of AVP and the ability of the collecting duct to increase its water permeability in response to AVP. The limited urinary concentrating ability of the infant appears to be due primarily to an inability to generate a corticomedullary osmotic gradient and diminished responsiveness of the distal nephron to AVP (323,324).

Corticomedullary Gradient

The capacity to concentrate the urine has been directly related to elongation of the loops of Henle and their penetration into the medulla (325). The inner medulla and renal papillae are poorly developed in the immature kidney. In the rat, the 1.6-fold increase in length of the renal medulla correlates well with the 1.5-fold increase in urine osmolality observed between 10 and 20 days of age (325). In addition to anatomic maturation of the loops of Henle, urinary concentration requires the generation of a high interstitial solute concentration gradient in the medulla, which is underdeveloped early in life (321,326,327). Generation of the corticomedullary osmotic gradient necessitates the postnatal maturation of several processes involved in urinary concentration: sodium reabsorption and urea sequestration by the TALH and functional activation of aldose reductase, an enzyme necessary for generation of intracellular osmolytes, important for maintenance of cell function in the concentrated milieu (326,328,329). These structural and functional limitations of the countercurrent multiplication and exchange systems prevent build-up and maintenance of a medullary gradient in the immature kidney.

Antidiuretic Hormone

The limited ability of the immature kidney to concentrate urine is not as a result of an inability to synthesize and secrete AVP. Circulating levels of antidiuretic

hormone (ADH) are elevated in preterm and term infants and decrease rapidly in term infants within 24 hours of birth (98,330,331). Studies in fetal and newborn animals (59,332,333), and in human infants (331,334), indicate a qualitatively appropriate response to osmolar or volume stimuli known to affect AVP release. Furthermore, exogenous administration of AVP or 1-des-amino-8-d-AVP (DDAVP) to healthy 1- to 3-week-old newborns leads to a response, albeit of shorter duration and reduced magnitude than that observed at 4 to 6 weeks (335). Cumulative evidence suggests that the blunted sensitivity of the fetal and neonatal kidney to AVP and limited concentrating ability of the neonatal animal is not as a result of a paucity of V₂ receptors (receptor to which ADH binds in the collecting duct) (336,337), aquaporin channels involved in water transport across renal tubule epithelia (338), or efficiency of coupling to second messengers (adenylate cyclase and protein kinase A activity) (339,340 and 341) after the first week of postnatal life, but is limited primarily by the poorly developed corticomedullary osmotic gradient.

Urinary Dilution

Premature infants (less than 35 weeks of GA) studied under conditions of maximal water diuresis decrease urine osmolality to 70 mOsm/kg, whereas infants more than 35 weeks of GA are able to reduce urine osmolality to 50 mOsm/kg (159). Although there is greater proximal sodium rejection in preterm than term infants, the high avidity of the distal nephron for sodium reabsorption allows the neonate, especially the preterm infant, to generate a free water clearance greater than that in adults (143,196,342). Despite the greater capacity for free water clearance, the ability of the neonate to excrete a hypotonic load is limited, presumably as a result of the low GFR.

Clinical Evaluation of Renalfunction and Disease

Early diagnosis of a renal anomaly may help to prevent complications, including those related to the kidney itself (e.g., progressive loss of renal function as a result of systemic hypertension, obstructive or reflux uropathy, or infection) and those related to other organs (e.g., cerebral hemorrhage, seizures or congestive heart failure [CHF] secondary to hypertension, ventricular arrhythmia secondary to hyperkalemia, urosepsis). In this section, clinical and laboratory features that should raise suspicion of a renal problem are reviewed and an approach to establish the correct diagnosis is presented.

Incidence of Renal and Urinary Tract Malformations

The incidence of renal and urinary tract malformations varies in different studies depending on the methodology used for detection: 0.2% to 0.6% by abdominal palpation (343,344 and 345), 7% to 9% in autopsy series (Table 42-1) (346,347), 0.1% to 1.4% by prenatal ultrasonography (US) (348,349,350,351 and 352), and 1% to 2% in prospective studies using US screening (353,354,355,356 and 357). A similar incidence (1.3%) was found using a perinatal approach that combined family history, prenatal US, physical examination, and case-oriented neonatal imaging (356). In one large series, the male-to-female ratio for hydronephrosis was 2.4:1, compared to 1.4:1 for parenchymal anomalies (358).

History

Family History

Positive family history should be sought for hereditary disease, including renal cystic disease, tubular disorders, and nephrotic syndrome. There is a 9% incidence of asymptomatic renal malformations—most often unilateral renal agenesis—in the first-degree relatives of infants with agenesis or dysgenesis of both kidneys or agenesis of one kidney and dysgenesis of the other (359). A study using US has confirmed that, in some families, bilateral agenesis or dysplasia is inherited as an autosomal dominant trait

P.993

(renal adysplasia) (360). The clinician should keep in mind that some autosomal dominant diseases have variable penetrance or time of presentation (e.g., adult-type polycystic disease) and that a new mutation may occur. Additionally, the history for prior fetal loss should be carefully reviewed, preferably with an autopsy review.

The risk of renal or urinary tract malformation or renal failure is increased by maternal diabetes and by certain medications or drugs, including trimethadione, thalidomide, cocaine, PGSI and ACE inhibitors (see Appendix G-2). Maternal diabetes, especially in poorly controlled cases, is associated with a higher incidence of urogenital malformations (2.6% vs. 1.2% in controls) (361) and neonatal renal vein thrombosis. The risk for renal or urinary tract malformations is higher in an infant of a diabetic mother with a caudal regression syndrome or a femoral hypoplasia- unusual facies syndrome (see Appendix G-2). Fetal alcohol syndrome is associated with unilateral renal agenesis, renal hypoplasia, ureteral duplication, and hydronephrosis (362). A meta-analysis showed that maternal cocaine abuse is associated with an odds ratio of genitourinary malformations of 5.0 (95% confidence interval 1.1 to 23.6); the odds ratio was 6.1 (95% confidence interval 1.2 to 31.3) in studies comparing cocaine-polydrug users to polydrug users without cocaine (363).

TABLE 42-1 INCIDENCE OF RENAL AND URINARY TRACT MALFORMATIONS IN INFANCY

Author	No. of Subjects	Selection Criteria	Method of Screening	Most Common Anomalies (Final Diagnosis)	No. of Subjects with Anomalies (% of Total)
Sherwood 1956	12,160	Consecutive NN	Palpation confirmation by IVU	Ectopia (7), horseshoe/fused kidneys (5), obstruction (6), Wilms (1)	22(0.2%)
Museles 1971	12,150	Consecutive NN	Palpation confirmation by IVU	Ectopia (7), horseshoe (4), agenesis (3)	22(0.2%)
Brion 1984	1,200	Consecutive NN	Prenatal US (2/3), physical examination, US screening for various indications	Hypoplasia/agenesis (4), obstructive uropathy (8), reflux (1)	15(1.3%)
Helm 1986	11,986	Consecutive pregnancies	Prenatal US	Hydronephrosis (9), VUR (3), mild dilatation (10), cystic disease (3)	33(0.3%)
Steinhart 1988	437	Healthy infants	US	VUR (3), obstructive uropathy (3)	6(1.4%)
Gillerot 1988	900	NN autopsies	Autopsy	Dysplasia/agenesis (30), polycystic kidneys (18), obstructive uropathy (11), cloacal exstrophy (4)	63(7%)
Scott 1991	1,061	NN in well-baby nursery	Postnatal US, followed by appropriate workup	Duplex kidney (1), solitary kidney (2), hydronephrosis (97), VUR (16), renal agenesis (33), MKD (15), dysplasia (6), PKD (11), duplex kidney (15), megaureter (10), urethral valves	11(1.0%)
Scott 1993	242,628	Northern Region Fetal Abnormality Survey	Population survey including both prenatal US and postnatal US	Hydronephrosis (97), VUR (16), renal agenesis (33), MKD (15), dysplasia (6), PKD (11), duplex kidney (15), megaureter (10), urethral valves	451(2%)
Jelen 1993	1,021	Consecutive neonates	Postnatal US	Hydronephrosis (6), MKD (2), duplication (4), agenesis (2)	20(2%)
Fugelseth 1994	22,310	Consecutive pregnancies	Prenatal US at 17 and 32 wk	Hydronephrosis (24), MKD (10)	47(0.2%)
Gunn 1995	3,856	Consecutive pregnancies	Prenatal US after 28 wk, confirmed by postnatal US at 6 d to 6 wk	Transient pyelectasis (216), obstructive uropathy (23), VUR (14), MKD (8), urethral valves (3)	54(1.4%)
Kim 1996	5,442	Consecutive pregnancies	Prenatal US confirmed by US	Hydronephrosis (37), MKD (5), PKD (2), renal agenesis (2), ectopic kidney (1), hypoplastic kidney (1)	48(0.9%)

IVU, intravenous urography; MKD, multicystic kidney dysplasia; NN, newborn infants; PKD, polycystic kidney disease; US, ultrasonography; VUR, vesicoureteral reflux.

Pregnancy

The diagnosis of a urologic problem may be obtained by US performed as a routine examination or as a part of the workup for another anomaly. A high maternal serum or amniotic alpha-fetoprotein (AFP) concentration is associated with several anomalies, including bladder exstrophy or myelodysplasia (which are associated with urinary tract malformations, see Appendix G-2), and with congenital nephrotic syndrome of the Finnish type (CNF). Increased maternal serum AFP concentration is associated with pyelectasis and thick-walled bladder (364). Oligohydramnios may result from amniotic sac rupture, prolonged leaking or from fetal oligoanuria. The latter can result from bilateral congenital renal disease, bilateral urinary tract obstruction, acquired fetal renal disease secondary to maternal administration of indomethacin or ACE inhibitors (365,366,367), or severe pregnancy-induced hypertension. Among many causes, polyhydramnios may be the first clue to the diagnosis of a nephrogenic defect of urinary concentration, whereas fetal hydrops may be the first sign of congenital nephrotic syndrome.

Physical Examination

Dysmorphism

Renal and Urinary Tract Anomalies Associated with Multiple Congenital Anomalies

Any dysmorphic feature (e.g., abnormal ears) should lead the clinician to look for other anomalies and structural defects. Appendix I-1 lists the major signs of multiple congenital anomalies associated with renal and urinary tract anomalies (see Chapters 38 and 43). The most typical sequence related to kidney disease is the oligohydramnios sequence, i.e., Potter syndrome, which may result from prolonged leakage of amniotic fluid or from intrauterine oligoanuria. Fetal deformation caused by severe oligohydramnios includes Potter facies, which is characterized by a redundant, wrinkled skin, flat nose, low-set ears, bilateral skin folds arising at the inner canthus, receding chin, and malposition of the hands and feet (368). Lung hypoplasia results from fetal compression as a result of the oligohydramnios (369) and, in some cases, massive abdominal distention. Even a short duration (1 week) of oligohydramnios can induce hypoplasia of the lung during the pseudoglandular period (12 to 16 weeks of GA) and the canalicular period (17 to 28 weeks of GA) (368,369,370 and 371).

Associations of Renal and Urinary Tract Anomalies with Single Signs

Upper urinary tract anomalies may be associated with several isolated anomalies (e.g., abnormal vertebrae, anorectal malformations) (see Appendix G-3); however, some of these associations are controversial (372,373 and 374). Ultrasonographic screening of infants with isolated single umbilical artery (UA) showed urinary tract malformations in 8/112 (7%) (373). A meta-analysis of studies using a more extensive urologic workup found a higher incidence (33/204, or 16.2 %); however, additional anomalies detected by this more extensive investigation were only minor (375). The presence of specific index signs should raise the suspicion of a known multiple congenital anomaly; the presence of vertebral or anorectal anomalies can suggest a possible VATER syndrome. Urinary tract abnormalities were detected in 6 infants with isolated preauricular tags (6/70; 8.6%) (376). Some signs may be an indication for performance of US only in some families (e.g., preauricular pits) (374). The risk of finding renal or urinary tract anomalies increases with the number of additional system anomalies and, in the case of hypospadias, with its severity (372).

Thus, it appears justified to obtain a US in newborn infants with specific types of single anomalies and in those with recognized multiple congenital anomalies.

Vital Signs and General Examination

Shock and asphyxia can lead to prerenal or intrinsic renal failure. Tachycardia, peripheral vasoconstriction, hypotension, or narrowing of the pulse pressure suggests hypovolemia or low-output cardiac failure, which places the infant at risk for prerenal failure. Tachyarrhythmia, premature ventricular contractions, or abnormal QRS complexes on cardiac monitoring may be the first sign of hyperkalemia, which may be as a result of, or related to, renal immaturity or renal failure. Seizures or coma may be as a result of hypertension or complications of renal failure.

Measurement and Evolution of Blood Pressure in the Neonatal Period

Accurate blood pressure measurement is obviously crucial not only to the evaluation of hypertension (see below), but also to the ongoing assessment of any neonate. Many neonates will have their blood pressure measured directly through an indwelling umbilical or radial artery catheter; this technique provides the most accurate method of measuring blood pressure, minor artifacts (such as from air bubbles or blood clots in the tubing) notwithstanding (377). Indwelling catheters also are helpful in the management of infants with

hypertension as they make it possible to obtain frequent blood pressure determinations. This is discussed in more detail below.

The most commonly used indirect method of blood pressure measurement is the oscillometric technique, which directly measures mean arterial pressure (MAP) based on the oscillations of the arterial wall; systolic and diastolic blood pressure are then back-calculated from the MAP using manufacturer-specific algorithms. These devices are usually sufficiently accurate for routine clinical use, although it is important to note that the readings obtained by oscillometric devices may differ between 1 to 5 mm Hg compared to directly measured blood pressure (378). Shock may also lead to inaccurate oscillometric measurements (379). Despite these issues oscillometric devices clearly are useful for measuring blood pressure in infants without indwelling arterial catheters, and in infants that have been discharged from the nursery.

Selection of a proper sized cuff is also crucial for correct indirect blood pressure measurement. As discussed in the Fourth Report of the National High Blood Pressure Education Program (380), the length of the cuff bladder should be 80% to 100% of the arm circumference and the length of the cuff bladder should be 80% to 100% of the arm circumference. Leg blood pressures tend to be higher than those obtained in the arm (381,382,383,384); therefore it is important to have the nursing staff document in which extremity an infant's blood pressure is being measured so that trends can be accurately followed over time.

Many studies have examined the pattern of normal blood pressure in normal and premature infants (384,385,386). Most recently, Zubrow and colleagues examined blood pressures obtained in over 600 infants of varying birth weights (BW) and GAs admitted to 14 neonatal intensive care units (NICUs) (387). They found that blood pressure at birth is closely correlated with GA and BW (Appendix G1a&b). There is then a predictable increase in blood pressure over the first 5 days of life that is independent of these factors. Thereafter, blood pressure continues to rise gradually, with the most important determining factor being post conceptual age (Appendix G1c). These data provide a clinically useful method of determining whether an infant's blood pressure is normal or elevated (388) (see Hypertension).

Blood pressure increases with the awake state, in the knee-chest position, with crying, pain, and during physical examination and procedures, or even during feeding (382,389,390 and 391). In some infants, blood pressure follows a circadian pattern (392). Tracking of blood pressure begins during the first months of life (393).

Chest

A small chest suggests hypoplastic lungs, which can be associated with renal and urinary tract malformations. Previous data suggesting an association of kidney and urinary tract malformations with polythelia, i.e., supernumerary nipples were not confirmed by a large study on 200 asymptomatic infants (394). Prerenal failure may result from CHF, PDA, and severe respiratory distress.

Abdomen

The physical examination of a newborn infant should include bimanual palpation of the abdomen for the presence of a normal kidney in each flank (212,213,225). The examination is easiest in the delivery room, before the bowel is filled with gas; later on, it is facilitated by relaxation of the abdominal wall musculature obtained, for instance, by eliciting the sucking reflex. Several characteristics of the kidneys should be evaluated, including location (normally in the flank; an ectopic kidney may be located in the pelvis), size (the normal size for a 3.3 ± 0.5 [mean \pm SD] kg infant is 4.2 to 4.3 ± 0.5 cm) (395), and long axis (normally cephalocaudal). A horseshoe kidney may be suspected if the lower pole is closer to the midline than the upper pole. The consistency of a normal kidney is firm, in contrast to a cystic or a hydronephrotic kidney, which may be depressible. The surface normally is smooth, but large cysts can be palpated in multicystic or autosomal dominant polycystic kidneys.

Two thirds of abdominal masses are genito-urinary in origin and may be as a result of a polycystic/multicystic kidney, renal vein thrombosis, congenital or acquired hydronephrosis (e.g., as a result of a fungus ball or papillary necrosis), or a renal tumor (396,397). A suprapubic mass suggests bladder distention, which may result from lower urinary tract obstruction or an occult spinal cord lesion. In some patients, one or both kidneys cannot be palpated. This may be as a result of a less than optimal examination (e.g., absence of patient relaxation, bowel distention), unilateral renal agenesis, renal malposition (in which case the kidney may be felt at another place in the abdomen), or renal hypoplasia or aplasia. Some abnormalities of the abdominal wall, such as bladder exstrophy, cloacal exstrophy, and prune-belly syndrome, are associated with renal anomalies. Sphincter dysfunction may suggest an occult spinal dysraphism.

The umbilical cord should be checked for the presence of a single umbilical artery. Ano-rectal anomalies or ambiguous genitalia, including severe hypospadias (372), should raise the suspicion of associated renal or urologic malformations. Percussion of the abdomen may disclose ascites or a large bladder. In the absence of hydrups fetalis,

P.995

neonatal ascites commonly is as a result of the rupture of an obstructed urinary tract (398).

Limbs

Motor and sensory dysfunction of the lower limbs suggests an occult spinal dysraphism. Several limb anomalies are part of syndromes or sequences associated with renal or urinary tract malformations, such as skeletal dysplasia, caudal regression syndrome, radial aplasia, femoral hypoplasia, rocker bottom feet, compression deformation, polydactyly, syndactyly, and hemihypertrophy.

Hydration

Serial measurements of net body weight should be compared to the normal evolution of postnatal weight (399). Signs of dehydration include weight loss, dry skin and mucosae, sunken fontanelle, and signs of hypovolemia. In newborn infants, generalized edema usually starts around the eyes, at the perineum, and on the lateral sides of the trunk. Edema may be a sign of renal failure or nephrotic syndrome, among other causes.

Clinical Observations

Time of the First Postnatal Voiding

With early feeding, 97% of all infants void within 24 hours after birth (including in the delivery room) (400). Urine produced in utero normally is dilute, with an average osmolality less than 200 mOsm/kg. Higher osmolality in utero may result from obstructive urinary tract disease, poor tubular reabsorption of sodium, administration of oxytocin or indomethacin to the mother, or intrauterine asphyxia. In contrast, urine produced after birth usually is isotonic or hypertonic, probably as a result of increased release of oxytocin and ADH.

Urine Output

In full-term infants, urine output after the first day of life increases progressively, in parallel with daily intake. In low BW (LBW) and VLBW infants, three phases occur in the early postnatal period: an oliguric phase, during which the urine output is always lower than the intake; a polyuric phase starting between 24 and 72 hours of age, during which the output exceeds the intake; and an adaptive phase, during which the kidney adjusts to the rate of fluid intake (401,402). A diuretic phase is observed in most infants, regardless of respiratory status or environment. The diuretic phase is associated with a high excretion of sodium and chloride, and, in much smaller amounts, potassium and bicarbonate (403).

Characteristics of Urination

The baby should be observed for dribbling or persistence of a large bladder after urination, suggesting either posterior urethral valves or neurogenic bladder. Urination through an abnormal location suggests hypospadias, epispadias, ambiguous genitalia, or both. Additional discussion can be found in Chapter 43.

Urinalysis

Urinalysis at the bedside includes the dipstick, which can help diagnose proteinuria, excretion of hemoprotein (hematuria, hemoglobinuria or myoglobinuria), glucosuria, and leukocyturia, and the measurement of urine specific gravity (SG) by refractometry. Urine SG is inversely proportional to the urine output. In neonates, the relationship between SG and osmolality differs from that in older subjects (404), and dipsticks do not provide a reliable assessment of urine osmolality (405). The rate of physiologic proteinuria in the neonate changes with GA and postnatal age (Table 42-2). The differential diagnosis of pink urine and of hemoprotein is discussed later in this chapter (see Differential Diagnosis of Hematuria). Massive glucosuria may occur when glycemia is greater

than 150 mg/dL, whereas mild glucosuria is common in VLBW infants even when glycemia is normal.

Laboratory Evaluation

Measurement of Glomerular Filtration Rate

GFR may be expressed in mL/min; mL/min/1.73 m² of BSA; mL/min/kg of body weight; or mL/min/kg of lean body mass; which of these units is most appropriate for infants is controversial (406).

To be an adequate marker for GFR, a substance must not be metabolized, must be completely filtered through the glomerulus, must not be secreted by the tubule, and must be eliminated from the body only by the kidney, unless GFR is determined by a classic clearance method (407). Adequate markers include inulin, polyfructosan, radionuclides such as 99mTechnetium-diethylenetriaminepentacetic acid (DTPA) and Cystatin C (408).

In the clinical setting, GFR often is estimated by creatinine clearance or by comparing Pcr to normal values for

P.996

GA and postnatal age (Figs. 42-5 and 42-6). Limitations of creatinine clearance as an assessment of GFR have been attributed to inaccurate determination of Pcr, effect of maternal creatinine load on creatinine concentration, tubular secretion of creatinine, passive back-diffusion of creatinine across leaky tubules in extremely preterm infants, and difficulty in obtaining complete urine collections in newborn infants, especially in girls. Cord blood creatinine concentration is almost equivalent to the maternal level. In full-term infants, Pcr decreases exponentially after birth (409), whereas in VLBW infants, it increases in the first 36 to 96 hours of life and then gradually decreases. In the most immature infants, the increase in Pcr is higher and the decrease is more gradual, probably as a result of a slower progression of glomerular function and a greater backflow across the immature tubular and vascular structures (410,411) (Figures 42-5 and 42-6).

TABLE 42-2 PROTEINURIA DURING THE FIRST DAYS OF LIFE

Gestational Age (wk)	No. of Infants	Mean and Range (mg/m ² /h)
≤28	5	0.86 (0.2-1.33)
30	12	2.08 (0-9.4)
32	15	2.32 (0-5.22)
34	15	2.48 (0-13.07)
36	17	1.27 (0-4.60)
40	26	1.29 (0-6.14)

From Jose PA, Slotkoff LM, Lilienfield LS, et al. Sensitivity of neonatal renal vasculature to epinephrine. *Am J Physiol* 1974;226:796-799, with permission.

Figure 42-5 Postnatal evolution of serum creatinine concentration (umol/L) in preterm infants. Values are given as mean and standard error (From ref. 411, with permission).

Figure 42-6 Postnatal evolution of creatinine clearance (mL/min/1.73 m²) in preterm infants. Values are given as mean and standard error (From ref. 411, with permission).

If measured reliably, Pcr is correlated with the half-life of medications eliminated by glomerular filtration (412,413 and 414). Nevertheless, the relationship between GFR and Pcr is hyperbolic, so that a fall in GFR of 50% may not be detectable by a change in Pcr. Thus, the clinician usually can use Pcr for routine estimation of GFR in most newborn infants, except immediately after birth or during sudden

P.997

changes in GFR. Formal measurements of creatinine clearance or GFR are recommended for patients with renal impairment.

A reasonably accurate estimation of GFR can be made by using an empirically derived formula (409), which has been applied to normal preterm and term infants (409,415)

- Preterm infants: Estimated GFR (ml/min per 1.73 m²) = 0.33 × length (cm)/Pcr (mg/dl)
- Term infants: Estimated GFR (ml/min per 1.73 m²) = 0.45 × length (cm)/Pcr (mg/dl)

Blood Urea Nitrogen

A high value of blood urea nitrogen (BUN) can result from catabolism, dehydration, high protein load (e.g., oral, intravenous, gastrointestinal bleeding), or renal failure. A low value of BUN can result from ECF expansion or decreased production of urea. The latter may be observed in association with anabolism, low protein intake, urea cycle disorder, liver failure, or liver immaturity (416).

Uric Acid

Serum concentration of uric acid is higher in cord blood than in maternal blood. Urinary uric acid concentration in full-term infants drops to its lowest value by the 7th day; its concentration in preterm infants remains significantly higher than in full-term babies during the first month of life (417). A high urinary uric acid to creatinine ratio is a marker of perinatal asphyxia (418).

Plasma Renin Activity

The most common indication for the measurement of PRA is the evaluation of hypertension. Normal levels of PRA are higher in the newborn infant than in older children or adults. This is discussed further in the section on Hypertension.

Genetic, Biochemical, and Molecular Diagnosis

The number of tests available for the diagnosis of congenital disorders is rapidly increasing (see Chapters 10, 12, 38, and 41). Classic chromosome analysis can be enhanced by high-resolution methods. Biochemical diagnosis is possible either by measuring enzyme activity or a chemical in a biologic fluid (e.g., high AFP concentration in maternal serum or amniotic fluid suggesting a diagnosis of congenital nephrotic syndrome in a high-risk family) or in cultured cells obtained from chorionic villi, amniotic cells, or fibroblasts (e.g., for diagnosing cystinosis).

There are a number of methods used in genetic analysis (see Chapter 38). In many disorders, the gene has been mapped to a specific chromosomal locus and is genetically linked to DNA markers. Genetic diagnosis is then possible on amniotic fluid, chorionic villous, or blood samples, if one or more specific alleles are informative, i.e., characteristic for the disease in a given family or in a given population (e.g., in CNF, see later in this chapter). If the gene responsible for a particular disease has been cloned and sequenced, the specific mutation in an affected individual or family can be determined by polymerase chain reaction (PCR), followed by sequence analysis or another method. Molecular diagnosis may be complicated by the fact that a similar phenotype may result from mutations of one of two or more genes, e.g., autosomal dominant polycystic kidney disease (ADPKD) (chromosomes 16, 4, and 2) (419,420,421,422,423) and for nephrogenic diabetes insipidus (NDI).

Urinary Acidification

Immaturity of renal tubular acidification results in a significantly lower value of serum bicarbonate concentration in VLBW infants than in full-term infants. In parallel, the serum base excess is often between -5 and -10 mEq/L in VLBW infants, compared with 0 to -5 mEq/L in full-term infants, and the anion gap, is normally 15 to 22 mEq/L in premature infants, compared to 12 ± 2 mEq/L (less than 15 mEq/L) in full-term infants. In newborn infants, metabolic acidosis often is secondary to asphyxia, hypoxia, shock, or sepsis. If metabolic acidosis is persistent, an inborn error in metabolism or a defect in tubular acidification, among other diagnoses, should be suspected. Measurement of urine pH, and of urine-to-blood carbon dioxide tension gradient is indicated to rule out distal renal tubular acidosis (RTA) (424) (see Tubular Function).

Microscopic Examination of Urine

The shape of erythrocytes in freshly voided urine should be observed under the microscope. The presence of deformed cells suggests hematuria of glomerular origin, whereas undeformed cells predominate in either massive hematuria or lower urinary tract disease. Leukocyturia is common in normal infants during the first few days of life (425); yet, leukocyturia may be lacking in a newborn infant with a positive urine culture, in contrast to older children. The presence of bacteria on a Gram stain is a better predictor of urinary tract infection (UTI). The presence of erythrocyte casts in the urine suggests the diagnosis of glomerulopathy, and leukocyte casts can be observed during UTI.

Urine Electrolytes and Osmolality

The measurement of urinary and blood osmolality, urea, creatinine, and electrolytes is indicated for the differential diagnosis of polyuria, hyponatremia and for the early diagnosis of oligoanuria.

Proteinuria

Maturation is associated with a decrease in the daily rate of proteinuria (see Table 42-2) and with qualitative

P.998

changes, which can be analyzed by two-dimensional gel electrophoresis (426). The first voided urine in 22- to 28-week-old infants contains many proteins and peptides, whereas urine in full-term infants contains much less polypeptides. Urinary excretion of lysosomal and brush border enzymuria and that of low molecular weight (LMW) proteins follow specific developmental patterns (427). LMW proteins i.e., beta2-microglobulin, myoglobin,

and retinol-binding globulin, are filtered through the glomerulus, reabsorbed, and catabolized by the tubule. As the tubular reabsorption of β 2-microglobulin increases with maturation, its fractional excretion decreases until 2 years of age (428). The urinary concentration of LMW proteins is a sensitive indicator of renal tubular damage as a result of asphyxia or medications (see Acute Renal Failure).

Imaging of the Kidney and the Urinary Tract

Ultrasonography and Doppler Flow Analysis

Ultrasonography is performed to screen for renal and urologic malformations or as one of the first steps in the workup of renal failure, oligoanuria, hypertension, UTI, or hematuria (429). Indications for the performance of neonatal US are shown in Table 42-3. Ultrasonography (US) has been found to be a sensitive and reliable method for the detection of nephrocalcinosis (NC). The bright foci are almost always located in the medulla, rarely in the pyelocalyceal system, and hardly ever in the cortex (430,431). NC can present as white dots or white flecks and diminishes gradually over a period of months to years. NC does not influence kidney length in the first 2 years of life (432, 433).

Recently, high-resolution images obtained with high frequency linear array transducers have allowed excellent characterization of renal parenchymal architecture and pathological conditions. In neonates, the US appearances are distinctive, because the renal cortex has echogenicity equal to or greater than that of liver and spleen, whereas in older children the cortex is hypoechoic relative to other organs (434). The differential diagnosis of US anomalies is presented in Table 42-4 (435,436,437 and 438).

Blood flow through renal vessels can be assessed by Doppler US, which is indicated for the evaluation of hematuria, hypertension, and acute renal failure (ARF), especially in a patient with UA catheterization. Pulsed-Doppler flow analysis i.e., duplex scanning, allows the measurement of blood flow velocity, which gives an assessment of RBF, and calculation of the ratio of end-diastolic minimum velocity to systolic peak velocity (i.e., diastolic-to-systolic ratio), thereby helping in the assessment of RVR (439,440 and 441).

Voiding Cystourethrogram

Vesicoureteral reflux (VUR) and bladder obstruction should be ruled out in patients with hydronephrosis, renal dysplasia or anomaly, trabeculated bladder, bladder distention, or myelomeningocele (442). Lateral views of the male urethra are mandatory for the diagnosis of posterior urethral valves (443). In a neonate with symptomatic UTI, US should be done initially to assess the presence of obstructive uropathy and signs of renal involvement. If no dilatation is seen and there is a good response to treatment, voiding cystourethrogram (VCUG) can be delayed. If US demonstrates an abnormal bladder, VCUG should be undertaken as soon as possible.

TABLE 42-3 INDICATIONS FOR ULTRASONOGRAPHY TO RULE OUT RENAL-URINARY TRACT MALFORMATIONS AND/OR ACQUIRED RENAL DISEASE IN NEWBORN INFANTS

History^a

Family history

First-degree relative with potter's syndrome (bilateral renal agenesis/dysgenesis), autosomal dominant polycystic kidney disease

Sibling with autosomal recessive polycystic kidney disease

Abnormal prenatal ultrasonography (kidney, bladder, ascites)

Oligohydramnios, unless normal postnatal renal function and oligohydramnios attributed to

Prolonged rupture of the membranes

Postdate delivery, subacute fetal distress

Physical examination or evidence for other congenital anomaly^{a,b}

Syndrome, sequence or field defect described in Appendix I-1^b

Any part of a possible VATER syndrome (vertebral anomalies, anorectal anomalies, tracheoesophageal fistula)

Preauricular pits, if family history

Supernumerary nipples

Congenital diaphragmatic hernia with additional anomalies

Lung hypoplasia, symptomatic spontaneous pneumothorax

Abnormal abdominal examination

Abnormal kidney palpation

Abdominal mass Bruit^c

Ascites

Single umbilical artery

Second- or third-degree hypospadias

Ambiguous genitalia

Evidence for renal disease

Renal failure, oligoanuria^c

Systemic hypertension^c

Urinary tract infection

Hematuria^c

Significant proteinuria

Nephrotic syndrome

Nephrocalcinosis and nephrolithiasis in preterm infants on prolonged diuretic therapy

^a The best timing of ultrasonography remains to be determined. A negative test immediately after birth does not rule out hydronephrosis and/or vesicoureteral reflux. A repeat test should be obtained within a few weeks (or earlier if clinically indicated).

^b The frequency of urinary tract anomalies in many of these entities has not been determined. Because a cost-benefit analysis has not been performed, the indication for neonatal ultrasonographic screening should be decided on an individual basis. The frequency of fetal urinary tract anomalies in association with maternal diabetes or cocaine use is probably too low to justify neonatal ultrasonography in asymptomatic infants.

^c These patients also should have Doppler ultrasonography.

TABLE 42-4 RENAL ULTRASONOGRAPHIC PATTERNS IN NEWBORN INFANTS

Normal appearance

Prerenal failure

Renal artery thrombosis

Congenital renal disease, e.g., renal tubular acidosis

Renal cystic disease (in which cysts develop late)

Developing hydronephrosis or vesicoureteral reflux

Increased cortical echogenicity

With increased corticomedullary differentiation in large kidneys

Beckwith-Wiedemann syndrome

With normal corticomedullary differentiation

Prerenal failure

Renal ischemia

Mild renal dysplasia

Congenital nephrotic syndrome, Finnish type

With loss of corticomedullary differentiation in normal to small kidneys^a

Severe renal dysplasia

Pyelonephritis, including renal candidiasis (often heterogeneous)

Renal tubular dysgenesis/glomerular dysgenesis^b

With loss of corticomedullary differentiation in large kidneys^a

Renal vein thrombosis

Edema results in decreased echoes

Hemorrhage results in increased echoes

Corticomedullary necrosis^c

Autosomal recessive polycystic kidney disease

Renal glomerular dysgenesis/tubular dysgenesis

Transient nephromegaly (benign)

Contrast nephropathy

Lymphangioma

Mesoblastic nephroma^d

Cysts(s)^e

See Appendix 1-3

Increased medullary echogenicity

Nephrocalcinosis

Medullary cystic disease

Tamm-Horsfall proteinuria, acute tubular necrosis

Medullary sponge kidney

Intrapyelic echogenicity

Renal candidiasis ("fungus ball")

Lithiasis

Hydronephrosis

This list does not include findings shown by Doppler ultrasonography.

^a Diffuse or heterogenous hyperechogenicity of cortex or whole kidney.

^b Renal size may be enlarged.

^c Renal size may be normal or enlarged.

^d Solid mass causing distortion of intrarenal collecting system, with occasional cystic areas corresponding to necrosis or hemorrhage.

^e Absence of cysts visualized by ultrasonography does not rule out a renal cystic disease in a newborn infant. Some entities result in development of cysts later in life, whereas others (e.g., autosomal recessive polycystic kidney disease) result in hyperechogenicity.

P.999

Renal Radionuclide Scan

Mercaptoacetyl triglycine (MAG 3) has become the isotope of choice in neonates and infants. It has a high protein binding and thus remains in the blood pool rather than being distributed in the extra vascular space, as does ^{99m}Tc-DTPA. The renal extraction of MAG 3 is virtually double that of DTPA (443,444). In contrast, ^{99m}Tc-dimercaptosuccinic acid (DMSA) binds to the proximal convoluted tubules and is only minimally excreted into the urine; it is preferred for the analysis of renal morphology and differential function. Typical indications for radionuclide studies include renovascular hypertension, lack of visualization of a kidney by US, preoperative evaluation of the severity of urinary tract obstruction, and evaluation of differential renal function. In normal newborn infants, routinely measuring GFR using radionuclides is not ethically justifiable, even though the amount of radioactivity is minimal. Therefore, normal values for age are not available.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are indicated in the diagnosis of renal tumors, renal abscess, and nephrolithiasis. MRI T2-weighted images (which emphasize the difference in transverse relaxation times between different tissues) are independent of renal function, and provide images in which water is bright, and with excellent contrast between normal and abnormal tissues (444). MRI offers many advantages: the contrast medium, gadolinium chelate, is not nephrotoxic, no ionizing radiation is used, and high resolution three dimensional images can be obtained (445). Lack of nephrotoxicity makes MRI the ideal modality to follow renal transplants (446). Additionally, MRI appears to be more sensitive than US in detecting a tethered cord in a patient with bladder distention and lack of VUR or urethral stenosis on VCUG. Gadolinium-enhanced magnetic resonance (MR) angiography using a fast three-dimensional gradient echo sequence allows a good depiction of the major vessels. However need for sedation, relatively high cost, and good results from US and scintigraphy have limited the use of MRI.

Other Investigations

Intravenous urography is no longer indicated in the neonatal period. Percutaneous antegrade pyelography may be diagnostic in some cases of cystic disease or urinary tract obstruction (447). Contrast angiography used formerly for the diagnosis of renovascular hypertension, aortic thrombus, or an abdominal tumor has been replaced by the less invasive modality of MR angiography.

Renal Pathology

Renal biopsy is indicated in nephrotic syndrome and may be indicated in polycystic kidney disease, hematuria, or persistent severe renal failure of unclear origin. Major contraindications to renal biopsy include bleeding diathesis, anticoagulant therapy, moderate or severe hypertension, solitary kidney, and intrarenal tumor (448). The technique involves visualization of the kidney using US, radioisotope, or radiopaque contrast. The most common complication

P.1000

is macroscopic hematuria, which occurs in 5% to 7% of biopsies.

Acute Renal Failure and Oligoanuria

ARF, usually defined as an acute deterioration in the ability of the kidneys to maintain the homeostasis of body fluids (449), is associated with an acute decrease in the rate of glomerular filtration, as opposed to isolated acute tubular dysfunction. Because the placenta fulfills that role in utero, congenital malformations associated with limitation of renal function will not lead to renal failure until birth. ARF in newborn infants is suggested by a progressive increase in the infant's serum creatinine above normal values for age in the context of normal maternal renal function (Fig. 42-5) (450,451).

Incidence

The incidence of intrinsic oliguric ARF in newborn infants admitted to the NICU ranges between 1% and 6% in retrospective studies, and between 6% and 8% in prospective studies (450,451,452).

Diagnosis

Intrauterine oligoanuria can be suspected when oligohydramnios develops in the absence of amniotic fluid leakage or rupture of the amniotic membranes; it can be as a result of a congenital urinary tract anomaly (e.g., urinary tract obstruction, renal agenesis, dysgenesis), to toxins (e.g., ACE inhibitors, indomethacin) (235,453,454), or to intrauterine asphyxia. If urine output alone is used to assess renal function, ARF often will be either overlooked or over diagnosed. Indeed, normal urine output is found in approximately one-third of neonates with ARF (450, 455), although low urine output may occur in the absence of ARF. Infants who have been subjected to perinatal as-phyxia, shock, hypoxemia, or various nephrotoxins are at risk of development of ARF. Clinical signs of ARF include syndromes or signs suggestive of renal or urogenital malformations, oligoanuria, polyuria, hematuria, proteinuria, fluid overload, dehydration, cardiac arrhythmia, and systemic hypertension. Other signs include decreased activity, seizures, anemia, vomiting, and anorexia. Sometimes ARF is suspected on the basis of electrolyte abnormalities or elevated plasma levels of medications (e.g., aminoglycosides).

ARF is characterized by decreased GFR and renal tubular function compared to normal values for either postconceptional age or GA and postnatal age. Although the diagnosis of ARF is strongly suggested by a Pcr that is above the upper limit of normal, during the first days of life such an elevation also may result from abnormal maternal renal function. Thus, measuring GFR or following Pcr over time is required to diagnose ARF in a newborn infant during the first few days of life. Because renal tubular function changes with maturation, it is important to use criteria appropriate for age; indices developed for more mature subjects are not indicative of intrinsic renal failure in VLBW infants.

Etiology

A wide variety of malformations and prenatal, perinatal, and postnatal events may cause neonatal renal failure (Table 42-5) (451,452,453,454,455,456,457,458,459,460,461,462). The most common type of acute intrinsic renal failure is ATN, which is discussed in the next section.

Pathophysiology of Acute Tubular Necrosis

The evolution of acute tubular necrosis (ATN) is characterized by three successive phases: initiation, maintenance, and recovery. Although ATN may be precipitated by a single event, its development is multifactorial and involves vascular, i.e., hemodynamic, nephronal, and cellular, i.e., metabolic factors (449).

Vasoconstriction of the afferent arterioles plays a major role in the initiation phase of ATN (463,464 and 465). Increased renal vascular resistance results from changes in the relative concentrations of vasoconstrictive agents such as PRA, adenosine, thromboxane, endothelin, and platelet activating factor, and vasodilator agents such as natriuretic peptides, NO, PGs, and prostacyclin. The increase in PRA, which results from the stimulation of the juxtaglomerular apparatus by the high solute content of damaged tubules, helps maintain glomerular filtration by vasoconstricting the efferent arteriole. During the maintenance phase of ATN, the main factors are nephronal and cellular. The main cellular injury comes in the form of programmed cell death (apoptosis). Renal cellular injury is accompanied by release of free oxygen radicals, changes in intracellular calcium metabolism, phospholipid breakdown, altered cell polarity, and secondarily, loss of tight cell junctions between cells, loss of the cell brush border, and disruption of the cytoskeleton, leading to disruption of major cellular functions, e.g., Na⁺/K⁺-ATPase, and cell swelling. All these processes, except damage caused by free oxygen radicals, are accompanied by cellular ATP depletion, thereby limiting cellular restoration with reperfusion, an energy consuming process. When cellular ATP decreases, the concentration of intracellular heat shock transcription factor rises. Proximal tubular cells loaded with heat shock protein and then exposed to ischemic damage had significantly less ATP release after ischemia than nonheat shock protein-loaded cells and a marked reduction in apoptosis. Generation of heat shock protein and lactic dehydrogenase after anoxic injury in neonatal kidneys provides a better defense mechanism against ischemic renal injury compared to adult kidneys.

The production of local growth factors decreases during the early phase of ATN; the tubular epithelium only regenerates during the recovery phase. GFR initially increases in parallel with a decrease in intratubular pressure and casts; GFR then increases in parallel with RPF and urine output

P.1001

(452). Unless enough fluid is provided to compensate for the large amounts of urine lost during the polyuric phase, hypovolemia may develop and slow the recovery or even cause a secondary deterioration of renal function. Random-ized trials are needed to determine strategies to reduce the severity of ARF with the least side effects (466). Although many candidate drugs have been studied, none have proven effective in clinical trials.

TABLE 42-5 ETIOLOGIC CLASSIFICATION OF ACUTE NEONATAL RENAL FAILURE

Parenchymal malformation^a

Renal agenesis

Renal hypoplasia

Simple hypoplasia

Oligonephronic hypoplasia

Renal dysplasia

Multicystic

Hypoplastic

Aplastic

Associated with urinary tract obstruction or vesicoureteral reflux

Nephron dysgenesis

Tubular dysgenesis: congenital hypernephronic nephromegaly with tubular dysgenesis = congenital tubular dysgenesis = isolated congenital renal tubular immaturity

Glomerular dysgenesis:

Idiopathic

Secondary to maternal administration of indomethacin or angiotensin-converting enzyme inhibitors

Polycystic kidney disease

Adult type (autosomal dominant)

Infant type (autosomal recessive)

Other

Acquired renal dysfunction or lesion^b

Asphyxia/hypoxia/ischemia

Functional (may lead to prerenal or intrinsic renal failure)

Systemic hypotension, shock, hypovolemia, severe dehydration

Renal artery vasoconstriction, e.g., nephrotoxins, endotoxin, endothelin

Reverse diastolic blood flow (preeclampsia, patent ductus arteriosus)

Prenatal/perinatal/postnatal asphyxia

Respiratory distress, hypoxemia

Sepsis

Heart failure, extracorporeal membrane oxygenation, cardiopulmonary bypass

surgery

Hyperviscosity, polycythemia

Severe anemia

Vascular

Arterial/arteriolar thrombosis/embolism/stenosis

Cortical/medullary necrosis, renal infarction

Venous thrombosis

Urinary tract obstruction (see Table 42-7)

Urinary tract infection

Disseminated intravascular coagulation

Drugs

Antibiotics (aminoglycosides, amphotericin, acyclovir)

Non steroid anti-inflammatory agents

Tolazoline

Alpha-Adrenergic agents

Angiotensin-converting enzyme inhibitors

Radiocontrast agents

Cyclosporine

Toxins

Hemoglobinuria

Myoglobinuria

Hyperoxaluria

Benzyl alcohol

Polysorbate

Ethylene glycol

Uric acid nephropathy

Glomerular disease

Membranous glomerulonephritis (IgG-mediated)

Congenital syphilis

Diffuse mesangial sclerosis

^a May not cause acute renal failure until after the neonatal period.

^b May occur *in utero*.

Renal Blood Flow

Decreased RBF may result from multiple mechanisms such as reverse diastolic flow, hypotension, heart failure, and vasoconstriction (Table 42-5). In mothers with preeclampsia, absent or retrograde diastolic blood flow in the fetal aorta and UA predicts several perinatal complications, including renal failure (467).

RBF velocity remains low for at least 1 week in VLBW infants with intrauterine growth retardation (468). Prevention of prerenal failure includes correction of any abnormality in and maintenance of adequate oxygenation, ventilation, blood pressure, cardiac output, hydration (see Chapter 21), blood glucose, and hematocrit, and prevention and early treatment of sepsis. Preliminary data suggest that indomethacin-mediated renal vasoconstriction and ARF may be reduced by using prior volume expansion and by using a low dose and a slow infusion of indomethacin (469). Although furosemide increases urine output in patients receiving indomethacin for treating a PDA, the routine use of furosemide in these patients cannot be recommended (470,471).

Urine Output

In asymptomatic low-risk full-term infants receiving routine care, low or even absent urine output (detected by checking the number of wet diapers) during the first 24 hours of life is a normal event, assuming adequate fluid intake. If spontaneous urination is not observed within an additional 12 hours, i.e., at 36 hours of life, the baby should be reexamined for possible urinary retention, and the bladder should be catheterized.

P.1002

In contrast, in premature infants and in patients with suggestive history, symptoms, or abnormal physical examination, urine output should be measured from birth. If there is no urine by 24 hours of life or if subsequent output is less than 1 mL/kg/h, the bladder should be catheterized; suprapubic pressure (i.e., the Credé maneuver) should be avoided, because of the risk of VUR, and rarely for bladder or renal rupture (472). Patients at high risk for renal failure (e.g., shock, extracorporeal membrane oxygenation [ECMO], or major surgery) should have their bladder catheterized to measure the hourly urine output.

If polyuria develops, possible diagnoses include hypervolemia, tubular dysfunction, diabetes insipidus, glucose overload, the polyuric phase of ATN, and the polyuric phase of postrenal failure (e.g., after decompression of the bladder by catheterization).

Perinatal Asphyxia

The risk for and severity of ARF increases with the severity of asphyxia (473,474 and 475). ARF associated with asphyxia is predominantly nonoliguric (474). Thus, unless Pcr is monitored daily in the severely asphyxiated neonate, renal failure will be easily missed. Early diagnosis of ARF secondary to perinatal asphyxia is suggested by the finding of increased tubular LMW proteinuria

immediately after birth (476,477 and 478). Asphyxiated infants with a urine output less than 1 mL/kg/h for 36 hours usually have a high urinary concentration of beta2-microglobulin and clinical signs of hypoxic-ischemic encephalopathy. A dipstick may help detect hematuria, myoglobinuria, and proteinuria. Oligoanuria in these infants may result from prerenal, i.e., functional-mediated failure mediated in part by endothelin (479), intrinsic renal failure (e.g., ATN), or syndrome of inappropriate secretion of ADH (SIADH).

Prevention and Early Diagnosis of Acute Renal Failure

The first step is to identify infants at high risk for renal failure or oligoanuria immediately after birth or after predisposing events (Figs. 42-5 and 42-6). In these infants, urine collection should be initiated right away, and vital signs, electrolytes, and renal function should be followed serially. If urinary tract anomalies are suspected, a complete urologic workup should be considered (see Chapter 43). Decompression of the urinary tract by bladder catheterization or surgical intervention, or both, may be indicated. Oliguric renal failure develops in 22% of patients on venoarterial ECMO and may develop in patients on venovenous ECMO in the absence of changes in cardiac output, blood pressure, or hypoalbuminemia; the exact pathophysiology of the renal dysfunction in such infants remains to be elucidated (480,481).

General Approach in Oligoanuria

The diagnosis of oligoanuria, i.e., urinary output less than 0.5 to 1.0 mL/kg/h should be confirmed by demonstrating the absence of urine by bladder catheterization. Delayed micturition has been described in association with transient bladder distention attributed to severe perinatal asphyxia (482). Bladder puncture should be avoided because of the high likelihood of causing trauma.

Once oligoanuria is confirmed, the history should be reviewed for severe asphyxia, respiratory failure, hypotension, shock, and renal toxins. Intake and output over the last few days should be reviewed. The physical examination should seek evidence of weight change, dehydration, malformations, respiratory failure, CHF, shock, hypotension, and central nervous system disease. General care should be optimized, including measures to support ventilation, oxygenation, cardiac output, functional circulatory volume, and ECF volume.

Urine and Blood Analysis

The differential diagnosis of oligoanuria includes not only renal failure but also SIADH and decreased urine production secondary to the administration of ADH or its analogs (Table 42-6). The differentiation between prerenal and true renal ARF is presented in Table 42-7.

Urine should be examined promptly for protein, cellular elements and crystals, electrolytes, creatinine, and SG or osmolality. A blood sample should be obtained for

P.1003

hematocrit, electrolytes, creatinine, BUN, and glucose; other tests (e.g., serum concentration of xanthine or uric acid, oxaluria) may be indicated based on history or initial results. Plasma osmolality can be either measured or calculated from the following formula:

TABLE 42-6 DIFFERENTIAL DIAGNOSIS OF OLIGOANURIA

TABLE 42-6 DIFFERENTIAL DIAGNOSIS OF OLIGOANURIA

Renal failure

Prerenal (see Table 42-7)

Intrinsic (see Table 42-7)

Postrenal

Bladder retention

Urethral valves

Meningomyelocele, tethered cord

Massive vesicoureteral reflux

Bilateral ureteral obstruction

Ureteropelvic junction obstruction

Ureterovesical junction obstruction, ureterocele

Lithiasis

Fungus ball

Extrinsic compression

Uroascites (i.e., ruptured urinary tract)

Secondary to urinary tract obstruction

Bladder perforation (umbilical artery catheterization or direct bladder trauma)

Syndrome of inappropriate secretion of antidiuretic hormone

Exogenous administration (to the mother or the newborn infant) of

Antidiuretic hormone, desmopressin

Oxytocin

Non steroidal anti-inflammatory agents

Acute bladder distension without renal failure

Curarization

Neurogenic bladder

Hematoma of the anterior wall of the bladder (traumatic suprapubic aspiration)

TABLE 42-7 DIFFERENTIAL DIAGNOSIS: PRERENAL VS. INTRINSIC OLIGURIC RENAL FAILURE^a

	Prerenal	Intrinsic
FENa(%)	≤1	>3
UNa (mmol/L)	≤20	>50
U _{SG}	>1,025	<1,014
U Osm (mOsm/kg)	≥500	≤300
U/P osm ^b	≥1.2	0.8-1.2
U/Pcr	High (>40)	Low (9.7±3.6)
BUN/Pcr (mg/mg)	>30	<20
Rena! failure index ^c	Low (<1)	High (>4)
UItrasonography ^d	Normal	May be abnormal ^d
Response to challenge ^e	UO >2 mL/kg/h	No↑UO

^a FENa is obtained by dividing sodium clearance by glomerular filtration rate and multiplying by 100. FENa and UNa are high (falsely suggesting an intrinsic renal failure) after diuretic administration, volume expansion, urinary excretion of nonabsorbable solutes (glycosuria, mannitol, glycerol, bicarbonate [in metabolic alkalosis]), adrenal insufficiency, or gestational age <28 wk. FENa increases transiently in normal full-term infants immediately after birth and in premature infants during the diuretic phase. FENa is also high in case of prolonged urinary tract obstruction and in chronic renal failure. Conversely, FENa and UNa are low (falsely suggesting prerenal failure) in acute renal failure due to severe vasoconstriction (e.g., indomethacin, radiocontrast nephropathy, sepsis, early phase of myoglobinuria), in acute urinary tract obstruction, and in some cases of nonoliguric ATN.

^b Although plasma osmolality can be estimated using the formula:

$$\text{Posm} = 2 \times \text{PNa (mEq/L)} + \text{gl (mg/dL)/18} + \text{BUN (mg/dL)/2.8}$$

Where PNa is plasma sodium concentration, gl is glycemia and BUN is blood urea nitrogen, the measured value of Posm is preferable, especially in critically ill patients, because of large differences in the case of sick cell syndrome (leaking cellular membranes), and in infants with a birth weight <1,000 g (Giacoaia 1992).

^c Renal failure index = $\text{U Na} \times \text{Pcr}/\text{Ucr}$

^d The ultrasonography in "intrinsic" renal failure may show increased echogenicity of the pyramids, which probably corresponds to precipitation of Tamm-Horsfall protein, signs of renal vein thrombosis, renal artery thrombosis, adrenal hemorrhage, hydronephrosis, cystic kidney disease, renal dysplasia, hypoplasia, or other pathology (see Table 42-5).

^e The challenge corresponds to the administration of 20 mL/kg of crystalloid (more should be given if there is evidence of hypovolemia) and/or 1 mg/kg of furosemide. Normalization of the urine output after such a challenge may correspond to a prerenal failure or to the polyuric phase following an oliguric renal failure. See text for additional comments.

FENa, fractional excretion of sodium; UNa, urinary sodium concentration; U_{SG} , urine specific gravity; U_{osm} , urine osmolality; U/P osm , ratio of urine to plasma osmolality; U/Pcr , Urine to plasma creatinine ratio; BUN/Pcr , ratio of blood urea nitrogen to plasma creatinine concentration; UO , urine output

$$\text{Posm (mOsm/kg)} = 2 \times \text{Na (mEq/L)} + \text{glucose (mg/dL)/18} + \text{BUN (mg/dL)/2.8.}$$

Use of this formula is not recommended for infants with a BW less than 1,000 g, in whom it may substantially underestimate true osmolality (483).

While waiting for the results of these tests and ordering a renal US, and in some instances a renal scan, an initial therapeutic decision often can be made. This is especially important in patients in whom no urine can be obtained for analysis. Prerenal failure is a reasonable presumptive diagnosis in the presence of respiratory failure, CHF, dehydration, or shock, if osmolality or SG is high in the absence of casts in the urine. Rapid correction of the problem may be the only therapeutic intervention needed. The SIADH can be suspected in cases of severe neurologic dysfunction, pneumothorax, or pleural effusion, with weight gain, oligoanuria, high urinary SG and hyponatremia.

The urine obtained initially, i.e., before any diuretic or fluid challenge should be sent for urinalysis and urine chemistry for the assessment of tubular function. Various indices and tests have been proposed to differentiate ATN from prerenal or functional failure, by the presence of

tubular dysfunction in ATN (484,485). FENa is the preferred index. A FENa greater than 3% (>6% in preterm <32 weeks) (485) suggests a diagnosis of intrinsic failure and a value less than 2.5% a prerenal failure; however, several exceptions exist (Table 42-7). Renal failure index (RFI) is sometimes used as an alternative to FENa:

$$\text{RFI} = \text{UNa} \times \text{Pcr/Ucr.}$$

Cutoff points for diagnosis of ATN are RFI more than 4 in term and more than 8 in preterm infants less than 32 weeks.

Asphyxiated newborn infants may manifest transient tubular dysfunction associated with a normal or mildly decreased GFR and a normal or decreased urine output. Their tubular dysfunction is characterized by a positive

P.1004

dipstick test for blood, moderate tubular proteinuria, i.e., LMW proteins and N-acetyl- β -D-glucosaminidase [NAG], and a FENa that is either normal or mildly increased (476,477,486,487 and 488). In contrast, ATN is associated with marked proteinuria, markedly decreased GFR, and often oligoanuria. Urinary concentration of myoglobin and retinol-binding protein, but not NAG, can be used to differentiate between normal transient tubular dysfunction and ATN (476,477). Renal and bladder US may establish a diagnosis of urinary tract obstruction, uro-ascites, or renal cystic disease (see Appendix G-4), suggest renal vein or artery thrombosis, adrenal hemorrhage, or show abnormal cortical, medullary, or pyelocalicial echogenicity (see Table 42-4) (435,436,437,438,489,490,491). One common finding is increased echogenicity of the pyramids (494,495), which may correspond to the precipitation of Tamm-Horsfall protein in patients with ATN.

The diagnosis of SIADH is suggested by a plasma osmolality less than 280 mOsm/kg, a ratio of urinary to plasma osmolality that is greater than 1, high urine SG, and an inappropriate increase in weight. The strict criteria used for the diagnosis of SIADH in adults rarely are met in newborn infants. In most instances, inappropriate levels of ADH are found in patients with abnormal renal function, because asphyxia is a common cause of both problems. The treatment of SIADH usually includes fluid restriction with a normal sodium intake; hypertonic glucose may be necessary to treat severe hypoglycemia secondary to drastic fluid restriction, and furosemide (with careful replacement of the sodium lost in the urine) may be needed in patients with severe CHF secondary to fluid overload. Hypertonic saline is indicated to raise natremia to 125 mEq/L in patients developing central nervous system signs (e.g., seizures, coma) associated with severe hyponatremia.

Challenge Test

A challenge test is indicated only if the etiology of the renal failure is not evident from the assessment of risk factors, clinical signs, US, and urine indices (see Table 42-7). This can be a fluid challenge (20 mL/kg of crystalloid solution, e.g., isotonic saline) followed by a diuretic challenge (usually furosemide 1 mg/kg intravenously) in a nondehydrated infant. Although patients who fail to respond to furosemide may respond to bumetanide (5 mg/kg/dose intravenously), a more potent loop diuretic, this medication has not been evaluated prospectively in acute neonatal oligoanuria.

A diuretic challenge test should be done first in patients thought to be hypervolemic or in heart failure, whereas a fluid challenge should be done first in those thought to be hypovolemic. If the first challenge test does not yield a satisfactory response, defined by a normal urine output, the other test should be considered. Although normalization of the urine output is most commonly observed in prerenal failure, it also may be coincidental with the beginning of the polyuric phase

of an intrinsic renal failure, or with the transformation of an oliguric into a nonoliguric renal failure (492). The correct diagnosis may be suggested by renal US and by the rapidity of GFR recovery, rather than by the FENa, which is increased by the challenge itself. In any of these situations, the prognosis usually is good. In contrast, if anuria persists despite optimization of general care and double-challenge test, the diagnosis of intrinsic renal failure is likely, severe fluid restriction is indicated, and the prognosis is guarded.

Nonoliguric Renal Failure

Nonoliguric renal failure is characterized by a sudden decrease in GFR and tubular function in the absence of oligoanuria. Thirty to fifty percent of neonates with ARF are nonoliguric (450,493). The ARF observed in one third of patients who receive cardiopulmonary bypass surgery typically is nonoliguric (456). Renal failure without oliguria may be overlooked in the absence of routine measurement of blood chemistries and urinalysis (450,451). It may be confused initially with the polyuric phase of an intrinsic or postrenal renal failure, especially after an undiagnosed oligoanuria episode, or with prerenal failure that has been treated by the administration of fluids for hypovolemia (492). Although the prognosis of nonoliguric renal failure usually is better than oliguric renal failure (455), it can be complicated by symptomatic hyperkalemia (484).

Treatment of Acute Renal Failure

Supportive Treatment and Prevention of Complications

In our experience, prompt treatment of ARF and its complications avoids the need for renal replacement therapy (e.g., dialysis, continuous arteriovenous hemofiltration [CAVH]) in most patients. Some researchers, however, argue that early institution of replacement therapy may result in improved mortality and morbidity.

Supportive treatment of infants with ARF should be aimed at maintaining homeostasis of all vital systems. Some patients may need major respiratory and cardiovascular support (495), and all such patients require adequate fluid and electrolyte balance and adjustment of the dosage of medications that are eliminated by the kidney (450,496,497). Early diagnosis and treatment may help prevent many complications of ARF, such as water or medication intoxication and hyperkalemia. The prognosis of ARF depends not only on the severity and the duration of the renal injury, but also, and perhaps mainly, on the overall status of the patient.

Use of low dose dopamine for improving renal function remains controversial. In hypotensive premature infants (29-34 weeks of GA) with respiratory distress syndrome, non randomized trials suggest that the infusion of dopamine at a rate of 5 to 20 $\mu\text{g}/\text{kg}/\text{min}$ results in a transient elevation in blood pressure compared to controls, followed by increases in urine output, creatinine clearance, and natriuresis (498,499). A systematic review failed to provide enough evidence to recommend routine use of

P.1005

low dose dopamine for improving renal function and urine volume in critically ill neonates (500). Two small randomized trials have assessed the effect of low-dose dopamine in preterm infants (501,502). Cuevas and associates (502) found that in preterm infants with respiratory distress syndrome and a GA greater than or equal to 30 weeks, dopamine at 1 or 2.5 $\mu\text{g}/\text{kg}/\text{min}$ increased blood pressure and natriuresis but did not significantly increase GFR and urine output compared with controls. Lynch and associates (501) found that in oliguric preterm infants with BW greater than 1250 grams, dopamine infusion at a dose of 2.5 $\mu\text{g}/\text{kg}/\text{min}$ did not affect blood

pressure but increased GFR and urine output and that a dose of 7.5 µg/kg did not affect blood pressure or GFR but increased urine output compared with controls receiving a dose of 0.5 µg/kg/min.

In severely asphyxiated newborn infants, one prospective randomized study showed that infusion of dopamine at low dose (2 to 5 µg/kg/min) increased systolic blood pressure and urine output and decreased the incidence of abnormal Pcr (503). Another randomized clinical trial showed that theophylline (antiadenosine effect) improved renal function in asphyxiated full term neonates; additional data are needed before recommending routine use of theophylline in asphyxiated term neonates for improving renal function (504,505).

Fluid and Electrolytes

Water and sodium metabolism: In the presence of oligo-anuria refractory to the initial fluid and diuretic challenge, fluid restriction is indicated. Fluid intake is limited to ongoing sensible losses, i.e., gastrointestinal losses, urinary output, third-space losses, drainage, plus 25 mL/kg/24 hours in a full-term infant, and 50 to 100 mL/kg/24 hours in a LBW or VLBW infant to replace insensible water loss. Neither sodium nor potassium should be administered routinely during this phase. However, babies with nonoliguric renal failure may have very large sodium losses, up to 10 mEq/kg/day, and these must be replaced on the basis of serial sodium measurements and clinical assessment. If fluid restriction is not initiated early in the course of ARF, fluid overload will result, with potential CHF, pulmonary edema, and pulmonary hemorrhage. If massive fluid overload leads to severe CHF, hemo (dia) filtration may be indicated.

Hyperkalemia: Patients with ARF often develop hyperkalemia, i.e., a potassium concentration greater than 6.5 mEq/L (506,507). Factitious hyperkalemia can result from hemolysis or clot formation during sampling, i.e., release of potassium from erythrocytes or platelets or from interference with the measurement of potassium concentration by benzalkonium released from a heparin-coated umbilical catheter (508). If hyperkalemia is associated with hyponatremia, hypoglycemia, and hypotension, a diagnosis of adrenal insufficiency should be considered (see Chapter 39). This most often results either from congenital adrenal hyperplasia or from bilateral adrenal hemorrhage; the latter may be suspected on the basis of anemia with thrombocytopenia, jaundice, and bilateral abdominal masses, and confirmed by US.

The treatment of hyperkalemia includes discontinuing any potassium intake; discontinuing any medication that could cause hyperkalemia (e.g., indomethacin, ACE inhibitors, potassium-sparing diuretics); and correcting hypovolemia using isotonic saline to promote tubular secretion of potassium. Simultaneous administration of several forms of therapy (Table 42-8) often is required for treating life-threatening hyperkalemia (501,506,509,510,511,512,513,514,515,516). The use of glucose-insulin, albuterol and cation-exchange resins for treating hyperkalemia has been assessed by randomized trials in neonates.

If electrocardiographic changes are associated with hyperkalemia, administration of calcium chloride or calcium gluconate is indicated; this will rapidly, but only transiently, decrease myocardial cell excitability, but will not decrease potassium concentration (see Table 42-8) (510). Thus, the administration of calcium should be followed immediately by at least one method to decrease the potassium concentration.

Several methods (Table 42-8) have been proposed to induce cellular uptake of potassium, including the combination of glucose and insulin, albuterol, bicarbonate, and exchange transfusion with washed packed cells. Glucose-insulin infusion is more efficient in correcting hyperkalemia than bicarbonate or cation exchange resins, and equally efficient as albuterol. If glucose and insulin are infused, the initial ratio for VLBW infants (500 to 1,000 g) should be approximately 2.2 g/U (511); the ratio should be adjusted (range 1-3 g/U) according to the

evolution of the glycemia.

Albuterol increases cellular uptake of potassium by inducing Na⁺/K⁺-ATPase activity through cAMP, independently of the action of insulin or aldosterone, and by inducing an increase in serum insulin level (517). A randomized trial in preterm neonates showed that nebulized albuterol (400 µg) decreases potassium level by 0.7 mEq/L within 4 hours and 1.1 mEq/L within 8 hours vs. no significant change in the saline group (517). Intravenous albuterol infusion (4 µg/kg over 5 minutes) reduces serum potassium by 1.48 ± 0.5 mEq/L and 1.64 ± 0.5 mEq/L at 40 and 120 minutes, respectively, in hyperkalemic children (512,518). However, a serious word of caution is required because albuterol administration increases serum potassium during the first 3 minutes, presumably through alpha-receptor stimulation (517,519). Nebulized albuterol transiently increases serum potassium by more than 0.1 mEq/L (up to 0.4 mEq/L) in half the adult patients with renal failure and intravenous albuterol transiently increases potassium by 0.65 mEq/L in baboons (519,520). Therefore albuterol should not be used as the first line of treatment, and calcium should be available in case an acute arrhythmia develops.

Although sodium bicarbonate (1 mEq/kg) has been recommended for treating hyperkalemia; its efficacy in patients with renal failure is controversial: one study showed

P.1006

lower efficacy than either glucose-insulin or albuterol (521) and another study showed no efficacy (522). Repeated doses of bicarbonate may result in hyponatremia. Furthermore, addition of bicarbonate to other therapies (insulin-glucose or albuterol) does not increase their efficacy. Until randomized trials are available, bicarbonate administration is indicated to treat acidosis related to renal failure, but its potential benefits on hyperkalemia (reduction of serum potassium by H/K exchange in mineral acidosis) should be weighed against the potential risk for intraventricular hemorrhage (IVH).

TABLE 42-8 TREATMENT OF HYPERKALEMIA IN RENAL FAILURE

Medication	Dose (iv Unless Otherwise Specified)	Mechanism	Onset of Action	Duration
Calcium chloride	0.25-0.5 mEq/kg over 5-10 min	Modifies myocardial excitability	1-3 min	30-60 mm
Calcium gluconate	0.5-1 mEq/kg over 5-10 min			
Sodium bicarbonate	1 mEq/kg over 10-30 min	Intracellular uptake of K	5-10 min	2 h
Glucose + Insulin	0.5 g/kg/h 1 U/2.2 g glucose (1-3) ^a	Intracellular uptake of K	30 min	4-6 h
Albuterol	4-5 µg/kg over 15-20 min ^c	Intracellular uptake of K	30-40 min	>120 min
Cation exchange resin (Na/Ca polystyrene sulfonate)	1 g/kg intrarectally q 6 h ^b	Exchange of K for Na or Ca	1-2 h	6 h
Exchange transfusion ^d	2/3 washed RBCs reconstituted with 5% albumin	Uptake of K by RBCs	Minutes ^e	>12 h

Peritoneal dialysis	Use a dialysate with low K concentration	Dialysis	Minutes ^e	No limit
Hemo(dia)filtration		Filtration (and dialysis)	Minutes ^e	Days

^a The preparation of an insulin drip requires saturating the plastic tubing with the insulin solution before infusing to the patient. The average ratio of glucose to insulin associated with maintenance of normal glycemia in very-low-birth-weight infants is 2.2 ± 0.6 g/U (mean \pm SD) (Lui).

^b Oral administration of polystyrene resin should be avoided in very-low-birth-weight infants and those with poor peristalsis (risk for concretions) (Ohlson). Substantial load of calcium or sodium may result from the respective resin. The effect on potassium concentration is slower than glucose insulin combination.

^c Since administration of albuterol may cause a transient increase in serum potassium concentration, it should not be used as the first medication to treat hyperkalemia (see text for details). The iv preparation is not available in the United States. Albuterol is also efficient by aerosol.

^d Many blood banks do not wash red blood cells anymore

^e These techniques are both rapid and extremely effective in correcting potassium levels. The time to set them up may be the limiting factor: other techniques may be used to stabilize the infant initially.

Modified from ref 510.

Exchange transfusion with washed, packed erythrocytes reconstituted with plasma or albumin may reduce potassium concentration efficiently and for as long as 12 hours (516); however, many blood banks no longer perform this procedure. Hyperkalemic infants requiring red blood cell transfusions should receive either fresh blood or blood passed through a sodium polystyrene sulfonate filter, which removes most of the potassium (523).

Although cation-exchange resins offer the potential advantage of removing potassium permanently from the body rather than increasing cellular uptake, their use in neonates is not recommended because of low efficacy and safety. Hyperkalemic neonates treated with cation-exchange resins have a slow onset of potassium response (514), more prolonged hyperkalemia and more frequent IVH than those treated with glucose-insulin (524). Side effects of these resins include sodium overload (if using sodium polystyrene sulfonate but not if using a resin with calcium instead of sodium), bowel obstruction, perforation and bleeding (515).

Renal replacement therapy, especially CAVH, is the procedure of choice for hyperkalemic infants with severe oliguric ARF and for those on ECMO (525).

Acid-Base and Mineral Disturbances

Metabolic acidosis develops rapidly in most infants with ARF. It may require the administration of large doses of sodium bicarbonate, which may aggravate fluid overload

Hypocalcemia develops rapidly in almost all patients with ARF. It may result from hyperphosphatemia and increased deposition of calcium in injured tissues, especially in rhabdomyolysis; skeletal resistance to PTH, which results from decreased hydroxylation of vitamin D (526); and, in aminoglycoside-induced ARF, parathyroid dysfunction secondary to hypomagnesemia, which is as a result of increased tubular loss (527). Hypercalcemia may occur as a late complication of rhabdomyolysis, as a result of reabsorption of calcium deposited in

necrotic tissues. Hyperphosphatemia is as a result of tissue damage (e.g., severe asphyxia, shock, and rhabdomyolysis) and decreased urine excretion (526). Additionally, ARF usually causes hypermagnesemia, which may result from decreased excretion and from shift from the intracellular space (528).

During the oliguric phase, no intake of magnesium (e.g., antacids) or phosphate should be provided, to limit both

P.1007

hypermagnesemia and hyperphosphatemia. The polyuric phase of ATN is associated with increased urinary excretion of phosphate and magnesium. Intravenous calcium may be required to treat severe hypocalcemia (low ionized calcium with either symptoms or electrographic changes) or hyperkalemia with electrocardiographic changes; however, additional intravenous calcium should not be given routinely until the plasma phosphate level has been reduced to normal, to limit the risk of ectopic calcification. The hyperphosphatemia is managed by the addition of calcium carbonate to feeds. This binds phosphate, rendering it insoluble and thereby reducing its absorption. Aluminum hydroxide is not used anymore as a phosphate binder because of the risk of neurotoxicity.

Polyuric Phase

The oliguric phase of ARF is followed by a polyuric phase. During this phase, serial measurements of urine electrolytes and hourly monitoring of the urine output are imperative to adequately replace urinary losses and prevent dehydration, hyponatremia, and hypokalemia. In some cases, bicarbonate, phosphate, and magnesium need to be given to replace urinary losses. When GFR approaches normal levels, fluid intake should be decreased gradually and carefully, although following weight, serum chemistries, and urine output. Replacing the urine output volume for volume for an indefinite duration would cause an adaptive persistence of the polyuria. However, some patients may not recover a normal urinary concentrating ability despite normalization of GFR; these patients still need high fluid intake (529).

Nutrition

If fluid restriction is required, glucose intake often is minimal, and severe hypoglycemia may develop unless a hypertonic solution of glucose is infused through a central venous catheter. If refractory hypoglycemia occurs because of low glucose intake, steroids or a continuous infusion of glucagon can be given. If this is unsuccessful, hemofiltration should be initiated. This technique will allow increased fluid and glucose intake while rapidly correcting the hypervolemia.

Adequate nutrition should be provided to assure anabolism, thereby reducing renal load (530). Breast milk or low-protein formula should be initiated as soon as possible; if the infant cannot be fed, total parenteral nutrition (TPN) should be initiated. If the ARF is severe, the usual amino acid solution should be replaced by essential *L*-amino acids supplemented with *L*-histidine (Levamin Essential; Leiras, Turku, Finland), initially given at a dose of 0.5 to 1 g/kg/d.

Hematologic Disturbances

Anemia associated with ARF may result from several factors, including decreased erythropoietin production, abnormal or ineffective erythropoiesis, impaired iron use, and shortened erythrocyte survival. Transfusion of packed erythrocytes may be necessary. Bleeding tendency may result from abnormal platelet function and, in some patients (e.g., those with renal venous thrombosis), from thrombocytopenia.

Adjustment of Medication Dosage

The interval of administration of medications with renal elimination (e.g., antibiotics, paralyzing agents, theophylline, antiepileptic drugs, and digoxin) should be adjusted to actual renal function (spontaneous or renal replacement therapy) to avoid toxic levels. The latter might, in turn, increase the severity of the renal failure (see Nephrotoxicity). Although there are insufficient data to calculate adjustment of dosage in newborn infants, predictions can be made from the relationship between Pcr and the half-life of serum concentration of a particular drug (412,413,414). Monitoring drug levels will allow additional adjustments. When possible, medications with minimal or no renal toxicity should be chosen.

Renal Replacement Therapy

Renal replacement therapy is indicated for failure of conservative management to improve severe fluid overload, hyperkalemia, metabolic acidosis, hyperphosphatemia, hypocalcemia, or hypertension, or for allowing provision of adequate nutrition and drug administration (518,531). Modalities include peritoneal dialysis, hemodialysis, hemofiltration, and hemodiafiltration (532,533,534,535,536,537,538).

Peritoneal dialysis is contraindicated in patients with respiratory failure and should be used with caution in those with peritonitis (533). In patients with liver failure, the dialysis solution should contain bicarbonate (instead of lactate) (534). The other techniques require either heparinization, which is contraindicated in premature infants because of the risk of intraventricular hemorrhage, or prostacyclin (536). CAVH, first used in neonates in 1985, is the technique of choice for the treatment of massive fluid overload. Availability of large-bore intravascular catheters in a patient on ECMO makes this technique particularly easy to initiate. Pump-assisted venovenous hemofiltration is now preferred in most pediatric centers over arteriovenous hemofiltration. If renal failure persists beyond the neonatal period, chronic dialysis and renal transplantation may be necessary (see Chronic Renal Failure).

Before renal replacement therapy is initiated, serious consideration should be given to the possibility that the patient may have either a dysmorphic syndrome with a very poor prognosis regarding the future quality of life, or severe irreversible multiorgan failure. Immediate survival depends mostly on nonrenal problems, whereas ultimate prognosis also depends on the severity of bilateral renal parenchymal disease (537,538).

Prognosis

The short-term prognosis for neonatal ARF depends on the general condition of the infant and the status of all major

P.1008

organs and systems. A team approach to management is crucial and should include a neonatologist, nephrologist, urologist, geneticist, and radiologist.

Acquired Renal Failure

In one series, the mortality rate in patients with oliguric ARF as a result of acquired conditions, i.e., asphyxia and sepsis was 60% and even higher in those with congenital heart disease (451). A similar mortality rate (61%) was observed in a series of infants requiring peritoneal dialysis in the first 60 days of life (532). For newborn infants in whom ARF develops although on ECMO, the prognosis is grim. In contrast, the prognosis for nonoliguric renal failure or for prerenal

failure is excellent, unless major arrhythmia secondary to hyperkalemia develops or multiorgan failure develops. Long-term abnormalities in GFR and in tubular function are common in acquired and congenital causes of ARF. In one series, limited urinary concentrating ability tested using DDAVP was observed at 1 to 36 months of age in 11% of patients who had a neonatal Pcr more than or equal to 1.5 mg/dL (529). Fanconi syndrome has been reported as a sequela of renovascular accident in the neonatal period (539).

Congenital Urinary Tract Malformations

Congenital malformations of the kidney and the urinary tract are important not only in the immediate neonatal period, but also they constitute a major cause of chronic renal failure. The reader is referred to Chapter 13 for the description of specific malformations.

Immediate mortality of infants with congenital urinary tract malformations depends primarily on the severity of respiratory failure associated with lung hypoplasia and pulmonary hypertension (540). Infants with severe pulmonary hypoplasia, often associated with typical Potter syndrome, die within the first postnatal hours or days. The presence of bilateral renal parenchymal disease is the major factor predicting poor renal function in cases with congenital renal or urinary tract malformations. Patients with prenatal diagnosis of bilateral urinary tract obstruction should have a comprehensive assessment, including family history, ultrasonography, karyotype, AFP, specific biochemical or genetic tests as indicated, and serial urine biochemical analyses (Table 42-9) (541,542,543,543a). Malformations of the kidney and the urinary tract have been linked to mutations of paired homeobox-2 gene (PAX-2) and the angiotensin type 2-receptor gene located on the X chromosome (544). If prenatal assessment demonstrates severe urinary tract obstruction with oligohydramnios in a fetus without a lethal disease and without evidence for renal dysfunction suggestive of bilateral renal dysplasia (541), intervention may be indicated to alleviate oligohydramnios and thus limit or prevent lung hypoplasia. Depending on GA, one may then consider either intrauterine decompression of the urinary tract or elective premature delivery after steroid administration to the mother. Serial determinations of urine indicators appear more reliable in predicting long-term renal function than single measurements (541,542,543). Chronic renal failure (CRF) may develop despite early surgical intervention for urinary tract obstruction or reflux (545).

Special Considerations

Structural anomalies of the kidneys and urinary tract are discussed in Chapter 43.

Tubular Dysgenesis

Several cases of perinatal ARF have been described in association with immature nephrons, predominantly with either glomerular lesions or tubular lesions. Oligohydramnios developed in most patients during the second trimester. These infants died in utero or soon after birth.

The administration of ACE inhibitors during pregnancy can result in oligohydramnios, lung hypoplasia, and neo-natal renal failure with oligoanuria for 3 to 9 days, hypotension, hypoplasia of the calvaria, and, in many cases, perinatal death (453,454). Pathologic examination may show tubular dysgenesis with abundant presence of renin in glomeruli and preglomerular arterioles, suggesting up-regulation of the renin-angiotensin system (RAS) (546). Similar lesions may occur in one kidney, with renal artery stenosis secondary to arteritis or medial arterial calcinosis (547).

Oberg and associates found signs of renal tubular dysgenesis in 11 of 21 donor twins with twin-

to-twin transfusion but in none of the 17 recipient twins (548). Pathophysiology in the donor twin presumably involves reduction in renal perfusion and glomerular filtration with secondary up regulation of renin synthesis. The histological features of tubular dysgenesis are similar to that seen in fetuses exposed to ACE inhibitors during pregnancy. In contrast, the recipient kidney shows downregulation of RAS and histology shows kidneys with multiple hemorrhagic infarcts and hypertrophy of mesangial cells as seen in hypertensive nephropathy.

Intrauterine growth restriction is associated with congenital oligonephropathy and with an increased incidence of hypertension, type II diabetes, hyperlipidemia, CRF, and coronary heart disease in adulthood (549). Congenital oligonephropathy is characterized by a significantly reduced number of glomeruli, which may adversely affect renal development. Animal studies support a role of abnormal maturation of RAS (550).

Prenatal administration of both cyclo-oxygenase type 1 and 2 (COX-1 & 2) inhibitors (e.g., indomethacin, nimesulide) has been associated with perinatal death, bleeding diathesis, ileal perforation, premature ductal closure, fetal oligoanuria, oligohydramnios, and transient or prolonged neonatal renal failure (requiring chronic dialysis) with hematuria and casts (551,552). Pathology may show immature tubules and glomeruli, massive cortical necrosis, or ischemic changes in the cortex associated with cystic dilation of the superficial nephrons and increased intrarenal renin (367).

TABLE 42-9 ASSESSMENT OF THE FETUS WITH BILATERAL RENAL MASS

Procedure	Significance and Interpretation
Family history	Autosomal dominant polycystic kidney disease, autosomal recessive polycystic kidney disease, hereditary renal dysplasia
Comprehensive ultrasonography	Dymorphic syndrome (e.g., skeletal dysplasia) Lung hypoplasia (secondary to abdominal mass, oligohydramnios, or both) Abnormality of central nervous system, spinal cord, heart, gastrointestinal tract, limbs Tumor (obstructing urinary flow) Hydrops, ascites Oligohydramnios, polyhydramnios Cortical cysts or abnormal echogenicity suggest renal dysplasia; however, hydronephrosis may be difficult to differentiate from cystic dysplasia Large trabeculated bladder in a male suggests a diagnosis of posterior urethral valves
DNA analysis	Fetal karyotype to rule out trisomy 13, 18, 9 Molecular genetics (for specific diagnoses)
Alpha-fetoprotein	If abnormal for gestational age: Low: consider diagnosis of trisomy High: consider myelomeningocele

Assessment of renal function^a

Abnormal fetal urine composition (especially progressive worsening on serial analysis) predicts poor long-term renal function and thus is a contraindication to fetal intervention

- Sodium >95th percentile for gestational age (100 mEq/L at 20 wk)^b
- Chloride >90 mEq/L
- Osmolality >210 mOsm/kg
- Calcium >2 mmol/L (8 mg/dL)
- Phosphate >2 mmol/L
- Beta 2-microglobulin >4 mg/L
- Protein >20 mg/dL
- Urine output <2 mL/h
- Abnormal amino acid concentration for gestational age
- High fetal serum level of beta₂-microglobulin:
 - >4.9 mg/L (95% confidence interval at 18-39 wk) or >5.6 mg/L

^a Serial measurements of urine biochemistry are more predictive of long-term outcome than a single measurement, because serial results show more pronounced deviation from the normal with increasing gestation in fetuses with renal dysplasia.⁵⁴³

^a The 95th percentile is approximately 120, 90, 70 and 60 mEq/L at 18, 21, 24 and 27 weeks, respectively.⁵⁴³

P.1009

Renal Artery Thrombosis

The clinical presentation of renal artery thrombosis is a variable combination of hyperreninemic systemic hypertension, hematuria, thrombocytopenia, severe oligoanuric ARF (if the lesion is bilateral), and loss of femoral pulses and of blood flow to the lower extremities. Renal artery thrombosis is often but not always (553) associated with a history of UA catheterization (554,555,556 and 557). Although mechanical injury and alteration of blood flow in the relatively small arteries of neonates is the major stimulus, other contributing factors may include an immature fibrinolytic system, partly as a result of physiological deficiency in protein C, or plasminogen, hemodynamic factors, and inherited deficiencies of the naturally occurring circulating anticoagulants (hereditary antithrombin III deficiency) (558). The incidence of thrombi in infants with a UA catheter in place ranges between 24% and 95% (559,560). These thrombi may become symptomatic when massive or when embolism occurs.

Real-time US may be normal or show increased cortical echogenicity or nephromegaly. The diagnosis of renal artery thrombosis is confirmed by MR angiography or color Doppler sonography. MR angiography is superior to color Doppler sonography in the evaluation of renal vasculature (561).

ARF associated with bilateral renal artery thrombosis may require prolonged replacement therapy (e.g., peritoneal dialysis) (555). The indications for surgical treatment are not clear (562,563). Systemic anticoagulation, thrombolysis and, if it fails, thrombectomy should be considered for patients with refractory hypertension and those with massive aortic thrombus

resulting in major complications (e.g., compromised limb perfusion, renovascular hypertension or anuria) (555,562,563). The other patients usually can be treated with antihypertensive agents and symptomatic management of the complications of ARF; heparinization may help limit further extension of the thrombus. Although renal artery thrombosis often results

P.1010

in localized or diffuse renal hypotrophy, renal function often improves to a level that is close to normal, and hypertension resolves in most patients within a few months (564,565). Fanconi syndrome may occur in rare patients (565).

Renal Venous Thrombosis

Neonatal renal venous thrombosis is an uncommon condition. It may be associated with polycythemia; severe perinatal asphyxia; severe dehydration, sometimes with shock; maternal diabetes; angiography for congenital cyanotic heart disease; and adrenal hemorrhage (566,567). Suboptimal fibrinolysis in stressed newborn infants may be an important factor (568). Renal venous thrombosis presents clinically as the association of a unilateral or bilateral palpable flank mass with hematuria, proteinuria, and, in some cases, oligoanuria.

Ultrasonography of the kidney shows a typical image, characterized by enlargement of the kidney, loss of definition of the corticomedullary junction, abnormal focal or generalized increase in echo amplitude of the renal parenchyma, and decrease in the size and echo amplitude of the central echo complex (567). The diagnosis of renal venous thrombosis is confirmed by MR angiography or color Doppler sonography. In cases in which patency of the IVC is unclear on MR angiography, color Doppler sonography should also be performed (561).

Ultrasonography and Doppler studies show whether the thrombosis extends to the inferior vena cava. The acute complications of renal venous thrombosis include ARF, systemic hypertension, and disseminated intravascular coagulation. The lesion ultimately may result in renal atrophy (569,570). Thrombophilia should be ruled out with appropriate investigations.

Conservative and supportive therapies are indicated. The indications for surgery are not clear. Although unproven, in the presence of consumption coagulopathy, administration of heparin may be considered. The therapeutic decision should take into account the risk of disseminated bleeding and intraventricular hemorrhage, especially in premature infants (571).

In cases associated with bilateral renal venous thrombosis or inferior vena cava thrombosis, similar results have been reported using either thrombectomy or thrombolysis (572,573).

Cortical Necrosis and Medullary Necrosis

Renal cortical or medullary necrosis is the most severe type of ARF. The most common causes of renal necrosis include severe asphyxia and shock (574,575). Idiopathic arterial calcification is a rare cause of renal infarction (576). The symptomatology is not specific and includes oligoanuric ARF, proteinuria, and hematuria that is often grossly apparent. The kidneys often are enlarged; renal US shows homogeneously hyperechoic kidneys, with loss of sharp corticomedullary definition (437). The renal scan shows either very poor renal function or nonvisualization of the kidneys. Calcifications may become visible both on the US and the abdominal radiography. The treatment is similar to that described previously for ATN. The prognosis of bilateral global cortical necrosis is dismal; the diagnosis has been made most often at autopsy. Patients with focal or unilateral necrosis may recover, but often have chronic hypertension and CRF. Infants with medullary necrosis typically have persistent limitations in urinary concentrating ability.

Postrenal Failure

Postrenal failure may result from urinary tract anomalies, extrinsic compression of the urinary tract, fungal infection (fungus ball) or, rarely, urolithiasis (577) (see Hypercalciuria, Nephrocalcinosis, and Nephrolithiasis, and Chapter 43). The medical treatment of postrenal failure is similar to that of intrinsic renal failure. Decompression of the urinary tract (see Chapter 43) often results in an increase in GFR and a polyuric phase, which usually is transient. During the polyuric phase, severe dehydration, hyponatremia, and hyperkalemia may develop despite adequate increase of serum aldosterone levels (578). Sequential adjustment of fluid and electrolyte intake to these losses may help prevent or limit such complications. When GFR comes to baseline within 1 week after corrective surgery, fluid intake should be reduced slowly and carefully, taking into account the fact that limited urine-concentrating ability is expected in association with dysplastic kidneys. The evolution of renal function depends on the degree of renal dysplasia, which is very common in congenital urinary tract obstruction, and the frequency of UTI, which is related to VUR, urinary stasis, and the presence of an indwelling catheter.

Nephrotoxicity

Several agents that cross the placenta (see [Chapter 15](#)) can damage the fetal kidney, including aminoglycosides, ACE inhibitors, heavy metals, and organic solvents ([Table 42-10](#)) ([579](#)). Chapters 15 and 56 provide a discussion of the relevant pharmacokinetics. Nephrotoxicity may result from renal ischemia or direct cytotoxicity, or both. Direct cytotoxicity is related to the concentration of drug or metabolite in renal tubular cells, which depends on the concentration of free drug in the plasma, GFR, and tubular transport.

Nephrotoxicity may present as oligoanuria, ARF, drug toxicity caused by decreased clearance of a medication with renal excretion, hypotension, hematuria, proteinuria, RTA, nephrocalcinosis or nephrolithiasis, polyuria, abnormal plasma electrolyte concentrations, or cardiac arrhythmia (see [Table 42-10](#)). Because most NICU patients are exposed to multiple drugs as well to episodes of hypoxemia and ischemia, it often is very difficult to determine whether a particular drug is the major renal offender.

TABLE 42-10 NEPHROTOXIC EFFECTS OF VARIOUS AGENTS

Substance	Renal Side Effects
Drugs	
Aminoglycosides	Proteinuria, increased urinary excretion of Na, K, Mg, and glucose, Fanconi syndrome, myelin figures, decreased concentrating ability, decreased RBF, polyuric ARF, ATN, interstitial nephritis
Methicillin	Interstitial nephritis
Amphotericin B	Hyperkaliuria, hyposthenuria, NDI, hypernatriuria, ATN, oliguria, RTA, nephrocalcinosis
Acyclovir	Crystalluria, obstructive nephropathy
Indomethacin	Decreased RBF, ATN, oligoanuria, hyponatremia, hyperkalemia, nephron dysgenesis, and oligohydramnios (<i>in utero</i>)

Tolazoline	Hypotension and hypoxemia resulting in decreased GFR, ATN, oliguria, hematuria
Adrenergic agents	Decreased RBF, ATN
ACE inhibitors	Hypotension, decreased RBF, ATN, nephron dysgenesis (<i>in utero</i>)
Radiocontrast agents	Decreased RBF, oliguric ATN, Tamm-Horsfall proteinuria, nephromegaly with US similar to ARPKD, increased urinary excretion of uric acid
Cyclosporine	Renal vasoconstriction, decreased RBF and GFR, interstitial nephritis
Loop diuretics	Nephrocalcinosis, nephrolithiasis
Ifosfamide	Fanconi syndrome
Toxins	
Hemoglobin	ATN
Myoglobin	ATN
Oxalate	Nephrocalcinosis, nephrolithiasis, oxalosis with ARF
Benzyl alcohol	Cardiovascular collapse, ATN
Polysorbate (in iv tocopherol)	ATN
Uric acid	Crystalluria, ATN
Organic solvents (toluene)	Fanconi syndrome, aminoaciduria, hyperchloremic acidosis
Alcohol (fetal alcohol syndrome)	Distal RTA
Ethylene glycol (in paracetamol)	ARF, metabolic acidosis

ACE, angiotensin-converting enzyme; ARF, acute renal failure; ARPKD, autosomal recessive polycystic kidney disease; ATN, acute tubular necrosis; GFR, glomerular filtration rate; NDI, nephrogenic diabetes insipidus; RBF, renal blood flow; RTA, renal tubular acidosis.

Prevention of nephrotoxicity includes avoiding teratogens during pregnancy, adjusting the daily dose of medications excreted by the kidney according to measured or predicted GFR and to serum drug levels, avoiding known toxins ([458](#), [580](#), [581](#)), and avoiding, if possible, nephrotoxic drugs, especially synergistic combinations.

Specific Considerations

Aminoglycosides

Aminoglycosides cause renal vasoconstriction mediated by thromboxane B2 ([582](#)) and direct cellular toxicity, especially in the proximal tubule, which absorbs the drug and stores it in lysosomes. Eventually, tubular necrosis, tubular atrophy, intratubular myeloid bodies, and interstitial nephritis may develop ([583,584](#)).

Aminoglycoside nephrotoxicity often presents as isolated proteinuria, reversible polyuric ARF with a high FENa, or transient tubular dysfunction ([585,586](#)).

Laboratory findings may include proteinuria, decreased GFR, decreased urine-concentrating ability, glucosuria, increased urinary excretion of sodium, potassium, calcium, and magnesium, alterations in tubular transport of organic acids, and, rarely, a Fanconi syndrome ([528,585,586,587,588](#) and [589](#)). The most sensitive indicator of nephrotoxicity is the detection of proteinuria (initially brush border enzymes, e.g., trehalase, and LMW proteins; after 1 week of therapy, cytoplasmic and lysosomal enzymes, e.g., NAG) ([590,591](#)) or phospholipiduria ([592](#)).

Gentamicin, kanamycin, and tobramycin are more nephrotoxic than amikacin or netilmicin ([584,590](#)). Studies in infants and children, in contrast with those in adults, have failed to show an additive toxicity of vancomycin and aminoglycosides ([593,594,595](#)). The daily dose of aminoglycosides should be adjusted according to Pcr and to serum drug levels. Pcr, serum electrolytes, urinalysis, and urine output should be followed serially in high-risk patients; sodium and potassium intake should be adjusted to urine losses. In patients with severe nephrotoxicity and in those with renal failure, a less toxic antibiotic should be used. A number of studies have compared the safety of the traditional multiple daily dosing of gentamicin (2.5 mg/kg) to the higher dose (4-5 mg/kg) extended dose interval in neonates. The trials did not report any nephrotoxic events for either regimen ([596,597](#)). An association was reported between single dose gentamicin regimen (4 mg/kg every 24 hours) and clinically significant hypocalcemia in full-term neonates ([598](#)).

Nonsteroidal Antiinflammatory Agents

Vasoactive forms of nonsteroidal antiinflammatory agents such as indomethacin, aspirin and ibuprofen can induce renal hypoperfusion in neonates, especially preterm neonates, resulting in usually reversible, oliguric ARF (79). These drugs abolish the vasodilatory effects of prostaglandins, which maintain an effective GFR. Nonsteroidal antiinflammatory agents, when used during pregnancy for preventing toxemia and preterm birth or for treating polyhydramnios, easily pass the placenta. Postnatally these agents may be infused for closing a PDA or given orally for specific tubular disorders (see section on tubular dysfunction).

Indomethacin has traditionally been the choice, but recently, ibuprofen has been advocated for its less severe renal toxicity (596). A systematic review (600) has shown that administration of ibuprofen reduced the risk of oliguria (urine output <1 ml/ kg/hour) (relative risk 0.22, 95% confidence interval 0.09, 0.51) but increased the risk for oxygen requirement at 28 days, as compared to indomethacin.

Indomethacin is excreted into the urine through the organic secretory pathway of the proximal tubule, which explains higher levels in more immature patients (601). Indomethacin administration was found to transiently decrease RBF in premature infants with symptomatic PDA (440). Some patients develop transient renal dysfunction, associated with a fall of PRA from the high levels that are attributed to renal hypoperfusion before closure of the PDA, and a transient rise in the plasma level of AVP (602). During prolonged administration of indomethacin, i. e., up to 1 week, hormonal levels normalize, and renal function tends to improve (602,603). Indomethacin causes NAG enzymuria and increases the proximal tubular reabsorption of solutes (e.g., Na⁺), the corticomedullary gradient, and the hydroosmotic effect of ADH. The latter two changes result in an increased ratio of urine to plasma osmolality and decreased free water clearance, leading to water retention and dilutional hyponatremia (604,605,606). Indomethacin administration may also cause oliguric ARF and decreased renal K⁺ excretion, resulting in hyperkalemia. The latter may result from hyporeninemic hypoaldosteronism, decreased Na⁺ delivery to the distal tubule, or ARF. Maternal administration of indomethacin may induce nephron dysgenesis (see Acute Renal Failure) (551,552), oligohydramnios, and neonatal renal failure (604). However, perinatal indomethacin does not seem to affect long-term renal growth, structure or function in children born at less than 33 weeks of gestation (607).

Indomethacin is contraindicated if Pcr is elevated, i.e., Pcr greater than 1.8 mg/dL and in the presence of oligoanuria or hyperkalemia. The incidence of nephrotoxicity is increased by the combination of indomethacin with other nephrotoxins. One randomized trial showed that decrease in renal blood flow

velocity and in urine output is observed with bolus indomethacin administration but not with continuous infusion (608). Two systematic reviews of randomized clinical trials found no evidence to support the use of dopamine (609) or furosemide (610) to prevent renal dysfunction in indomethacin treated preterm neonates.

During a course of indomethacin, Pcr, serum electrolyte concentrations, and urine output should be monitored. The interval of drug administration should be adjusted according to Pcr or GFR, and fluid intake should be adjusted according to urine output. If oligoanuria develops, a challenge dose of furosemide should be given; fluid restriction should be initiated if oligoanuria persists.

Amphotericin B

Amphotericin B causes nephrotoxicity by renal vasoconstriction (611) and by its affinity to sterols, which are important components of membranes. Functional tubular alterations include an increase in urinary pH, in fractional excretion of Na⁺, K⁺, and phosphate, and in NAG enzymuria (612). Prolonged administration results in glomerular lesions, interstitial edema, focal tubular atrophy, and nephrocalcinosis (613). In newborn infants, amphotericin administration often increases Pcr and BUN, and transiently reduces serum potassium level (614); increasing potassium intake can prevent hypokalemia. Acute signs of nephrotoxicity may include decreased RBF and GFR, azotemia, oligoanuria, increased urinary excretion of Na⁺, K⁺, phosphate and bicarbonate, and hyposthenuria. Later complications may include NDI, distal RTA, and nephrocalcinosis (613,615). The incidence and prognosis of renal damage depend on the total dose of amphotericin administered (613). Nephrotoxicity may be limited by using a slow infusion (616), adjusting the daily dose to GFR and to minimum inhibitory and fungicidal concentrations (617), and avoiding hypercholesterolemia (618). If oligoanuric ARF develops, amphotericin should be withheld temporarily and restarted later, either at a lower dose or preferentially using a liposomal formulation at a similar or higher dose (619). Liposomal amphotericin has limited toxicity and is well tolerated in neonates including VLBW babies (620,621,622).

Acyclovir

Acyclovir administration may result in an increase in urine beta2-microglobulin and an obstructive nephropathy mediated by crystalluria that may lead to ARF (623). The risk of nephropathy can be minimized by adjusting the interval of administration for GA and renal function, by using a slow infusion, and by providing sufficient fluid intake to maintain adequate urinary output (623,624). If acyclovir is considered in a patient who also needs fluid restriction, the urine should be checked regularly for crystalluria and increased Pcr. If renal dysfunction

is observed, the dose of acyclovir should be withheld or decreased, and fluid intake increased temporarily.

Radiocontrast Agents

Radiocontrast agents may cause ischemia, direct toxicity, and tubular obstruction by Tamm-Horsfall protein (625)

P.1013

or by uric acid crystals resulting from increased uricosuria (626). The signs of radiocontrast nephrotoxicity may include poor visualization or a prolonged nephrogram, proteinuria with casts, and oliguric ARF (625). In newborn infants who need angiography or CT with contrast, a low-osmolality agent is preferred. Adequate hydration should be provided before the procedure.

Angiotensin-converting Enzyme Inhibitors

Administration of ACE inhibitors during pregnancy has been associated with tubular dysgenesis, oliguric ARF, hypotension, hypoplasia of the calvaria, and perinatal death, and is therefore contraindicated (see Acute Renal Failure) (365,366,454). Neonates born in ARF after maternal ACE inhibition have a high mortality rate using conservative management; peritoneal dialysis may be considered to treat the ARF and to remove the ACE inhibitor (454). Postnatal ACE inhibition may cause profound hypotension, decreased RBF, and oliguric ARF (627,628), especially in association with hypovolemia. These hypotensive events respond to massive volume expansion but not to ino-tropes. ACE inhibition also enhances the renal toxicity of aminoglycosides (582).

Myoglobinuria-Hemoglobinuria

Rhabdomyolysis causes major shifts between intra- and extracellular electrolytes, shock, severe renal vasoconstriction, hyperuricemia, thrombi in the glomerular capillary tufts as a result of disseminated intravascular coagulation, intratubular hemoprotein casts, formation of free radicals, and peroxidation of lipids (629,630). The low incidence of neonatal rhabdomyolysis (631,632) may result from the low myoglobin content of immature muscle, especially in premature infants (633). Myoglobinuria should be suspected in severely asphyxiated full-term infants with a strongly positive reaction for heme in the absence of microscopic hematuria.

Chronic Renal Failure

The definition of chronic kidney disease (CKD) in infants and children, levels of severity of CKD, and recommended practice guidelines for management of

pediatric CKD have recently been refined through the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (K/DOQI) process (634). A patient can be considered to have CKD if either of the following criteria is present:

- Kidney damage for ≥ 3 months, as defined by structural or functional abnormalities of the kidney, with or without decreased glomerular filtration rate (GFR); or
- $\text{GFR} \leq 60 \text{ mL/min/1.73 m}^2$ for ≥ 3 months, with or without other signs of kidney damage.

The levels of severity of pediatric CKD are outlined in Table 42-11.

Stage	GFR (ml/min/1.73 m²)	Description
1	≥ 90	Kidney damage with normal or increased GFR
2	60-89	Kidney damage with mild reduction of GFR
3	30-59	Moderate reduction of GFR
4	15-29	Severe reduction of GFR
5	<15 (or dialysis)	Kidney failure

¹ Adapted from reference 634
 Abbreviations used in table: GFR, glomerular filtration rate.

Incidence

The incidence of pediatric end-stage renal disease (ESRD) is three to eight cases per one million children (age range 0 to 16 years) (635,636 and 637). Only 6% of children with ESRD are under 3 years of age (637). Renal transplantation is the preferred treatment modality for infants and children with ESRD, and is performed more commonly in children than in adults (638). As of 2003, of the 8399 renal transplants in children between 0 and 18 years of age registered in the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS), only 5% were performed in children under 1 year of age (639). For those infants and children not receiving renal transplants, peritoneal dialysis is more common overall than hemodialysis, especially in the youngest age groups (638).

Etiology

As might be expected, inherited/congenital etiologies of renal failure are common in infants and children with CKD. A recent review of 10 years of data collected from pediatric nephrology centers in Britain and Ireland demonstrated that most children reaching ESRD under the age of 2 had such underlying diagnoses as renal dysplasia, structural problems, and other inherited conditions, with relatively few having acquired conditions such as glomerulonephritis or cortical necrosis (Table 42-12) (640). Structural disease also compromised the majority of children less than 1 year of age entered into the NAPRTCS chronic renal insufficiency database (639). These forms of renal disease are usually characterized by slow rates of progression, meaning that preemptive renal transplantation can usually be planned.

Management of CKD in Infancy

Infant CKD is a complex condition requiring intensive, specialized management to avoid the many complications of renal insufficiency and promote normal growth and development. Management can be generally divided into two categories—conservative management, which encompasses

P.1014

all of the medical therapies short of dialysis and transplantation, and renal replacement therapy, which include both dialysis and transplantation. [Table 42-13](#) summarizes the many problems encountered in infants with CKD and the usual approaches to management of each problem.

TABLE 42-12 DIAGNOSES OF CHILDREN WHO REACHED END STAGE RENAL FAILURE BEFORE THE AGE OF 2 YEARS DURING THE 10 YEARS 1988-97 INCLUSIVE¹

Diagnosis	Treated	Not Treated	Antenatal Diagnosis (%)
Renal dysplasia	57	7	40
Posterior urethral valves	44	0	84

The most crucial aspect of managing an infant with CKD is ensuring adequate nutrition. As mentioned previously, most infants with CKD have underlying structural renal disease as the etiology of their CKD. These conditions are characterized by tubular dysfunction leading to salt and water wasting, which in turn produces unique requirements not only for

adequate caloric intake, but also for adequate intake of sodium and water to achieve normal growth rates (see the earlier discussion on sodium balance). A recent report demonstrated that infants and young children with CKD who were fed with dilute, sodium-supplemented feedings had superior growth compared to similar patients who were fed with high caloric density formulas (640).

Most infants with CKD will require placement of a feeding gastrostomy to maintain adequate intake of fluid, formula, and medications.

TABLE 42-13 CONSERVATIVE MANAGEMENT OF INFANTS WITH CKD

Problem	Usual Therapy	Comment
Acidosis	Alkali (Na citrate, NaHCO ₃)	Correction of acidosis necessary to maintain anabolism and promote normal growth
Anemia	Recombinant erythropoietin	Iron supplementation always necessary during erythropoietin treatment
Anorexia	Nasogastric or gastrostomy feeds	Nearly all infants with CKD require supplemental feedings
Hyperphosphatemia	Low-phosphate formula; phosphate binders	CaCO ₃ most commonly used phosphate binder in infancy; avoid aluminum containing binders
Secondary hyperparathyroidism	Vitamin D analogues (DHT, calcitriol)	Maintain serum intact PTH in normal range in pre-dialysis CKD patients; avoid calcium*phosphorous product >70
Uremia	Low-protein diet	Do not restrict protein intake below RDA for age; infants with CNS require increased protein intake
Growth failure	Supplemental feedings; rHGH	Correction of all above problems must be achieved prior to instituting rHGH treatment
Neurodevelopmental delay	"Early intervention" services	Most infants require some combination of physical, occupational and speech/feeding therapies

Abbreviations used in table:

CaCO₃, calcium carbonate; CKD, chronic kidney disease; CNS, congenital nephrotic syndrome; DHT, dihydrotachysterol; Na, sodium; NaHCO₃, sodium bicarbonate; RDA, recommended daily allowance; rHGH, recombinant human growth hormone.

Other aspects of the management of CKD in infants and children have been reviewed elsewhere ([641](#),[642](#),[643](#),[644](#),[645](#)). It should be noted that common complications of acute renal failure, such as hyperkalemia and hypertension as a result of fluid overload, are uncommon in infants with CKD because of the polyuria that accompanies the structural forms of renal disease that occur in infancy ([645](#)). No matter what the underlying etiology, infants with CKD require the services of a multidisciplinary team consisting of pediatric nephrologists, pediatric renal dietitians, pediatric surgeons and other medical personnel geared toward meeting their unique needs.

Infant Dialysis

As with acute renal failure, once conservative measures prove insufficient to control the manifestations of CKD, then renal replacement therapy becomes necessary. The most common indication for the elective institution of dialysis in infancy is growth failure; the most common nonelective indication is probably persistent renal insufficiency following neonatal acute renal failure.

Peritoneal dialysis is by far and away the most common dialysis modality employed in infants requiring chronic renal replacement therapy ([638](#),[639](#) and [640](#),[645](#)). The reasons for this are multiple, but include the relative ease of achieving access compared to hemodialysis, avoidance of exposure to blood products, and the ability to provide care in the home setting. Even with meticulously provided care, complications of peritoneal dialysis in infants are common and include infection (especially peritonitis) and catheter malfunction ([640](#),[645-647](#)). Chronic hemodialysis is technologically feasible in infancy, but in most pediatric nephrology centers it is reserved for infants who have failed peritoneal dialysis, or for the rare infant in whom peritoneal dialysis is impossible for surgical or social reasons.

It should be emphasized that in infants, chronic dialysis is almost universally considered a temporary measure until renal transplantation can be performed. One of the major reasons for this is the poor survival rates of infants on dialysis compared to older children: According to the NAPRTCS dialysis registry, survival of children less than or equal to 1 years of age at the initiation of dialysis was 86.6% after 1 year, 76% after 2 years and 70.5% after 3 years, compared to survival rates of 97.9%, 94.9% and 92% at the same time intervals for children more than or equal to 12 years of age at the initiation of dialysis ([639](#)). This comparatively poor survival is for the most part a consequence of other co-morbid conditions in many infants who require chronic dialysis ([647](#),[648](#)).

Withholding care is still sometimes considered when an infant is found to have severe CKD requiring renal replacement therapy ([649](#),[650](#)). The usual reasons cited in such cases are the enormous demands on the infant's family and the historically uncertain long-term outcome of such infants. However, as documented in numerous series over the past decade, infants receiving chronic dialysis can be reasonably expected to maintain normal

growth rates and achieve near-normal neurodevelopmental progress (640,646,647,651). Advances in the success of renal transplantation in infants (643,649,652) add further weight in favor of providing dialysis when an infant is found to have irreversible CKD. Although it is true that this requires an enormous commitment on the part of the infant's family and medical team, it can be said that provision of chronic dialysis is now the standard of care for infants with severe CKD, and that withholding or withdrawing dialysis should be considered only in unusual circumstances (645,650,653).

Renal Transplantation

The advantages of renal transplantation in infants and children with CKD are numerous. Chief among them are improved growth and development compared to long-term dialysis, and a more normal quality of life (640,643, 654,655,656). These benefits explain why renal transplantation is considered the preferred renal replacement modality for infants and children with ESRD, and why it is performed more commonly in children than in adults. Transplantation in infancy remains a somewhat rare event, however; only 5% of the pediatric renal transplants reported to the NAPRTCS registry were performed in children under 1 year of age (639). The success of renal transplantation in infancy has increased markedly compared to one or two decades ago (643,649,652). This improvement has occurred in parallel with numerous improvements in all aspects of transplant medicine, especially advancements in pretransplant management and in immunosuppressive regimens.

It should be noted that undertaking renal transplantation before the age of 1 year remains somewhat controversial, primarily because of historically poor rates of graft and patient survival. The most recent NAPRTCS data show that recipient age continues to have a significant impact on graft survival for cadaveric transplants, with recipients less than or equal to 1 year of age having a 5-year graft survival of just 54% compared to 70% for older children (639). However, no similar difference in graft survival was seen for recipients of transplants from living donors. Long-term allograft renal function appears to be unaffected by recipient age for both cadaveric and living-donor transplants (639). However, posttransplant patient survival is markedly lower for infants (<24 months old at transplant), particularly for recipients of cadaver donor grafts. Fortunately, this has been improving over time: the 3-year patient survival for recipients of cadaver grafts has increased from 78% between 1987 and 1994 to 94% in 1995 and later. For infants receiving living donor grafts, 3-year survival also improved from 88% in 1987 to 1994 to 95% in 1995 and beyond (639). This improvement in patient survival adds further impetus to pursuing a goal of transplantation for infants with irreversible CKD, and should, over time, make this goal less controversial and more accepted as standard of care.

Summary

As can be deduced from the preceding sections, the overall prognosis for infants with CKD has improved considerably over the last 2 to 3 decades. This may have resulted not only from changes in treatment but also from a change in the patient population associated with an earlier diagnosis. As indicated in [Table 42-12](#), many infants with structural forms of CKD are now routinely diagnosed antenatally ([640](#)), thus enabling planning for the future. When such infants are identified, multidisciplinary teams consisting of an obstetrician, neonatologist, pediatric nephrologist and pediatric surgeon or urologist can meet with the family to discuss the infant's short- and long-term prognoses, thereby helping the family to make informed decisions about the infant's postnatal care.

Hypertension

Definition

In newborn and premature infants, systemic hypertension is best defined as systolic and/or diastolic blood pressure that persistently exceeds the mean + 2 standard deviations for infants of similar postconceptual age (388). The graphs published by Zubrow et al. (Appendix G1c) are probably most useful in this regard (387). After one month of age, hypertension is defined as systolic and/or diastolic blood pressure >95th percentile for that infant's age and gender (380). These normative values can be found in the curves published in the Second Task Force report (657) (Appendix G1d).

As with older children, the diagnosis of hypertension should not be made based on a single reading. If the infant is critically ill and continuous blood pressure monitoring reveals sustained blood pressure elevation over several hours, then hypertension should be diagnosed and appropriate investigation and intervention initiated. For less critically ill infants still in the NICU, a pattern of elevated readings over 1 to 2 days should be sufficient to make the diagnosis of hypertension. For older infants who are being followed as outpatients, then at least three elevated readings should be documented over 1 to 2 weeks before a diagnosis of hypertension is made (380).

Incidence

Although one recent series found that 28% of infants with BWs less than 1,500 grams had at least one elevated blood pressure documented during their NICU stay (658), the actual incidence of hypertension in neonates is very low, ranging from 0.2% in healthy newborns to between 0.7% and 2.5% in high-risk newborns (659,660,661,662,663). Certain categories of infants are at significantly higher risk, however. For example, hypertension is relatively common in patients with a history of UA catheterization (3%) (664) and those with bronchopulmonary dysplasia (BPD) (as high as 43%) (660). In one series, it also was associated with PDA and intraventricular hemorrhage (663). On the other hand, hypertension is so uncommon in otherwise healthy term infants that routine blood pressure determination is not even recommended (665).

Etiology and Pathophysiology

Although numerous conditions are known to cause hypertension in the neonate or older infant (Appendix G1e), a clear etiology can be determined in only approximately one-third of hypertensive newborn infants (661,666). The most important categories of causes of neonatal hypertension include renovascular hypertension, renal disease, and bronchopulmonary dysplasia (388,661).

Renovascular Hypertension

The most common cause of neonatal renovascular hypertension is aortic or renal thromboembolism related to UA catheterization (664). This was first demonstrated in the 1970's by Ford and associates (667) and Bauer and associates (668). Hypertension may develop either while the catheter is in place or long after its removal (669) and may be associated with a history of renal failure or hematuria. Associated signs may include ARF in patients with bilateral involvement, hematuria, and loss of femoral pulses and blood flow to the lower extremities in patients with extensive aortic thrombosis. Although there have been several studies that have examined duration of line placement and line position ("low" vs. "high") as factors involved in thrombus formation, these data have not been conclusive (670,671,672). Thus, the assumption has been made that the cause of hypertension in such cases is related to thrombus formation at the time of line placement, probably related to disruption of the vascular endothelium of the umbilical artery. Such thrombi may then embolize to the kidneys, causing areas of infarction and increased renin release. A similar phenomenon has been reported in infants with dilatation of the ductus arteriosus (673). The Cochrane Group has recently attempted to resolve the controversy regarding UA catheter placement (674). They analyzed 11 randomized clinical trials and one study using alternate assignments to compare the incidence of morbidity and mortality for high vs. low catheter tip placement. The placement of a catheter tip was defined as high when located in the descending aorta above the diaphragm and low when placed in the descending aorta above the bifurcation but below the renal arteries. The reviewers concluded that high catheter position causes fewer clinically obvious ischemic complications and possibly decreases the frequency of

aortic thrombosis. As far as hypertension was concerned, however, it was concluded that it seems to appear with equal frequency among infants with high or low placement.

Congenital vascular anomalies responsible for neonatal renovascular hypertension include stenosis or hypoplasia

P.1017

of the renal artery (675,676) and segmental intimal hyperplasia (677). All these conditions may involve the aorta and the renal arteries. Unilateral renovascular stenosis may cause a reversible syndrome characterized by hypokalemic alkalosis, salt-losing syndrome, and hyperechogenicity of the contralateral kidney (678).

Hypertension may rarely result from two types of infiltration of the arterial wall. Idiopathic arterial calcification of infancy is characterized by calcium deposits in all layers of the arteries, including the aorta and the coronary arteries, and in the heart valves (679,680,681 and 682). Some of these deposits may be visible on a plain radiogram. Most cases have been diagnosed at autopsy. Hypertension typically fails to respond to standard antihypertensive medication and to nephrectomy; biphosphonate, calcium antagonists, or PGE1 may be successful (681,683). Galactosialidosis may result in intimal infiltration by sialyloligosaccharides and hyperreninemic hypertension (684).

Other causes of renovascular hypertension include neonatal renal arterial embolism in the absence of UA catheterization (673), intramural hematoma of the renal artery (685), renal venous thrombosis (686), external compression of the renal artery by a hydronephrotic kidney (687), adrenal hemorrhage (688), and urinoma (689). Finally, a neonate with hypertension as a result of an aneurysm of the abdominal aorta was recently reported (690); this fortunately rare condition may present with intractable congestive heart failure.

Bronchopulmonary Dysplasia

Many infants with BPD develop hypertension (653,691). This phenomenon was first described in the mid-1980s by Abman and colleagues (653). In a

study of 65 infants discharged from a neonatal intensive care unit, the incidence of hypertension in infants with BPD was 43%, vs. an incidence of 4.5% in infants without BPD. Investigators were unable to identify a clear cause of hypertension, but postulated that hypoxemia might be involved. Over half of the infants with BPD who developed hypertension did not display it until after discharge from the NICU, highlighting the need for measurement of blood pressure in NICU "graduates," whether or not they have lung disease (666).

Abman's findings have been reproduced by other investigators, most recently in 1998 by Alagappan (692), who found that hypertension was twice as common in VLBW infants with BPD compared to the incidence in all VLBW infants. Because all of the hypertensive infants required supplemental oxygen and aminophylline, development of hypertension appeared to be correlated with the severity of pulmonary disease. Anderson and colleagues have demonstrated that the more severe the bronchopulmonary dysplasia (defined as a greater need for diuretics and bronchodilators), the higher the likelihood of the development of increased blood pressure (693).

These observations reinforce the impression that infants with severe BPD are clearly at increased risk and need close monitoring for the development of hypertension. This is especially true in infants who require ongoing treatment with theophylline preparations and/or corticosteroids; as many as 30% of infants receiving dexamethasone for BPD manifest hypertension (694). If severe hypertension develops, the risk of intraventricular hemorrhage, CHF, and renal failure may outweigh the possible beneficial effects of steroids on the lung disease.

Renal Causes of Hypertension

Hypertension is a common complication of renal anomalies and diseases such as polycystic kidney disease (PKD) (695), renal hypodysplasia (696), hydronephrosis (697), and interstitial nephritis (661). It is well known that both autosomal dominant and autosomal recessive polycystic kidney disease (PKD) may present in the newborn period with severe nephromegaly and hypertension (695,698,699). With recessive PKD, the median age of onset of hypertension was recently reported to be 16 days (700); the majority of affected infants will be discovered to be hypertensive during the first year

of life (698). The most severely affected infants with recessive PKD are at risk for development of congestive heart failure as a result of severe, malignant hypertension. Bilateral nephrectomy may be life saving in such infants.

Although much less common than in PKD, hypertension has also been reported in infants with multicystic dysplastic kidneys (661,701,702). This is somewhat paradoxical, as such kidneys are usually thought to be nonfunctioning. In fact, the case has been made that hypertension in such patients is the result of another coexisting urologic abnormality such as parenchymal scarring (703). Another possible explanation is increased renin production by macrophages within the dysplastic kidney (704).

Renal obstruction may be accompanied by hypertension, even when there is no compression of the renal artery. This has been seen for example in infants with congenital ureteropelvic-junction obstruction (661,663), and sometimes may persist following surgical correction of the obstruction (705). Hypertension has also been described in infants with congenital primary megaureter (706). Ureteral obstruction by other intraabdominal masses may also be accompanied by hypertension. The mechanism of hypertension in such instances is unclear, although the RAS has been implicated (707,708). Finally, unilateral renal hypoplasia may also present with hypertension (696), although this is uncommon.

Hypertension as a result of acquired renal parenchymal disease is less common than that as a result of congenital renal abnormalities. However, severe ATN, interstitial nephritis, or cortical necrosis may be accompanied by significant hypertension (661,663), usually as a result of fluid and sodium overload or hyperreninemia. Hemolytic-uremic syndrome, which has been described in both term and preterm infants (709), is usually also accompanied by hypertension. Such hypertension may be

P.1018

extremely difficult to control, requiring treatment with multiple agents (709).

Genetic Causes of Hypertension

Genetic forms of hypertension that may present in the neonatal period fall into two broad categories, namely hypertension resulting from a single-gene

disorder, and hypertension occurring as one feature of a malformation syndrome. Single-gene disorders causing hypertension with reported cases in infancy include Liddle's Syndrome (710,711), glucocorticoid-remediable aldosteronism (GRA) (712,713), and Gordon's Syndrome (pseudohypoaldosteronism type II) (663).

Liddle's syndrome is an autosomal dominant, low-renin form of hypertension characterized by elevated renal sodium reabsorption that results from activating mutations in the β or γ subunit of ENaC. These mutations result in an increased number and prolonged half-life of channels at the cell surface (714,715). The genetic defect has been localized to a single segment of chromosome 16 that encodes the ENaC subunits; several different mutations have been described, all of which either cause a frameshift mutation or introduce premature stop codons (716). This condition must be differentiated from 11- β -HSD2 deficiency (see Chapter 41). The treatment, i.e., the administration of KCl and an aldosterone-independent K-sparing diuretic, such as triamterene or amiloride, results in normalization of the electrolyte and acid-base balance and the blood pressure.

GRA is an autosomal dominant disease characterized by early onset of hypertension with normal or elevated aldosterone levels despite suppressed plasma renin activity (717). GRA is caused by a chimeric gene that results from unequal crossing-over the aldosterone synthase and 11 β -hydroxylase genes on chromosome 8. The resulting chimeric gene is expressed in the adrenal fasciculata and encodes a protein product with aldosterone synthase enzymatic activity whose expression is regulated by ACTH. Consequently, aldosterone synthase activity is thus ectopically expressed in the adrenal fasciculata under control of ACTH rather than ANG II. Aldosterone secretion becomes inexorably linked to cortisol secretion, and maintenance of normal cortisol levels results in constitutive aldosterone secretion, which leads to expanded plasma volume and hypertension (718).

Gordon's syndrome (pseudohypoaldosteronism type II) is an autosomal dominant disorder characterized by hypertension, hyperkalemia and metabolic acidosis. It may rarely be diagnosed during the neonatal period in patients with a family history (719). It has been linked to mutations of genes on chromosomes 1, 17 and 12 that encode the WNK kinases, a family of serine-threonine kinases (720,721). These mutations lead to increased

expression of WNK1 and WNK 4 in the distal nephron. Although the exact mechanism by which these mutations produce hypertension is unclear, hyperactivity of the Na-K-Cl cotransporter of the loop of Henle has been postulated.

Malformation syndromes that may cause hypertension include Williams Syndrome (renal artery stenosis), Turner's Syndrome (aortic coarctation), neurofibromatosis and Cockayne Syndrome (722). Usually the hypertension in these syndromes presents beyond the neonatal period, but infantile presentations with hypertension have been described.

Other Causes of Hypertension

Coarctation of the thoracic aorta (see Chapters 33 and 34) is easily detected in the newborn period based on decreased pulses and lower blood pressures in the lower extremities compared to the upper extremities (723). It has been reported in numerous case series of neonatal hypertension (659,661,663,666,724). Hypertension may persist in these patients even after surgical repair of the coarctation (725). Repair early in infancy seems to lead to an improved long-term outcome compared to delayed repair (723).

Endocrine disorders, particularly congenital adrenal hyperplasia, hyperaldosteronism and hyperthyroidism constitute easily recognizable clinical entities that have been reported to cause hypertension in neonates (726,727,728,729). Several adrenal disturbances can induce hypertension directly; they should be differentiated from Liddle's syndrome.

Hyperthyroidism is associated with systolic hypertension and sustained tachycardia and, sometimes, with episodes of supraventricular tachycardia (729).

Tumors, including neuroblastoma, Wilms tumor, and mesoblastic nephroma may all present in the neonatal period and may produce hypertension, either because of compression of the renal vessels or ureters, or because of production of vasoactive substances such as renin or catecholamines (730,731,732,733 and 734).

Neurologic causes of hypertension include intracranial hypertension, drug withdrawal, seizures, and familial dysautonomia. Seizures are common complications of severe hypertension; in turn, blood pressure may increase

transiently during seizure episodes (735). Narcotic withdrawal should be treated as described in Chapter 56. Appropriate pain relief should be given before and after surgical procedures (see Chapter 57). A discussion of treatment of intracranial hypertension is presented elsewhere (see Chapter 51).

Iatrogenic causes of neonatal hypertension are usually obvious but important to consider. If the infant is hyper-volemic secondary to excessive administration of sodium or fluids, intake should be restricted and a diuretic administered. It is imperative to eliminate hidden sources of sodium, such as isotonic saline used to flush an arterial line and sodium-containing medications (e.g., antibiotics). If fluid restriction is not possible and severe hypertension with CHF is present, hemofiltration should be strongly considered.

If hypertension is induced by a medication, one may consider withholding it, decreasing the dose, or using an infusion instead of repeated injections. As noted earlier, dexamethasone may cause blood pressure elevation relatively

P.1019

commonly (694,736,737); if this occurs, a decision must be made regarding the possible benefits of continued steroid treatment vs. the risks of hypertension. Hypertension induced by pancuronium probably is mediated by release of catecholamines (738,739,740); blood pressure may normalize after replacing pancuronium with vecuronium.

Hypertension develops in 11% to 92% of neonates receiving ECMO (741,742 and 743), and may result in serious complications, including intracranial hemorrhage (741) and increased mortality (744). Despite extensive investigation, the exact pathogenesis of this form of hypertension remains poorly understood. Fluid overload, altered handling of sodium and water, and derangements in atrial baroreceptor function have all been proposed as causative factors (741,742). Nicardipine infusions are commonly used to treat this form of hypertension (745,746,747).

Hypertension may develop after surgery. Of four patients who developed hypertension after surgical repair of an abdominal wall defect, three had edema of the lower extremities and normal PRA, and one had evidence for ureteropelvic obstruction and high PRA (748). The duration of hypertension

in these patients ranged from 12 days to 6 months. Hypertension appearing after primary closure for bladder exstrophy may be related to traction for skeletal immobilization (749).

Clinical Features and Investigation

Mild-to-moderate hypertension may be asymptomatic (750,751).

Symptomatic presentations, such as congestive heart failure, seizures, poor feeding and lethargy, are nonspecific and may be as a result of the underlying disease, the hypertension itself, or its complications (e.g., neurologic, cardiovascular).

The first step in the evaluation is to determine whether the infant is indeed hypertensive, or if the blood pressure rises only during periods of agitation, pain, crying, feeding, or performance of procedures. As discussed earlier, only infants with persistent blood pressure elevation should have the "diagnosis" of hypertension made and diagnostic work-ups initiated.

A relatively focused history should be obtained, paying attention to determining whether there were any pertinent prenatal exposures, and to the particulars of the infant's nursery course and any concurrent conditions. The procedures that the infant has undergone (e.g., umbilical catheter placement) should be reviewed, and the current medication list should be scrutinized. Easily identifiable causes of hypertension such as fluid overload or medication-induced hypertension should be able to be identified at this stage, and appropriate measures taken to correct the problem.

The physical examination should similarly focus on identifying obvious problems that may be causing the blood pressure elevation. Blood pressure readings should be obtained in all four extremities to rule out coarctation of the thoracic aorta. The general appearance of the infant should be assessed, with particular attention paid to the presence of dysmorphic features. Careful cardiac and abdominal examinations should be performed. Table 42-14 lists physical exam findings associated with specific causes of hypertension.

TABLE 42-14 PHYSICAL EXAM FINDINGS IN HYPERTENSIVE INFANTS

Finding	Probable Cause of Hypertension
Abdominal bruit	Renal artery stenosis
Ambiguous genitalia	Congenital adrenal hyperplasia
Bilateral flank masses	PKD; UPJ obstruction (bilateral); tumor
Bulging anterior fontanelle	Intracranial hemorrhage
Diminished LE pulses	Aortic coarctation
Edema	Fluid overload; Congenital Nephrotic Syndrome
Elfin facies	Williams Syndrome (renovascular)
Unilateral flank mass	UPJ obstruction; tumor
Widely spaced nipples; neck folds	Turner's Syndrome (coarctation)

Abbreviations used in Table 42-14: LE, lower extremity; PKD, polycystic kidney disease; UPJ, Ureteropelvic junction.

All hypertensive neonates should have a urinalysis and routine blood chemistry tests (see Appendix G1f). If hypertension appears to be iatrogenic or secondary to drug withdrawal, specific therapy can be tried before additional investigations are performed. If no cause is evident, or if a renal or renovascular etiology is suspected, the workup usually will include US of the kidneys, adrenals, aorta, and bladder, with a flow study, i.e., Doppler US, of the aorta and the renal arteries. Renal scans,

angiography, MRI, or CT may be indicated in specific patients. If there is any suspicion of hydronephrosis or reflux, urine obtained by suprapubic aspiration or bladder catheterization should be sent for bacterial and fungal culture. Of 17 patients with fungal uropathy, hypertension was one of the presenting signs in seven (752).

PRA should be obtained as part of the work-up in most hypertensive infants. If PRA is elevated compared to age-appropriate normal values for the same laboratory, consideration should be given to obtaining a renal scan in addition to the renal US and Doppler. Renal microemboli from a UA catheter, however, can elude detection by any of these means. High PRA may be secondary to the administration of diuretics or adrenergic medications or to severe respiratory disease; mild elevations of PRA may be seen in normal infants. Conversely, one normal value of PRA does not exclude hyperreninemic hypertension.

Treatment

Treatment of neonatal hypertension should be tailored to the severity of the hypertension and the infant's overall clinical status. For example, critically ill infants with acute

P.1020

onset of severe hypertension should be treated with an intravenous agent administered by continuous infusion, as this will allow the greatest control over the magnitude and rapidity of the blood pressure reduction. These infants should have their blood pressure lowered by no more than 25% over the first eight hours to prevent cerebral ischemia (753,754). On the other hand, relatively well infants with mild hypertension may be treated with oral antihypertensive agents. Recommended doses for intravenous and oral antihypertensive drugs can be found in Tables 42-15 and 42-16.

Of the many intravenous antihypertensive agents available, nicardipine has emerged as the most useful for management of severe neonatal hypertension (746,747,755, 756). It can be precisely titrated to the desired antihypertensive effect, and may be continued for prolonged periods of time without loss of antihypertensive efficacy (746). Alternative agents that may be given by continuous infusion include esmolol, hydralazine, labetalol and sodium nitroprusside. Esmolol and labetalol may be contra-indicated in

infants with lung disease, and nitroprusside can only be used for limited periods of time (usually <72 hours) because of the accumulation of thiocyanate (757). Intravenous agents that can be administered by intermittent bolus injection include hydralazine and labetalol. The intravenous ACE inhibitor enalaprilat has been reported to be effective in cases of severe neonatal hypertension (758); however, our anecdotal experience suggests that this agent may cause sudden, oliguric acute renal failure similar to that reported for oral enalapril (759,760)—given this, we do not recommend use of enalaprilat in neonates.

The choice of oral antihypertensive medications is more controversial. Whereas ACE inhibitors are considered the drugs of choice for adults and children with renovascular hypertension and some centers have had good success in neonates as well (388), many neonatologists have serious concerns about the potential major side effects (761). Other medications, such as a β -blocker or, in the case of a hypertensive crisis, a potent vasodilator, should be tried first. The advantage of a β -blocker such as propranolol is that it reduces the secretion of renin and the release of norepinephrine; however, it may also cause bronchoconstriction or hypoglycemia, making its use problematic in some infants.

Of the available vasodilators, the calcium channel blockers isradipine and amlodipine have found widespread use (762,763,764). Both may be compounded into stable extemporaneous suspensions (765,766). Older vasodilating agents such as hydralazine and minoxidil may also be useful in selected infants, or when the newer agents are not available.

Surgery is indicated for treatment of neonatal hypertension in a limited set of circumstances (767). In particular, hypertension caused by ureteral obstruction or aortic coarctation is best approached surgically. For infants with

P.1021

renal arterial stenosis, it may be necessary to manage the infant medically until it has grown sufficiently to undergo definitive repair of the vascular abnormalities (768). Infants with hypertension secondary to Wilms tumor or neuroblastoma will require surgical tumor removal, possibly following chemotherapy. A case has also been made by some authors for prophylactic removal of multicystic-dysplastic kidneys because of the risk of development of hypertension (769), although this is controversial (770).

TABLE 42-15 INTRAVENOUS ANTIHYPERTENSIVE AGENTS

Drug	Class	Dose	Route	Comments
Diazoxide	Vasodilator (arteriolar)	2-5 mg/kg/dose	RAPID bolus injection	NOT RECOMMENDED. Slow injection ineffective; duration unpredictable.
Enalaprilat	ACE Inhibitor	15 ± 5 mcg/kg/dose Q 8-24 hr	Bolus injection	NOT RECOMMENDED. May cause prolonged hypotension and acute renal insufficiency.
Esmolol	β blocker	Drip: 100-300 mcg/kg/min	Continuous infusion	Very short-acting; continuous infusion necessary.
Hydralazine	Vasodilator (arteriolar)	Bolus: 0.15-0.6 mg/kg/dose Q4 hr Drip: 0.75-5.0 mcg/kg/min	Bolus or continuous infusion	Tachycardia frequent sideeffect; Must administer Q4hr when given IV bolus
Labetalol	α & β blocker	Bolus: 0.20-1.0 mg/kg/dose Drip: 0.25-3.0 mg/kg/hr	Bolus or continuous infusion	Heart failure, lung disease relative contra-indications

Nicardipine	Ca ⁺⁺ channel blocker	Drip: 0.5-4 mcg/kg/hr	Continuous infusion	May cause reflex tachycardia
Sodium Nitroprusside	Vasodilator (arteriolar & venous)	Drip: 0.5-10 mcg/kg/min	Continuous infusion	Thiocyanate toxicity can occur with prolonged (>72 hr) use or in renal failure.

Abbreviations and symbols used in Table 42-15:

a, alpha; ACE, angiotensin converting enzyme; β, beta; Ca⁺⁺, calcium; hr, hour; IV, intravenous; kg, kilogram; mcg, micrograms; mg, milligrams; Q, every.

TABLE 42-16 ORAL ANTIHYPERTENSIVE AGENTS

Drug	Class	Initial Dose	Inreval	Maximum Dose	Comments
Amlodipine	Ca ⁺⁺ channel blocker	0.06 mg/kg	QD-BID	0.6 mg/kg/day	May have slow/gradual onset of effect
Captopril	ACE Inhibitor	0.01 mg/kg/dose	TID	2 mg/kg/day	1st dose may cause rapid drop in BP; monitor serum creatinine and K ⁺
Chlorothiazide	Thiazide diuretic	5 mg/kg/dose	BID	30 mg/kg/day	Monitor electrolytes
Clonidine	Central α agonist	0.05-0.1 mg/kg/dose	BID-TID	Not established	May produce dry mouth & sedation; rebound HTN with abrupt discontinuation
Enalapril	ACE inhibitor	0.08 mg/kg/dose	QD-BID	0.58 mg/kg/day	Monitor serum creatinine and K ⁺
Hydralazine	Vasodilator (arteriolar)	0.25-1.0 mg/kg/dose	TID-QID	7.5 mg/kg/day	Tachycardia & fluid retention common side-effects

Hydrochlorothiazide	Thiazide diuretic	1 mg/kg/dose	QD	3 mg/kg/day	Monitor electrolytes
Isradipine	Ca ⁺⁺ channel blocker	0.05 mg/kg/dose	TID-QID	0.8 mg/kg/day	Suspension may be compounded; useful for both acute & chronic HTN
Labetalol	α and β blocker	2 mg/kg/dose	BID	20 mg/kg/day	Monitor heart rate; avoid in infants with BPD
Minoxidil	Vasodilator (arteriolar)	0.1-0.2 mg/kg/dose	BID-TID	1 mg/kg/day	Most potent oral vasodilator; excellent for refractory HTN
Propranolol	β-blocker	0.5-1.0 mg/kg/dose	TID	8-10 mg/kg/day	Monitor heart rate; avoid in infants with BPD
Spirolactone	Aldosterone antagonist	0.5 mg/kg/dose	BID	3.3 mg/kg/day	Potassium "sparing;" monitor electrolytes.

Abbreviations and symbols used in Table 42-16:

α, alpha; ACE, angiotensin converting enzyme; β, beta; BID, twice daily; BPD; bronchopulmonary dysplasia; Ca⁺⁺, calcium; HTN, hypertension; K⁺, potassium; kg, kilogram; mg, milligrams; QD, once daily; QID, four times daily; TID, three times daily.

Prognosis

The prognosis of neonatal hypertension depends on etiology, timing of the diagnosis, presence of complications, and response to therapy. Patients in whom hypertension is diagnosed on the basis of neurologic, cardiovascular, or renal decompensation have a high mortality rate. The mortality rate of patients with idiopathic calcification of the arteries or with massive aortic thrombosis remains high despite aggressive therapy. The long-term prognosis for newborn infants with thromboembolism of the renal artery or the aorta is good, often with progressive resolution of the hypertension within a year and only mild-to-moderate decrease in renal function (770,771,772). Hypertension in patients with BPD tends to resolve after 6 months of age (773). On the other hand, patients with polycystic kidney disease are likely to have persistent hypertension throughout childhood (700,774). And as noted earlier, infants who undergo repair of aortic coarctation are at risk for persistent or recurrent hypertension (725).

Diuretics

The effects of diuretics on water and solute excretion are summarized in Table 42-17. The pharmacology of diuretics is described in detail in Chapter 56. This section reviews the strategy in using diuretics in neonates. The choice of diuretic depends on the acuity of hypertension or fluid overload, the adequacy of renal function, and the expected side effects. For emergencies (e.g., cardiovascular or respiratory failure as a result of fluid overload), loop diuretics are the best choice because of their rapidity of action and their potency. In most patients, fluid restriction should be initiated along with diuretic therapy.

P.1022

P.1023

Hyponatremia is a common complication when thiazides are initiated without fluid restriction, because they do not impair urinary concentrating ability. Mild hyponatremia (130-135 mEq/L) does not justify additional sodium intake; the latter would initiate the vicious cycle of diuretic-low serum sodium concentration-increased sodium intake-more hypertension or lung edema-more diuretic. However, potassium and chloride depletion should be prevented.

TABLE 42-17 EFFECTS OF VARIOUS TYPES OF DIURETICS ON URINE AND SOLUTE EXCRETION

Type of Diuretic	Site of Major Action	Elimination	Urine Characteristics								
			FeNa (%)	Volume	CH ₂ O	K ⁺	Ca ²⁺	Mg ²⁺	H ₂ PO ₄ ⁻	Cl	HCO ₃ ⁻
CA inhibitors	PCT	Secretion	3-6	+	+	+++	0, +	0, +	++	0	+++
Osmotic	Loop	Filtration	>10	+++	+	+	+	+	++	+	+
Loop	TAI > PCT ^a	Secretion	15-30	+++	+, - ^b	++	++ +	++	++	+++	+, ^c
Thiazides	DCT > PCT	Secretion	5-10	++	0	+ +	-, + ^d	++	++	+++	+, - ^c
Metolazone	DCT > PCT	Secretion	4-7	+++	0, -	0	-	+	+	++ +	0
Spironolactone	CD	Metabolization	2-3	+	0	-	++	+	+	+	0

Other K-Sparing	CD > DCT _e	Variable ^f	2-3	+	0	-	-	-	+	+	+
-----------------	-----------------------------	-----------------------	-----	---	---	---	---	---	---	---	---

Most of these studies were performed in adults,
+, increase; 0, no change; -, decrease.

CA, carbonic anhydrase; CD, connecting tubule and collecting duct; CH₂O, free water clearance; DCT, distal convoluted tubule; FeNa, fractional excretion of sodium; loop, thin Henle's loop; PCT, proximal convoluted tubule; TAL, thick ascending loop of Henle.

^a Ethacrynic acid at usual doses does not have any significant effect on proximal tubule reabsorption. Note that ethacrynic acid is not recommended because of its ototoxicity.

^b Decreased CH₂O during water loading and increased CH₂O during dehydration.

^c Despite decreased reabsorption of bicarbonate related to the inhibition of carbonic anhydrase, the acute result is a "contraction" alkalosis. Chronic administration results in increased urine acidification in the distal part of the nephron (see text).

^d Thiazides may be associated with hypercalciuria after salt loading.

^e Amiloride causes mild metabolic acidosis by decreasing Na/H exchange, especially in the DCT.

^f Amiloride is not metabolized and acts on the luminal side. Triamterene is hydroxylated in the liver.

Modified from ref. 67.

Both hypokalemia and hypochloremic metabolic alkalosis may occur during thiazide or loop diuretic administration, unless the patient has renal failure or appropriate preventive therapy is initiated (775). Acute thiazide or loop diuretic administration results in a "contraction" alkalosis because of a reduction of the ECF volume and a relatively low bicarbonate concentration in the urine (776,777). During chronic diuretic administration, metabolic alkalosis results from increased distal urine acidification, which may be as a result of hypokalemia, mineralocorticoid excess, and increased delivery of Na⁺ to the distal convoluted tubule, in which protons are secreted in exchange for Na⁺. There is serious concern about the effects of metabolic alkalosis associated with diuretic therapy in patients with chronic lung disease (776). Thus, KCl should be added as soon as diuretic therapy is initiated, except in the presence of renal failure, to prevent potassium depletion and metabolic alkalosis.

Resolution of peripheral edema is neither an emergency nor a priority. An effective circulatory volume and a normal blood pressure should be maintained at all times; this is especially critical during vasodilation (e.g., antihypertensive medications, general anesthesia). In a patient with low circulatory volume and abnormally low serum protein concentration (e.g., postoperative phase, third-space losses, nephrotic syndrome, hydrops fetalis) with visceral (e.g., pleural, peritoneal, pericardiac) fluid accumulation, the circulatory volume should be expanded with colloids before administration of diuretics.

Thiazides (or metolazone if CRF) have been used as first choice for chronic diuretic therapy, to minimize bone calcium loss and prevent nephrocalcinosis and nephrolithiasis. However, this calcium-sparing effect disappears after sodium load during sodium replacement and with the addition of spironolactone. During chronic therapy, the efficacy of a single diuretic decreases progressively, because of compensatory mechanisms that increase sodium reabsorption at other sites of the nephron (778,779). Thus, the combination of two diuretics with different sites of action may be required. The addition of spironolactone to a thiazide has not been conclusively proven to be beneficial (780,781).

TABLE 42-18 METHODS OF DIAGNOSING BACTERIURIA/URINARY TRACT INFECTION IN NEWBORN INFANTS

Method	Bacteria/ml	Organism Species	Interpretation
Suprapubic Aspiration	Any	One	Positive
Catheterization	1,000-10,000	One	Positive only if pt symptomatic or if dilute urine sample
	1,000-10,000	Two or more	Contaminated
	>10,000	One	Positive
Clean-catch	10,000-100,000	One	Positive only if pt symptomatic or if dilute urine sample
	10,000-100,000	Two or more	Contaminated
	>100,000	One	Positive

Intermittent doses of furosemide can be added to this regimen when necessary. In refractory patients, the association of metolazone and furosemide should be considered (778). Patients on chronic diuretic therapy should have regular US screening (see Nephrocalcinosis and Nephrolithiasis).

Bacteriuria and Urinary Tract Infections

In infants, bacteriuria can be diagnosed with certainty only by culturing samples obtained by invasive techniques (bladder catheterization or suprapubic aspiration). There is no consensus, however, about the magnitude of bacteriuria required to reach significance (Table 42-18). Bacteriuria in newborn infants can be either asymptomatic or an indication of pyelonephritis, which is characterized by local and systemic inflammatory response. Similarly, candiduria can be asymptomatic, cause hydronephrosis, or be part of a disseminated infection. Lower UTI, i.e., cystitis usually cannot be diagnosed on clinical grounds in newborn infants, except when associated with hematuria.

Frequency in Newborn Infants

The frequency of bacteriuria ranges between 0% and 2.0% in an unselected neonatal population and between 0.6% and 10% in an NICU population (782,783,784,785,786,787,788). Risk factors include prematurity (frequency of bacteriuria is 0.1%-10%) (783,785,787,788), male gender (male-to-female ratio

P.1024

ranges from 1:1 to 9:1 in newborn infants) and urinary tract anomalies (785,786,787,788). The higher incidence of UTI in boys than in girls in infancy results from the higher frequency of structural abnormalities (785,786) in males and from the higher bacterial counts and higher prevalence of *Escherichia coli* in uncircumcised infants (789). Circumcision reduces the risk for UTI in infancy (790) to a rate that is similar to that in females (786). However, the risk for UTI rises for 2 weeks after ritual Jewish circumcision (791). VUR is less frequent in extremely LBW infants who developed UTI than in infants weighing 1001-1500g (792). UTI often occurs in association with neonatal sepsis (785). In one series, *Candida* spp were responsible for 25 of 60 (42%) hospital-acquired UTI in a NICU (793).

Pathophysiology

The risk of UTI depends on bacteriologic factors (see Chapter 48) and host characteristics. Periurethral cultures obtained in uncircumcised infants show higher total bacterial counts, and a higher prevalence of *E. coli* than cultures obtained in circumcised infants (789). The normal defense against UTI includes maintenance of an adequate flow of urine; complete emptying of the bladder, and presence of an anatomic barrier, i.e., the bladder outlet. These defense mechanisms may be compromised by urinary tract obstruction, VUR (see Chapter

43), bladder dysfunction (e.g., neurogenic bladder), or manipulation (e.g., prolonged or repeated bladder catheterization) (794,795). Immune defenses in general are described in Chapter 45. In the case of pyelonephritis, endocytosis of bacteria is performed by inflammatory cells and by proximal tubular cells.

Pathology

Acute pyelonephritis is characterized by the presence of polymorphonuclear leukocytes in the glomeruli, tubules, and interstitium (796). Some glomeruli are completely destroyed, whereas others are infiltrated with leukocytes and surrounded by fibrin. The tubules are necrotic, dilated, and their lumens are filled with leukocytes and bacteria. Suppuration may develop in the kidney, often with multiple abscesses, and in other parts of the genitourinary tract. Chronic or recurrent pyelonephritis is characterized by infiltration of inflammatory cells, loss or hyalinization of glomeruli, and atrophy of tubules, with obstruction of the lumen with colloid casts. The development of renal scars may not occur until after 1 year of life.

Clinical Presentation

The clinical presentation of UTI in newborn infants may include one or more of the following signs:

- Growth failure and gastrointestinal symptoms. Failure to thrive, excessive weight loss, poor feeding, diarrhea, and vomiting are the most common clinical features of neonatal UTI.
- Jaundice. The hyperbilirubinemia observed in newborn infants with UTI may be either direct or indirect and sometimes is associated with hemolytic anemia. It is commonly the main clinical feature at presentation and may be the only sign of UTI in some infants (797).
- Temperature instability or fever (temperature $\geq 38^{\circ}\text{C}$). UTI has been reported in 7.5% to 11% of febrile infants presenting to the emergency room during the first 8 to 12 weeks of life (798,799).
- Irritability, lethargy.
- Abnormal urination. This includes poor urinary stream, malodorous urine, and polyuria, which may lead to severe dehydration.

Signs associated with bacteremia (e.g., respiratory distress) or with focal infection (e.g., mucocutaneous candidiasis, omphalitis).

- Hypertension. This may develop as a result of hydronephrosis associated with the UTI (see Complications) (800).

Laboratory Features

Urinalysis

Based on specimens obtained by bladder catheterization or suprapubic aspiration, only one-half of febrile outpatients with documented UTI during the first 3 months of life had an abnormal urinalysis, defined either by the presence of more than five leukocytes per high power field or by the presence of any bacteria (798). The positive predictive value of pyuria on samples obtained by suprapubic aspiration ranges between 71% (pyuria greater than 10 leukocytes/mm³) (782) and 96% (pyuria \geq 20 leukocytes/mm³) (787). Thus, the presence of pyuria, at least on a sample obtained by suprapubic aspiration, is suggestive of UTI, whereas the absence of pyuria is insufficient to rule it out (788,801,802). Microscopic demonstration of yeast cells in urine obtained by suprapubic aspiration or bladder catheterization is very suggestive of candiduria.

Urine Culture

The incidence of UTI during the first 3 days of life is very low, making urine culture superfluous during an evaluation for sepsis at that age (802,803). If antibiotic therapy is to be started immediately because of suspicion of sepsis in an infant who is more than 3 days of age, urine should be obtained by suprapubic aspiration or by bladder catheterization (See Table 42-18) (805). Agents most commonly responsible for neonatal UTI include *E. coli* and other gram-negative rods such as *Klebsiella*, *Enterobacter*, *Citrobacter*, and *Serratia*. Common gram-positive organisms causing UTI include *Staphylococcus aureus* and *Enterococcus*. The incidence of early onset group B *Streptococcus* infections has decreased as a result of the use of intrapartum antibiotic prophylaxis (806). *Candida* species are a frequent cause of UTI acquired in the NICU (807).

P.1025

Complications

Acute complications of UTI in newborn infants include bacteremia, suppuration, VUR, urolithiasis, urinary tract obstruction, sometimes associated with

hypertension or ARF, severe hydromineral imbalance (808), methemoglobinemia (809) and ARF, which may result from urinary tract obstruction or massive VUR. Bacteremia develops in 29% of infants with UTI under 1 month of age and in 31% to 43% of neonates with UTI (810,811,812). Occasionally, UTI is also associated with meningitis. Among NICU patients with hospital-acquired UTI (VLBW infants), bacteremia was present in only 3 of 35 cases (8%), whereas candidemia was present in 13 of 25 (52%) infants with candidal UTI (807). Suppurative complications of UTI, extremely rare in newborn infants, may occur in the kidney, the perirenal area, the prostate, and other genitourinary organs (813,814).

Vesicoureteral reflux is observed commonly during the acute stage of UTI (815); it often decreases or disappears after treatment and may reappear at the time of recurrent infections (816). Intraparenchymal reflux is associated with a high risk of renal scarring (see Chapter 43). Bacterial UTI can be associated with urolithiasis or with hypertension in hydronephrotic infants (817). As many as one third infants with mycotic UTIs develop fungus balls (807), which may obstruct the renal pelvis or the bladder outlet (800,817,818,819). This obstruction may lead to the development of an abdominal mass, systemic hypertension, or anuria.

Investigation

Pyelonephritis vs. Bacteriuria

Pyelonephritis, which presents a high risk for renal scarring, should be differentiated from asymptomatic bacteriuria, which presents a low risk. Clinical and laboratory features suggesting the diagnosis of pyelonephritis include fever, an increase in blood leukocyte count with a left shift, an elevated sedimentation rate, an increase in the serum concentration of C-reactive protein, and renal tubular dysfunction (820,821,822). Unfortunately, none of these tests, alone or in combination, can reliably establish the diagnosis or predict the development of renal scars (820). Neonates with UTI should be evaluated for sepsis.

Imaging

Imaging for UTI includes US, followed by VCUG or DMSA scan, or both (823). Ultrasonography of the entire urinary tract may detect urinary tract malformations, hyperechogenic areas suggestive of pyelonephritis (437,819), and renal pyelectasis or ballooning during voiding, both suggestive of VUR (823,824). The American Academy of Pediatrics routinely recommends postnatal US in 2-month to 2-year old children with febrile UTI (825), although this examination may be avoided in those with normal, late-pregnancy US, normal voiding pattern, no abdominal mass, and good response to treatment of the UTI and a normal basic metabolic panel when rehydrated (826) Routine early postnatal US in young children with a postnatal age at least equal to one month and with febrile UTI has

a low yield (826) and has minimal impact in patient care (827). Color Doppler cystogram may show signals from the bladder to the ureter during the course of bladder filling (828). Whereas US and color Doppler are sensitive to detect VUR, the sensitivity of US to detect pyelonephritis has not been evaluated.

The VCUG may be done immediately after documenting sterilization of the urine. Alternatively, if the US is negative, the VCUG may be delayed for approximately 1 month, i.e., after resolution of transient, low-grade, UTI-related VUR (816). Significant VUR is very unlikely, and VCUG may be avoided, if US (especially with color Doppler cystography) and DMSA scan are all normal (823-825,828,829).

Cortical defects observed on DMSA scans performed 1 month after a UTI are associated with pyelonephritis, VUR, and the development of renal scars (830-832). Because ^{99m}Tc-DMSA binds to the proximal tubules and is excreted only minimally into the urine, it yields excellent visualization of the parenchyma and detection of cortical defects (833). The presence of areas of decreased cortical uptake of DMSA is a reliable indicator of pathologic inflammatory changes of acute pyelonephritis (830). The role of VCUG and DMSA scan in extremely LBW infants with UTI has not been established (834).

Renal Function

Renal glomerular and tubular function should be assessed at the time of the diagnosis and during treatment and follow-up. Especially in patients with obstructive urinary tract disease, UTI can result in transient or permanent decrease in GFR or in tubular dysfunction, characterized by RTA, pseudohypoaldosteronism, decreased urine concentrating ability, or increased NAG enzymuria (835).

Treatment

The treatment of UTI is discussed in Chapter 47. The interval of administration of the antibiotics may have to be adjusted according to their levels and to GFR (412). Third-generation cephalosporins, piperacillin, and aztreonam (836) are alternatives to the ampicillin-gentamicin combination and are chosen according to local epidemiology. A repeat urine culture should be obtained during treatment and after completion of the antibiotic therapy. In the case of failure to respond to treatment, US should be repeated, antibiotic therapy may have to be adjusted, and a systemic infection or other foci should be ruled out. Low-dose antibiotic therapy may be indicated after the initial 10-day course until the VCUG or the DMSA scan is performed, at least in those patients with abnormal US (837). Long-term prophylaxis may be used in patients with high risk of recurrence (e.g., severe VUR).

Therapy for asymptomatic bacteriuria in the absence of bacteremia can be given orally after the first few days. It is possible that shorter courses for the treatment of asymptomatic bacteriuria may be adequate (837), but this has not been evaluated in newborn infants. Although most neonatologists recommend treating bacteriuria regardless of the presence or absence of symptoms (838,839), growing evidence supports simple observation of infants and children with asymptomatic bacteriuria (837,840). However, additional experience in newborn infants must be obtained before withholding therapy for asymptomatic bacteriuria can be recommended.

Surgical intervention may be required for patients with severe VUR and those with urinary tract obstruction (see Chapter 43) (841-843). If a fungus ball is associated with urinary tract obstruction or does not disappear during systemic treatment, daily washings with amphotericin B through a bladder catheter or a nephrostomy tube may be necessary (842,843).

Long-term Complications and Follow-Up

In patients with pyelonephritis or urinary tract anomalies, GFR, urinary concentrating ability, and tubular acidification should be assessed serially. Additionally, US may demonstrate the formation of urolithiasis (844,845,846). The development of renal failure, once a common complication of UTI in small children, is observed only rarely, except in patients with major urinary tract malformations and renal dysplasia.

Although the association between segmental hypoplasia of the kidney, i.e., Ask-Upmark kidney, VUR and UTI has been known for years (847,848), the development of renal scars remains a serious potential complication (849). In patients in whom UTI develops before 1 year of age, approximately one-half of the kidneys with VUR will develop renal scars, and 70% of the kidneys that eventually develop scars have VUR (829). Several risk factors for formation of renal scars can be identified early, including UTI associated with specific strains of *E. coli* (824), grades III to IV VUR, especially if complicated by recurrent infections (849,850), and abnormal DMSA scan at the time of the UTI (831). In the piglet model, the DMSA scan was shown to have a sensitivity of 85% and a specificity of 97% for detection of scars caused by VUR and UTI (851). Infants at risk for chronic renal scarring need long-term follow-up by a nephrologist and a urologist, including repeat urine cultures and sequential isotopic scans, and they should be considered for prophylactic antibiotic therapy (816).

Prevention

Although circumcised male infants have a decreased incidence of UTI (786,787,788), routine circumcision has not been recommended by the American

Academy of Pediatrics (852). Infants with neurogenic bladder associated with myelodysplasia often receive intermittent bladder catheterizations and anticholinergic medication. This method has been shown to result in a lower frequency of long-term deterioration of the radiologic appearance of the kidney, despite a relatively high incidence (19% to 42%) of bacteriuria-UTI (853,854).

A recent meta-analysis of subjects with VUR comparing trials with antibiotics alone or a combined approach with reimplantation surgery/chemoprophylaxis demonstrated a reduction of UTI in the combined approach only up to 2 years of age. Subsequently, the frequency of all forms of UTI was similar in these 2 groups (855). Prophylactic antibiotics include low dose Amoxicillin or Cephalexin as a daily or twice daily dose up to 6 weeks to 2 months of age and subsequently replaced by Co-trimoxazole (1-2 mg/kg of trimethoprim component) or nitrofurantoin (1-2 mg/kg) given as a single evening dose. Data from another study indicate that children without VUR of grade 3 or greater are not at a higher risk of UTI in the absence of prophylactic antibiotics (856). Neonatal VUR resolves or improves in a large majority of patients by 4 years without somatic growth restriction or hypertension (76% in low grade and 59% in high grade reflux)(857).

Tubular Dysfunction

This section deals with tubular disorders that present commonly in the neonatal period, including those for which early onset of treatment during the neonatal period may modify or delay the evolution toward renal failure. The reader is referred to other sources for discussion of uncommon disorders not included here (858).

Hypercalciuria, Nephrocalcinosis, and Nephrolithiasis

Normal values of the urinary calcium-to-creatinine ratio in full-term infants are less than 0.86 mg/mg (2.42 mMol/ mMol) between 5 days and 7 months (859). Nephrocalcinosis and nephrolithiasis are increasingly recognized in infants with hypercalciuria, most often in premature infants (see next section) (Table 42-19). Prenatal development of nephrocalcinosis has been detected in neonatal familial hyperparathyroidism (860). Hypercalciuria may result from increased calcium intake or ingestion, decreased tubular reabsorption (861) (see sections on Renal Tubular Acidosis and Hypokalemic Salt Losing Nephropathies), or increased bone calcium reabsorption or uptake. Nephrocalcinosis and nephrolithiasis also may result from the precipitation of calcium phosphate or oxalate in the absence of hypercalciuria (see Primary Oxaluria type I and Oxalosis). Finally, nephrolithiasis may result from high urinary concentrations of cystine (see Cystinuria), uric acid (see Uric Acid), xanthine (see Xanthinuria), 2,8-dihydroxyadenine (see Adenine Phosphoribosyltransferase Deficiency), or acyclovir (see Nephrotoxicity), and may occur in association with UTI (see Urinary Tract Infection) and with obstructive urinary tract malformations (844,845,846). Nephrocalcinosis may decrease renal tubular function, whereas

P.1027

nephrolithiasis may cause hematuria, colic, dysuria, UTI, hydronephrosis, ARF, and CRF. The treatment of asymptomatic urolithiasis is high fluid intake and specific therapy when available; lithotripsy and surgical treatment are discussed in Chapter 43.

**TABLE 42-19 MECHANISMS OF NEPHROCALCINOSIS AND
NEPHROLITHIASIS IN INFANCY**

Hypercalciuria

Increased calcium intake or absorption with/without hypercalcemia

Excessive calcium intake (PO or IV)

Rapid calcium infusion

Hypervitaminosis D

Fanconi syndrome if excessive vitamin D administration

Phosphate depletion, low phosphate intake

X-linked hypophosphatemia (during phosphate and vitamin D administration)

Decreased renal tubular reabsorption

Diuretics (loop diuretics, spironolactone, thiazides if sodium intake or extracellular volume is increased)

Osmotic diuresis

Distal renal tubular acidosis (RTA type I)

Arthrogyrosis multiplex congenita with renal and hepatic anomalies

Bartter's syndrome and related syndromes

Autosomal dominant hypocalcemia

Dent's disease (hypercalciuric nephrolithiasis)^a

Increased bone reabsorption or decreased bone uptake

Primary hyperparathyroidism (including neonatal familial hyperparathyroidism)

Secondary hyperparathyroidism

Acidosis

Chronic corticosteroid therapy

Hypophosphatasia

Hyperthyroidism

Idiopathic hypercalcemia

Other mechanisms

Factors facilitating precipitation of calcium phosphate/oxalate

Low urine output

Alkaline urine

Absence of inhibitors: citrate, inorganic phosphate, magnesium

Oxaluria (primary or secondary)

Other causes of nephrolithiasis

Cystinosis

Cystinuria

Oxaluria (primary or secondary)

Hyperuricemia

Classical hereditary xanthinuria

Adenine phosphoribosyltransferase deficiency (2,8-dihydroxyadenine lithiasis)

Acyclovir

Urinary tract infection

Obstructive urinary tract malformations

^a Youngest patient described is 1 yr old.

Nephrocalcinosis and Nephrolithiasis in

Premature Infants

Nephrocalcinosis or nephrolithiasis, detected by ultrasonography in 20% to 60% of premature infants with a GA less than 32 weeks, is predominantly as a result of hypercalciuria (862,863,864,865,866,867). Hypercalciuria may result from increased calcium intake or gastrointestinal absorption, decreased renal tubular calcium reabsorption, and abnormal regulation of bone mineral content (Table 42-19) (868). Chronic use of discontinuous daily calcium infusions is associated with recurrent periods of hypercalcemia and hypercalciuria. High enteral calcium intake may be associated with hypercalciuria in the absence of hypercalcemia (869). Insufficient phosphate intake may result in hypophosphatemia, hypercalcemia, hypercalciuria, and osteopenia of prematurity (870). Increasing the

phosphate intake in these patients reduces calcemia and calciuria (871). Several authors have found a significant association between administration of furosemide and hypercalciuria in LBW infants (863,865,872). Hypercalciuria also may be induced by spironolactone (873,874) or by thiazides in patients with increased sodium intake or extracellular volume (868,875,876). Addition of acetate to the TPN reduces calciuria without affecting serum levels of calcium, PTH, or vitamin D (877). Acute and chronic acidosis induce bone calcium reabsorption and hypercalciuria. Other factors may contribute to the development of nephrocalcinosis. One study using multivariate analysis showed that risk factors for nephrocalcinosis included duration of ventilation, toxic gentamicin or vancomycin levels, low fluid intake during week 3, and male gender (878). The risk for lithiasis and nephrocalcinosis increases with high saturation levels, which result from low urine output or high urinary oxalate or urate (879,880). To prevent hypercalciuria, VLBW infants should receive enough phosphate and should receive neither discontinuous calcium infusions nor excessive doses of vitamin D. If chronic diuretic therapy is indicated, the drug of choice is a thiazide (or metolazone if CRF), without sodium supplementation, and renal US should be done to assess for possible nephrocalcinosis or nephrolithiasis. Nephrocalcinosis appears to resolve spontaneously in 40% to 50% of cases on follow up, but can be associated with recurrent UTI, renal colic, and hematuria. Patients with persistent calcifications at 1 to 2 years of age show signs of tubular dysfunction, including a decrease in tubular reabsorption of phosphate, increase in FENa, and limitation of distal renal tubular acidification (881). Thus, hypercalciuric patients with nephrolithiasis or nephrocalcinosis should receive a thiazide without sodium supplementation; if an additional diuretic is required, amiloride or triamterene may be considered (882).

Primary Hyperoxaluria TYPE I and Oxalosis

Primary hyperoxaluria type I, i.e., glycolic aciduria is an autosomal recessive disorder as a result of a functional deficiency of the hepatic peroxisomal enzyme alanine: glyoxylate aminotransferase (AGT) (883), which leads to oxalosis, i.e., progressive accumulation of calcium oxalate in various tissues. The AGT gene has been cloned and mapped to chromosome 2q36-37 (884,845,886). The diagnosis is

strongly suggested by a high oxalate-to-creatinine ratio in the urine (887,888,889,890) in the absence of secondary causes for oxaluria (e.g., TPN or vitamin B6 deficiency), and is further supported by measuring glycolic aciduria and L-glyceric aciduria (889,891). Definitive diagnosis is possible by measuring AGT in a liver biopsy or by DNA analysis.

Approximately 12% of patients present in infancy, with anorexia, failure to thrive, vomiting, dehydration, and fever; presentation in the neonatal period is rare (892,893,894). Renal damage includes nephrocalcinosis, urolithiasis, and renal failure. In pyridoxine-responsive patients, therapy includes pyridoxine, inhibitors of calcium oxalate precipitation, large fluid intake (2 L/m²/d), and later dialysis and renal transplantation (895,896,897). In pyridoxine-resistant patients, the treatment of choice is either early liver transplantation or combined hepatorenal transplantation for end stage renal disease (898).

Disorders of Purine Metabolism

Two disorders of purine metabolism may lead to nephrolithiasis in infancy: classic xanthinuria and adenine phosphoribosyltransferase deficiency.

Classic Xanthinuria

Classic xanthinuria is an autosomal recessive disorder with two genotypes. Type I is an isolated defect of the xanthine dehydrogenase (XDH) gene, which has been mapped to chromosome 2p22-23 (899,900). Classic xanthinuria type II is a combined defect of XDH and aldehyde oxidase (900a), which results from a functional defect of the human molybdenum cofactor sulfurase gene (HMCS) gene (901). Both disorders cause severe neonatal encephalopathy, lens dislocation, and microcephaly. Additionally, xanthinuria may result from the administration of allopurinol (inhibitor of xanthine oxidase) to a patient with high uric acid production, i.e., Lesch-Nyhan syndrome or treatment of malignancy. Classic xanthinuria may present with complications of xanthine urolithiasis or with ARF; some patients eventually develop CRF, duodenal ulcers, myopathy, or arthropathy, whereas others remain asymptomatic. The association of ARF with a history of hematuria or red-brown deposits on the diaper or in the urine sediment should raise the suspicion of classic xanthinuria (902). US

may show the lithiasis. Classic xanthinuria is diagnosed by demonstrating high levels of xanthine and hypoxanthine and low-to-undetectable levels of uric acid in plasma and urine. Early treatment of xanthinuria with high fluid intake, a diet low in purines and adequate therapy of nephrolithiasis and its complications yields an excellent prognosis.

Adenine Phosphoribosyltransferase Deficiency

Adenine phosphoribosyltransferase deficiency is an autosomal recessive disorder as a result of mutations of the adenine phosphoribosyltransferase deficiency gene, which has been cloned and mapped to chromosome 16q24 (903). Two types have been characterized: patients with type I (mainly Caucasians) have no enzyme activity in their erythrocyte lysates, whereas those with type II (Japanese) have some residual activity. DNA analysis shows that these two types correspond to different mutations (904). The defect causes an increase in urinary excretion of 2,8-dihydroxyadenine, which is very poorly soluble. The disease presents with the complications of lithiasis, which can develop even in the neonatal period. The diagnosis can be suspected by visualizing round brown crystals in the urine sediment and confirmed by measuring erythrocyte adenine phosphoribosyltransferase deficiency activity and by DNA analysis. The treatment of this disorder includes a high fluid intake, allopurinol, alkali, and a diet low in purines. The prognosis depends on renal function at the time of the diagnosis; patients with ESRD require renal transplantation in addition to disease-specific therapy.

Familial Hypocalciuric Hypercalcemia

Familial hypocalciuric hypercalcemia (FHH) may correspond to three different genotypes. Type I, the most common, is an autosomal dominant disorder resulting from a defect in the human calcium sensor receptor (CaSR) gene, which has been cloned and mapped to chromosome 3q21-q24 (905,906,907). Type II has been mapped to chromosome 19p13.3, and type III to chromosome 19q13 (908,909,910). Inactivating mutations of the CaSR gene increase both the parathyroid calcium set point, i.e., serum calcium concentration that results in a 50% reduction in maximum PTH release and the set point for renal tubular reabsorption of calcium. Analysis of several families has shown that FHH is the heterozygous, benign form, whereas neonatal severe hyperparathyroidism is the life-threatening

homozygous form (911,912). In contrast, activating mutations of the CaSR gene result in autosomal dominant hypocalcemia, which is associated with urolithiasis (see Table 42-19) (861).

The diagnosis of FHH is based on family history of hypercalcemia, a low urine calcium-to-creatinine ratio (less than 0.03 mg/mg), a low fractional excretion of calcium (less than 0.016, or 1.6%), and high magnesium and low phosphate concentrations in the serum (913,914,915). Hypercalcemia and hypermagnesemia result from an increase in their tubular reabsorption and in their release from bone, whereas hypophosphatemia results from a decrease in renal tubular reabsorption. In most patients with FHH, PTH levels are within normal limits for normocalcemic controls but inappropriately high for the serum Ca²⁺ concentration. The differential diagnosis includes other causes of neonatal hypercalcemia (see section on Nephrocalcinosis and Nephrolithiasis and Chap. 36), and multiple endocrine neoplasia syndromes (see Chapter 39). FHH is usually a benign disorder that fails to respond to parathyroidectomy (916). However, some patients with FHH have recurrent pancreatitis. Some neonates with FHH have transient self-limited hyperparathyroidism (917). In contrast, those with neonatal severe hyperparathyroidism

P.1029

have severe hypercalcemia, high serum alkaline phosphatase activity, and typical radiographic bone changes; these patients may require total parathyroidectomy followed by administration of 1,25(OH)₂D₃ (918,919).

Fanconi Syndrome

Fanconi syndrome is characterized by generalized dysfunction of the proximal tubule. The cardinal signs are renal glucosuria, renal phosphaturia, and generalized aminoaciduria; other features, present inconsistently, include proximal RTA (pRTA), tubular proteinuria, increased urinary excretion of urate, sodium, potassium, and calcium, and decreased ability to concentrate the urine and to secrete PAH (919a). In some cases, distal tubular dysfunction is present, and the disease evolves toward renal failure, with less evidence of tubular dysfunction.

Because several transport systems are deficient in this syndrome, the pathophysiologic process presumably involves a global disturbance, such as

an alteration of the integrity of the tubular membranes or of sulfhydryl-requiring enzymes (919a).

Idiopathic cases of Fanconi syndrome most often are sporadic, although autosomal recessive, autosomal dominant, and X-linked recessive transmission have been described (920). Fanconi syndrome occurs in association with a variety of disorders (Table 42-20), the most common of which is cystinosis (921). Disorders associated with late-onset renal dysfunction will not be reviewed here. General discussion of inborn errors of the metabolism can be found in Chapter 41.

The clinical presentation of Fanconi syndrome includes polyuria, polydipsia, dehydration, and failure to thrive. Signs include acidosis, hypophosphatemia, and rickets. The diagnosis is confirmed by the demonstration of glucosuria in the presence of a normal glycemia (less than 120 to 150 mg/dL), decreased tubular reabsorption of phosphate, and generalized hyperaminoaciduria. The prognosis of Fanconi syndrome depends on the underlying disorder.

TABLE 42-20 CAUSES OF FANCONI SYNDROME IN INFANCY

Idiopathic		Secondary	
	Inherited Disease of the Metabolism (AR unless specified)	Acquired	
Isolated	GRACILE syndrome	Renovascular accident in neonatal period	
ARC syndrome (AR)	Cystinosis	Interstitial nephritis	
	Fructose-1-phosphate aldolase deficiency Hepatorenal tyrosinemia type 1	Medications: valproate, aminoglycosides, ifosfamide ^a	
	Galactosemia	Renal transplantation	

	Glycogenosis with Fanconi S (Fanconi-Bickel S)	Toluene, heavy metal poisoning
	Oculocerebrorenal (Lowe) syndrome (X-linked)	Vitamin D deficiency rickets
	Vitamin D-dependent rickets	Dysproteinemia
	Disorders of the energy metabolism	Nephrotic syndrome
	Pearson's syndrome (maternofetal transmission) Cytochrome-c oxidase deficiency Pyruvate carboxylase deficiency Carnitine palmitoyl transferase I deficiency	

^a Fanconi syndrome also has been reported after administration of other medications in older patients. S, syndrome. Abbreviations: AR, autosomal recessive; ARC, arthrogyrosis, renal tubular dysfunction and cholestasis

The treatment includes administration of sodium citrate or bicarbonate, and as required, water, potassium, phosphate, and carnitine (922). Once rickets has developed, careful administration of vitamin D is required; excess vitamin D may result in hypercalciuria and nephrocalcinosis. Indomethacin, a PGSI, has been given successfully to some patients (923,924). Specific dietary therapy for fructose intolerance, galactosemia, or tyrosinemia results in disappearance of the Fanconi syndrome. In many other diseases, treatment serves only to slow the deterioration of renal function.

Special Considerations

Cystinosis

The reported incidence of cystinosis ranges between 1:20,000 and 1:326,000 (858). It is an autosomal recessive lysosomal transport disorder,

characterized by accumulation of cystine, as a result of a defect in the carrier-mediated transport of cystine from the lysosomes to the cytosol (925). Cystinosis results from inactivating mutation of the CTNS gene, mapped to the short arm of chromosome 17p13 (926), which encodes cystinosin, a lysosomal cystine transporter. The infantile, i.e., nephropathic type of cystinosis is the most severe form (858,927) and is characterized by fluid and electrolyte loss, aminoaciduria, glycosuria, phosphaturia, RTA, rickets, and growth restriction, with onset of symptoms generally between 6 and 12 months of age. At birth, patients with cystinosis appear normal except for lighter skin and hair pigmentation than siblings. In some patients, the initial presentation may suggest a diagnosis of Bartter syndrome or of nephrogenic diabetes

P.1030

insipidus (NDI) (927). Retinopathy may be detected within the first weeks of life (928), whereas characteristic corneal opacities appear only after 1 year. Laboratory findings include urinary excretion of typical cystine crystals, besides features of Fanconi syndrome. Progressive deterioration of the GFR leads to ESRD at a median age of 9.2 years (929).

PCR detection assays have been established, providing basis for rapid molecular diagnosis of cystinosis (930). Prenatal diagnosis is made by direct measurement of cystine in cultured amniocytes or chorionic villi cells. The mutational spectrum varies with different populations (931). Genetic counseling could be offered to families of specific ethnic backgrounds by screening of the most common mutation, e.g., G339R in Jewish-Moroccan and Amish-Mennonite populations (931).

The treatment of cystinosis in infancy includes alkalinization and supplementation of water, potassium, carnitine (922), phosphate, and vitamin D. Indomethacin, a PGSI, may reduce urinary losses and improve growth; however, it also may transiently decrease GFR (923,924). The treatment of choice is the administration of cysteamine, i.e., β -mercaptoethylamine hydrochloride (which is poorly tolerated and has persistent nauseating odor) or phosphocysteamine (which lacks the foul taste and odor of cysteamine). These agents help deplete cells of cystine (932). Treatment improves growth and delays the progression toward renal failure (933,934), especially if initiated soon after birth (935).

Arthrogryposis, Renal Tubular Dysfunction, and Cholestasis Syndrome

This is an autosomal recessive syndrome seen predominantly in Pakistanis. Renal tubular dysfunction ranges from isolated RTA to complete Fanconi syndrome, and hepatic histology shows various combinations of cholestasis, intrahepatic biliary hypoplasia, giant cell hepatitis, lipofuscin deposition, and fibrosis. Additional features observed in some patients include failure to thrive, NDI, neurogenic muscular atrophy (resulting in arthrogryposis), cerebral malformations, ichthyosis, dysmorphism, nerve deafness, and abnormality in platelet morphology (936). At least 2 candidate genes (FIC1 and HNF1) have been identified (937).

Glycogen Storage Disease with Fanconi Syndrome (Fanconi-Bickel Syndrome)

More than 112 patients have been described with Fanconi- Bickel syndrome, i.e., glycogen storage disease [GSD] with Fanconi syndrome. This syndrome is caused by homozygous or compound heterozygous mutations within GLUT2, the gene encoding the most important facilitative glucose transporter in hepatocytes, pancreatic β cells, enterocytes, and renal tubular cells. It is characterized by the association of hepatomegaly secondary to glycogen accumulation, glucose and galactose intolerance, fasting hypoglycemia, Fanconi syndrome, and severely stunted growth (938). In the kidney, glycogen accumulation is limited to the proximal tubule, with maximal levels in the straight part. This syndrome should be differentiated from phosphorylase b kinase deficiency (939) or from GSD type I (often as a result of glucose-6-phosphatase deficiency), which is associated with late onset of proximal tubular dysfunction in approximately 15% of the cases (940).

Fever, vomiting, growth failure, and rickets develop in the patients within 6 weeks to 10 months of birth, followed by hepatomegaly, protuberant abdomen, moon-shaped face, and fat deposition around the shoulders and the abdomen (920,941). Kidneys of most patients are relatively large. Laboratory findings include glucosuria on the first day of life, galactosemia on the fourth day, and hypophosphatemia by the eighth week. The Fanconi syndrome, initially severe, tends to improve. Hepatic glycogenosis causes a

tendency toward hypoglycemia, ketonuria, hypercholesterolemia, and hypertriglyceridemia, but no lactic acidosis. Particular attention should be given to treating possible acute decompensations at the time of surgery or infections. Hypoglycemia can be prevented by frequent protein-enriched feedings, by uncooked cornstarch (942), and restriction of galactose intake. The treatment of the nephropathy is nonspecific.

Growth Retardation, Aminoaciduria, Cholestasis, Iron Overload, Lactic Acidosis, and Early Death Syndrome

Growth retardation, aminoaciduria, cholestasis, iron overload, lactic acidosis, and early death (GRACILE) syndrome is an autosomal recessive metabolic disorder of Finnish disease heritage, characterized by fetal growth retardation, lactic acidosis, Fanconi type aminoaciduria, cholestasis, and iron overload. It is caused by a missense mutation in the BCS1L gene, which is located on chromosome 2q33-37 and encodes a mitochondrial protein needed for the assembly of the mitochondrial chain complex III. Prenatal diagnosis can be performed on linkage analysis in families with at least one affected child. Typical histological changes may be present in early fetal life (943,944,945).

Galactose-1-Phosphate Uridyl Transferase Deficiency

Galactosemia (see Chapter 39) is an autosomal recessive disorder that results in intracellular accumulation of galactose-1-phosphate in various tissues, including the kidney. The galactose 1-phosphate uridyltransferase gene has been cloned and mapped to chromosome 9p13 (946,947,948). Most neonatal screening programs routinely measure the activity of the red blood cell enzyme. Symptoms of the severe form often develop in the neonatal period, soon after initiating lactose intake, i.e., milk, and include hypoglycemia, anorexia, vomiting, diarrhea, hepatomegaly, jaundice, and hypoprothrombinemia (949). Renal dysfunction develops within 2 weeks after initiation of galactose intake; it is characterized by severe proteinuria, generalized aminoaciduria, and a significant defect in transport of phosphate, bicarbonate, and PAH (949-951). Lactose

intake leads to galactosuria, which produces a positive test for reducing substances but no glucosuria. Removing lactose and galactose from the diet results in rapid resolution (949).

Hereditary Fructose Intolerance

Hereditary fructose intolerance (HFI) is an autosomal recessive disorder as a result of deficiency in fructose-1-phosphate aldolase (liver aldolase B), which normally is present in the liver, small intestine, and renal cortex (see Chap. 41). Mutations lie within exon 5 of the aldolase B gene. This gene has been cloned and mapped to chromosome 9q21.3-q22.2 (952,953). In patients with HFI, ingestion of fructose results in the accumulation of fructose-1-phosphate in these tissues. Although fructose is not part of the normal diet in the neonatal period, the routine use of sucrose has been recommended for sedation during neonatal procedures (954,955). In patients with HFI, a single dose of fructose will induce serious hypoglycemia, hypophosphatemia, generalized hyperaminoaciduria, RTA, proteinuria, and phosphaturia, and transient fructosuria or glucosuria, or both (956,957). The diagnosis of HFI is suggested by the history of fructose or sucrose intake, the presence of reducing substances in the urine, hyperaminoaciduria, and high plasma concentrations of methionine and tyrosine, and by the clinical response to removal of fructose and sucrose from the diet. HFI can be diagnosed by measuring aldolase activity in liver biopsy specimens or by screening for mutations using reverse dot-blot procedure (958). Removal of fructose and sucrose from the diet results in normalization of tubular function within 2 weeks.

Hepatorenal Tyrosinemia

Hereditary tyrosinemia type I, i.e., hepatorenal tyrosinemia, tyrosinosis (see Chap. 41) is an autosomal recessive disorder as a result of a deficiency in fumarylacetoacetate hydrolase (FAH or fumarylacetoacetase) (959). The disorder is most common in the Saguenay-Lac St.-Jean region of the province of Quebec and in Scandinavia (960). The gene coding for this enzyme has been cloned and mapped to chromosome 15q23-q25

(961,962,963). Approximately 35 mutations have been described so far (964). Renal tubular dysfunction results from the accumulation of succinylacetoacetate and succinylacetone. Prenatal diagnosis is possible by measurement of succinylacetone in amniotic fluid and of FAH activity in amniocytes or chorionic villi and by restricted fragment length polymorphism in informative families (961,962,963). Hepatorenal tyrosinemia can be differentiated from transient neonatal tyrosinemia by a high blood concentration of succinylacetone in the former.

Clinical presentation includes failure to thrive, a cabbage-like odor, vomiting, diarrhea, severe metabolic acidosis, hepatomegaly, jaundice, melena, ascites, edema, fever, and tubular dysfunction (965,966). Renal dysfunction includes hyperaminoaciduria, severe phosphaturia, and variable degrees of RTA, glucosuria, and proteinuria (965,966). Early presentation (less than 2 months) of tyrosinemia type I is associated with liver failure and death by the age of 1 year in most untreated patients. Removal of phenylalanine, tyrosine, and methionine from the diet normalizes tubular function but does not prevent death from liver failure, recurrent bleeding, hepatocellular carcinoma, or porphyria-like syndrome with respiratory failure (967,968). Liver transplantation has considerably changed the survival rate; these patients have normal GFR but tubular dysfunction (968). Promising results suggest that administration of 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) may decrease the production of succinylacetone, the incidence of crises, and the need for liver transplantation (969,970).

Oculocerebrorenal Syndrome of Lowe

Oculocerebrorenal (OCRL) syndrome of Lowe is a rare X-linked disorder caused by mutations of the OCRL1 gene, which has been cloned and mapped to chromosome Xq25-q26 (971,972,973). Deficiency in the OCRL1 gene product, a phosphatidylinositol 4, 5-bisphosphate (PIP₂)-5-phosphatase, raises intracellular concentration of PIP₂, leading in turn to decreased actin stress fibers and abnormal distribution of actin binding proteins, and disruption of tight junctions and adherens junctions (974).

The phenotype includes major abnormalities in the eyes (including cataracts), nervous system (mental retardation), and kidneys (Fanconi

syndrome) (see Appendix G-2) (975). Glomerular involvement develops progressively in childhood and eventually leads to renal failure in the second to fourth decade (976,977). Lowe syndrome can be diagnosed prenatally by identification of defective mRNA expression of the OCRL1 gene in cultured amniocytes (978). Urinary trehalase protein concentration and trehalase catalytic activity by ELISA has recently been used to help in the diagnosis of renal tubular damage in Lowe syndrome, Dent's disease, and congenital nephrotic syndrome (979). Treatment of the Fanconi syndrome includes alkalization therapy (Polycitra) with carnitine supplements, supplementation of phosphate once serum alkaline phosphatase increases (suggesting bone resorption) and, in some patients, supplementation with potassium or calcium.

Disorders of Energy Metabolism

These disorders have a wide range of presentation, including multiorgan dysfunction, lactic acidosis, hematologic disturbances (e.g., pancytopenia), growth failure, liver failure, pancreatic insufficiency, myopathy, cardiopathy, nervous system and sensorial disturbances, and nephropathy (see Chapter 41). Some of the genes involved are coded by nuclear deoxyribonucleic acid (DNA), whereas other genes are coded by mitochondrial DNA, resulting in maternal inheritance (980). Renal involvement most often consists of Fanconi syndrome, although some patients develop RTA, Bartter syndrome, chronic tubulointerstitial nephritis, nephrotic syndrome, or renal failure (981). Pathology may

P.1032

show cytoplasmic vacuolization of tubular cells and giant mitochondria. Neonatal or infantile involvement of the kidney may occur in several disorders, including Pearson's marrow-pancreas syndrome (maternal inheritance), fatal infantile mitochondrial myopathy, cytochrome c oxidase deficiency, pyruvate carboxylase deficiency, carnitine palmitoyl transferase I deficiency, and phosphoenolpyruvate carboxykinase deficiency (980,981,982,983,984,985,986,987,988,989).

Nephrogenic Diabetes Insipidus

NDI is a rare inherited disease characterized by the failure of kidney to respond to AVP because of a receptor or postreceptor defect, despite raised serum concentrations of AVP (990). Congenital NDI is most often transmitted as an X-linked trait, as a result of mutations of the vasopressin receptor (AVPR2) gene (991), coding for the basolateral vasopressin V2 receptor in the collecting duct (992). The gene has been cloned and mapped to chromosome Xq28 by linkage analysis (993). In some families, NDI is an autosomal recessive trait, which results from mutations of the apical aquaporin-2 water channels (994).

Symptoms of congenital NDI include polyuria, dehydration, fever, constipation, and failure to thrive. Pertinent laboratory findings include a persistently low urine osmolality despite hypernatremic dehydration, without other tubular dysfunction. In the past, severe episodes of dehydration with hypertonic encephalopathy resulted in a 16% prevalence of long-term neurologic problems (995). Although a more recent series showed a 14% risk for cognitive delay and a 47% risk for attention deficit hyperactivity disorder, there was no association between test performances and hypernatremia (996).

The differential diagnosis of NDI includes several entities causing polyuria (Table 42-21). The diagnosis of NDI is confirmed by the failure to concentrate the urine and to increase urinary cAMP in response to intranasal administration of DDAVP, in contrast to patients with central diabetes insipidus, i.e., ADH deficiency (997). Patients with defective V2 receptors, but not those with defective aquaporin 2, have abnormal extra renal response of the V2 receptors to administration of DDAVP or desmopressin (994). Aquaporin 2 cannot be detected in the urine from patients with mutations in the aquaporin-2 gene and is found at lower concentration than normal in those with mutations of the V2 receptor (998). Diagnosis in utero can be made by linkage analysis if other family members have the disease (993). Female carriers of the X-linked trait are asymptomatic, but may have mild impairment of urine-concentrating ability.

		necrosis Malnutrition
PG, prostaglandin.		

Treatment of acute hypernatremic dehydration includes correction of the free-water deficit, i.e.:

$$\text{Water deficit} = 0.6 \times \text{body weight} \times [(\text{Na}/140) - 1],$$

Where water deficit is in liters, body weight is in kg, and Na is plasma sodium concentration in mM/L.

Chronic therapy to reduce urine output most often includes the combination of chlorothiazide, indomethacin, and potassium supplements (999,1000). Preliminary data suggest that an alternative treatment may be the use of amiloride (0.3 mg/kg/day po three times a day) and hydrochlorothiazide, without potassium supplements (993,1001). Gene therapy holds promise in the treatment of NDI (1002).

Hypokalemic Alkalosis

The differential diagnosis of hypokalemic alkalosis in infancy is given in Table 42-22. The discussion in this section is limited to the renal causes.

Hypokalemic Salt Losing Tubulopathies (Bartter-like Syndromes)

This group of closely related hereditary tubulopathies share hypokalemic metabolic alkalosis, hyperreninemic

P.1033

hyperaldosteronism with normal blood pressure, hyperplasia of the juxtaglomerular apparatus, and impaired urinary-concentrating ability (1003). These tubulopathies, all transmitted as autosomal recessive traits, have been classified into three types of phenotypic entities: the antenatal variant, the classical variant, and the Gitelman syndrome.

TABLE 42-22 DIFFERENTIAL DIAGNOSIS OF HYPOKALEMIC ALKALOSIS

Inadequate intake

Cl⁻-deficient diet

Insufficient K and Cl in iv

Gastrointestinal losses

Primary hyperaldosteronism

Cushing syndrome

Congenital adrenal hyperplasia (with hypertension):

11 β -hydroxylase deficiency

17 β -hydroxylase deficiency

11 β -hydroxysteroid dehydrogenase deficiency

Cystic fibrosis

Neonatal or antenatal Bartter syndrome (hyperprostaglandin E syndrome), the most severe form, is characterized by polyhydramnios, premature birth, life threatening episodes of salt and water loss in the neonatal period, hypokalemic alkalosis, and failure to thrive, and hypercalciuria and early onset nephrocalcinosis (1004). Some patients have a distinctive appearance: thin with small muscles and a triangular facies characterized by prominent forehead, large eyes, protruding ears, and drooping mouth.

Strabismus is frequently present. Increased urinary PGE₂ excretion has been considered a characteristic feature (1005). This condition is genetically heterogeneous. Type I results from loss-of-function mutations of the SLC12A1 gene, which has been mapped to chromosome 15q 15-21 and encodes the renal bumetanide-sensitive Na-K-2Cl co transporter (also termed NKCC2, BSC1, and ENCC2) of the TALH. Type II results from loss-of-function mutations of the KCNJ1 gene, which is located on chromosome 11q24-25 and encodes ROMK, a potassium channel expressed in the TALH and in the CCD (1006). A third type of antenatal Bartter syndrome, with sensorineural deafness, has been described in nine consanguineous families, and mapped to chromosome 1p31; the gene responsible for this syndrome has not yet been determined (1007,1008). Patients with type I present during early neonatal period with massive NaCl wasting, hypokalemia, and metabolic alkalosis (1009). In contrast, neonates with type II, especially those prematurely (1010), may present with mild NaCl wasting and a biochemical picture mimicking pseudohypoaldosteronism type I, i.e. hyponatremia, hyperkalemia, and metabolic acidosis. In these patients, the typical features of Bartter syndrome may manifest within 3 to 6 weeks; however renal potassium loss is less pronounced than in NKCC2-deficient patients. The association of pseudohypoaldosteronism-1 (PHA-I) with polyhydramnios has been controversial, thus postnatal transient hyperkalemia in the context of polyhydramnios and prematurity should raise the diagnosis of ROMK mutations (1011). Prenatal diagnosis has been made in the past by high Cl content of the amniotic fluid. Amniotic fluid Na, K, Ca, and PGE₂ are normal. Trophoblastic DNA analysis will soon allow early and accurate diagnosis.

Classical Bartter syndrome (Type III) occurs in infancy or early childhood. It is characterized by marked salt wasting and hypokalemia, leading to polyuria, polydipsia, volume contraction, muscle weakness, and failure to thrive. Hypercalciuria and nephrocalcinosis may occur (1012). This syndrome results from mutations of the CLCNKB gene, mapped to chromosome 1p36, which encodes the renal chloride channel ClC-Kb (1010,1013).

Gitelman syndrome (Type IV) is a Bartter-like condition with hypomagnesemia and hypocalciuria, and mild presentation usually in older children and adults (1010).

In the immediate neonatal period, dehydration and electrolyte imbalance often require continuous saline infusion. Administration of indomethacin in the early postnatal period is not only unnecessary but also dangerous in patients with type II, and has potential side effects, e.g., NEC and renal failure. Prenatal treatment with indomethacin is also useless and dangerous for the fetus. However, at 4-6 weeks of age, the patient will benefit greatly from this therapy and eventually, of KCl supplementation. Long-term prognosis is guarded and lack of therapeutic control may lead to slow progression to chronic renal failure (1006).

Renal Tubular Acidosis

Plasma bicarbonate (HCO_3^-) concentrations normally are lower than subsequent values in the term newborn and even lower in premature or VLBW infants (1014). Metabolic acidosis in newborn infants usually is normochloremic, with an increased serum anion gap. The most common cause is lactic acidosis resulting from asphyxia, ischemia, hypoxemia, or local tissue damage. Less commonly, it is as a result of a congenital metabolic disorder (see Chapter 41) or to renal failure.

The diagnosis and classification of RTA has traditionally been made on the basis of functional studies. Four types of RTA have been described: classic distal, i.e., type I, pRTA, i.e., type II, hyperkalemic distal, i.e., type IV, which is the most common type of RTA, and mixed proximal and distal, i.e., type III (Table 42-23) (1015). Application of molecular

P.1034

biology techniques has opened a new perspective to understanding the pathophysiology of inherited cases of RTA (1016).

TABLE 42-23 ETIOLOGY OF RENAL TUBULAR ACIDOSIS IN INFANCY

Proximal RTA (Type 2)	Hyperkalemic RTA (Type 4)	Distal RTA (Type 1)	Mixed (Type 3)
<p>Primary AR, AD Sporadic transient</p>	<p>Early childhood hyperkalemic RTA</p>	<p>With bicarbonate wasting in infancy and early childhood) Sporadic With cystic fibrosis</p>	<p>Familial hyperparathyroidism with hypercalciuria and RTA (Nishiyama) VLBW infant</p>
<p>Secondary</p>			
<p>Fanconi syndrome Metachromatic leukodystrophy^a Mitochondrial diseases Hereditary nephritis Tetralogy of Fallot^a Vitamin D deficiency Vascular accident in NN period Hereditary nephritis Carbonic anhydrase inhibition Carbonic anhydrase II</p>	<p>1: Primary hypoaldosteronism, adrenal insufficiency 2-3: Hyporeninemic hypoaldosteronism^b with chronic renal disease 4: Pseudohypoaldosteronism-1 with or without salt wasting 5: Partial unresponsiveness to aldosterone</p>	<p>Hypergammaglobulinemia (i.e., maternal Sjögren syndrome) Fetal alcohol syndrome Toluene, amphotericin B, lithium Hypercalcemic hyperthyroidism Vitamin D intoxication Nephrocalcinosis Medullary sponge kidney Urinary tract obstruction</p>	<p>Carbonic anhydrase II deficiency (with osteopetrosis) (AR) Hyperparathyroidism Nephrocalcinosis and Fanconi syndrome Renal transplantation</p>

deficiency with osteopetrosis (AR)
Drugs and toxins:
valproic acids, heavy metals
Deficiency in NBC-1 (pRTA with glaucoma)

Tubulointerstitial disease
Urinary tract obstruction, UTI
Unilateral dysplastic kidney or RVT
Drugs (e.g., KCl, K-sparing diuretics, heparin, ACE inhibitors, PGSI, cyclosporine)
Toxins

Carnitine palm itoyltransferase type I deficiency (1)
Carbonic anhydrase II deficiency with osteopetrosis (AR)
AR with sensorineural deafness: deficiency in B1 subunit of H⁺ - ATPase
AR without sensorineural deafness: deficiency in A-4 subunit of H⁺ - ATPase
AD: mutation of SLC4A1 gene: deficiency in Cl⁻/HCO₃⁻ exchanger AE1

Renal tubular acidification also may be deficient in the case of renal failure (i.e., normochloremic metabolic acidosis) or of acute diarrhea (hypochloremic metabolic acidosis) (see text).

^a The only patients with this type of RTA were diagnosed after 12 mo of age.

^b Types 2 and 3, associated with hyporeninemic hypoaldosteronism, are seen mostly in adults.

ACE, angiotensin-converting enzyme; AD, autosomal dominant; AR, autosomal recessive; H⁺ -ATPase, proton pump (ATPase); NBC-1, Na-HCO₃ co-transporter, NN, neonatal; PGSI, prostaglandin synthetase inhibitor, pRTA, proximal renal tubular acidosis; RTA, renal tubular acidosis; RVT, renal venous thrombosis; UTI, urinary tract infection; VLBW, very low birth weight.

Clinical presentation of RTA includes polyhydramnios, polyuria with episodes of dehydration, failure to thrive, vomiting, and serum biochemical disturbances. Failure to thrive appears to be a direct consequence of acidosis; correction of acidosis often results in catch-up growth, unless other complications (e.g., rickets, renal failure) have developed.

Differential Diagnosis

The differential diagnosis of metabolic acidosis depends on the findings of hypertension, hyponatremia and salt wasting, hyperkalemia, generalized proximal tubular dysfunction, decreased ability to acidify the urine, UTI, nephrocalcinosis, or urinary tract malformation. Further workup (e.g., measurement of urinary ammonium, titratable acid, or PCO_2 ; ammonium chloride, sodium sulfate, or bicarbonate loading) may be required in specific cases, in consultation with a nephrologist (1015,1017,1018).

Proximal Renal Tubular Acidosis

pRTA or RTA type II is characterized by hyperchloremic metabolic acidosis as a result of impaired capacity of proximal tubule to reabsorb HCO_3^- (1014). pRTA could potentially result from loss-of-function mutations of one of three $\text{Na}^+/\text{HCO}_3^-$ co-transporters (NBC 1-3), apical membrane-bound and cytosolic carbonic anhydrase isozymes, or apical NHE3 (1004,1014). pRTA may occur as a manifestation of a generalized proximal tubular dysfunction (Fanconi syndrome), as part of mixed acidosis (type III), or as an isolated disease. Primary isolated pRTA is usually transient, whereas persistent pRTA may be associated with ocular abnormalities. A mutation in the SLC4A4 gene mapped to chromosome 4q21 and encoding the $\text{Na}^+-\text{HCO}_3^-$ co transporter (NBC-1), has been described in pRTA with bilateral glaucoma (1019).

The diagnosis of pRTA is suspected when the serum bicarbonate concentration is low for age and urinary pH is inadequately low (except if RTA is mixed) in the presence of mild-to-moderate acidosis. The diagnosis is confirmed either by the presence of a Fanconi syndrome or by measuring the urinary concentration of bicarbonate at various

P.1035

serum levels during a bicarbonate infusion. Alternatively, the serum bicarbonate can be raised to normal by administration of bicarbonate or

citrate supplement, with subsequent observation of the serum bicarbonate level at which the urine becomes acid.

Treatment consists of the administration of sodium bicarbonate or citrate (initially 5 to 10 mEq/kg/d) and potassium citrate. In some patients, acidosis will persist despite administration of high doses of alkali; hydrochlorothiazide or PGSI may be beneficial. Patients with Fanconi syndrome require additional therapy (see Fanconi Syndrome).

Distal Renal Tubular Acidosis

Several criteria have been proposed for the diagnosis of defects in distal RTA (dRTA) (1020,1021,1022), including the inability to decrease urinary pH below 5.5 during metabolic acidosis, limited urinary ammonium concentration, limited urinary PCO_2 , and decreased difference between urinary and arterial blood PCO_2 . dRTA is almost always observed in children as a primary entity, which may be inherited either as a recessive or dominant form. Autosomal dominant dRTA has been associated with mutations in the SLC4A1 gene encoding the $\text{Cl}^-/\text{HCO}_3^-$ exchanger AE1 (1023). Most patients with autosomal recessive dRTA and nerve deafness have mutations in the ATP6B1 gene encoding the B-1 subunit of H^+ -ATPase (1023). Autosomal recessive dRTA without deafness may result from mutations of the ATP6VOA4 gene encoding the A-4 subunit of the H^+ -ATPase (1024).

In classic or type I RTA, there is no defect of potassium secretion; nephrocalcinosis and nephrolithiasis are common (1025). The development of nephrocalcinosis is attributed to the association of hypercalciuria, high urine pH, and hypocitraturia (1026). Idiopathic RTA type I in infants can be associated with bicarbonate wastage. It can be hereditary and may be associated with several other conditions (see Table 42-23). The treatment includes the administration of sodium bicarbonate or citrate and potassium citrate. Administration of citrate is important for the prevention of nephrolithiasis.

Hyperkalemic dRTA or type IV is the most common type of dRTA. It results from the association of defects in K^+ and H^+ secretion at the level of the collecting duct. Primary type IV RTA or early childhood hyperkalemic RTA has been described in some infants and children who presented with failure to thrive and frequent vomiting (1027). These patients had isolated signs of

dRTA with hyperkalemia, without nephrocalcinosis, and responded well to alkali therapy. Secondary cases of type IV RTA can be divided into five groups, which include hypoaldosteronism and impaired or absent renal response to aldosterone (see Table 42-23) (1017,1025). Type IV RTA is also common in patients with obstructive uropathy. The treatment of type IV RTA includes correction of the metabolic acidosis, limitation of potassium intake, and specific therapy for each specific disorder, e.g., surgical correction of obstructive uropathy (1017).

Mixed Renal Tubular Acidosis

In some disorders, both proximal and distal RTA is present; this is known as mixed RTA or type III (see Table 42-23). VLBW infants during the first days or weeks of life have a mild degree of mixed tubular acidosis, with lower normal values of serum bicarbonate concentration and higher urine pH despite metabolic acidosis (see Renal Physiology). Patients with the carbonic anhydrase II deficiency syndrome may have proximal, distal, or mixed RTA. This autosomal recessive disorder results from one of several mutations of the CA2 gene, which has been cloned and mapped to chromosome 8q22 (1028,1029). Patients with this disorder develop metabolic acidosis, osteopetrosis, growth retardation, mental retardation, and cerebral calcifications (1030). The majority of patients come from the Mediterranean area and the Middle East.

Pseudohypoaldosteronism

PHA consists of unresponsiveness of the collecting duct to mineralocorticoids. PHA type I (PHA-11) is an autosomal recessive or dominant disorder characterized by severe neonatal salt wasting, hyperkalemia, and metabolic acidosis. The clinical presentation may include polyuria, anorexia, failure to thrive, and vomiting (1031). Patients often develop hypercalciuria and nephrocalcinosis (1032). Although polyhydramnios has been attributed to PHA1, it is likely that most cases may have been as a result of undiagnosed antenatal Bartter syndrome as a result of ROMK mutation.

Autosomal recessive PHA-1 results from a mutation of either one of the three subunits (α , β , γ) of ENaC (1033, 1034). The disease locus maps to chromosome 16p12.2- 13.11 in some families and to 12p13.1-pter in other families. This type of PHA1 also causes respiratory symptoms, which may

include cough, rhinorrhea, and recurrent respiratory infections, and in one case report, RDS unresponsive to surfactant (1035,1036,1037).

Autosomal dominant PHA-1, caused by loss-of-function mutations in the mineralocorticoid receptor gene (MLR), (1038) is a milder form, wherein symptoms are limited to the kidney.

The differential diagnosis of hyponatremia with hyperkalemia and metabolic acidosis with normal anion gap includes adrenal insufficiency and hypoaldosteronism (see Chapter 41), acquired partial PHA (or unresponsiveness to aldosterone), and antenatal Bartter syndrome as a result of a mutation of ROMK (See Table 42-23). Laboratory findings in PHA include hyperreninemia, hyperaldosteronism, and increased urinary excretion of aldosterone and tetrahydroaldosterone; in contrast, urinary excretion of 17-hydroxy- and 17-ketosteroids should be interpreted cautiously (1031,1039). Prenatal diagnosis of PHA may be suggested by polyhydramnios with high concentrations of sodium and aldosterone in the amniotic fluid (1031). The treatment of PHA consists of administering large amounts of sodium chloride although limiting potassium intake.

Indomethacin administration may help reduce urine output, natriuresis, P.1036

calciuria, and nephrocalcinosis; however, it also may decrease GFR (1039).

Hyperphosphaturic Syndromes

Hyperphosphaturia results from decreased proximal tubular reabsorption. Whereas severe hyperphosphaturia may result from hyperparathyroidism or Fanconi syndrome, mild hyperphosphaturia occurs after administration of diuretics (e.g., loop diuretics, carbonic anhydrase inhibitors, thiazides) or from drugs or toxins that are toxic to the proximal tubule. Other causes of hypophosphatemia (e.g., rickets and phosphate depletion) are discussed in Chapter 36. We will review briefly the hereditary forms of hyperphosphaturia that are pertinent to infancy.

X-linked Hypophosphatemia

X-linked hypophosphatemia (XLH), also called familial hypophosphatemic rickets or vitamin-D-resistant rickets, is the most common disease associated with hyperphosphaturia in infancy. It is as a result of a mutation of the PHEX gene, a phosphate-regulating gene that is flanked by RFLPs. It

is mapped to chromosome Xp22.1 and has been cloned (1040,1041,1042). Clinical signs, including bone deformations, usually appear after the first year of life. In neonates from affected families, hypophosphatemia and low tubular reabsorption of phosphate can already be detected during the first month of life (1043). The treatment includes oral phosphate supplementation and 1(OH)D₃ or 1,25(OH)₂D₃. This therapy improves but does not cure the bone disease, causes nephrocalcinosis in 60% of the patients (1044,1045), and may cause renal failure or hyperparathyroidism. Preliminary results suggest beneficial effects of using 24,25(OH)₂D₃ instead of 1,25(OH)₂D₃ (1046). Thiazide diuretics decrease urinary calcium excretion and prevent progression of nephrocalcinosis in children with XLH (1047).

Hypophosphatemic Rickets with Hypercalciuria

Hypophosphatemic rickets with hypercalciuria (HHRH; OMIM 241530) is an autosomal recessive disorder with rickets, bone pain, muscle weakness, failure to thrive, hypophosphatemia with hyperphosphaturia, normocalcemia with hypercalciuria, high plasma 1,25(OH)₂-D₃ concentration, low PTH concentration, and elevated plasma alkaline phosphatase activity. The treatment consists of the administration of supplemental phosphate (1048,1049). Possible candidate genes for HHRH include those encoding renal phosphate transporters or their regulators, except NPT2 (1050).

Autosomal Dominant Hypophosphatemic Rickets

Autosomal dominant hypophosphatemic rickets (ADHR, OMIM 193100) is a rare, less severe disorder, with autosomal dominant inheritance with variable penetrance (1051). Patients with early presentation show phosphate wasting. Low serum phosphorus concentrations, rickets, osteomalacia, and lower extremity deformities characterize this condition as early as 1 year. Other features include short stature, bone pain, and dental abscesses. ADHR results from missense mutations in a gene encoding a new member of the fibroblast growth factor (FGF) family, FGF23 (1052). Treatment consists of administration of vitamin D, with phosphate supplementation in some patients.

Vitamin-D-Dependent Rickets Type I

Vitamin-D-dependent rickets type I (VDDR I) is an autosomal recessive disorder, also called pseudo vitamin D deficiency type I (PDDR) or hereditary selective deficiency of 1,25-alpha-(OH)2D3. VDDR I results from mutations in the 25-hydroxyvitamin D 1-alpha hydroxylase gene, mapped to 12q4 by linkage analysis (1052). Increased phosphaturia results from hyperparathyroidism, in turn as a result of a defect of 1-alpha-hydroxylation of vitamin D in the proximal tubule (1053).

Infants with this disorder present with the typical signs of rickets, including hypotonia, tetany, irritability, motor retardation, deformations, and growth failure. Serum levels of 1,25(OH)2D3 are very low or undetectable, resulting in decreased gastrointestinal absorption of calcium. This disorder should be differentiated from other causes for deficiency in 1-alpha-hydroxylase (e.g., Fanconi syndrome, RTA, or X-linked hypophosphatemia). Patients with VDDR I respond to the administration of physiologic doses of 1-alpha-OHD3 or 1,25-alpha-(OH)2D3 (1053).

Hereditary Generalized Resistance to 1,25(OH)2D3

Hereditary generalized resistance to 1,25(OH)2D3 is an autosomal recessive disorder, also called vitamin-D-dependent rickets type II (VDDR II), hypocalcemic vitamin D-resistant rickets (HVDRR), or vitamin D dependency type II or pseudo vitamin D deficiency type II. In patients with this disorder, lack of sensitivity of target organs to 1,25(OH)2D3 (1054) results from heterogeneous mutations of the vitamin D receptor (VDR) gene (1055,1056). This gene has been cloned and mapped to chromosome 12q13-14, i.e., close to the gene for VDDR I (1055,1057). Patients present with rickets and some with alopecia by 2 to 12 months of life (1058). Serum levels of 1,25(OH)2D3 are very high. Rickets in these patients responds with limited success to high doses of oral calcium and supraphysiologic doses of 1,25(OH)2D3 (1058). In some patients, vitamin D analogs may partially or completely restore the responsiveness of the mutated VDR (1059).

Glucosuria

Several disorders are associated with renal glucosuria: an isolated defect, or primary glucosuria, which is a benign condition, congenital glucose-galactose malabsorption,

P.1037

Fanconi syndrome, and other rare entities. They all are associated with mild-to-moderate glucosuria, which does not require specific therapy (1060,1061).

Neonates with glucose-galactose malabsorption develop severe, watery, acidic diarrhea and dehydration. This disorder is as a result of one of several mutations of the intestinal Na-D-glucose co transporter (SGLT1). The corresponding gene, mapped to chromosome 22q13.1, has been cloned; mutations can be detected prenatally (1062,1063,1064).

In VLBW infants, the incidence of glucosuria is increased because of two factors: decreased tubular reabsorption of glucose (see Renal Physiology) and instability of glycemia (1065). At a mean GA of 29 weeks, glucosuria appears when glycemia exceeds 152 ± 8 mg/dL (1065). Massive glucosuria is uncommon in VLBW infants; however, it may lead to osmotic diuresis and, thus, dehydration and loss of electrolytes (1065,1066).

Uric Acid

Hyperuricemia

Hyperuricemia may result from a decrease in urinary excretion of uric acid, from an increase in its production, or from both. Uric acid excretion decreases after administration of several drugs (e.g., diazoxide, diuretics, dopamine, ethambutol), during lactic acidosis, and in association with maternal toxemia, ECF contraction, renal failure, hypertension, and lead intoxication. Decrease in urinary excretion of uric acid may result in higher serum levels but not in renal toxicity.

Increased production of uric acid is observed after perinatal asphyxia, after fructose administration (especially in patients with fructose intolerance), in Down syndrome, neoplasia, hypoxanthine-guanine phosphoribosyltransferase deficiency (Lesch-Nyhan syndrome), superactivity of 5-phosphoribosyl-a-1-pyrophosphate synthetase, and type I

glycogenosis. In the latter condition, hyperuricemia results both from an increased production and from decreased excretion as a result of lactic acidosis. Because the risk of uric acid precipitation is favored by a high urinary concentration and a low urine pH, the newborn infant is at relatively low risk for tubular obstruction by uric acid crystalluria, despite low ability of the immature renal tubule to reabsorb uric acid. The prevention of uric acid nephropathy in patients at high risk includes maintaining a high tubular flow rate by the administration of high volumes of alkaline fluids (1067). Uric acid crystalluria with tubular obstruction has been described rarely in newborn infants with ARF secondary to perinatal asphyxia (1068). ARF may be observed also in Lesch-Nyhan syndrome (577). Allopurinol is indicated for infants with hyperuricemia secondary to neoplasia and should be given before chemotherapy in specific patients (1069).

Defects of Tubular Handling of Uric Acid

Increased urinary excretion of uric acid may result from various medications (e.g., ascorbic acid, glycine, citrate, and iodinated radiocontrast agents) and from rare defects in tubular handling of uric acid. These disorders may be suspected on the basis of family history, low serum concentration of uric acid, or crystalluria. Early diagnosis may allow specific therapy and prevention of urolithiasis, which may develop later in childhood.

Amino Acidurias

Several systems of tubular transport of amino acids are known. For many of the defects of these transporters, a firm diagnosis can be made only after a few months of age, i.e., when the normally high excretion of amino acids in infants starts to decrease. We discuss here only those disorders of amino acid transport that may cause symptoms in infancy, i.e., Fanconi syndrome (see corresponding section in this chapter), cystinuria, and lysinuric protein intolerance (LPI).

Cystinuria

Cystinuria is an autosomal recessive disorder as a result of a defect of the D2H or human rBAT protein, which is responsible for renal and gastrointestinal transport of the dibasic amino acids cystine, lysine, arginine, and ornithine (858,1070). Cystinuria has been classified into three phenotypes, based on the degree of intestinal uptake of cystine by

homozygotes and the level of urinary dibasic amino acids in heterozygotes (1071): type I (silent carriers), type II (marked elevation) and type III (mild elevation). Mutations in the SLC3A1 gene, which has been mapped to chromosome 2p21 and encodes rBAT, cause type I cystinuria (1070,1072,1073,1074,1075). Mutations of the SLC7A9 gene, which have been mapped to chromosome 19q13.1 and encodes b0.+AT (a putative subunit of rBAT that normally heterodimerizes with rBAT), cause nontype I cystinuria (i.e., types II and III) (1076). Urolithiasis usually develops within the first 2 decades, but rarely may occur by the end of the first year of life. Urinary cystine calculi may produce considerable morbidity including urinary obstruction, colic, and infection and, in severe cases, loss of kidney function (1004).

Neonatal urinary screening programs have shown an average prevalence of approximately 1 in 7,000, with a range of 1:2,000 in England to 1:15,000 in the United States (1077). Neonatal screening offers the possibility of monitoring children before formation of cystine stones; this is particularly important for patients at highest risk for lithiasis (type I/I homozygous cystinuria) (1078). Prevention of stone formation includes hydration and alkalinization of the urine; D-penicillamine and α -mercaptopyrionylglycine are effective in decreasing the rate of stone formation in patients with lithiasis (1079).

Lysinuric Protein Intolerance

Lysinuric protein intolerance (LPI, hyperdibasic aminoaciduria type 2, or familial protein intolerance) is an autosomal

P.1038

recessive disorder as a result of a defect of the basolateral transport of the cationic amino acids lysine, arginine, and ornithine in the renal tubule and the gastrointestinal tract (858). LPI results from loss-of-function mutations of the SLC7A gene on chromosome 14q12 which encodes the γ +L amino acid transporter-1 (γ +LAT-1) (1080,1081,1082). Half of the patients with LPI have been described in Finland, where the prevalence is 1:60,000. Most breast-fed infants are asymptomatic, although some may develop symptoms of hyperammonemia during the neonatal period. Within 1 week of weaning or increase in the protein intake, most infants affected with this disorder

develop nausea, vomiting, and mild diarrhea. Later on, patients present with poor feeding, failure to thrive, severe hypotonia, hepatosplenomegaly, osteoporosis, seizures, coma and developmental delay. Some may develop interstitial pulmonary infiltration, alveolar proteinosis, or severe renal involvement, including glomerular and tubular damage, which progresses rapidly to CRF (1083,1084).

Demonstrating markedly increased lysinuria in contrast to only moderate increase in ornithine and arginine establishes the diagnosis. Other findings include abnormal plasma amino acid concentrations, anemia, leukopenia, thrombocytopenia, and postprandial increases in urinary orotic acid and plasma ammonia. The treatment consists of administering a low-protein diet supplemented with citrulline. Hyperammonemic episodes are treated with ornithine, arginine, or citrulline, sodium benzoate, and sodium phenylacetate.

Storage Disorders

Storage disorders that may affect the neonatal kidney include ARC syndrome and Fanconi-Bickel syndrome (see Fanconi Syndrome), and two lysosomal storage disorders, i.e., sialidosis and galactosialidosis.

Sialidosis Type II

Sialidosis is an autosomal recessive disorder as a result of mutations of the lysosomal sialidase gene, mapped to chromosome 6p21.3 (1085), and encoding sialidase (alpha-N-acetyl-neuraminidase), an enzyme that catalyzes the catabolism of sialoglycoconjugates (858). The deficiency of sialidase results in lysosomal accumulation of sialylglycoproteins and oligosaccharides. Patients with sialidosis type II develop Hurler-like phenotype, dysostosis multiplex, mental retardation, and hepatosplenomegaly, and may later develop cherry red spot macula and myoclonus. Patients with the congenital form develop ascites and/or hydrops fetalis and die either in the neonatal period or during infancy. Some patients develop nephrosialidosis, which is characterized by severe proteinuria and progressive nephrotic syndrome. Pathology consists of foamy enlargement of glomerular and tubular epithelial cells (1086). Prenatal diagnosis is possible by demonstrating absence of neuraminidase activity in amniotic or chorionic villi cells (1087).

Congenital Nephrotic Syndrome

Nephrotic syndrome is defined by the association of marked proteinuria (more than 1 g/m²/d) with hypoalbuminemia (less than 2.5 g/dL), hyperlipidemia and edema. A nephrotic syndrome is called congenital if it presents within the first 3 months of life. This definition is based on the natural history of the Finnish type, the most common type of nephrotic syndrome in newborn infants.

Finnish Type (CNF or NPHS 1, OMIM 256300)

The incidence of CNF is estimated to be 1.2 per 10,000 births in Finland (1093), but is considerably less frequent in other countries (e.g. 1:50,000 in North Americans) (1094a). CNF should be suspected if there is a history of CNF in a sibling, hydrops fetalis or edema of the placenta, i.e., placental weight greater than 25% of BW, or an elevated AFP or total protein concentration in the amniotic fluid. Because the disease begins *in utero* in all patients, an increased AFP (more than 10 SD above the mean amniotic fluid concentration during the second trimester) is a reliable indicator of the disease (1093).

CNF is an autosomal recessive disorder caused mainly by mutations in the nephrin gene (NPHS1), mapped to chromosome 19q13.1, which encodes nephrin, a putative transmembrane protein belonging to the immunoglobulin superfamily of adhesion molecules (1095). In Finnish families, four main CNF haplotype categories have been observed (1096). Analysis of nonFinnish families suggests that most patients with CNF share the same disease locus (1097).

P.1039

The natural history of the disease is based on experience before the availability of renal transplantation in young patients (1093,1096,1097,1098,1099,1100,1101). The mean GA was 36.6 ± 1.8 weeks (mean ± SD), and 42% of the infants were premature (less than 37 weeks of GA). Many infants were small for GA, especially those with a GA at or above 37 weeks. In some patients, the typical signs of nephrotic syndrome (i.e., edema, proteinuria, hypoalbuminemia) did not develop until the third month of life. The disease was resistant to steroids or cytotoxic medications (1098). Complications included severe failure to thrive and ascites in all patients, severe bacterial infections in 85%, hypothyroidism, pyloric stenosis in 12%, and thrombotic events in 10% (1098). An increase in Pcr or BUN was observed in 20% of the patients, but none had frank uremia. One-half of the patients died by 6 months of life, and all of them by 4 years.

The proteinuria, initially very selective, i.e., almost entirely albumin as a result of increased permeability of the glomerulus only for small proteins, increases progressively and becomes nonselective, corresponding to increased sieving coefficient and to tubular damage (1101). Blood chemistry is significant for low serum albumin concentration and total thyroxine concentration (as a result of urine loss of thyroxine-binding globulin) (1102), a normal or mildly elevated Pcr, and hyperlipidemia. Ultrasonography shows enlarged kidneys, increased echogenicity of the renal cortex, decreased differentiation between cortex and medulla and poor visualization of the pyramids (1103). Tubular dilations may be misinterpreted as other causes of cystic disease, including autosomal recessive PKD (1104).

The diagnosis of CNF can be confirmed by linkage analysis or by renal biopsy. The latter shows irregularities of the glomerular basement membrane and thinning of the lamina densa (1105), followed by fusion of the epithelial cell foot processes, all of which are similar to the findings in minimal-change, steroid-sensitive nephrotic syndrome. On light microscopy, changes include obliteration of capillary loops and glomerular hyalinization, and dilated tubules from both proximal and distal origin (microcystic disease).

Infants with CNF require intensive management, which includes repetitive administration of albumin and diuretics for ascites, thyroxin, anticoagulation, oral and parenteral hyperalimentation, and the treatment of multiple complications (1098). Chronic renal insufficiency develops between 6 and 23 months of age. As a consequence, most patients eventually receive dialysis while waiting for transplantation. Aggressive therapy, including bilateral nephrectomy (performed in one series at a mean age of 1.2 years) and peritoneal dialysis until transplantation when the infant reaches about 10 kg, allows normal growth and development, a patient survival rate of 97%, and a graft survival rate of 94%, 81% and 81% at 1, 3, and 5 years after transplant (1106). Recently, conservative management of CNF with captopril and indomethacin, sometimes in combination with unilateral nephrectomy, has been described to significantly improve plasma albumin concentration, reduce

the need for albumin infusion and duration of hospitalization, maintain normal growth and allow delay of dialysis, and transplantation for at least three years (1107).

Other Causes

Differential Diagnosis

The entities associated with congenital nephrotic syndrome may be differentiated by the natural history of the disease; by the presence of associated anomalies (e.g., in Denys-Drash syndrome); by maternal and neonatal serology (TORCH syndrome and lupus); by measuring AFP concentration in the amniotic fluid, which is consistently elevated only in CNF; by DNA analysis in specific families; and by renal biopsy. Nevertheless, classification of a patient into one of the major entities may not be possible (1100). Specific therapy may be available for some patients (e.g., those with congenital infection).

Diffuse Mesangial Sclerosis

The second most common cause of congenital nephrotic syndrome is diffuse mesangial sclerosis (DMS), which appears to represent a heterogeneous group of disorders (1100). The onset varies between the second trimester of gestation and 33 months of age. In contrast to CNF, CRF develops rapidly in these patients and is the major cause of death in the absence of dialysis and renal transplantation. Renal venous thrombosis is a frequent complication. In most families, DMS is transmitted as an autosomal recessive trait. Histologic examination of the glomeruli shows mesangial cells embedded in a periodic acid-Schiff-positive and silver-positive fibrillar network occluding the capillaries. Tubular changes are similar to those seen in CNF, and interstitial fibrosis is more pronounced than in CNF. Patients with DMS present with proteinuria (with or without nephrotic syndrome), sometimes hematuria, often arterial hypertension, and progressive CRF leading to ESRD within a few months to 2 years from the onset.

In some infants, DMS is part of Denys-Drash syndrome, which also includes ambiguous genitalia—most often male pseudohermaphroditism, i.e., 46XY karyotype—and Wilms tumor (1108). Denys-Drash syndrome is associated with mutations of the Wilms tumor suppressor gene (WT1) (1109). In these patients, the WT1 expression is abnormal and is associated with increased expression of PAX2 gene, which encodes a transcription factor normally expressed early during development. Increased expression of PAX2 is associated with podocyte hyperplasia (1110). Several patients have presented with incomplete forms of Denys-Drash syndrome (i.e., only two of the three signs of the triad) (1108). DMS is also common in Galloway-Mowat syndrome, an autosomal recessive disorder that includes microcephaly, abnormal gyral pattern, developmental delay, and nephrotic syndrome. Renal pathology in this syndrome may show diffuse mesangial sclerosis, focal segmental sclerosis, mesangial proliferation, or basement membrane and tubular anomalies (1111,1112). In a consanguineous family with previously

P.1040

affected siblings, prenatal diagnosis may be suggested by demonstration of enlarged hyperechogenic kidneys with amniotic fluid at the upper limit of normal and normal amniotic fluid concentration of AFP (1113).

Congenital Infection

Nephrotic syndrome as a result of congenital infection is seen most commonly in congenital syphilis (1114,1115), in which case the lesion is characterized by epimembranous or proliferative glomerulopathy, with diffuse deposits of immunoglobulin and treponemal antigen along the glomerular capillaries and sub epithelial electron-dense deposits (1114). The condition responds very well to the administration of penicillin. The nephrotic syndrome associated with congenital toxoplasmosis is less common (1116,1117). The lesion is characterized by the deposition in the glomeruli of immunoglobulin, complement, and *Toxoplasma* antigen and antibody. It may respond to administration of pyrimethamine, sulfadiazine, and steroid. Congenital nephrotic syndrome has also been reported in a few patients with congenital cytomegalovirus infection (1118,1119).

Other Causes

Some cases of congenital nephrotic syndrome are associated with dysmorphic features, such as pachygyria, microcephaly, buphthalmos, or disturbances of neuronal migration. Nephrotic syndrome may result from sialidosis type II (see Sialidosis) or from type I carbohydrate-deficient glycoprotein syndrome

(1120,1121,1122,1123). Transient cases of congenital nephrotic syndrome have been described as a result of maternal transmission (1124), intoxication with mercury, or nail patella syndrome (1125). Of three infants reported to have infantile systemic lupus erythematosus and congenital nephrotic syndrome, one had steroid-responsive membranous glomerulopathy (1126,1127).

Hematuria and Proteinuria

Differential Diagnosis of Hematuria

Pink or red urine or coloration of the diaper may result from hematuria, hemoglobinuria, myoglobinuria, uric acid, porphyria, or bile pigments. Red-brown deposits on the diaper may result from xanthinuria. The presence of blood on the diaper also may result from rectal bleeding or vaginal mucoid sanguinous discharge caused by maternal hormone withdrawal. On a dipstick test, the reagent strip based on the orthotolidine peroxidase reaction will give a positive reaction with hemoglobinuria, myoglobinuria, hematuria, or other oxidants, such as hydrogen peroxide and ascorbic acid. A dipstick can detect 5 to 20 intact erythrocytes per microliter of urine, and 0.05 to 0.3 mg of free hemoglobin per 100 mL of urine, which corresponds to 2 to 10 lysed erythrocytes per microliter. The diagnosis of hematuria requires visualization of an excessive number of erythrocytes in an uncontaminated specimen of urine (usually >5 RBC's/hpf).

Incidence

Gross hematuria during the first month of life occurred in 35 of 132,050 admissions (0.21 of 1000) to a major tertiary center between 1950 and 1967 (1128). In a more recent series, the incidence of hematuria during the first 48 hours of life was much lower in normal full-term infants (0 of 63) than in patients admitted to the NICU (48 of 78); none of these patients, however, had abnormalities on physical examination or had proteinuria, hypertension, or abnormal values of Pcr or BUN (1129). Transient hematuria was found in 76% of asphyxiated newborns (1130). In another series, hematuria was estimated to occur in 62% of newborn infants with UA catheter in place and US evidence of an arterial clot, and in 25% in those without evidence for a clot (1131). Hematuria was present in one-half of infants with ARF secondary to cardiac surgery and in two-thirds of newborn infants with irreversible ARF (1132,1133).

Etiology

Hematuria may occur in a wide variety of diseases, including bleeding diatheses and renal and postrenal disorders. PGSI-mediated hematuria may be as a result of platelet dysfunction, ATN, or tubular dysfunction. Congenital infections (e.g., syphilis, toxoplasmosis, cytomegalovirus) may cause thrombocytopenia or, rarely, glomerulonephritis. Common congenital causes of hematuria include hydronephrosis, PKD, tumors, and sponge kidneys. Acquired causes include asphyxia, coagulation abnormalities, infectious and vascular disorders, and nephrotoxicity.

Evaluation

The first step is to confirm the diagnosis of hematuria by the demonstration of erythrocytes in fresh urine voided spontaneously or after gentle suprapubic pressure (Fig. 42-7). Suprapubic aspiration is contraindicated, because it can cause microscopic or macroscopic hematuria. If the patient is anuric, despite treating possible conditions that might be causing prerenal failure and despite a diuretic challenge and a fluid challenge (see Acute Renal Failure), the bladder should be catheterized using a lubricated 3.5Fr to 5Fr catheter; however, one should take into account that this procedure could in itself cause hematuria.

The history may disclose familial nephritis. Maternal history may be positive for diabetes (suggesting renal venous thrombosis, infection, thrombocytopenia, glomerulonephritis), autoimmune disease, or recent use of PGSI. The patient's history should be reviewed, especially for asphyxia, sepsis, shock, hypertension, renal failure, medications, and placement of a UA line. Pertinent points in the physical examination include hypertension, bruising, edema (suggesting ARF or glomerulonephritis), an abdominal mass that may indicate hydronephrosis, cystic disease, adrenal hemorrhage, and, rarely, renal trauma and bruit (suggesting renovascular disease). In some patients, the presumptive etiology is obvious (e.g., bleeding disorder, bladder

trauma, severe asphyxia, ATN, renovascular disease, glomerulonephritis, nephrotic syndrome).

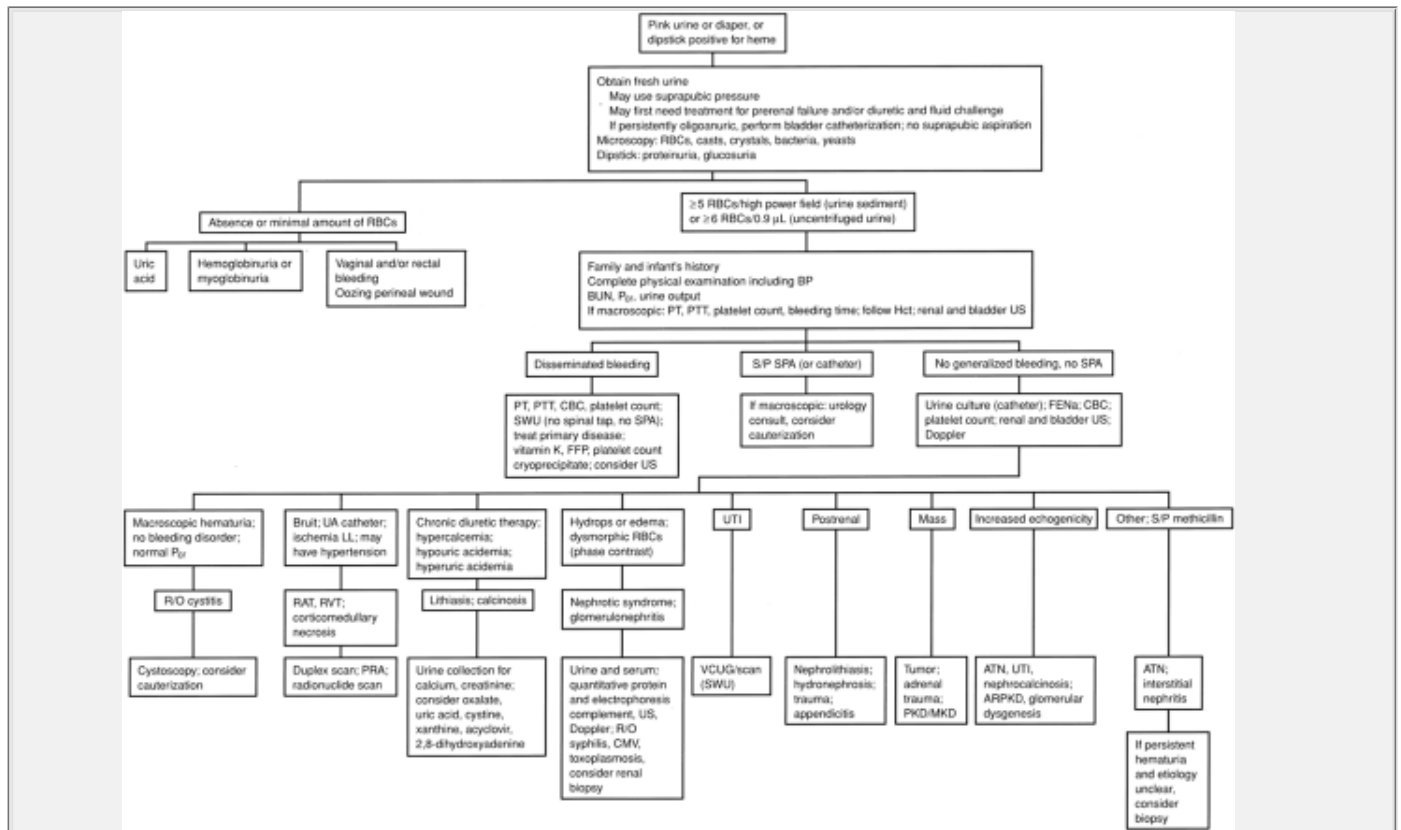

Figure 42-7 Differential diagnosis of hematuria. ARF, acute renal failure; ARPKD, autosomal recessive polycystic kidney disease; ATN, acute tubular necrosis; BP, blood pressure; BUN, blood urea nitrogen; CBC, complete blood count; CMV, Cytomegalovirus; FeNa, fractional excretion of sodium; Hct, hematocrit; LL, lower limbs; MKDIPKD, multicystic/polycystic kidney disease; P_{Cr} , plasma creatine concentration; PRA, plasma renin activity; PT, prothrombin time; PTT, partial thromboplastin time; RAT, renal artery thrombosis; RBC, erythrocyte; R/O, rule out; RVT, renal venous thrombosis; S/P, status post; SPA, suprapubic aspiration; SWU, sepsis workup; UA, umbilical artery; UO, urine output; US, ultrasonography; UTI, urinary tract infection; VCUG, voiding cystourethrogram.

The initial workup should include a microscopic examination of the urine, dipstick test, and measurement of urine output, BUN, and Pcr (see Fig. 42-7). Most patients should have a bladder and renal US and a urine culture. Microscopic examination of the urine may show dysmorphic erythrocytes or erythrocyte casts indicating glomerulonephritis, bacteriuria, yeast forms, or crystalluria. The latter may be the first clue to a diagnosis of urolithiasis. The dipstick may show glucosuria or proteinuria. If either of these is present, additional specific investigations should be obtained. If a glomerular disease is suspected, fresh urine should be examined using phase contrast microscopy, which is the method of choice for identifying the presence of dysmorphic erythrocytes; however, this method is unreliable in determining the origin of massive hematuria.

Transient microscopic hematuria during the first 48 hours of life may be insignificant (1129), as long as the infant is asymptomatic, i.e., has no bleeding diathesis and does not exhibit other evidence of a renal lesion (e.g., no familial renal disease; normal physical examination, blood pressure, urine output, Pcr, BUN and US; no erythrocyte casts in the urine).

In patients with macroscopic hematuria, the first diagnoses to exclude are bleeding disorder, trauma, and cystitis. In those patients, coagulation tests, platelet count, and bleeding time should be assessed, and a renal and bladder US should be obtained. Purpura, excessive bleeding after venipuncture, or thrombocytopenia suggests that hematuria is as a result of a bleeding disorder. Specific treatment for sepsis or endocarditis and the bleeding disorder should be initiated. If renal function and urine output are normal, and hematuria disappears after resolution of the bleeding diathesis, no additional renal workup is required. It should be remembered, however, that thrombocytopenia with hematuria may occur in association with renal diseases, such as renal venous thrombosis and UTI with sepsis. Macroscopic hematuria also may occur after suprapubic

aspiration or catheterization of the bladder; if hematuria disappears rapidly, US is normal, and urine output,

BUN, and Pcr remain normal, no additional investigations are required. In patients with massive hematuria in whom a bleeding disorder has been excluded, cystoscopy should be performed, unless the presumptive etiology is renal.

All other patients should have a urine culture, and a renal and bladder US, which may disclose an intravascular thrombus, renal venous or arterial thrombosis, cystic kidney disease, lithiasis or nephrocalcinosis, hydronephrosis, adrenal hemorrhage, or other anomalies. The association of hematuria with UA catheterization, an abdominal bruit, or blanching of the lower extremities, especially with hypertension, strongly suggests the diagnosis of a renovascular etiology (1131,1134). Hematuria is an unusual complication of nephrolithiasis or nephrocalcinosis during the neonatal period; it has been reported in one 10-week-old patient with familial hypercalciuria (1135).

Glomerulonephritis is a rare occurrence in newborn infants. It should be suspected if the patient has either hydrops or generalized edema with massive proteinuria or erythrocyte casts or dysmorphic erythrocytes. These patients should be assessed for possible congenital syphilis, toxoplasmosis, cytomegalovirus infection, various causes of nephrotic syndrome, familial nephritis, and immune-mediated glomerulonephritis. Consultation with a pediatric nephrologist should be obtained, and a renal biopsy should be considered.

For the other patients, the differential diagnosis includes a wide range of diseases; US is the most important initial investigation. Further workup depends on the clinical presentation (e.g., hypertension, ARF) or presumed etiology (e.g., ATN, cystic disease, tumor). If hematuria persists without obvious etiology, a renal biopsy should be considered.

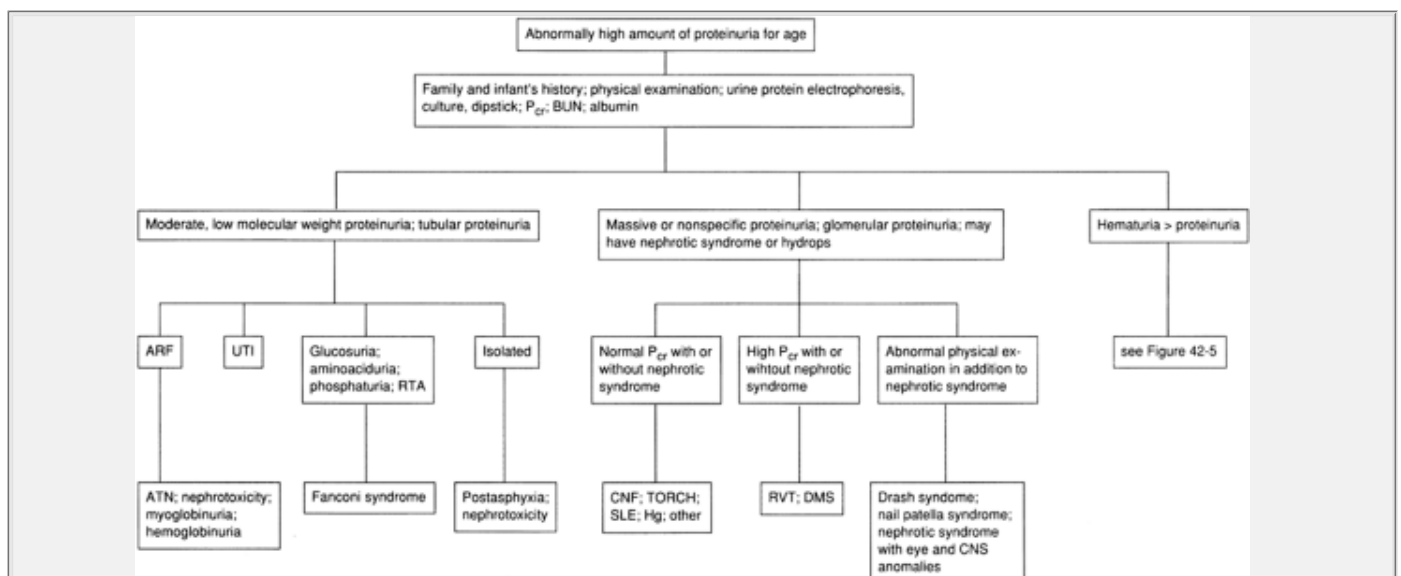

Figure 42-8 Differential diagnosis of proteinuria. AFR, acute renal failure; ATN, acute tubular necrosis; BUN, blood urea nitrogen; CNF, congenital nephrotic syndrome (Finnish type); DMS, diffuse mesangial sclerosis; Hg, mercury intoxication; P_{cr}, plasma creatine concentration; RTA, renal tubular acidosis; RVT, renal venous thrombosis; SLE, systemic lupus erythematosus; UTI, urinary tract infection.

Differential Diagnosis of Proteinuria

Proteinuria may be suggested by a positive (1+) dipstick test. The degree of proteinuria can be quantified by a timed collection or spot urine protein:creatinine ratio. Abnormal proteinuria is defined according to normal values for age (see Table 42-2).

Incidence

Increased proteinuria occurs frequently in newborn infants admitted to the NICU; it is associated with various types of renal injury. The detection of increased tubular proteinuria is a sensitive screening test for renal damage after perinatal asphyxia (1136), and for tubular damage as a result of nephrotoxicity (see Acute Renal Failure; Nephrotoxicity).

Etiology

Proteinuria of tubular origin, the most common type, never is massive. It includes LMW proteins, i.e., <60,000 kD, which are freely filtered through the glomerulus. Additionally, in some patients, lysosomal proteins such as NAG can be found in the urine. Although tubular proteinuria can be isolated, it is associated most often with perinatal asphyxia or renal ischemia, UTI, ARF, Fanconi syndrome, or nephrotoxicity (see Acute Renal Failure; Tubular Dysfunction).

P.1043

In contrast, proteinuria of glomerular origin includes proteins with higher molecular weight such as albumin. It may become massive and lead to nephrotic syndrome (see Congenital Nephrotic Syndrome, above).

Evaluation

Because proteinuria occurs frequently, an extensive workup is not indicated unless there is evidence for renal disease. Apart from the history and physical examination, a major step in the differential diagnosis is the differentiation between tubular and glomerular proteinuria. This can be obtained by electrophoresis of urinary proteins or by quantitative measurement of specific LMW proteins and albumin (Fig. 42-8). Additionally, there may be evidence of tubular damage (e.g., glucosuria, RTA). Discussions of specific disorders are provided elsewhere in this chapter.

Chapter 43

Structural Abnormalities of the Genitourinary Tract

George W. Kaplan

Irene M. McAleer

A discussion of neonatal pediatric urology in essence encompasses most of pediatric urology. Although, there are age-specific problems that do not present in early infancy, problems present primarily or specifically in the neonatal period. It is these latter lesions on which this discussion will focus. The almost universal use of antenatal ultrasonography, especially with Doppler and 3-dimensional (3D) imaging, has had a profound effect on detection, management, and understanding of many lesions of the urinary tract. Genitourinary anomalies account for approximately 50% of all antenatally sonographically detected lesions; hydronephrosis represents about two-thirds of these genitourinary abnormalities (1). Information from ultrasonography has been further complemented with magnetic resonance imaging (MRI) imaging, fetal bladder urine specimen measurements of electrolytes, osmolality, and β 2-microglobulin. *In utero* surgical therapy is also possible with improved fetal surgical techniques, although the benefits derived from fetal surgery are not clear (2,3,4,5).

To properly understand and interpret the symptoms and findings seen in most congenital urologic problems, understanding the significant events of embryogenesis of the lesions seen is essential. Abnormalities of embryogenesis will be addressed as the resulting anomalies are covered.

The ureteral bud arises from the mesonephric duct at 4 to 5 weeks of gestation, the kidney begins to form at 6 weeks, and the bladder develops during the sixth to seventh week. The Wolffian duct is then incorporated into the bladder (Fig. 43-1). It is not until week 10 of gestation that urine production begins, and it is usually not until 14 to 16 weeks of gestation that the urinary tract is evident on antenatal ultrasonography (6). A number of anomalies may result from disordered embryogenesis of the ureter or kidney. Most genitourinary anomalies seem to occur sporadically, although some of the abnormalities are familial and others are related to chromosomal abnormalities.

IMAGING

The overall incidence of detection of fetal anomalies is currently about 1%. Urologic diagnostic imaging in the fetus, the newborn, and, to some extent, in the infant, is limited by the renal function (see Fig. 43-1). Neonatal renal functional parameters may be sufficient to maintain homeostasis: they may not suffice to produce the accuracy of diagnosis as expected from some imaging examinations used in older children and adults.

Ultrasonography and voiding cystourethrography are not dependent on renal function and, hence, assume even greater diagnostic import than in other age groups. Improved ultrasonographic equipment, resolution, and techniques are identifying fetal anomalies with greater accuracy resembling similar studies obtained in children and adults. Doppler imaging of the renal vessels *in utero* can suggest the presence of 1 or 2 functioning kidneys and Doppler imaging of the hypogastric vessels can delineate the presence or absence of the bladder if there is difficulty in reliably locating the bladder. Intravenous urography and, to a lesser extent, renal scintigraphy depend on renal function to produce images and consequently may be less reliable than in the adult; newer scintigraphic agents and techniques have made evaluation of the neonatal kidneys more reproducible and reliable (Fig. 43-2).

ANOMALIES OF THE KIDNEY

With normal embryogenesis as background, the anomalies and problems that may be encountered can be anticipated, because most have an embryologic basis. Some are incompatible with life, which may lead to an early demise; some are of no clinical significance, but most are potential sources of morbidity that can be minimized if the children are treated at an early age.

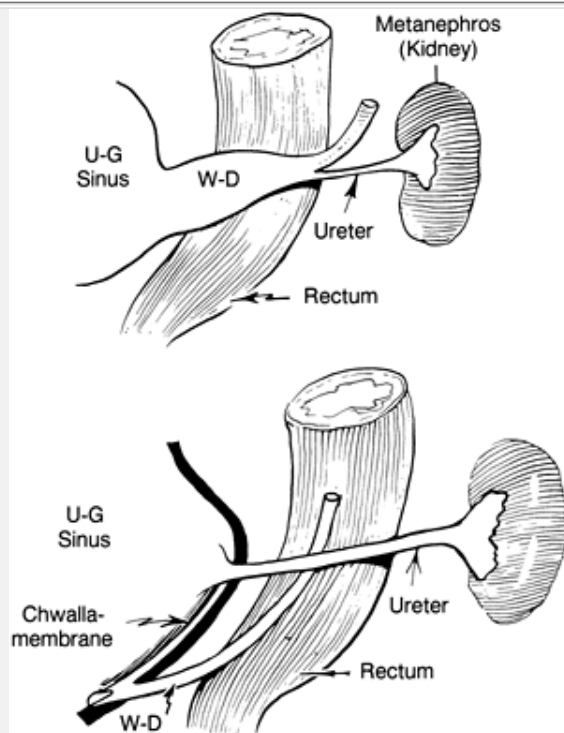

Figure 43-1 Incorporation of the wolffian (i.e., mesonephric) duct (W-D) into the urogenital sinus (U-G). From Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology*, vol. 1. Philadelphia: WB Saunders, 1976:504, with permission.

Figure 43-2 A: An excretory urogram in a newborn infant. The right kidney barely concentrates contrast (arrow); there is no evidence of the left kidney. Contrast is apparent in the bladder (arrow). **B:** An isotope renal scan the next day demonstrates the presence and function of two kidneys. The child was normal.

Renal anomalies include the cystic diseases and abnormalities of number, position, and rotation. If the pronephros fails to develop, the mesonephros will not develop, resulting in renal and ureteral agenesis and absence of the ipsilateral genital ducts in the male. If the mesonephric duct develops but the mesonephros does not, there will be renal agenesis but the genital ducts will be present and there might be a blind-ending ureter.

Nephrogenesis is induced by the ureter; therefore, normal nephrogenesis depends on the ureteral bud meeting normal metanephrogenic blastema (7). If the ureter fails to meet the metanephric blastema, a blind-ending ureter might result. When the ureter meets a degenerating portion of the metanephrogenic blastema (i.e., the cephalic or caudal end of the blastema), renal dysplasia may result (7).

Renal Agenesis

Renal agenesis can be unilateral or bilateral. Bilateral renal agenesis obviously is incompatible with extrauterine life. In cases of bilateral renal agenesis, there is no in utero urine production; thus, there is marked oligohydramnios and the affected fetus may exhibit the deformational changes of Potter syndrome (8). Adequate amniotic fluid is required for normal lung development so the lungs may be hypoplastic. The incidence of bilateral renal agenesis is roughly 1 in

P.1068

4,000 to 5,000 births (8). Renal agenesis sometimes may be associated with sirenomelia (8). Bilateral renal agenesis can be diagnosed antenatally by a combination of sonographic findings that include lack of identifiable renal masses, no demonstrable renal vessels on Doppler imaging, absent bladder, and severe oligohydramnios (6). For reasons that are unclear, some infants with this diagnosis have normal or near-normal levels of amniotic fluid. Renal agenesis must be considered postnatally when Potter facies are noted, when there is no urinary output within 24 to 48 hours, or when there is evidence of ventilatory failure with small lungs on chest radiograph. The postnatal diagnosis can be inferred ultrasonographically by the absence of identifiable kidneys or renal vessels with Doppler and the absence of urine in the bladder. Renal scintigraphy is used to prove that there is no identifiable functioning renal tissue. When the postnatal diagnosis of bilateral renal agenesis is made and confirmed, attempts at life support, which may have been initiated because of respiratory distress, should, in our opinion, be abandoned. There may be a familial inheritance of bilateral renal agenesis, with one review reporting up to 3% of siblings of probands having bilateral renal agenesis (9).

The incidence of unilateral renal agenesis is roughly 1 in 500 to 1,500 (8,10). There is a higher incidence of contralateral renal abnormality in patients with unilateral renal agenesis when compared to the general population, being generally obstructive or refluxing in nature. One-third of the patients with a solitary kidney in one series required some form of surgical procedure on the solitary unit (11). Unilateral renal agenesis may be associated with congenital scoliosis and with vaginal and uterine agenesis (12,13). It is the most common nonskeletal anomaly seen with imperforate anus (14). Unilateral renal agenesis previously was not thought to affect longevity or health as long as the contralateral kidney was normal. Recent experimental studies have suggested that renal injury may be produced in the solitary kidney by hyperfiltration and that a reduced protein diet may be somewhat protective. Clinical studies of patients with a solitary kidney (e.g., transplant donors, trauma victims) have, at this point, failed to confirm this (15).

Brenner and associates have noted that most people with unilateral renal agenesis do not develop progressive renal disease but longstanding hyperfiltration in most people with a solitary kidney from any etiology may cause glomerular hypertension which may be the culprit for developing progressive glomerular damage with subsequent proteinuria and renal insufficiency (16). Goldfarb and associates reviewed renal function in donor nephrectomy patients and found that renal function was well preserved in most donors over a prolonged follow-up averaging 25 years with some increase in proteinuria found in some patients but with only marginal significance in the group as a whole (17).

Renal Ectopia and Fusion

Failure of renal ascent will result in a pelvic kidney and may be associated with vaginal or vertebral anomalies (12). If the two metanephrogenic masses come into contact with each other in the pelvis, they may fuse and form a pancake or a horseshoe kidney (13). The embryogenesis of crossed ectopia, with or without fusion, is harder to explain but might result from lateral bending and rotation of the tail bud of the embryo, thereby altering the course of ascent (13).

Renal malrotation, or incomplete rotation, occurs when the ascending kidney, maintains its early fetal orientation and its renal pelvis is directed anteriorly. Malrotation is routinely present in fusion anomalies and in pelvic and crossed ectopias, and is also occasionally seen in kidneys located in the renal fossa. Incomplete rotation is of no clinical significance, but may cause difficulties in some imaging study interpretation: it may also be important in planning reconstructive procedures.

Abnormalities of renal position (i.e., ectopia) are interesting anomalies that generally, are of no clinical import but may become apparent because of trauma (i.e., hematuria), a palpable mass, or associated urologic abnormality. The ectopic kidney may be located in the chest or the pelvis. Thoracic kidneys usually are associated with eventration of the diaphragm and are of no clinical significance except as a finding on a chest radiograph (18). Pelvic ectopia is the most common of the abnormalities of position and often is associated with

vesicoureteral reflux or ureteropelvic junction obstruction (19). Additionally, girls with müllerian anomalies have an increased incidence of pelvic kidney compared to the general population; hence, the finding of a pelvic kidney in a girl warrants further investigation of the genital tract to uncover associated anomalies (20).

Fusion anomalies, such as horseshoe or pancake kidneys, may present in the same way that anomalies of position present. Horseshoe kidneys are found with increased frequency in girls with Turner syndrome (21). There is an increased incidence of ureteropelvic junction obstruction in horseshoe kidneys (19). Some patients with horseshoe kidneys may have increased stone formation, as a result of relative urinary stasis with drainage from the nondependent renal pelvis. Crossed ectopia with or without fusion (i.e., one kidney is found on the opposite side of the side of ureteral bud development) is uncommon. When crossed ectopia occurs, the left kidney more commonly crosses to the right side than vice versa (22). By definition, the ipsilateral ureteral orifice is located on the anatomically appropriate side of the body (i.e., the left ureter is on the left side of the trigone and the right ureter is on the right side of the trigone). There is an increased incidence of vesicoureteral reflux and of ureteropelvic junction obstruction in crossed ectopic kidneys (19). Patients with crossed ectopia have an increased incidence of skeletal and cardiac abnormalities (14).

Supernumerary Kidney

The presence of a supernumerary (i.e., third) renal mass is a very rare anomaly; the clinical significance of this is determined by associated pathologic conditions (23). The supernumerary kidney usually is small, and more often caudal than cranial to the normally placed kidney. Many patients and some physicians confuse a supernumerary

P.1069

kidney with duplication of the collecting system and incorrectly, refer to ureteral duplication as a third kidney.

Cystic Disease

Renal cystic diseases are a group of disorders seen in pediatric urologic practice that frequently will present in the neonatal period. Because there is no uniform system of classification, there can be difficulty in communication between disciplines. An accurate diagnosis is needed for prognosis and for genetic counseling. It is for this reason that communication must be clear. Table 43-1 is a classification scheme that has been clinically useful in our practice.

Autosomal recessive polycystic kidney disease (ARPKD), as the name implies, is an inherited disorder whose mode of transmission follows a mendelian recessive pattern. Its reported incidence is between 1 in 6,000 to 1 in 14,000 pregnancies. In this disorder, formerly known as infantile polycystic disease, the kidneys are very large and often occupy the entire retroperitoneum (Fig. 43-3). The cysts are small and are actually enlargements of the collecting ducts (24). The liver almost always is abnormal. At times there will be periportal hepatic fibrosis as a significant part of this complex. Death in the neonatal period is secondary to either renal or pulmonary failure. Those who survive the neonatal period usually will exhibit decreased renal function and hypertension, but at times liver failure as a result of hepatic fibrosis may be the most prominent part of the clinical picture (25). Imaging studies such as antenatal or postnatal ultrasonography, computed tomography (CT) or intravenous urography usually are diagnostic with very large kidneys demonstrating a sunburst streaking pattern.

ADPKD is inherited in a mendelian dominant fashion and is more common than the recessive form. It usually does not present until adult life, hence its former name, adult polycystic disease. These patients usually present with hypertension, hematuria, urinary tract infection, or renal failure. When this problem presents in childhood, it may do so as an abdominal mass or may be found with ultrasound as either antenatal evaluation, screening for polycystic disease, or coincidentally when an ultrasound is being obtained for some other evaluation. Imaging studies will prove diagnostic, because multiple large cysts that splay and distort the collecting system will be present. Although there often are associated hepatic cysts, liver failure is not usually a clinical feature of this disorder. Microdissection studies have shown that the cysts are as a result of abnormal branching of the collecting tubules and cystic dilations of portions of the nephron (26). Generally, detectable cysts may not develop until middle to late adult life; hence, the disease is undetectable clinically until they appear.

TABLE 43-1 CLASSIFICATION OF RENAL CYSTIC DISEASE

Polycystic disease
 Autosomal recessive
 Autosomal dominant
 Renal cortical cysts in hereditary syndromes
 Tuberous sclerosis
 von Hippel-Lindau disease
 Meckel syndrome
 Zellweger cerebrohepatorenal syndrome
 Jeune asphyxiating thoracic dysplasia
 Syndromes of multiple malformations that include cortical cysts
 Renal medullary cysts
 Familial juvenile nephronophthisis
 Medullary cystic disease
 Renal retinal dysplasia
 Medullary sponge disease
 Renal dysplasia
 Multicystic kidney disease
 Other cystic dysplasias
 Multilocular mesoblastic nephroma
 Other cystic diseases
 Simple cysts, single or multiple
 Unilateral segmental cystic disease

Figure 43-3 An excretory urogram in a 2-day-old girl with autosomal recessive polycystic kidney disease shows the sunray appearance of the contrast material and the enormous renal size. From Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology*, vol. 2. Philadelphia: WB Saunders, 1976:686, with permission.

Tuberous sclerosis can mimic both autosomal recessive and autosomal dominant polycystic disease in that lesions grossly similar to either form of polycystic disease can be found in the tuberous sclerosis complex (27). Microscopically, lesions characteristic of tuberous sclerosis will be seen on biopsy of the affected kidneys. Angiomyolipomas (i.e., renal hamartomas), are the more commonly seen renal lesions in patients with tuberous sclerosis.

Multicystic kidney disease, with a frequency of 1 in 3,000 pregnancies (11), is the most common form of cystic

P.1070

disease seen in neonates. Originally defined by Spence and associates (28), this is a unilateral (or bilateral) lesion in which the entire kidney is replaced by cysts of varying sizes. Grossly, there is no recognizable renal tissue present, but microscopically there may be dysplastic renal elements in the septa between the cysts (Fig. 43-4). Bilateral multicystic kidney disease is incompatible with life. Multicystic kidney disease is sporadic and is not inherited. Some multicystic kidneys involute, probably by absorption of the cyst fluid. This can occur antenatally or in the first few months of life. It is likely that many cases of presumed renal agenesis are multicystic kidneys that have undergone involution.

Multicystic kidneys usually are detectable with antenatal ultrasonography, but occasionally can present during infancy as palpable masses. Ultrasonography will demonstrate multiple, variably sized cysts in a random pattern (Fig. 43-5), and the affected kidney is generally without function on renal scan or intravenous urography.

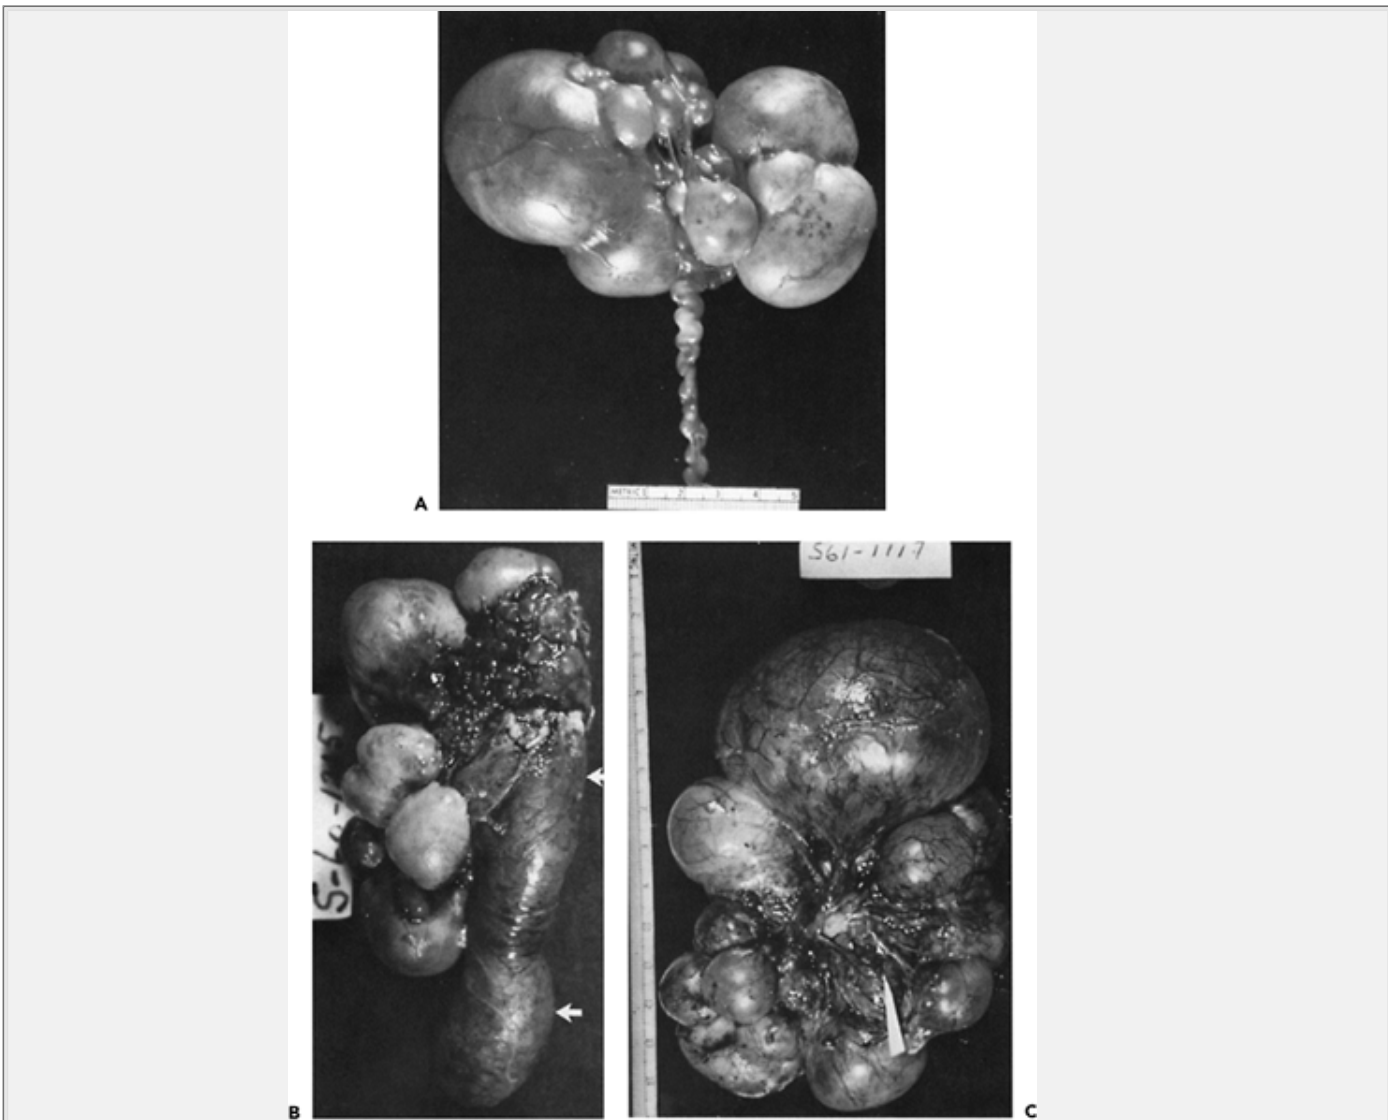

Figure 43-4 Three examples of the variety of multicystic diseases. **A:** Multicystic kidney with a torturous atretic ureter. The cysts vary in size and appear to be held together by fibrous tissue. **B:** Multicystic kidney in a 1-month-old girl. The dilated pelvis and proximal ureter are indicated (arrows). **C:** Multicystic kidney in a 4-day-old girl. No ureter was found during the nephrectomy. From Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology*, vol. 2. Philadelphia: WB Saunders, 1976:210, with permission.

Figure 43-5 An abdominal ultrasonographic study carried out in an infant with multicystic (i.e., cystic dysplastic) kidney.

There is a great deal of controversy surrounding the management of these lesions; traditional therapy had been nephrectomy, but many pediatric urologists advocate observation because the incidence of sequelae such as infection, pain, hypertension, or malignancy is very low. Nephrectomy seems a reasonable alternative to lifelong follow-up, however, and is our current recommendation if the kidney does not completely involute within 6 to 12 months. At the present time, a Multicystic Kidney Registry is collecting data on cases that are followed with observation. Roughly 25% of the patients with multicystic kidney disease have an obstructive lesion such as ureteropelvic junction obstruction on the contralateral side, and it is this fact that will determine the patient's ultimate prognosis. Since the inception of the Multicystic Kidney Registry, vesicoureteral reflux has been found to be more common than obstruction. Involution, if it occurs, may take many years to occur; up to 50% of those followed for 3 to 5 years had no change in the multicystic kidney appearance on ultrasound (29).

ANOMALIES OF THE URETERS AND BLADDER

Duplication and Triplication of the Ureters

Multiple ureteral buds or premature division of the ureteral bud could produce ureteral duplication or triplication (30). If there are multiple ureteral buds, one bud is likely to meet degenerating rather than normal nephrogenic tissue. This could account for the increased incidence of renal dysplasia in the upper pole of a duplicated system (4). Duplication of the urinary collecting system is one of the more common abnormalities seen in the urinary tract; its occurrence is about 0.8% (30). Approximately 12% of sibs and parents were affected with ureteral duplication when reviewing family inheritance probands. (9) Duplication can be either complete or incomplete. Incomplete duplication is usually of no clinical significance, there can be ureteroureteral reflux between the two limbs of the partial duplication resulting in dilation of one of the ureters, usually the lower one. Complete duplication occurs once in every 500 cases (30). Complete duplication, generally of no clinical significance, is associated with a higher incidence of other abnormalities in the urinary system. These abnormalities include both vesicoureteral reflux and obstruction.

Vesicoureteral reflux probably is the more common of the anomalies associated with ureteral duplication, and usually occurs into the lower moiety of a duplicated system (Fig. 43-6). Duplication is seen in approximately one in five people with vesicoureteral reflux, which is much higher than its incidence in the general population (31). The grade of reflux associated with a complete duplication usually is greater than that seen with a single system. Obstruction is common when the upper moiety of a complete duplication is abnormal, Both obstruction and vesicoureteral reflux associated with duplications may present as either mass lesions or urosepsis; many of these duplications are diagnosed in utero, with hydronephrosis seen in the upper or lower segments of the duplicated systems.

If the ureteral bud arises from a locus that is more cranial or caudal than normal, ureteral ectopia, vesicoureteral reflux, or paraureteral diverticula might be produced (32). Ectopic ureteroceles probably result from abnormalities of the ureteral bud and ureteral ectopia (33). Simple ureteroceles are thought to be produced by persistence of the Chwalla membrane (i.e., the membrane covering the distal end of the ureter during development) (34).

Ureteral obstruction occurs primarily at the ureteropelvic and ureterovesical junctions. These obstructions usually are intrinsic in nature, and the ureter may be of normal or reduced caliber externally (35,36). Multicystic kidney disease has been said to result from ureteral obstruction early in gestation or may be secondary to disordered induction of the metanephrogenic mass by a faulty ureteral bud (37). Kitagawa and associates demonstrated an animal model for development of a multicystic kidney by obstructing the fetal lamb urethra (male) or ureter (female) at 60 days gestation, and proposed that the cysts developed only when the obstruction occurs after the glomeruli start to produce urine. (38)

Bladder Anomalies

Agensis of the bladder could result if the allantoic stalk failed to develop (39); it also could occur if there was bilateral failure of ureteral migration with bilateral ureteral

ectopia, because migration of the ureters is necessary for formation of the trigone, which may be necessary for enlargement of the allantoic stalk (40). Urachal anomalies occur because of a general mesodermal failure, as in the prune-belly syndrome, or because of delayed closure of the urachus (41). Duplications of the bladder and urethra often are associated with duplications of the hindgut and lower spinal cord. Hence, it would seem that splitting of the hind end of the embryo might be responsible for this type of anomaly (42).

Figure 43-6 A: An intravenous urogram in a girl with complete, bilateral duplication of the collecting system. Note the blunting of the lower calyces. **B:** A cystogram in the same child demonstrates reflux into both lower collecting systems only. From Belman AB. The clinical significance of vesicoureteral reflux. *Pediatr Clin North Am* 1976;23:707, with permission.

Posterior urethral valves probably result from abnormal insertion and persistence of the mesonephric ducts distal to the Müllerian tubercle (type I), or from persistence of the cloacal membrane (type III) (43). Type II valves probably do not exist as an obstructing lesion (see Fig. 43-17).

Ureteral Ectopia

Ureteral ectopia exists when the ureter opens in a position other than its normal location at the corner of the trigone. Ectopia may occur in ureters of single or duplex kidneys (Fig. 43-7). The most common form of ureteral ectopia is lateral ureteral ectopia, in which the ureteral orifice lies within the bladder lateral to its normal position. This is the etiologic mechanism for primary vesicoureteral reflux (see Vesicoureteral Reflux). Significant medial or distal ureteral ectopia, less common than lateral ureteral ectopia, will cause clinical pathologic conditions that vary depending on the location of the ureteral orifice and the gender of the patient. An abnormal proximal budding locus on the mesonephric duct allows the ureteral bud to remain in prolonged contact with the Wolffian duct, so that the medially ectopic ureteral orifice may open anywhere along the course of the Wolffian duct (Fig. 43-8). In males, this includes the posterior urethra, seminal vesicles, vas deferens, or epididymis (44). In females, the ectopic ureter may open into the urethra, the uterus, or proximal vagina, or along the course of Gartner's duct in the anterolateral wall of the vagina. If a medially ectopic ureter opens within the confines of the bladder, no clinical abnormality occurs. If, however, the ureter opens within the confines of the bladder neck mechanism, obstruction of the involved renal unit or vesicoureteral reflux may occur.

Figure 43-7 Development of ectopic ureter. U, ureter; U-G, urogenital; W-D, Wolffian duct. From Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology*, vol. 1. Philadelphia: WB Saunders, 1976:510, with permission.

P.1073

In females, ectopic ureteral orifices that lie distal to the internal sphincter mechanism of the bladder neck can cause incontinence (45). Older girls usually present with constant dampness that is associated with an otherwise symptom-free, normal voiding pattern. Infant girls may be constantly wet or have a purulent discharge if the system is infected. Physical examination suggests the diagnosis if urine can be seen welling up in the vagina or if a spurt of urine is seen coming from the perineal ectopic ureteral orifice. Many are not diagnosed by physical findings alone. Eighty percent of these ectopic ureters arise from the upper pole segment of a total ureteral duplication, and CT, MRI, or diuretic renography with radionuclide agents will better delineate the anatomy. Occasionally, intravenous urography may suggest the diagnosis (45). However, the ectopic segment frequently functions poorly and it may not be visible on excretory urography even with delayed radiographs. A high index of suspicion and an awareness of the radiographic clues to a nonvisible duplication (i.e., the drooping lily sign) often will lead to the diagnosis (Fig. 43-9). Because an ectopic vaginal ureter may drain a poorly functioning and thus nonvisualizable single renal unit, congenital absence of one kidney in a girl with incontinence must not be accepted as a diagnosis without a thorough investigation. This investigation should include abdominal sonography, nuclear renal scan; occasionally computed tomography or MRI may be the only way to define the anatomy (46).

Figure 43-9 Excretory urogram in an infant with ureteral duplication. Ectopic ureters from upper segments produced massive displacement of lower segments, leading to a misdiagnosis of abdominal mass and neuroblastoma. From Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology*, vol. 1. Philadelphia: WB Saunders, 1976:518, with permission.

Treatment of the ectopic ureter depends on the presence or absence of significant function in the involved renal unit. If the ureter drains an otherwise healthy system, ureteral reimplantation into the bladder will correct the problem and preserve maximal renal function. If the ureteral anomaly is associated with a duplex kidney and there is good function in both segments of the kidney, ipsilateral ureteroureterostomy is indicated. Generally, the involved renal unit functions poorly, so excision of the involved segment is indicated. The distal ureteral stump is left undisturbed to avoid compromise of the normal sphincter mechanisms. The male infant with an ectopic ureter frequently presents with an antenatal ultrasound finding suggestive of ureteral dilatation, a mass, urinary tract infection, or epididymitis (44). In boys, an ectopic ureter will arise more frequently from a nonduplicated kidney, and can drain into the male genital tract anywhere from the prostatic urethra to the epididymis. Treatment is similar to that for females.

Ureterocele

A ureterocele is a cystic dilation of the distal submucosal or intravesical portion of a ureter. Ureteroceles account for a

P.1074

broad spectrum of associated or secondary pathologic conditions, and constitute one of the more complex and confusing groups of anomalies of the lower urinary tract (47).

Ureterocele in children most commonly involve the end of the upper pole ureter of a duplex kidney (i.e., ectopic ureterocele), but may less commonly involve a single-system ureter (i.e., simple ureterocele) (48). The etiology of ureteroceles is uncertain. Failure of reabsorption of the Chwalla membrane from over the ureteral orifice has been proposed as an obstructive etiology (34). It seems more likely that ureteroceles result from an intrinsic defect in the ureteral bud itself, and from faulty or delayed incorporation of the ureteral bud into the urethra and bladder base (45).

Ureteroceles associated with a single-system ureter (i.e., simple ureteroceles) tend to be intravesical and in the normal position. Intravesical ureteroceles in children often are also associated with hydronephrosis of varying degrees (49).

Ureteroceles may be associated with significant derangement of the upper and lower urinary tract. The ureterocele most commonly originating from the upper pole ureter of a duplex kidney is associated with secondary pathology; the most frequently noted associated condition is hydronephrosis, with impaired function or dysplasia of the upper pole system and obstruction or reflux in the ipsilateral lower pole system (Fig. 43-10). Contralateral reflux or obstruction also may occur. The pathophysiology of the associated findings is easily understood by recognizing that a ureterocele may dissect under the trigonal epithelium and deform the ipsilateral or contralateral ureterovesical junction, causing various combinations of vesicoureteral reflux or obstruction in any or all of the ureters (50). Ten percent of ureteroceles occur bilaterally (47). If the ureterocele prolapses into, or otherwise occludes, the bladder outlet, bilateral hydronephrosis and relative bladder outlet obstruction may occur.

Figure 43-10 Ectopic ureterocele. From Malek RS, Kelalis PP, Burke EC, et al. Simple and ectopic ureterocele in infancy and childhood. *Surg Gynecol Obstet* 1972;134:611, with permission.

Ureteroceles occur more commonly in females and usually manifest in early childhood; the ratio of occurrence in males and females is 1:6 cases (47). Most of our patients have presented during the first year of life. Most are now diagnosed antenatally with ultrasound but, historically, the most common presentation was that of a febrile infant found to have a urinary tract infection. If the ureterocele prolapses into the urethra, difficult voiding or azotemia may prompt evaluation. Ureterocele is the most common cause of urinary retention in the female infant. Rarely, a ureterocele will prolapse through the external urethral meatus in a female and present as an introital mass.

Classically, the diagnosis of a ureterocele is fairly straightforward. Renal and bladder ultrasonography will reveal the upper tract dilation and the wall of the ureterocele in the bladder (51). This can be seen antenatally. The intravenous urogram, if obtained, commonly shows complete ureteral duplication with upper pole hydronephrosis and the characteristic lucency of the ureterocele in the bladder. Cystography is necessary to establish the presence or absence of associated vesicoureteral reflux and to assess the integrity of the detrusor muscle backing the ureterocele. A diuretic renal scan can outline the function of the involved upper pole segment and any measurable obstruction of any of the segments, and is helpful in determining the best surgical

approach.

The choice of treatment of a ureterocele depends on several factors. The age and clinical condition of the patient, the presence or absence of significant function in the involved renoureteral unit, and the presence of reflux or obstruction in the ipsilateral or contralateral uninvolved ureters all influence the choice of therapy. In the critically ill, septic infant, transurethral or transvesical unroofing or puncture of the ureterocele may provide decompression and allow stabilization of the child until his or her clinical condition allows definitive treatment. Alternatively, placement of a temporary percutaneous nephrostomy into the involved renal unit often can be done without the need for general anesthesia. The best form of definitive treatment has been debated over the years. If an intravesical ureterocele is associated with a single kidney and minimal hydronephrosis, simple excision of the ureterocele and reimplantation of the involved ureter should suffice. However, cystoscopic puncture of the ureterocele may also correct the problem without need for further surgical intervention (52). Even if the system is duplex, an en bloc ureteral reimplantation can be performed if the ureters are not too dilated (47).

Generally, definitive management of the hydronephrotic upper tract associated with a ureterocele depends on the function of the obstructed segment. If sufficient function exists in the involved unit, pyeloureterostomy or ureteroureterostomy to the ipsilateral uninvolved unit is

P.1075

appropriate (47). In the most common situation, however, function usually is so poor that removal of the involved upper pole unit may be necessary (47). Some patients have had distal ureterocele reconstruction without heminephrectomy with good initial results. The upper pole should be followed for resolution of the hydronephrosis. Some centers have described definitive endoscopic treatment of the ureterocele by puncturing the ureterocele with an electrocautery probe (53). Initially promising success rates have not proven to be as good as predicted (52). Woodard found that 80% of his patients required further surgery when transurethral puncturing of ureteroceles was used as primary therapy (178). Puncture of the ureterocele is appropriate initial management for unstable or septic patients and in select patients with intravesical ureteroceles as potentially definitive treatment. Debate centers over the management of the distal ureter and ureterocele itself. If upper pole nephrectomy has been performed, the distal ureter and ureterocele may collapse, alleviating any associated pathologic condition caused by the mass effect of the ureterocele. If there is significant reflux into the ureter associated with the ureterocele (which is uncommon), or if the ureterocele tends to evert into the dilated ureter prior to initial surgical intervention, excision of the involved ureter and marsupialization of the ureterocele is preferred. Depending on the function of the upper pole moiety, either heminephrectomy or upper to lower pole ureteroureterostomy generally is also necessary. This obviates the need for a secondary, delayed surgical excision of the ureterocele because of recurrent urinary tract infections or persistent reflux (50). At times, preliminary cutaneous diversion of the involved ureter with delayed reconstruction is warranted, to allow maximal recovery of function before deciding on the need for nephrectomy vs. reconstruction (47).

Ureteropelvic Junction Obstruction

Obstruction at the ureteropelvic junction probably is the most common cause of a palpable abdominal mass in the newborn, and is the most common cause of antenatal hydronephrosis. This lesion usually is the result of narrowing of the ureter at the junction of the renal pelvis with the ureter. Because the renal pelvis is compliant, there can be a great deal of renal preservation despite massive dilation of the kidney behind the obstruction (Fig. 43-11) (54).

Figure 43-12 A: An abdominal ultrasonogram in a newborn infant demonstrates a single, large echo-free region consistent with hydronephrosis. **B:** A delayed renal scan in a newborn infant with right hydronephrosis secondary to ureteropelvic junction obstruction.

The diagnosis of ureteropelvic junction obstruction can be made sonographically because there is a sonolucent central mass within the renal area surrounded by thin renal parenchyma (Fig. 43.12A). A grading system has been suggested by the Society for Fetal Urology to better standardize terminology and interpretation of renal ultrasound findings (55). The system is based on the severity of renal pelvis and calyceal dilatation and the renal parenchymal thickness (Fig. 43-13). Vesicoureteral

P.1076

reflux must be excluded from the differential diagnosis using voiding cystography. The function of the obstructed kidney can be determined by radionuclide scanning (Fig. 43-12B). One of the advantages of radionuclide scintigraphy is that the physiologic significance of dilatation can be determined by administering furosemide (56). If the dilatation is of significance, there will be retention of the radionuclide behind the obstruction, whereas if there is no physiologic significance to the hydronephrosis, the administered diuretic will cause the radionuclide to wash out rapidly from the dilated system. To obtain valid results, the patient must be adequately hydrated and have adequate bladder drainage to prevent false interpretation of obstruction on the scan as a result of dehydration or bladder distention (57). It is becoming apparent, in some instances, that presumed significant hydronephrosis in the newborn is physiologically insignificant and may with time, stabilize or improve and require no treatment. Those instances that are physiologically significant, may require repair, generally dismembered pyeloplasty, resulting in improved drainage and renal function in some instances (54).

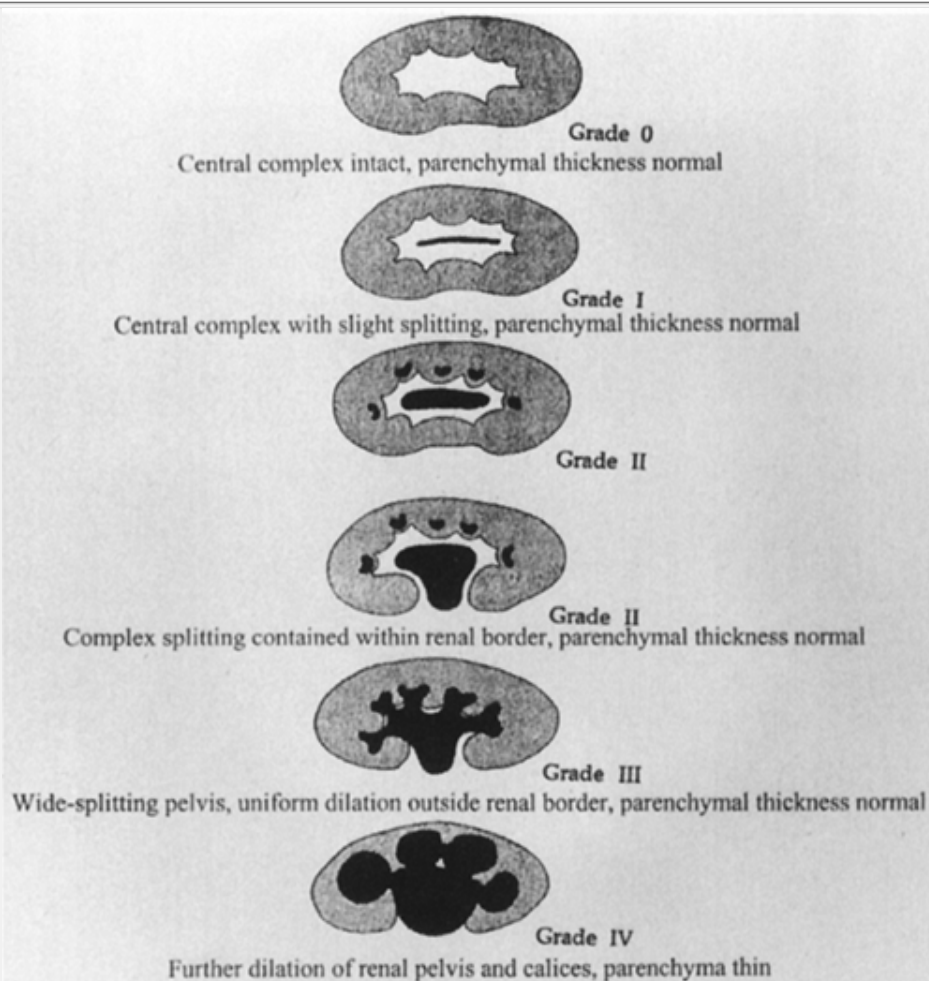

Figure 43-13 Society for Fetal Urology grading system for ultrasonographically detected hydronephrosis. From Baskin LS. Prenatal hydronephrosis. In: Baskin LS, Kogan BA, Duckett JW, eds. Handbook of pediatric urology. Philadelphia: Lippincott-Raven, 1997:11, with permission. Modified by Curt Powell, M.D.

Ureterovesical Obstruction

Obstruction at the ureterovesical junction is not nearly so common as obstruction at the ureteropelvic junction, but it is far from rare (36). Lower ureteral obstruction may present as marked hydroureteronephrosis (i.e., a mass), but may sometimes present as urinary infection (Fig. 43-14). As with ureteropelvic obstruction, it has become apparent that not all ureterovesical obstructions are physiologically significant and some require no treatment. Radionuclide scanning with diuretics is helpful in making the diagnosis of a physiologic obstruction (56). At times, however, an antegrade pyelogram with a pressure perfusion study is necessary to determine the significance or lack of significance of an apparent narrowing at the ureterovesical junction (58). These lesions, if identified as obstructive, are treated by excision of the obstructing segment, tailoring or tapering of the dilated ureter, and reimplantation of the ureter into the bladder (59).

Vesicoureteral Reflux

Vesicoureteral reflux is the most common abnormality of the urinary system seen in children; it may occur in 1 of 100 births (12). The actual incidence is unknown, but it is at least as common as cryptorchidism or hypospadias. Genome mapping, performed on families with primary vesicoureteral reflux who also have associated reflux nephropathy, has found an association with a locus on chromosome 1 which is also seen in some families with vesicoureteral reflux (60). Vesicoureteral reflux is known to

P.1077

be a familial problem. When one child in a family is identified as having reflux, as many as 30% to 50% of the siblings of that child may have vesicoureteral reflux (61). For that reason, it is thought that all younger siblings of any proband identified to have reflux should be screened (62). It also has been found that transmission of reflux from a previously refluxing parent to his or her children is approximately 66% (61). The normal ureterovesical junction is a relatively efficient mechanism that allows egress of urine into the lumen of the

bladder, but, because of its oblique course through the ureteral wall, prevents the bladder urine from reentering the ureter (Fig. 43-15) (63). It is obvious that there is maturation of the ureterovesical junction with both time and growth, because infants have a much higher incidence of vesicoureteral reflux than do older children (64).

Figure 43-14 Left ureterovesical obstruction in a 3-month-old boy who presented with unresponsive diarrhea. Urine culture was positive, and radiographic evaluation demonstrated significant pathology, as is evident in this illustration. The diarrhea resolved with treatment of the urinary infection. The ureterovesical obstruction was treated surgically. From Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology*, vol. 1. Philadelphia: WB Saunders, 1976:276, with permission.

Figure 43-15 Normal ureterovesical junction. From Harrison JH, et al, eds. *Campbell's urology*, 4th ed. Philadelphia: WB Saunders, 1979:1597, with permission.

Reflux is graded on an international grading scale of 1 to 5 (65). The major significance of this grading system is that the higher the grade of reflux, the more likely it is that reflux will persist despite somatic growth, and the more likely that there is associated or eventual reflux nephropathy. Conversely, the lower the grade of reflux, the more likely there will be spontaneous resolution of the vesicoureteral reflux without reflux nephropathy (66).

Although the presence of hydronephrosis suggests an abnormality in the urinary tract, many patients with significant vesicoureteral reflux will have a normal ultrasound study. The radiologic confirmation of vesicoureteral reflux is accomplished by voiding cystourethrography. Generally, this should not be performed while the child is actively infected; if an infection has been the presenting sign, voiding cystography may be performed once the urine is sterile and the patient afebrile and under treatment. Because renal scarring is produced easily in the neonate, it is especially important to establish the presence or absence of vesicoureteral

reflux before discontinuing antibiotics in patients who have presented with urinary infection.

Once reflux is demonstrated, especially in the infant, the patient should be maintained on low-dose antibacterial therapy until resolution of the reflux, hopefully preventing urinary tract infections. The choices of agents are limited in the newborn, but amoxicillin is a reasonable alternative until hepatobiliary maturation is sufficient to allow the use of sulfa or nitrofurantoin. A reasonable initial daily suppression dose would be 10 to 25 mg/kg of amoxicillin. With growing concerns of bacterial resistance to amoxicillin, low dose sulfamethoxazole-trimethoprim or nitrofurantoin may be used if carefully monitored. Breakthrough infection, while the patient is on antibacterial suppression or if there is poor parental compliance, suggests the need for surgical repair, either with open surgical techniques or endoscopic techniques.

Exstrophy

Exstrophy of the bladder is a rare, but extremely significant, abnormality (Fig. 43-16). It affects roughly 1 child in every 25,000 live births. Exstrophy is not commonly associated with abnormalities in other organ systems, and the remainder of the urinary tract usually is normal in these children. Functional reconstruction of the exstrophic bladder can be a formidable surgical undertaking, but in experienced hands can result in a continent child with a relatively normal upper urinary tract (67). The major factor affecting the success of closure in terms

P.1078

of continence seems to be the size of the exstrophic bladder at presentation.

Figure 43-16 Complete bladder exstrophy in a male child. Note that the penis is epispadiac, short, and stubby.

Figure 43-17 Exstrophy of the cloaca. **A:** Diagram of the external anatomy. **B:** In a patient with exstrophy of the cloaca, the anatomic features as numbered include exomphalos (1), ileum that has prolapsed through the proximal bowel orifice (2), and the hemibladders lying on either side of the exstrophic bowel (3). Note the absence of an anus (4) and of definable external genitalia. From Paquin AJ. Ureterovesical anastomosis: the description and evaluation of a technique. *J Urol* 1954;82:573, with permission.

The epithelium of the exstrophic bladder is grossly normal at birth, but becomes hyperplastic very shortly

thereafter if the bladder is not closed. It is preferable, if possible, that the exstrophic bladder be left uncovered and kept moist using plastic wrap pending closure, assuming that closure can be accomplished in the newborn period. Gauze or petroleum gauze should not be used, as these can dry the bladder surface and denude the urothelium.

Functional closure of exstrophy is traditionally a staged procedure. In the first stage, iliac osteotomies are performed to facilitate closure. Even though osteotomy can be omitted, especially in newborns, success rates are higher when osteotomy is used (68). The exstrophic bladder is dissected free from the anterior abdominal wall, closed into a sphere, and dropped back into the pelvis. The abdominal wall then is closed over the bladder. There is no attempt at the first stage to produce urinary continence. After 2 to 3 years, a second-stage procedure is performed in an attempt to produce urinary control. Mitchell has recently advocated bladder closure and epispadias repair as a one-stage procedure, with good initial results that include continence after the single procedure in a significant number of the patients so treated (69).

In the past, ureterosigmoidostomy was used as an alternative to functional closure. In this operation, the ureters were anastomosed to the colon and the patient voided a mixture of urine and stool. There are metabolic abnormalities (e.g., hyperchloremic acidosis) associated with this form of diversion, and it has become apparent that patients who have been treated by ureterosigmoidostomy have an increased risk for development of adenocarcinoma of the colon at some time after their diversion (70). These patients should have routine surveillance colonoscopy. Similarly, the unclosed exstrophic bladder is at high risk for development of adenocarcinoma of the bladder in the second or third decade of life (71). Functional closure seems to obviate this latter risk.

Exstrophy of the cloaca is a severe anomaly, once thought incompatible with long-term survival. In this anomaly, two halves of an exstrophic bladder are separated by a midline strip of exteriorized cecum (Fig. 43-17) (72). The ileum may prolapse through the bowel plate. Additionally, the child has an imperforate anus with almost no colon present distal to the exstrophic bowel plate. The small intestine is often short, and there may be a malrotation anomaly. The genital tubercle is split and widely separated. Hence, it is very difficult to produce a functional penis in boys with this anomaly (73). Genetic males with cloacal exstrophy were previously raised as females, but this practice is now questioned as some gender reassigned patients have expressed the view that they are uncomfortable with their assigned role (74). Some of these individuals are now being reassigned based on their genotypic karyotype. Each patient's ultimate gender of rearing should be carefully discussed and determined with the parents, with great thought and open discussion about these complexities. These children often have spinal dysraphism and a neurogenic bladder and bowel. For this reason, and the very short colon, a functional anus is almost impossible to produce, and permanent colostomy, incorporating the exstrophic bowel, is the bowel diversion of choice. Because the colon is short, it is best to preserve as much as possible to improve water reabsorption. Permanent ileostomy, although used in the past, may lead to problems with dehydration and short gut syndrome. Because of the problems with a short gut, a staged reconstruction is generally recommended by addressing the bowel problems with initial colostomy and considering further reconstruction once patient survival and bowel function is better determined. Ultimate bladder closure uniting the two halves of the exstrophic bladder, utilizes

P.1079

iliac osteotomy before anterior closure. Although normal urinary control usually is not possible, dryness provided by clean intermittent catheterization is a reasonable goal.

Patent Urachus

The urachus is a tube that connects the urogenital sinus and the allantois between months 3 and 5 of intrauterine life. The urachus normally regresses first to a small-caliber, epithelialized tube and then into a sealed, obliterated cord by term or during the neonatal period. It may remain patent up to the infraumbilical area in the premature infant (75). Thirty-two percent of all bladders have tubular remnants of the urachus noted at necropsy (76). Significant urachal anomalies are rare; they occur twice as often in males as in females (76).

Complete failure of obliteration of the urachus results in a persistent communication between the bladder and the umbilicus that leaks urine intermittently or continuously. It is the most common urachal anomaly encountered. The etiology of this condition is unknown. It has been suggested that bladder outlet obstruction may be a contributing factor, although the chronology of embryologic events suggests that the urachal lumen obliterates before urethral tubularization. Ultrasonography can frequently diagnose a persistent tract up to the umbilicus. The diagnosis may ultimately be confirmed by retrograde fistulography, instillation of methylene blue

into the tract or intravesically, or injection of indigo carmine intravenously. A voiding cystourethrogram occasionally will demonstrate the communication, but is more useful to look for other associated lower urinary tract anomalies such as obstruction or vesicoureteral reflux. A persistent omphalomesenteric duct must be considered in the differential diagnosis. In infants with minimal umbilical drainage that causes a small stain on the diaper, an umbilical granuloma or a patch of gastric mucosa may be at fault (77). Iatrogenic creation of a vesicumbilical fistula, during an umbilical artery cutdown, has been reported (75). Treatment of a patent urachus consists of complete extraperitoneal excision of the urachus with an attached cuff of bladder to completely remove any urachal remnant in the bladder and prevent possible cancer development in residual tissue. Attempts should be made to preserve the umbilicus.

Megacystis Microcolon Intestinal Hypoperistalsis Syndrome

Megacystis microcolon intestinal hypoperistalsis syndrome (MMIHS) was first described in 1976 and is considered rare (78). The disorder, thought to be an autosomal recessive trait, affects females more than males (4:1 preponderance) and generally is fatal within the first year of life. In a large review of 72 patients only 10 survived, with 9 on parenteral nutrition. Most patients die from sepsis, liver failure and postoperative complications (79). Presentation includes abdominal distention, an abdominal mass (i.e., a distended bladder), and functional intestinal obstruction characterized by bilious vomiting and absent or decreased bowel sounds. The small bowel is short, dilated, and hypoactive, and may have associated malrotation and an accompanying microcolon but no anatomic obstruction. The abdominal musculature generally is lax. Many of these patients are now presumptively diagnosed prenatally with ultrasonography demonstrating a large bladder, generally with a thin wall, bilateral hydronephrosis, with normal or increased amniotic fluid (thought to be as a result of the microcolon) (80).

The etiology is unknown. Treatment consists of parenteral alimentation and urinary diversion by means of a cutaneous vesicostomy. Patients with Ochoa urofacial syndrome also may present with megacystis in infancy (81).

Posterior Urethral Valves

The most common lesion obstructing the lower urinary tract in a boy is the lesion termed posterior urethral valves, occurring in 1:8000 to 1:25000 live births (82) (Fig. 43-18). The name is a misnomer, because the valves are really a diaphragm or membrane that traverses the urethra from a point just distal to the verumontanum in which it connects with urothelial folds (71,84). Dewan and colleagues have extensively studied the anatomy of this membrane with videocystourethrography, and prefer to classify this anomaly as a congenital posterior urethral membrane (COPUM) as a result of its variable morphological expression (84). Embryologically, these membranes occur because there is an abnormal anterior insertion and persistence of the distal extent of the Wolffian duct (43). To understand the clinical picture of urethral valves, one must consider the dynamics and pathophysiologic consequences of the obstruction itself. The valves are best considered as a rigid membrane, despite their frequently flimsy nature. The vesical neck also is a relatively rigid area. With antegrade flow of fluid, this membrane obstructs. When obstruction is present, the urethra dilates proximally and elongates. The detrusor hypertrophies, with resultant trabeculation and sacculation in response to the extra work involved in voiding. Detrusor hypertrophy also produces relative hypertrophy of the vesical neck.

The prostatic urethra becomes dilated in a fusiform manner between the two relatively rigid points, creating a subvesical chamber. If there is a primary abnormality of the ureterovesical junction, or if a paraureteral sacculum develops, vesicoureteral reflux may result. The presence of bilateral vesicoureteral reflux increases the possibility that renal failure will eventually occur. Hydronephrosis may develop, with or without reflux. Renal parenchymal damage in the form of renal dysplasia or interstitial nephritis, with or without superimposed pyelonephritis, often is concomitant or a result of the urethral obstruction. Renal dysplasia is frequently present at birth in infants with posterior urethral valves, and has been found as early as 15 weeks of gestational age in the fetus (85).

Osathanondh and Potter (86) state that dysplasia is a consequence of intrauterine urinary obstruction. In

P.1080

experimental animals, intrauterine urethral obstruction early in gestation usually has led to a patent urachus, without hydronephrosis or dysplasia—a situation that does not correspond to the clinical sequence in humans (87). Later in gestation, experimental intrauterine urethral obstruction results in hydronephrosis without dysplasia (88). Recent experimentation creating urethral obstruction or ureteral obstruction at different stages in gestation in the lamb may produce a kidney similar to a MCDK (if earlier in gestation) or an obstructed

hydronephrotic kidney similar to those seen with posterior urethral valves (if later in gestation) (38).

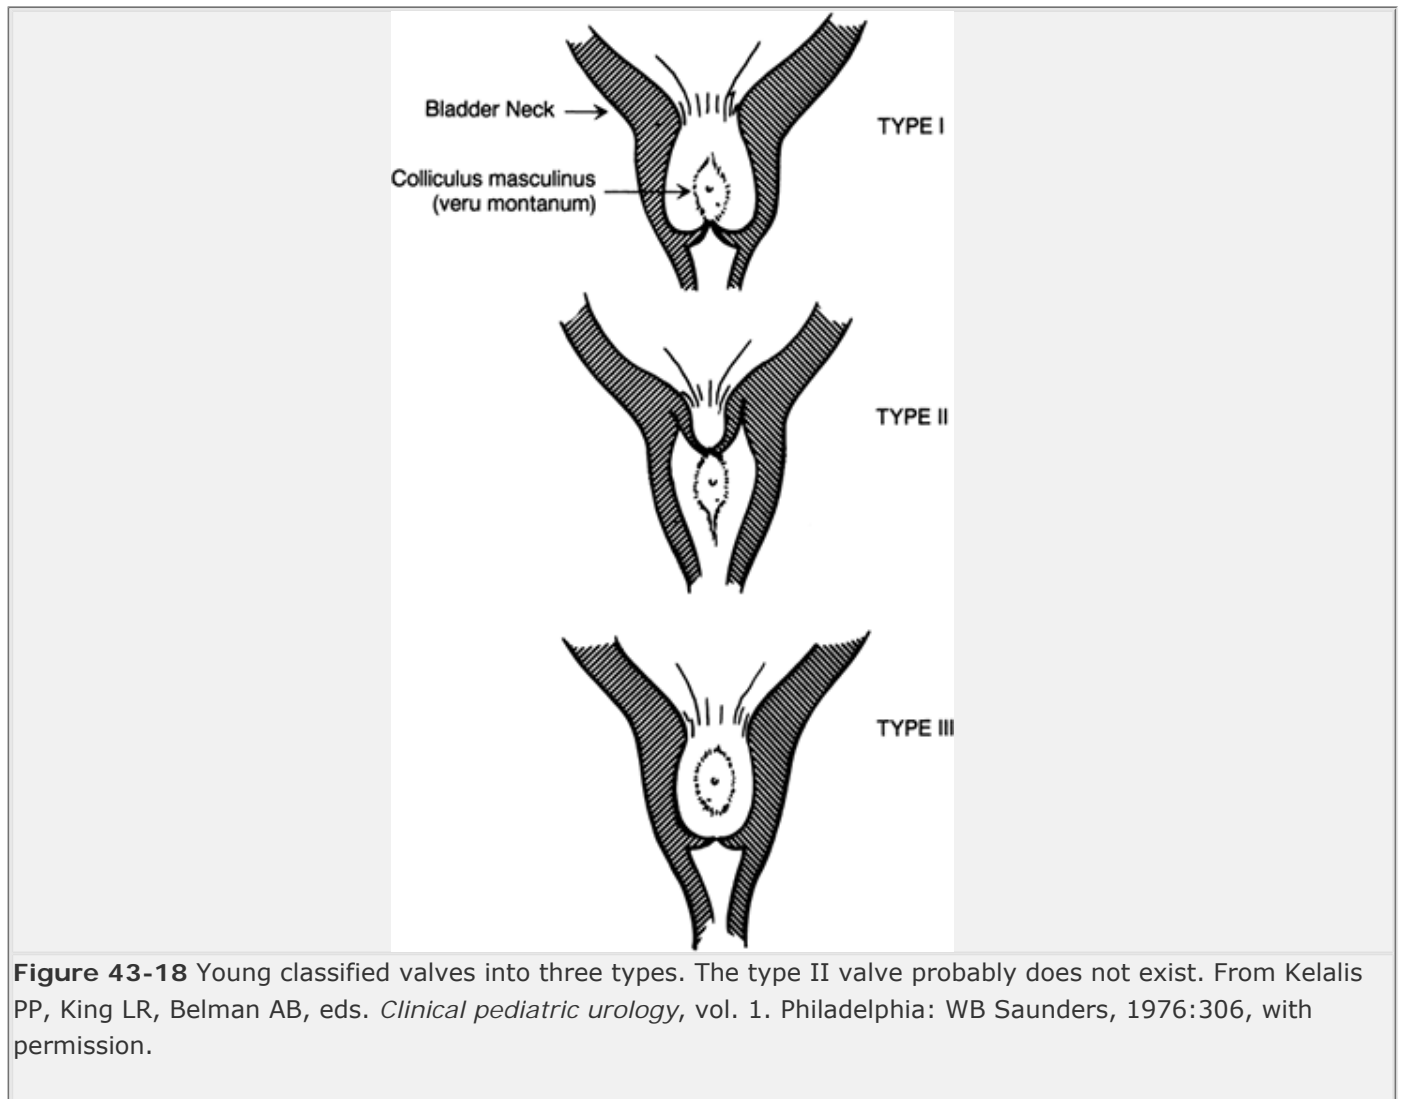

Figure 43-18 Young classified valves into three types. The type II valve probably does not exist. From Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology*, vol. 1. Philadelphia: WB Saunders, 1976:306, with permission.

Clinically, dysplasia is found more often in association with severe vesicoureteral reflux (89). Additionally, dysplasia often is unilateral and not bilateral, as one would expect if it resulted from intrauterine urethral obstruction. Maizels and Simpson (90), using chick embryos, showed that dysplasia results from problems associated with the renal blastema and not from obstruction of the ureter. Dysplasia, when present, may represent a primary abnormality of the ureterorenal unit and may have no direct causal relationship to the presence of intrauterine urethral obstruction.

The clinical presentation of the infant with posterior urethral valves often is related to the severity of the obstruction. Virtually all of the signs and symptoms seen in the boy with posterior urethral valves are secondary to the obstructive nature of the valves, the effect of intrauterine oligohydramnios, or the presence of superimposed urinary infection or azotemia (10,91). Routine use of ultrasonography has increased the detection of a thick walled bladder with a keyhole configuration, with or without hydroureteronephrosis, and oligohydramnios suggestive of posterior urethral valves however postnatal confirmation of valves is only about 39% to 40% (4).

If not detected antenatally, 25% to 50% of boys with posterior urethral valves present during the neonatal period (92). The nonrenal features of Potter syndrome may be seen in newborns with posterior urethral valves, including intrauterine growth deficiency, pulmonary hypoplasia, limb positioning defects (e.g., talipes equinovarus), and the characteristic Potter facies. All are thought to be as a result of a deficiency of amniotic fluid and subsequent fetal compression. The incidence of other organ system anomalies not directly attributable to urethral obstruction is low (93). A palpably enlarged bladder, urinary tract infection, ascites, pulmonary difficulties, such as isolated pneumothorax, failure to thrive, or gastrointestinal disturbances may lead to investigation. A strong urinary stream does not preclude the diagnosis of posterior urethral obstruction (94). Pulmonary hypoplasia will present with respiratory distress, especially with spontaneous pneumothorax or pneumomediastinum, which is an unusual but important symptom of valves in newborns. Any full-term boy with respiratory distress should be suspect for a renal problem. Hydronephrosis is present in 90% of infants with valves (94).

Boys who present with posterior urethral valves in infancy have a poorer prognosis than children who present symptomatically at an older age, especially if serum creatinine levels are higher than 0.8 mg% or 1.0 mg% at 1 month after treatment of the valves. Presumably, this is because there is a high incidence of renal dysplasia associated with this type of presentation.

Urinary ascites is a less common presentation for children with posterior urethral valves (95). The presence of ascitic fluid in a newborn infant should prompt investigation of the urinary tract, because urinary ascites is responsible for one-third of all cases of neonatal ascites (96). Ascites is rarely as a result of frank perforation of the urinary tract (97); most often it is as a result of leakage of urine through the renal fornices and transudation of fluid across the peritoneal membrane into the peritoneal cavity (98). The ascitic fluid usually has a chemical content equivalent to that of serum, because the peritoneal membrane has passively dialyzed the high urea and creatinine content of urine into the vascular system. These children may not have marked hydronephrosis because the urinary tract has been decompressed by leakage of urine (98). These boys often present as extremely ill infants, but occasionally appear to be initially healthy except for

P.1081

abdominal distention. Their prognosis regarding renal preservation often is better than that of a child who does not present with urinary ascites, presumably because the leakage of urine from the distended system protects the upper urinary tract from the ravages of high intraluminal pressure (98). Occasionally, a localized retroperitoneal urinoma will form. The diagnosis of urinary ascites usually is made clinically, and confirmed by ultrasound examination or a plain radiograph of the abdomen demonstrating bowel displaced to the central abdomen and a ground-glass appearance of the remainder of the abdomen.

Twenty-five to 50% of patients with posterior urethral valves have vesicoureteral reflux at presentation (10,99). In one-half of cases, the reflux is bilateral. When there is massive unilateral vesicoureteral reflux associated with posterior urethral valves, the kidney on the refluxing side often is dysplastic and does not function at presentation or subsequently. This is the so-called VURD syndrome (valves, unilateral reflux, and dysplasia). VURD syndrome was initially thought to have a protective effect on the nonrefluxing kidney, but recent long term follow up of some patients with VURD have found that only 25% of the boys between ages 5 and 8 years had normal renal function (100). Marked hydronephrosis without vesicoureteral reflux usually carries a better prognosis for long-term renal function than does the presence of bilateral vesicoureteral reflux. In patients with posterior urethral valves, if reflux is present, it will resolve with relief of obstruction in one-third to one-half of cases (99).

Obstructive uropathy will be suggested on ultrasonography by findings such as bilateral hydronephrosis or by a distended, thick-walled bladder. Patients with posterior urethral valves often have a dilated and elongated posterior urethra that can be imaged sonographically and has been termed the keyhole bladder. Perirenal urinoma or ascites also can be detected.

The single most important study in the diagnosis of infravesical obstruction is the voiding cystourethrogram. An adequate study requires complete visualization of the urethra from the bladder neck to the meatus and oblique and lateral projections of the urethra during voiding without a catheter in the urethra, because an indwelling catheter may obscure the lesion.

Posterior urethral valves appear as a sharply defined transverse or oblique lucency, with proximal urethral elongation and distention and diminution of flow distal to the valve. The bladder neck may be secondarily thickened and collar-like. The bladder usually is trabeculated with saccules or diverticula, especially paraurethral diverticula (Fig. 43-19). Vesicoureteral reflux is often present at diagnosis, and the refluxing ureters frequently are grossly dilated and tortuous.

Functional imaging studies of the upper urinary tracts will determine the degree of upper tract damage produced by lower tract obstruction. Historically, intravenous urography has been used routinely in upper tract imaging but may be inconclusive, especially if renal function is poor. If function is sufficient for radiographic visualization and if delayed radiographs are obtained, marked hydroureteronephrosis should be evident. Delayed filling, visualizing a poorly functioning renal unit, may be secondary to vesicoureteral reflux rather than evidence of renal function. In the newborn or azotemic infant in whom obstruction is suspected, a radionuclide renal scan usually provides more information than excretory urography. A scan allows estimation of differential renal function. Scintigraphy also is safer than excretory urography because it eliminates the need for iodinated contrast agents, which have a risk for associated morbidity.

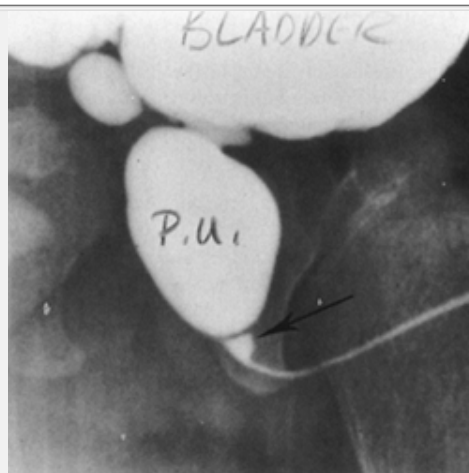

Figure 43-19 Voiding cystourethrogram in a newborn boy with posterior urethral valve (arrow). The prostatic urethra (PU) is dilated, and the bladder is trabeculated with multiple diverticula (upper left).

When these infants first present, resuscitative measures may be necessary to treat associated urinary infection, replace fluid and electrolytes, and, most important, drain the urinary tract. A small intraurethral catheter (e.g., a feeding tube) often will suffice to drain the urinary tract for a few days. Once the child is stable, the valves must be either transurethrally resected primarily or the urinary tract should be drained for a prolonged period using a cutaneous vesicostomy. Many of these infants are anticipated in advance because of suggestive antenatal imaging; they can be followed closely immediately after birth and may not require resuscitative measures, because the child generally is evaluated almost immediately after birth.

The long-term outlook for infants who present with posterior urethral valves is only fair, because approximately 50% of boys who present with posterior urethral valves eventually will progress to renal failure and transplantation despite treatment (101). This does not mean that a fatalistic attitude must be adopted, but, nonetheless, expectations must be realistic. If the serum creatinine

P.1082

is normal at 2 years of age, the prognosis for long-term normal renal function is good but not perfect (102). In a long-term follow-up of 11 to 22 years of children with urethral valves, one-third had poor renal function: 10% who survived childhood had died of renal failure; 21% had end-stage renal disease or chronic renal failure; and 46% had diurnal enuresis. Diurnal enuresis increased the likelihood that there would be progression to renal failure (103).

In utero intervention, with vesicoamniotic shunts or primary fetal endoscopic ablation of valves, has not improved survival or renal function in this group of patients; many expire before delivery as a result of premature rupture of membranes or sepsis, and many of those who survive go on to develop chronic renal failure and renal transplantation (3,4,5,104).

Renal Tumors

Fortunately, tumors of the urinary tract are rare in infancy and those that do occur tend to exhibit a benign behavior. Variants of Wilms' tumor can be seen in the neonatal period and include mesoblastic nephroma (105), nephroblastomatosis (106), and benign cystic nephroma (107). With the advent of frequent in utero ultrasonographic screening, many of these lesions are found as abnormally large kidneys or kidneys with a recognizable mass on ultrasound. Otherwise, they usually will present in infancy as a palpable flank mass and occasionally can produce hypertension (108).

Mesoblastic nephroma is the most frequent of these tumors. This recognized variant of Wilms' tumor behaves in an almost uniformly benign manner (105). Histo-logically, mesoblastic nephroma is composed largely of mesenchymal stroma with spindle-shaped fibrous or leiomyomatous cells. Ultrasonography will demonstrate a solid intrarenal mass. Computerized tomography will better delineate the mass characteristics, and may demonstrate tumor extension outside the renal bed. Although rarely obtained, radionuclide scans will show the mass as nonfunctioning tissue, and intravenous urography will reveal distortion of the calyceal architecture by the tumor. Ultrasound and computerized tomography will demonstrate the tissue characteristics more clearly than scintigraphy or pyelography. MRI with gadolinium may be necessary to better delineate subtle lesions. Nephrectomy is curative, but there have been a few reports of local recurrence and rare reports of distant

metastasis (105). Chemotherapy and radiation therapy are not necessary adjuncts to therapy.

Nephroblastomatosis can be diffuse or nodular (106). Diffuse nephroblastomatosis usually presents as marked enlargement of both kidneys. The kidneys are grossly enlarged and have a whitish hue. Biopsy reveals primitive metanephric epithelium resembling that seen in Wilms' tumor. This lesion usually responds to chemotherapy (i.e., actinomycin D). Nodular renal blastoma consists of microscopic foci of primitive metanephric epithelium and often is an incidental autopsy finding in infants. It is thought that Wilms' tumor may, in some instances, arise from foci of nodular renal blastema.

Benign cystic nephroma occasionally is classified with the cystic diseases, but more properly belongs with the renal tumors because elements of Wilms' tumor may be found in the septa between the cysts (109). As with the other tumors, patients with cystic nephroma present with a palpable mass. Ultrasonography will identify the mass as multiple cysts or as complex (i.e., mixed cystic and solid). Although enucleation of the mass is a theoretical therapeutic option, nephrectomy usually is the treatment of choice. Despite the presence of Wilms' tumor elements in the septa, chemotherapy is not necessary for cure.

Renal Vein Thrombosis

Another renal lesion that has a definite predilection for the neonatal period is renal vein thrombosis (110). This problem usually results from hemoconcentration secondary to dehydration, and is often seen in infants of diabetic mothers. It also may be seen in infants with cyanotic congenital heart disease, sickle-cell disease, or perinatal stress or sepsis. Sludging in the intrarenal venules occurs, with subsequent thrombosis. The thrombus then tends to propagate centrally. The infants present with a palpable mass, hematuria, albuminuria, and thrombocytopenia. If both kidneys are involved, the infant will become uremic. Treatment is supportive and involves correction of the underlying problems. Surgery (i.e., nephrectomy) was once thought essential to survival; however, it is recognized that nephrectomy is unnecessary and that, if collateral circulation is present, there may be renal recovery. Thrombectomy is of no help because the problem is in the peripheral rather than the central veins. Thrombolytic agents developed for clot lysis may be considered for treatment of bilateral renal vein thrombosis.

Adrenal Hemorrhage

At times, either spontaneously or in association with renal vein thrombosis, there may be hemorrhage into the adrenal gland (111). Hemorrhage also can occur following a traumatic delivery, sepsis, or asphyxia. The infant may present with icterus (from absorption of hemoglobin) and an abdominal mass. Ultrasonography will demonstrate a sonolucent or solid mass above the kidney. This may also be detected with antenatal ultrasonography as an adrenal mass. It must be followed postnatally to differentiate it from a congenital neuroblastoma or neural crest tumor (CT may be required to differentiate an adrenal tumor from an adrenal hemorrhage). Over the course of a few weeks, the mass, if as a result of adrenal hemorrhage, will be reabsorbed or, rarely, will form an adrenal pseudocyst (112). If the latter occurs, percutaneous drainage is the preferred mode of therapy. Otherwise, no therapy is necessary. Adrenal calcification often is seen several weeks after an adrenal hemorrhage. Adrenal hemorrhage can occur

P.1083

bilaterally in 10% of patients, and it occurs more commonly on the right side.

Prenatal Ultrasonography

The advent of high-resolution, real-time ultrasonography has allowed the antenatal diagnosis of many anomalies of the urinary tract. It has become apparent with time, however, that diagnostic accuracy in utero is not complete and that the natural history of some lesions is not as clear-cut as once thought (113). The hope that antenatal intervention might result in improvement in outcome has proven ill-founded (114). The maternal risk of morbidity with intervention has been reported to be as high as 4% to 5% (115), and there are no clear-cut examples of improvement in fetal outcome as a result of such interventions (10,116). Studies of the results of postnatal treatment after antenatal identification of lesions have, however, clearly demonstrated improved outcome (115). There seems to be no advantage to early delivery; thus, the timing of delivery in fetuses with hydronephrosis generally is determined best by obstetric factors rather than fetal concerns (117).

As stated earlier, the fetal kidneys can be identified in the early part of the second trimester of pregnancy. Dilation of the renal pelvis and calices in a nonduplex system, without identification of a dilated ureter, suggests

the presence of ureteropelvic obstruction. It has become apparent that some instances of hydronephrosis resolve spontaneously and completely in utero, whereas most that are present at birth will stabilize or improve with time. Conversely, some seem to dilate progressively with time. Hence, not all dilations of the upper urinary tract are obstructive in nature (113). Most of those that are of significance prove to be secondary to narrowing at the ureteropelvic junction. In the hope of standardizing the descriptive terminology for the ultrasound findings with hydronephrosis, the Society for Fetal Urology has graded the severity of the hydronephrosis based on the extent of renal pelvis and calyceal dilatation and parenchymal thinning or atrophy (58).

In a duplicated system, there can be dilation of either the lower pole system or the upper pole system. Dilations of the lower pole system usually are as a result of ureteropelvic junction obstruction or to vesicoureteral reflux. Obstructions of the upper pole system usually are associated with hydroureter and often are accompanied by a ureterocele or an obstructed ectopic ureter. Solid intrarenal lesions most commonly are mesoblastic nephromas, with neuroblastoma occurring infrequently.

Ureteral dilation can, at times, be massive and may be confused with bowel on sonography; however, following the ureter from a dilated upper system down to the bladder usually will distinguish the dilated ureter from bowel because dilated ureters often do not demonstrate peristalsis. Although bilateral hydroureter may be associated with bilateral ureterovesical obstruction, it is more likely as a result of either high-grade vesicoureteral reflux, posterior urethral valves, or the prune-belly syndrome.

In a male fetus, a thick-walled, enlarged bladder often is secondary to posterior urethral valves or the prune-belly syndrome, especially if a keyhole posterior urethra is identified. In females, an enlarged bladder is more likely as a result of the megalocystis microcolon hypoperistalsis syndrome. Ureteroceles also can be identified by sonography in the bladder. No identifiable bladder on serial ultrasonography or on MRI imaging, suggests bilateral renal agenesis, bilateral single ureteral ectopy, or exstrophy of the bladder.

Lesions associated with hydronephrosis and normal amounts of amniotic fluid generally carry a good prognosis, whereas those associated with increased renal echogenicity and decreased amounts of amniotic fluid generally carry a poor prognosis for pulmonary maturation and renal function (118).

Abdominal Masses

The finding of an abdominal mass is not infrequent in the newborn nursery. An unselected series of infants in the newborn nursery revealed abdominal masses arising from the genitourinary tract in approximately 1 in every 500 admissions (119). It is quite clear from multiple reports that the urinary tract often is the source of a palpable abdominal mass in infants (120,121). In most reported series, approximately two-thirds of the infants presenting with an abdominal mass are found to have lesions in the urinary tract. In infancy, hydronephrosis and cystic kidneys are the most common lesions producing abdominal masses, whereas in older children tumors are more common (122). The obvious inference from these data is that ultrasonography, because the urinary tract is easily visualized, is the study most likely to identify the source of a palpable abdominal mass; frequently CT is required to better delineate solid abdominal masses. The physical and radiographic characteristics of the common abdominal masses of renal origin are listed in Table 43-2.

Hematuria

Hematuria in the infant can be a sign of renal vein thrombosis, acute tubular necrosis, renal calculi, urinary infection, or urinary tract obstruction (123). The presence of hematuria must be confirmed by examination of the urine, both chemically and microscopically. A positive chemical test may reflect hemoglobinuria, rather than hematuria, which implies the presence of cellular elements in the urine. Even more common than the presence of hematuria or hemoglobinuria, however, is concern about a red diaper in an infant. Two relatively common causes for red diapers are the presence of urates in the urine, giving a pink hue to the urine, especially in the diaper, and the growth of *Serratia* sp. on urine-soaked cloth diapers left standing. Obviously, these latter two situations are of no clinical consequence, but must be separated from true hematuria or hemoglobinuria in diagnostic considerations.

TABLE 43-2 ABDOMINAL MASSES OF RENAL ORIGIN

Mass	Texture	Renal Scan or Excretory Urogram	Ultrasonogram
Hydronephrosis	Smooth	Delayed drainage	Sonolucent
Multicystic kidney	Irregular	Nonfunction	Multiple large and small cysts (i.e., cystic dysplasia)
Polycystic kidney	Smooth (recessive); irregular or smooth (dominant)	Delayed function; distortion of collecting system Multiple large and small cysts (dominant)	Diffuse small cysts (recessive)
Tumor	Smooth	Distortion of collecting system	Solid
Renal vein thrombosis	Smooth	Poor function to nonfunction	Relatively normal renal architecture; enlarged kidney

P.1084

GENITAL ABNORMALITIES

Cryptorchidism

Undescended testes are a very common finding in the newborn period, affecting perhaps as many as 1 in every 50 newborn males (124). Most testes that are undescended at birth, however, will descend during the first 6 to 9 months of life, so that the incidence of cryptorchidism at 1 year of age is approximately 0.7% to 0.8%, which is exactly the same incidence that has been found in postpubertal males (124). The newborn examination is important in determining testicular position, because the cremasteric reflex at that time is weak to absent (125). If the testis is well descended in a newborn, it is unlikely that there will be problems with true cryptorchidism later in life. Optimal results from treatment of cryptorchidism are thought to be produced by interventions after the possibility of testicular descent has passed (i.e., beyond 6 months of age) and before adverse effects of testicular nondescent are seen histologically (i.e., approximately 1.5 to 2 years of age), hence before 18 months of age (126). Many children are now undergoing surgical treatment of cryptorchidism between 6 to 9 months old with good surgical and anesthetic results. There appears to be increased mobility of the cord structures at this age, even with very high inguinal or abdominal testes, which facilitates the relocation of the testis to the scrotum.

Penile Agenesis

Although many of the penile anomalies are common, some, such as agenesis of the penis, are rare, occurring in 1 in 10 to 30 million live births (Fig. 43-20). Penile agenesis suggests an early embryologic failure in the development of the genital tubercle. The urethra usually exits on the perineum or near the anal verge. Previously these children were raised as females, with castration and reconstruction of the external genitalia performed at an early age (127). Management of this and other previously sex reassigned conditions continues to be controversial, as some reports on long-term follow-up of these patients have called the practice of gender reassignment into question (74).

Penile Duplication

Penile duplication (i.e., true diphallia) is a rare anomaly that also may involve duplications of the urethra and bladder (Fig. 43-21) (128). Reconstruction of these anomalies involves complex decisions about functional capability of the urinary, genital, and gastrointestinal tracts, and appearance.

Microphallus

The boy born with an abnormally small phallus presents a true therapeutic dilemma. Most cases of microphallus are as a result of hypogonadism (128) and will respond to testosterone, but an occasional patient with microphallus has end-organ failure and will not respond to exogenous testosterone. It is notable that, despite the relatively common finding of microphallus in the newborn nursery, it is an extremely rare event to find an

adult with a phallus so small that it is incapable of sexual function.

The normal full-term newborn phallus measures approximately 3 to 3.5 cm in stretched length; the definition of microphallus requires a phallus that is less than 2.5 cm in stretched length, excluding ambiguous genitalia or the penis with hypospadias or chordee (129). To determine whether or not microphallus will respond to hormonal stimulation, 25 mg of testosterone enanthate is administered intramuscularly every 4 weeks for a total of 75 mg (see Chapter 39) (130). Some element of response usually is evident after the first dose. In most instances, after the course is completed, the child has a relatively normal phallus. If there is no response to testosterone, gender reassignment can be considered, but male gender assignment may still be preferable in most infants with micropenis (131).

In a recent long term review of patients with micropenis raised as either male or female, then reassessed as adults, half of the men were dissatisfied with their genitalia but generally satisfied with their gender of rearing, whereas most who were raised as women (80%) were

P.1085

dissatisfied with their genitalia and required several surgeries to gender convert to female appearance. Interestingly, those raised as female were also satisfied with their sex of rearing. (131)

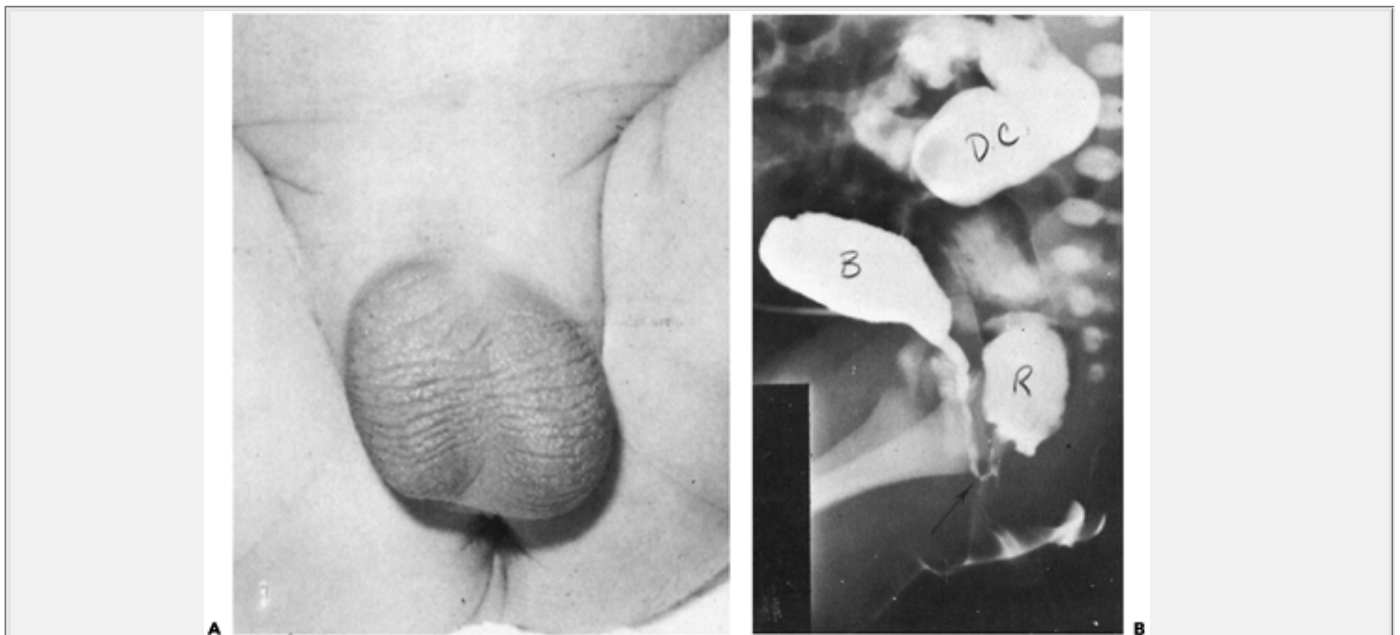

Figure 43-20 A: Genetic boy born with complete penile agenesis. **B:** An antegrade cystourethrogram in a genetic boy with penile agenesis. The bladder is full (B), and there is communication between the urethra and rectum (arrow). The rectum (R) and descending colon (DC) are filled with voided contrast material.

Hypospadias

The term hypospadias, by definition, refers to the abnormal location of the urethral meatus somewhere ventral to the normal glanular tip (Fig. 43-22); however, the term actually encompasses a complex that includes chordee (i.e., a ventral curvature of the penis on erection) and an abnormality of the prepuce or torsion of the penis. Although it is traditional in some circles to categorize hypospadias by degrees (i.e., first, second, and third), it is more helpful to describe hypospadias by the location of the meatus and the presence or absence of chordee (Fig. 43-23). At times, the hypospadiac meatus is quite stenotic and can be very difficult to see, especially in the newborn.

It has become obvious that the sibling of a child with hypospadias has an increased (14%) chance of having hypospadias (132). It is thought that hypospadias is inherited as a multifactorial problem. The historic incidence of hypospadias is 1 in 300 live births. The apparent incidence of hypospadias, particularly more proximally located hypospadias, appears to be increasing over the past few decades in the United States and some Scandinavian countries but it does not appear to have an increased occurrence in all countries (133,134). There has also been a reported 5-fold increased incidence of hypospadias in males conceived by in vitro fertilization; this may be as a result of maternal progesterone use but a definite etiology has not been determined (135). It once was thought that there might be associated abnormalities of the upper urinary tract in children with

hypospadias, but critical analysis of series of children with hypospadias who have been uniformly investigated reveals that there is no increased incidence of upper tract abnormalities when children with hypospadias are compared to those of the general population (136). Routine karyotype evaluation of patients with hypospadias and cryptorchidism does not seem warranted, except in more severe cases of perineal hypospadias or ambiguous genitalia (137).

Most forms of hypospadias can be surgically corrected and, if the patient's health warrants, it is preferable to perform this surgery in the first year of life, typically after 6 months of age. Circumcision should be delayed in children with hypospadias as the foreskin is commonly used for the repair of these problems. Physical findings suggesting hypospadias are an abnormality of the foreskin, an incomplete foreskin, and penile torsion or chordee. Whenever these abnormalities are noted, circumcision should be

P.1086

delayed until the child can be assessed by a hypospadiologist who can determine whether the foreskin will be necessary for the repair or if a repair is even necessary.

Figure 43-21 Duplication of the glans in a 2-year-old boy. From Kossow JH, Morales PA. Duplication of bladder and urethra and associated anomalies. *Urology* 1973;1:71, with permission.

Epispadias

Epispadias usually is associated with exstrophy, but occasionally appears as an isolated defect (Fig. 43-24). The incidence of isolated epispadias previously reported as 1 in 100,000 live births has now been estimated as occurring in 1 in 40,000 live births (138). The repair of this lesion is moderately difficult. The more severe degrees of epispadias usually are associated with urinary incontinence and are more common than those associated with continence. In incontinent cases, the bladder neck must be reconstructed. Children with epispadias tend to have a relatively short

P.1087

phallus and, although attempts at lengthening the phallus are somewhat helpful, this aspect of the problem sometimes defies correction.

Figure 43-22 The hypospadiac meatal position (arrow) is demonstrated by pulling the ventral shaft of skin away from the penis.

Figure 43-23 Classification of hypospadias based on anatomic location of the urethral meatus. The associated chordee is best described in terms of its severity (mild, moderate, or severe). Figure 43-24 Isolated epispadias without exstrophy. The bladder neck is intact in this child, who has good but not excellent urinary continence. Note also the incomplete duplication of glans.

Urethral Duplication

Urethral duplication is an uncommon anomaly, more commonly noted in boys, which can present either as a

partial or complete duplication. When there is a duplication it is more common that the urethras are oriented in an anteroposterior plane, rather than lying side by side. The more ventral urethra usually is the functional urethra, and the dorsal urethra often is stenotic and unusable (139). Repair of these anomalies must be tailored to the individual situation. Generally, duplication of the urethra in the female is seen with bladder duplication and is oriented side by side. Urethral duplication in a female with a dorsal urethra and a secondary vaginal urethra is very rare, generally presenting with urinary tract infections; the functioning female urethra is the more ventral urethral structure just as in the male (140).

Another variant of a duplicated urethra, or possibly an exstrophy variant, is the congenital prepubic sinus, which can occur in males or females as a small orifice located just above the pubis. The tract generally is removed surgically and can be traced down to the bladder or urethra in those cases described (141).

Ambiguous Genitalia

Ambiguity of the external genitalia is a quandary encountered with some regularity in the newborn nursery (see Chapter 39). These patients often pose difficult diagnostic and therapeutic challenges. It is important to establish a diagnosis rapidly. On physical examination, the presence or absence of palpable gonads is very helpful. If a gonad is palpably present, it almost certainly is a testis. Hence, bilaterally palpable gonads suggest very strongly that the patient is a genetic male. If a gonad is palpable only unilaterally, there probably is a testis on that side. There could conceivably be a normal testis, a streak gonad, or an ovary on the other side. If no testes are palpable, the patient could be an XX female, an XY male with abdominal testes or mixed gonadal dysgenesis, or a true hermaphrodite.

Chromosomal gender is established by karyotype. An XY male who is undervirilized could have Klinefelter syndrome, true hermaphroditism, 5 α -reductase deficiency, hypopituitarism, 17-hydroxylase deficiency, or 3 β -hydroxy steroid deficiency.

If the patient is an XX female, ambiguity could be produced by excessive maternal androgens or the adrenogenital syndrome, which is most commonly caused by a 21-hydroxylase deficiency. This latter must be considered in any phenotypically male patient with nonpalpable gonads, even if the genitalia appear completely masculinized, to avoid an Addisonian crisis in a patient with a salt-losing adrenogenital syndrome (Fig. 43-25).

Gender assignment (i.e., gender of rearing) should be accomplished as soon as possible after appropriate endocrinologic, karyotypic and anatomic evaluation, to assure that life threatening conditions do not occur and to avoid excessive parental anxiety. A team approach with neonatology, endocrinology, psychology, genetics and pediatric urology or surgery input will help the parents make as informed selection of the sex of rearing as possible with the information available at the time of review. Anxiety produced by indecision over gender assignment is exponentially increased by changes in gender assignment. The elements that should be considered are potential fertility, capacity for future psychosexual function, and the possibility for satisfactory reconstruction. This last factor mandates that an experienced surgeon participate in the decision regarding gender of rearing so that the parents will understand the surgical options, potential complications or multiplicity of procedures and lifelong medical treatments that might be required for either sex for chosen gender assignment. Psychological implications of reports of patient dissatisfaction with gender reassignment are that these feelings are typically expressed most strongly in adolescence and adulthood. Long-term surveys of 46 XY adults with ambiguous genitalia or micropenis at presentation have found that most individuals are rather satisfied with their sex of rearing either as male or female but each group has different psychosexual or surgical experiences that has affected their overall satisfaction with the appearance of their external genitalia. In a recent review, 46 XY individuals with newborn ambiguous genitalia who were raised as females generally

P.1088

had more acceptable appearing female genitalia and required fewer surgical procedures to achieve that appearance than those 46 XY individuals raised as males. The opposite case was found when surveying 46 XY micropenis patients and their external genitalia appearance and surgical experience (131,142,143).

Unfortunately, the choice of appropriate gender of rearing is made more difficult as more information is available with research in this area. Ongoing human and animal study may shed some light and facilitate decision making for gender assignment (144).

Figure 43-25 Voiding cystourethrogram in a genetic girl who was totally masculinized by adrenal hyperplasia. **A:** Utriculus masculinus (arrow), as would normally be expected in a male. **B:** Retrograde vaginohistogram reveals a normal vagina (v) and uterus (u), and an overflow of contrast into the urinary bladder (b).

Development of the Prepuce and Circumcision

The prepuce forms as a roll of epithelium that fuses ventrally at the frenulum. If there is failure of urethral development, this will interfere with development of the prepuce, so that abnormalities of the prepuce are very suggestive of other penile abnormalities (e.g., hypospadias, chordee, epispadias). Once the prepuce has covered the glans, its inner epithelial surface fuses with the epithelium of the glans and does not separate from it until some time in childhood (145). It is unusual for a male to have a completely retractable foreskin at birth. In the process of separation of the inner epithelial layer from the glans, cystic spaces form between the two layers and sometimes are filled with desquamated epithelial cells that form white, pearl-like beads or infantile smegma that can be seen through the overlying skin. Occasionally areas of infantile smegma may become inflamed or infected, although most drain spontaneously.

Because circumcision is so common in the United States, the natural history of preputial development has been lost, and one must depend on observations made in countries in which circumcision usually is not practiced. The foreskin in the newborn normally is not retractable. In a large series from Denmark, the foreskin was not completely retractable in most boys until puberty (146). Phimosis is defined as the inability to retract the foreskin. In early childhood, this is the normal physiologic state. Although by definition this may be phimosis, most children will develop normally and will not have problems as a result of the temporary inability to retract the foreskin. Forcible retraction of the prepuce tends to produce tears in the preputial orifice, resulting in scarring that may lead to pathologic phimosis.

Circumcision is performed for a multitude of reasons. Medically, carcinoma of the penis, pathologic phimosis, paraphimosis, some sexually transmitted diseases, and some urinary infections in infancy may be prevented by circumcision (147). If the overall population is considered on a public health or economic basis, the advantages to the individual patient perhaps may be mitigated by the cost of circumcising the entire male population to prevent problems in a minority. The cost of circumcision is further increased by the routine use of local anesthesia (see Chapter 57).

The benefits of circumcision are occasionally offset by complications that may arise from the procedure, just as they may arise after any other surgical procedure (148). The most common complications seen are hemorrhage and wound infection. Both are generally easily treated, minor annoyances. Serious complications including sepsis, amputation of part of the glans, loss of the entire penis, urethrocutaneous fistulas, bands of scar between the shaft and the glans (Fig. 43-26), denudation of the skin of the entire shaft of the penis, recurrent phimosis (Fig. 43-27), and urethral fistulas (Fig. 43-28) occur rarely (149). At times, parents are very unhappy with the cosmetic appearance of the penis even though the functional result is good.

Figure 43-26 Adhesions (arrows) between the distal foreskin and glans penis before (A) and after (B) surgical transection.

P.1089

Testicular Torsion

Torsion of the testis in the newborn usually presents as a firm, slightly enlarged testis. There rarely is much abnormality of the overlying skin. Neonatal torsion seems to be painless, and actually may be an antenatal event in as many as 72% of the cases (150,151). Twenty-eight percent of the neonatal cases develop in the postnatal period. Exploration of the testis that has undergone torsion in the newborn period probably is of limited value, because it generally is too late for testicular salvage (152). Ten percent of neonatal torsions are bilateral; some are asynchronous, and some are of the intravaginal rather than the extravaginal type. Exploration for neonatal torsion is warranted if the changes are found shortly after birth and performed expeditiously (less than 6 hours from the time of change in testicular examination). In one series, using an inguinal approach, up to 20% of testes torsed acutely in the neonatal period were salvaged (153); this may overrepresent actual salvage rates in the newborn time period. In the case of an obviously infarcted testis, contralateral exploration and testicular fixation when the infant is stable may prevent contralateral torsion (154).

Figure 43-27 In this patient with circumcision injury, excessive removal of skin from the shaft resulted in skin regeneration over the retracted glans, obscuring the glans. The appearance is that of amputation of the glans. From Belman AB. The penis. *Urol Clin North Am* 1978;5:17, with permission.

Testicular Tumors

Tumors of the testis occasionally present at birth or in early infancy (155). Teratomas of the testis, occurring in 19.7% of cases registered in the Prepubertal Testicular Tumor Registry, are benign and are treated by excision (156). On some occasions, this can be excision of the tumor only, leaving the remainder of the testis in situ; orchiectomy is necessary if the entire testis has been replaced by teratoma. A common tumor presenting in the

newborn testis is one of the gonadal stromal tumors, with Sertoli cell tumors being the most common (156,157). Although these tumors histologically may appear malignant, in infancy they invariably exhibit a benign behavior, and orchiectomy is curative. This is not the case when gonadal stromal tumors appear in later childhood because malignant behavior has been documented.

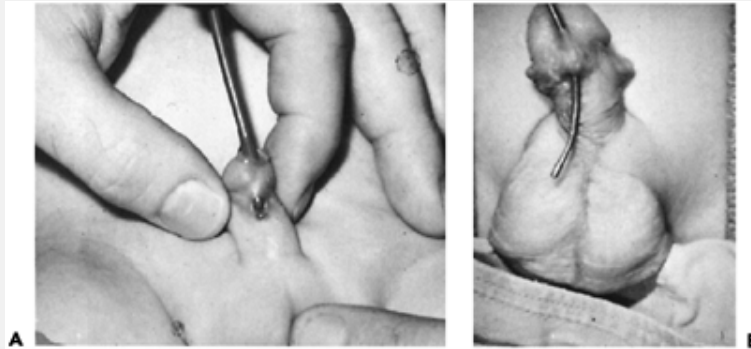

Figure 43-28 A, B: Two examples of circumcision injuries with secondary coronal fistulas. From Belman AB. The penis. *Urol Clin North Am* 1978; 5:17, with permission.

P.1090

Yolk sac tumors occur in infancy; approximately 30% of reported yolk sac tumors of the testis are identified in infancy. These malignant tumors are best treated by radical orchiectomy. As long as there is no evidence of metastatic disease, adjunctive chemotherapy, node dissection, or radiation therapy is thought to be unwarranted (158). α -fetoprotein (AFP) levels are elevated in patients with yolk sac tumors, AFP levels are normally elevated in infancy but should not be elevated in adults. Age-adjusted AFP levels will improve the usefulness of AFP measurements as a tumor marker in infants (159).

URINARY TRACT INFECTION

Infancy is one period of life during which there is reversal in the gender incidence of bacteruria. The overall incidence of neonatal urinary tract infections is somewhere between 1.5 to 5 cases per 1,000 live births. The male-to-female ratio is somewhere between 3:1 and 5:1 (160), whereas later in childhood and until later adult life, there is a female preponderance of patients with urinary infections. It has been documented that uncircumcised males are more likely to have urinary infections than are circumcised males (161). The incidence of urinary infection in uncircumcised males approximates 1 per 100. At times, the source of the urinary infection is hematogenous rather than ascending (162).

It is imperative that there be radiographic evaluation of any newborn with culture documented bacteruria. Vesicoureteral reflux is present in approximately one-half of those evaluated, and obstructive uropathy is not an unusual finding (163). Therefore, at a minimum, urinary tract evaluation with voiding cystourethrography and ultrasonography is indicated.

UROLOGIC ASPECTS OF MYELODYSPLASIA

Almost any child with myelodysplasia will have involvement of the urinary tract. This may be of little consequence in the newborn period, but it is essential that the patient be appropriately evaluated shortly after birth and that a surveillance program be instituted. It was thought that hydronephrosis was found at birth, in roughly 10% of children with myelodysplasia, but studies have suggested that some of the hydronephrosis formerly detected actually was a result of spinal shock after closure of the neurologic lesion and in many children resolved spontaneously (164). Although manual expression of the bladder (Credé maneuver) has been used to empty the bladders of children with myelodysplasia, it is not recommended because the intravesical pressures that are produced can be quite high, which can lead to upper tract deterioration, especially in patients with associated vesicoureteral reflux (165). Intermittent catheterization can be used successfully in both male and female infants if needed, and, in which these procedures are not successful or acceptable and bladder emptying is thought to be necessary, temporary cutaneous vesicostomy is a proven management modality (166). Children

with myelodysplasia, if at all possible, should be managed by a multidisciplinary team that includes neurologists, neurosurgeons, urologists, and orthopedic surgeons. With this approach, these children have an excellent chance of survival and development as productive citizens in modern society. In utero closure of the meningomyelocele defect has been done in several U.S. medical centers with mixed results (167).

PRUNE-BELLY SYNDROME

This lesion is a spectrum of abnormalities characterized by the triad of abdominal wall deficiency, hydronephrosis, and, in males, cryptorchidism. It is the abdominal wall defect that gives the characteristic appearance leading to its name. The incidence of this lesion has been estimated to be 1 per 35,000 to 50,000 live births (10,168). Males are affected ten times more frequently than females (169). There is no clear-cut evidence that this is an inherited disorder. Theories of embryogenesis include obstructive uropathy and mesenchymal dysplasia (170).

P.1091

There can be massive hydroureteronephrosis and the bladder often is very dilated. Because there is prostatic hypoplasia with dilation of the prostatic urethra, antenatal studies may not differentiate these patients from boys with posterior urethral valves. The kidneys often are dysplastic, and this dysplasia will determine prognosis (171). Although some affected children die in infancy, many today will survive. Reconstruction of the urinary tract, orchiopexy, and repair of the abdominal wall defect often are helpful in altering the outlook for these children (172).

UROLOGIC IMPLICATIONS OF IMPERFORATE ANUS

Because of the intimate relationships of the lower urinary and gastrointestinal tract development, the urinary tract will commonly be affected in a high proportion of children with imperforate anus; the higher the lesion, the greater the chance of urinary involvement (173). It is for this reason that all newborns with imperforate anus should be screened for urinary tract abnormalities with ultrasonography and a voiding cystourethrogram. Often there is a constellation of other associated anomalies which has come to be known as the VACTERL association (vertebral, anorectal, cardiac, tracheoesophageal, renal, radial, and limb abnormalities). Because three elements qualify as the association, when two elements are present, a third should be sought. This is a nongenetic, sporadically occurring lesion.

FEMALE GENITAL ABNORMALITIES

The female reproductive system is formed by the Müllerian or paramesonephric ducts. The Müllerian system differentiates into a female organ system when Müllerian inhibitory substance is absent. During the sixth to eighth week of gestation, the Müllerian ducts will form lateral to the wolffian ducts, cross medially, and fuse in the midline incorporating the urogenital (UG) sinus to form the uterovaginal canal by the tenth week of gestation. The fallopian tubes develop from the lateral ends of the Müllerian ducts. The vagina develops from the fused Müllerian ducts and the UG sinus. It is believed that the upper four-fifths of the vagina is Müllerian derived and the lower fifth is from the UG sinus. Vaginal formation is completed by the fifth month of gestation.

The external genitalia differentiates *in utero* during the 12th to 16th weeks. Passive development of the genital tubercle into the clitoris, the urethral folds into the labia minora, and the genital swellings into the labia majora occurs in the absence of fetal androgens.

Vaginal Agenesis

Vaginal agenesis (Meyer-Rokitansky-Kuster-Hauser Syndrome) occurs when the vaginal plate does not canalize. The incidence is reported as 1 in 4,000 to 5,000 live female births (174). The patients generally are 46XX females presenting with primary amenorrhea but having normal secondary female sex features. The ovaries and the external genitalia generally are normal, but the vaginal plate is not canalized and the uterus may be rudimentary. It is common to have associated genitourinary anomalies; renal anomalies are seen in 34% of the patients (175). Renal agenesis and ectopia are the most common findings. Patients also may have skeletal anomalies, particularly in the spine and ribs. Combinations of these anomalies has been termed as the MURCS association (Müllerian duct aplasia, renal aplasia, and cervicothoracic somite malformations). Surgical correction is individualized based on the location and development of the uterine and vaginal remnants (175).

Hydrocolpos and Hydrometrocolpos

If the vaginal canalization is incomplete, the hymen may be imperforate or a high transverse vaginal septum may be present. The infant may then present with distention of the vagina with glandular secretions stimulated by maternal estrogens, known as hydrocolpos, or distention of the vagina and the uterus with the same secretions, known as hydrometrocolpos. With current antenatal ultrasonography, this can be found prior to delivery, but many infants still present with an abdominal mass, possible urinary obstruction, and a bulging introital mass. Ultrasound imaging may demonstrate a fluid-filled or mixed density fluid-filled pelvis mass, and possibly a distended bladder with or without hydroureteronephrosis, if there is secondary urinary obstruction (Fig. 43-29).

Definitive treatment depends on the extent of vaginal canalization; this can be a simple hymenotomy or vaginoplasty or vaginal pull-through if there is a high septal defect. CT or MRI imaging with T2 weighted imaging may better delineate the remaining vaginal plate but occasionally, needle aspiration of the fluid with radiographic contrast injection and imaging is necessary to delineate the length of the vaginal plate.

Figure 43-29 Newborn female with imperforate hymen.

P.1092

Duplication or Fusion Anomalies

Duplication of the uterus and vagina occur if fusion of the Müllerian ducts is incomplete. The child may have two uteri, one or two cervixes with either a single vagina or two separate vaginas, or one or both vaginas may be open to the perineum. These malformations can be identified early in life by ultrasonography, but frequently will not present until adolescence. The typical presentation is a menstruating female having cyclic pelvic pain associated with menses and an enlarging pelvic mass. Treating vaginal duplication usually only requires incising the longitudinal vaginal septum. Successful pregnancies have been reported in some women with duplicated uteri.

Urogenital Sinus and Cloacal Abnormalities

Having a common urogenital sinus is a normal part of development in both sexes. If Müllerian ductal development arrests during the first trimester, a persistent urovaginal confluence or common UG sinus will be found at birth. Varying locations for the junction of the vagina and urethra occur, depending on the degree of vaginal differentiation. The earlier the arrest occurs, the higher the connection will be located. The anus may be located in its normal location or may be more anteriorly placed. These infants are found to have a common introital opening for urethra and vagina and a second opening for the anus. A flush genitogram will delineate the length of the common urogenital channel and the connections of the urethra and vagina. This is performed by placing a feeding tube or urethral catheter just inside the common opening and injecting contrast material in a retrograde fashion. The type of surgical reconstruction required is determined by the length of the common channel and the location of the urethral vaginal junction. This corrective surgery can be performed during the first year of life in most lesions (175). Total urogenital mobilization can be used to bring a high junction lesion to the perineum, generally without incontinence (176,177).

Figure 43-30 A: Newborn female with cloacal anomaly. Note single perineal orifice. **B:** Flush genitogram demonstrating a high confluence of the bladder, vagina, and bowel into a common cloaca.

A combined urogenital sinus and anorectal malformation is termed a cloacal anomaly. By 4 to 6 weeks of gestation, the urorectal septum should divide the common allantoic-hindgut confluence. If this does not occur, a common cloaca will be present at birth. Because of the imperforate anus, these infants have abdominal distention and a single perineal opening. Delineating the anatomy is important for appropriate surgical management. This generally requires a combined approach with pediatric general surgery and urology input. These infants typically will require diverting colostomy as initial treatment. A flush genitogram can define the urethral, vaginal, and bowel junctions to better plan ultimate reconstruction with bowel pull-through, formal vaginoplasty, and urethroplasty or a simple cutback vaginoplasty. Complete reconstruction can be contemplated during infancy and may be easier near 1 year of age. Delaying reconstruction until late childhood or puberty generally is more difficult, as a result of previous scarring from anal pull-through and the deeper, less mobile pelvis present in older girls (Fig. 43-30).

Ovarian Cysts

Ovarian cysts develop in the presence of hormonal stimulation and more commonly are seen after puberty. The fetal ovary is stimulated by fetal gonadotrophins, maternal estrogens, and placental chorionic gonadotrophin and may develop cysts during fetal development and infancy. Ovarian cysts are being found more frequently with the advent of prenatal ultrasonographic imaging. More than 250 cysts have been reported since 1975 (178). Many of these infants underwent surgical therapy with oophorectomy, cystectomy, or cyst aspiration because of the risk of ovarian torsion as a result of the cyst increasing the ovarian size and concerns about the occasional ovarian tumor. If discovered in utero by ultrasonography, the cysts can be followed until delivery. Vaginal delivery is possible in most cases, with cesarean section being reserved for very large cysts. Postnatally, small ovarian cysts (<4 cm) can be

P.1093

followed with serial ultrasonography, because most cysts will regress in the first 3 to 4 months of life. Larger cysts can be followed for involution or can be aspirated to provide conservation of the ovary. Laparoscopic or open surgery should be contemplated if there are complex ovarian cysts, symptomatic cysts, or cysts recur after aspiration. Conserving ovarian tissue by removing or unroofing the cyst is generally how most of these lesions are handled.

Introital Masses

Introital masses generally are determined at the first examination of the infant. The differential diagnosis for introital masses in female infants include imperforate hymen, prolapsing ureterocele, and Skene's or Gartner's cysts. Prolapsing ureteroceles may extrude through the urethral meatus. Paraurethral cysts (Skene's or Gartner's) also are present in newborn girls, and present with lateral displacement of the urethral meatus. These cysts involute or rupture spontaneously fairly quickly, so treatment usually is unnecessary.

ACKNOWLEDGMENT

The authors would like to thank A. Barry Belman for his generosity in allowing the republication of illustrations from his chapter in the third edition of this book.

Chapter 44

Surgical Care of Conditions Presenting in the Newborn

Gary E. Hartman

Michael J. Boyajian

Sukgi S. Choi

Martin R. Eichelberger

David M. Powell

Successful management of newborns with surgical conditions requires close cooperation among neonatologist, surgeon, anesthesiologist, and radiologist. The fragile nature and limited reserve of these infants are superimposed on the stress of the surgical condition and its operative correction. In addition to the physiologic concerns related to the surgical condition, special attention must be directed toward (a) temperature regulation, (b) fluid, blood, and glucose administration, and (c) monitoring of respiratory and cardiovascular performance.

Venous and arterial access for fluid administration and monitoring may be challenging. Peripheral venous access with a 22- or 24-gauge catheter provides adequate access for the most vigorous fluid resuscitation. Central venous access may be necessary in the unstable newborn or if peripheral access is unsuccessful. Umbilical artery catheterization provides vascular access and arterial monitoring and is a well-established procedure in even the smallest prematures. The umbilical catheter may be maintained in most operative procedures. Peripheral arterial access may be obtained using radial, ulnar, or posterior tibial puncture or cutdown.

Fluid requirements are usually significantly greater than maintenance, especially in situations with intestinal obstruction, peritonitis, or gastroschisis. Before the operation there may be extraordinary losses from the gastrointestinal (GI) tract or inflamed peritoneum. These losses continue in the postoperative period and are superimposed on the sodium and water retention associated with the stress response. The endocrine, metabolic, and cytokine response to operative stress, which has been well documented in adults, has been confirmed in neonates (1,2 and 3). Postoperatively, decreased urine volume may result from the surge in antidiuretic hormone, intravascular volume depletion, or both, limiting the utility of urine volume alone as a monitor of adequacy of fluid replacement. Additional assessments including skin temperature, quality of peripheral pulses, serial measurements of weight, hematocrit, and serum electrolytes and osmolality supplement urine volume as indicators of adequate volume replacement (4).

Temperature maintenance is a critical concern for all newborns, but in particular for those undergoing diagnostic studies and operative procedures in radiology and operating suites. A variety of means of temperature support may be utilized, including warming the environment, heat lamps, heating blankets, scalp and extremity wrapping, heated intravenous fluids and blood products, and heated inhaled anesthetic agents and surgical irrigating fluids. Temperature must be constantly monitored, and every effort made to minimize exposure to cold stress. Hypothermia is a potentially lethal condition, and the importance of temperature support cannot be overemphasized (5).

Anesthetic and postoperative pain management can minimize the magnitude of the stress response and accelerate the neonate's return to normal homeostasis in terms of cortisol, catecholamine, and insulin modulation (6). The expertise of all the specialists involved may be the advantage necessary to achieve survival and mandates close collaboration.

LESIONS OF THE HEAD AND NECK

Congenital abnormalities of the head and neck occur commonly in the newborn. Because of the short, fat neck of the baby, some of these lesions are not immediately apparent, and the examiner must be alert to their possibility to detect them.

Clefts of the lip or palate occur in approximately one of every 600 to 700 Caucasian newborns. The frequency is doubled in Asians and halved in African Americans. Cleft lip occurs somewhat more often in male patients and on the left side. The defect probably results from lack of the mesodermal reinforcement of the junction of the nasome dial and lateral facial processes that normally takes place in the sixth to seventh week of gestation. Multiple genetic influences seem to be more important than environmental factors. The cleft deformity ranges from minor notching to complete separation of the entire lip and nasal floor (Fig. 44-1). The defect may involve the lip, the lip and palate, or only the palate, and it may be unilateral or bilateral. Median cleft lip is rare and is usually associated with hypotelorism, microcephaly, and early death.

Airway obstruction is not typically a consequence of isolated cleft lip or palate. Initial care focuses on feeding the infant and counseling the parents. Swallowing and airway protection should be normal, but the negative pressure of the normal suck is vented through the cleft, resulting in inadequate inflow. Fatigue during feeding is common and may mimic satiation. Although suckling is not altogether discouraged, a baby with a complete cleft lip or any degree of cleft palate should be expected to suffer mechanical feeding difficulty. The solution may be to rely on an enlarged nipple aperture, a compressible bottle, or a syringe feeder. With the use of a positive-pressure delivery system, the feeding schedule should be normal.

Figure 44-1 Complete congenital cleft of the lip with associated cleft of the palate that extends forward through the alveolar ridge.

Lip closure is usually carried out at around 3 months of age. The major goals are muscle continuity, balanced lip height, the normal Cupid's-bow lip shape, a smooth and pout-free lip margin, a good nasal sill, adequate sulcus lining, and a minimal, well-placed scar. The wide, complete unilateral and the complete bilateral clefts present greater challenges. Preliminary lip adhesion for the unilateral case or presurgical orthodontics can improve anatomic associations and facilitate the definitive surgery. Residual nasal deformity is often a stubborn problem and may require secondary surgery.

Cleft Palate

The embryologic palatal shelves initially hang vertically and then rise to meet and fuse from front to back between weeks 7 and 12 of gestation. Interference with this process may result in complete, incomplete, or submucous cleft of the palate. Initial care is discussed in the section on cleft lip.

The major significance of this defect is the effect on speech. Normal modulation of speech requires reliable, dynamic palatal separation of the mouth from the nose. This requires a palate of adequate length, suppleness, and muscle power. Velopharyngeal incompetence or incomplete nasal closure results in hypernasal speech and significant communication disability.

Chronic or recurrent effusion and infection in an otherwise normal ear is common in the child with a cleft palate because eustachian tube function is compromised. This child usually needs myringotomies and ventilation tubes.

Early surgery seems to have a negative effect on facial growth, but the trend is toward closure during infancy because of the improved speech results. Most American surgeons choose 9 to 12 months of age as optimal timing for a single-stage closure.

Palatal closure is accomplished with local soft tissue. Mucoperiosteal flaps are mobilized and closed in the midline, with oral and nasal lining, effecting muscle apposition and reposition. No bone reconstruction is

involved. The goal is normal speech, and this is achieved in approximately 85% of patients. A second operation produces good results for almost all the remaining infants.

An essential concept in the treatment of these children is a multidisciplinary approach. The patient should be followed through adolescence by a team consisting of a plastic surgeon, otolaryngologist, audiologist, pedodontist, orthodontist, speech pathologist, geneticist, pediatrician, and social worker.

Pierre-Robin Sequence

The Pierre-Robin sequence is characterized by retrognathia or microgenia (i.e., small or recessed jaw or chin), glossoptosis, airway obstruction, and cleft palate. The lack of forward support of the tongue allows it to fall back and

P.1099

compromise the airway. The basic defect may result from intrauterine restriction of mandibular growth.

Intensive monitoring, including a home apnea monitor, is necessary for many patients. The airway can usually be maintained by conservative measures. Prone positioning allows the tongue to fall forward. An appropriately apertured board may facilitate this positioning, and a nasal airway may be useful. Early gavage feedings may obviate hazardous oral feedings. A lip-tongue adhesion may be performed in more difficult cases, but its effectiveness varies. Tracheostomy should be avoided, if possible, but it is sometimes the only safe choice. Management should be as conservative as the clinical situation permits. The airway problem is typically self-limited, resolving as the child grows.

MASSES IN THE NECK

Masses in the neck are common in children and may be congenital, infectious, or neoplastic. Thyroglossal duct remnants, branchial apparatus anomalies, and lymphangiomas (i.e., cystic hygromas) are the most common congenital pediatric lesions in the neck.

Thyroglossal Duct Remnants

Thyroid tissue left behind in an abnormal location during normal developmental descent can result in a thyroglossal duct cyst, which presents in the midline of the neck. Infection may lead to a cutaneous salivary fistula. After appropriate therapy for infection, treatment consists of resection of the cyst, the central portion of the hyoid bone, and dissection of the tract up to its origin at the foramen cecum (Sistrunk operation) (7,8 and 9).

Branchial Cleft Anomalies

Branchial clefts with their corresponding arches and pouches are embryologic structures that give rise to many of the components of the lower face and neck. Abnormal persistence of any portion of the branchial apparatus leads to specific anomalies about the face and neck (10,11).

Preauricular Tabs and Sinuses

These lesions are not true branchial cleft remnants because they originate from an abnormal formation of the ear rather than a branchial cleft component. The preauricular sinus almost always ends blindly, and excision is indicated to prevent recurrent infection in later years.

Cervical Fistulas

Fistulas that originate from the first branchial arch present in the neck just below the ear and communicate with the external auditory canal. A fistula originating from the second branchial arch is the most common branchial cleft remnant. The fistula usually extends from the skin of the lower neck upward along the sternocleidomastoid muscle and then passes inward between the internal and external carotid arteries to attach to the posterolateral pharynx just below the tonsillar fossa (Fig. 44-2). The presenting complaint is usually related to persistent or intermittent drainage onto the neck. Complete surgical extirpation is necessary for cure. A large incision in the neck can be avoided by the use of two or three small, neat, transverse stair-step incisions.

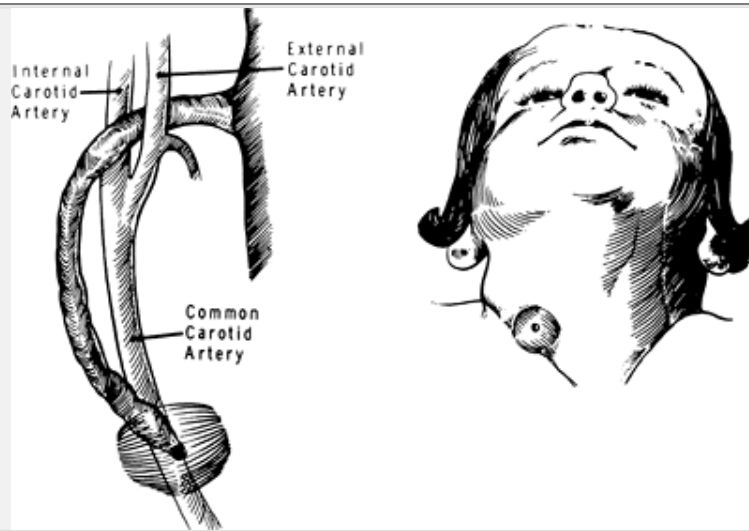

Figure 44-2 Brachial cleft cyst, which presents low in the neck as a mass or an opening in the skin, extends upward and laterally in the neck, and passes between the branches of the carotid artery to connect with the pharynx below the tonsillar fascia. From Nardi GL, Zuidema GD. *Surgery*, 3rd ed. Boston: Little, Brown, 1972, with permission.

Branchial Cyst

Approximately 10% of persistent branchial deformities are cystic. These invariably arise low in the anterior triangle of the neck and present as smooth cysts anterior to the sternocleidomastoid muscle. Dissection with excision is curative.

Cervical Cutaneous Tabs

Occasionally, a baby presents with a cutaneous tab in the skin of the anterior aspect of the neck. A small, irregular mass of cartilage may be contained in the skin tab. The cartilage is never associated with a fistula, and removal of this small appendage is not urgent.

Cystic Hygroma

Cystic hygroma (i.e., lymphangioma) is a congenital deformity arising from abnormal development of lymphatic channels (Fig. 44-3) (12). About 80% of these watery cysts occur in the neck, and most are located posterior to the sternocleidomastoid muscle. Other sites of occurrence are the groin, the axilla, and the mediastinum. The term "hygroma" suggests the watery fluid contained in the

P.1100

endothelium-lined spaces. The cyst may be unilocular, but more often there are numerous cysts of various sizes that permeate the surrounding structures and distort the local anatomy. Supporting connective tissue often shows extensive lymphocytic infiltration. Except in the case of a single large cyst, no definite cleavage plane is found between hygroma and normal tissue.

Figure 44-3 The typical cystic hygroma occurs in the lateral neck. The mass may extend into the scapular, axillary, or thoracic compartments, or the hygroma may present separately in any of these locations. Although depicted here as a single cyst, the hygroma is often a multiloculated, ill-defined mass. From Nardi GL, Zuidema GD. *Surgery* 3rd ed. Boston: Little, Brown, 1972, with permission.

The lesion is usually evident at birth. Occasionally, the mass occupies the entire submandibular region, distorting the subglottic area and compromising the airway. A supraclavicular mass may become prominent with the Valsalva maneuver. This form of cystic hygroma is usually associated with a mediastinal component. Some cystic hygromas contain nests of poorly supported vascular channels that are prone to bleeding and may produce sudden enlargement and discoloration of the lesion.

Symptoms are related entirely to the location and size of the mass. Disfigurement is often severe. Infection in the mass may lead to dangerous regional cellulitis, but after the infection subsides, the resultant intracystic fibrosis and scar may significantly reduce the size of the tumor mass. Prenatal ultrasonography has been used to diagnose cystic hygroma (13). This modality has demonstrated a hidden mortality with a high incidence of associated anomalies, including abnormal karyotypes and hydrops fetalis, when lymphangiomas are detected before 30 weeks of gestation.

Repeated aspiration of the cyst with injection of sclerosing agents is not recommended because any surgical excision that is subsequently required is rendered significantly more difficult by the sclerosing procedure. Elective surgical excision between 4 and 12 months of age is indicated for asymptomatic patients. Airway compression or recurrent infections may necessitate removal at an earlier age (14). Total excision is often impractical because of the extent of the hygroma and its proximity to vital structures. Important nerves and vascular structures must not be sacrificed in an attempt to achieve total excision of this benign lesion; multiple excisions of the residual hygroma are preferable. Postoperative wound drainage using closed-suction drains may reduce recurrence.

UPPER AIRWAY OBSTRUCTION CAUSING RESPIRATORY DISTRESS

A neonate is essentially an obligate nasal breather for the first several months of life. (Recently this belief has been challenged, and some investigators have proposed that a neonate is a preferential nasal breather [15].) Therefore, during the first few months of an infant's life, any nasal condition causing obstruction can cause respiratory difficulties. Typically a neonate with nasal obstruction presents with cyclic cyanosis (See Color Plate).

A newborn's epiglottis is softer and bulkier than that of older children and adults and is often tubular in shape. Excessive and redundant mucosa over the epiglottis and arytenoids can contribute to inspiratory stridor. The larynx in a newborn is a well-developed organ; however, it is one-third the size of an adult larynx. The subglottis of a neonate measures approximately 4.5 mm in diameter. Because of the smaller dimension, 1 mm of circumferential edema in the subglottis can reduce the cross-sectional area of a neonate's airway by more than 60% (16). The trachea and bronchi are also smaller in dimensions and are shorter than those in an adult. In addition to these anatomic differences, the airway structures in a neonate are more pliable, and its mucosa more reactive. Therefore, conditions that affect the airway such as epiglottitis and croup can have proportionately greater effect on a small infant's airway.

Evaluation of airway obstruction begins with a careful history regarding the characteristics of the stridor or other upper airway noises, voice quality, severity of airway symptoms, feeding difficulties, previous intubation history or other manipulation of the airway, other associated anomalies, and symptoms of gastroesophageal reflux or

aspiration. The great majority of airway abnormalities causing obstructive symptoms can be identified from the history alone (17). History is supplemented by physical examination and other evaluation modalities. High-kilovolt anterior-posterior and lateral soft tissue film of the neck can help in evaluation of the areas from nasal cavity to subglottis. Posterior-anterior and lateral chest x-rays can help to delineate tracheal and bronchial pathology. Other studies such as computed tomography (CT) scans and magnetic resonance imaging (MRI) may be needed to evaluate airway obstruction involving the nasal cavity, nasopharynx, and trachea.

Flexible nasopharyngoscopy and laryngoscopy can be performed at the bedside with monitoring. Areas from nasal vestibule to the vocal cords can be evaluated for functional and anatomic abnormalities. Flexible bronchoscopy with sedation is often suboptimal for evaluation of the subglottic, tracheal, and bronchial airways and is inferior to rigid endoscopy. Rigid endoscopy is usually performed in the operating room under general anesthesia but with

P.1101

spontaneous ventilation (no paralysis). This type of anesthesia enables the surgeon to evaluate the dynamics of the airway and any anatomic abnormalities.

Nasal Obstruction

Nasal Pyriform Aperture Stenosis

Congenital nasal pyriform aperture stenosis (anterior nasal stenosis) is secondary to the overgrowth of the nasal process of the maxilla (18). In this condition, the entrance into the nasal cavity known as the pyriform aperture is reduced to a slit-like opening. Because the pyriform aperture is the narrowest part of the nasal airway, even small changes in the cross-sectional area at this level can result in significant increase in nasal airway resistance and airway obstruction. Clinically, nasal obstruction causes apneic episodes and cyclic cyanosis, which is relieved by crying. Physical examination shows a bony, shelf-like projection of the posterior portion of the vestibule that almost completely obstructs the nasal cavity. The CT scan is the study of choice and helps to confirm the diagnosis and to define the anatomy of the nasal cavity and posterior choanae. Association of anterior nasal stenosis with midfacial dysostosis and endocrine and central nervous system abnormalities has been reported (19). Therefore, a genetic consult should be considered.

The infant is initially managed with a McGovern nipple or an oral airway with close monitoring. Gavage feeding may be necessary. If the infant is doing well, then discharge to home with an apnea monitor and a plan for close follow-up evaluations can be considered. If the infant does not tolerate an oral airway or continues to have significant nasal obstruction despite conservative management, then surgical intervention is necessary before discharge from the hospital. Sublabial approach with the use of microinstruments to remove portions of the nasal process of the maxilla is recommended (18). When the obstruction is mucosal rather than bony in nature, the diagnosis is likely to be stuffy nose syndrome, and it requires symptomatic medical treatment only.

Deviated Nasal Septum

Careful intranasal examination shows some septal deformities in as many as 70% of newborns, which may be secondary to intrauterine or birth trauma (20,21). Significant deviation of nasal septum secondary to traumatic delivery or the use of forceps is seen in approximately 1% of neonates. Physical examination shows tilted columella, deviation of the nasal septum and asymmetry of the nasal alae. Radiographic studies are not helpful. Closed reduction of the nasal septum by the use of gentle traction should be carried out during the first week of life. Careful examination of the nasal cavities to detect septal hematoma is essential. If this is present, a septal hematoma must be evacuated emergently because hematoma can lead to abscess formation and saddle nose deformity. Parents should be counseled that nasal growth disturbances can occur following trauma and that further nasal surgery may be necessary when the child is older.

Choanal Atresia

The simplest and the most widely held theory regarding pathogenesis of choanal atresia is that it results from the persistence of bucconasal membranes that normally involute during the seventh week of gestation. The incidence of choanal atresia is approximately one in 5,000 to 8,000 live births. Unilateral choanal atresia is twice as frequent as bilateral choanal atresia. Ninety percent of the atresia is bony; 10% is membranous. The female-to-male ratio is reported to be 2:1. In approximately 50% of the patients with choanal atresia, other associated

anomalies are seen. The most common anomaly associated with choanal atresia is the CHARGE association (coloboma, heart disease, atresia of the choana, retarded growth and development, genitourinary anomalies, ear anomalies and/or deafness) (22). For these reasons, a genetic consultation may be indicated for patients diagnosed with choanal atresia.

In cases of unilateral atresia, unilateral mucoid nasal rhinorrhea may be seen; however, significant respiratory distress is usually absent. In bilateral choanal atresia, characteristic cyclic respiratory obstruction is seen. Nasal obstruction leads to increasing respiratory effort and distress until the child cries and the nasal obstruction is bypassed temporarily. Diagnosis is established by the inability to pass a 6-Fr suction catheter through the nostril beyond 3 to 4 cm into the nasopharynx. The atretic plate can also be visualized using a fiberoptic nasopharyngoscope. The best method of delineating the atresia is by CT scan.

A neonate with bilateral choanal atresia is initially managed with oral airway or McGovern nipple and gavage feedings. Tracheotomy is rarely needed. Choanal atresia can be addressed by transnasal, transpalatal or endoscopic approaches (23,24). Emergent surgical correction for bilateral choanal atresia is seldom required and is reserved for those infants that can not be managed conservatively. Under these circumstances, a transnasal repair can be performed with a staged definitive transpalatal repair when the child is older. In a neonate who is easily managed by conservative means alone, surgical correction can be deferred for 1 to 2 years. Restenosis requiring revision surgery is not uncommon.

Congenital Midline Nasal Masses

Encephaloceles and gliomas arise from faulty closure of the foramen caecum at the third week of fetal development (25). Gliomas are locally aggressive lesions that can cause symptoms by enlargement and pressure effects on the surrounding structures. Approximately 30% of gliomas are intranasal and thus can cause nasal obstruction and septal deviation. Fifteen percent of gliomas have a fibrous connection to the dura. Basal encephaloceles herniate through a defect in the cribriform plate and usually present as intranasal masses and cause nasal obstruction.

P.1102

Congenital midline nasal masses are best evaluated by a combination of CT scan and MRI. Depending on whether there is a connection to the dura, gliomas may require a combined approach by the neurosurgery and otolaryngology services. Encephaloceles always have an intracranial connection and thus require an intracranial exploration. Early surgical intervention is advised to decrease the risk of meningitis and further enlargement of the mass with resulting cosmetic deformity.

Oropharyngeal Obstruction

Glossoptosis

Pierre-Robin sequence (PRS) consists of micrognathia, glossoptosis, and U-shaped cleft palate; it represents the best-known cause of glossoptosis. Pierre-Robin sequence results secondary to arrest in development of mandible at the seventh to the 11th week of gestation, which then leads to high position of tongue in the oral cavity and prevention of fusion of palatal shelves (26). It may present as an isolated anomaly or as a part of a syndrome such as Stickler's syndrome (see Chapter 38). Genetic consultation is advised.

Airway obstruction in neonates with PRS occurs because of the micrognathia, which causes posterior displacement of the tongue base. Obstruction is more severe in supine position and worsens during sleep or induction of anesthesia. Airway obstruction can be managed by positioning, placement of a nasopharyngeal airway, intubation, and tracheotomy (27). Most patients without other significant airway or neurologic deficits can be managed conservatively (28). For neonates with severe airway symptoms who do not respond to positioning or nasopharyngeal airway, a tracheotomy is required. Once it is performed, the tracheotomy tube remains in place until the cleft palate repair is completed.

Macroglossia

Macroglossia is seen in neonates with Beckwith-Wiedemann syndrome (BWS). Additionally, patients with BWS may have omphalocele, adrenal cytomegaly, and visceromegaly (29). BWS occurs secondary to sporadic mutation and has a mortality rate of over 20%. The airway obstruction seen in these patients is secondary to

macroglossia. Initial management consists of tracheotomy, followed by a tongue reduction procedure at a later date.

True macroglossia and relative macroglossia (a small oral cavity) can also be seen in neonates with Down syndrome; however, the size of the tongue rarely necessitates surgical intervention.

Laryngeal Obstruction

Laryngomalacia

Laryngomalacia is the most common cause of stridor in infants (30). Laryngomalacia describes the collapse of supraglottic structures on inspiration. The pathophysiology of laryngomalacia is unknown. Usually, it is a self-limited condition with mild symptoms that resolve by age 18 to 24 months.

Infants with laryngomalacia present with variable in-spiratory stridor that worsens with crying, feeding, and upper respiratory infections and improves with prone position. A small number of infants have more severe symptoms of airway obstruction consisting of retraction, feeding difficulties, failure to thrive, and cyanosis. Diagnosis is confirmed by flexible laryngoscopy, which shows inward collapse of the epiglottis, aryepiglottic folds, and the mucosa over the arytenoids during inspiration. In fewer than 5% of the infants, surgery is indicated to relieve severe obstruction and prevent pulmonary and cardiac complications (31). Surgery consists of trimming the supraglottic tissue with carbon dioxide laser or by sharp dissection (32). A tracheotomy is an alternative to supraglottoplasty (epiglottoplasty).

Vocal Cord Paralysis

Vocal cord paralysis accounts for approximately 10% of all congenital laryngeal anomalies (30). Unilateral paralysis does not cause significant airway symptoms; however, the infant may have a hoarse and breathy cry. Surgical intervention is usually not required. An infant with bilateral vocal cord paralysis (BVCP) presents with normal voice and cry, but with an inspiratory stridor. Central nervous system anomalies, in particular Arnold-Chiari malformation, are often associated with BVCP (30,33). The diagnosis of BVCP is made by flexible laryngoscopy. Radiographs of the airway and chest and, if indicated, CT scan of the brain should be obtained.

In BVCP associated with Arnold-Chiari malformation, neurosurgical decompression will result in resolution of BVCP. In most infants with idiopathic BVCP, tracheotomy is required to establish an airway. During tracheotomy, the entire airway should be inspected to exclude any additional airway anomalies. Definitive vocal cord lateralizing procedures can be done at a later date, if spontaneous resolution of the paralysis does not occur (34).

Laryngeal Atresia/Web

During embryogenesis, epithelium temporarily obliterates the laryngeal lumen. This epithelial plug is then resorbed during the seventh to eighth week of gestation (35). Failure of this resorption process can result in laryngeal web, subglottic stenosis (SGS), and laryngeal atresia. Laryngeal atresia is a rare and life-threatening condition that must be recognized in the delivery room and must be followed by an emergent placement of tracheotomy tube if the infant is to survive.

The most common laryngeal web is seen at the glottic level and affects the vocal cords (36). The web may be thick, causing severe obstruction, or thin and membranous. Infants with laryngeal web present with abnormal cry, stridor, and respiratory distress. Laryngeal web can

P.1103

cause cyanosis or unexplained airway obstruction at birth, which requires intubation or a tracheotomy. Laryngeal web is often associated with SGS. Diagnosis is made by airway films and rigid endoscopy. Definitive treatment options to allow decannulation include dilation, endoscopic microsurgical or laser division of the web, and an open repair (36).

Posterior Laryngeal Cleft

Posterior laryngeal cleft is often associated with other congenital anomalies such as esophageal atresia, tracheo-esophageal fistula, and tracheal and bronchial stenosis. Posterior laryngeal cleft is difficult to diagnose,

particularly if the cleft is limited to the interarytenoid region. Posterior laryngeal cleft has been classified into four types, with type 1 being a mild interarytenoid cleft above the level of the vocal cords and type 4 representing a complete laryngo-tracheoesophageal cleft (37).

Presenting symptoms depend on the extent of the cleft. Airway obstruction is not a prominent feature. Rather, aspiration, choking, cyanosis, and feeding difficulties are seen commonly. Stridor and voice abnormalities can be seen but are not common. Diagnosis is made by careful inspection of the posterior glottis during endoscopy. Laryngeal cleft can be repaired endoscopically or by an external approach using laryngofissure or lateral pharyngotomy.

Subglottic Stenosis

SGS is defined as narrowing of the airway at the level of the cricoid to less than 4 mm in a full-term infant and 3 mm in a premature infant. It is considered to be congenital if there has not been any previous airway manipulation. The stenosis may be cartilaginous or membranous. Many of the infants with congenital SGS may have only mild symptoms and go undiagnosed, whereas others may get intubated and thus diagnosed as having acquired SGS. Thus, the true incidence of congenital SGS is unknown. Acquired SGS is most commonly secondary to prolonged endotracheal intubation. One percent to 8% of infants who require prolonged intubation may acquire SGS (38). The injury to the subglottis is related to the duration of intubation, the size of the endotracheal tube (ETT), the degree of ETT motion, and the number of reintubations.

Infants with SGS can present with stridor, respiratory distress, and croupy barking cough. Others present with recurrent or prolonged croup and inability to be extubated after intubation, or obstructive apnea. Airway radiographs can show narrowing of the subglottic airway; however, the definitive diagnosis is made on rigid endoscopy. For infants who have severe airway obstruction and fail repeated attempts at extubation, a tracheotomy or anterior cricoid split (ACS) can be considered. An ACS can be performed only in infants without other underlying airway abnormalities that contribute to the airway obstruction and who have good pulmonary reserve (39). Any need for ventilatory support, oxygen requirement over 30%, congestive heart failure, and respiratory infection are contraindications to ACS.

Anterior cricoid split involves opening of the upper two tracheal rings, cricoid cartilage, and lower half of the thyroid cartilage in the anterior midline and presumably works by decompressing the airway. Postoperative intubation for 7 to 10 days and meticulous care to avoid ETT plugging and accidental extubation are imperative. Systemic corticosteroid is administered beginning 24 hours preextubation and continues for 72 hours postextubation. If ACS is successful, a tracheotomy can be avoided. Patients who fail ACS can undergo revision ACS or a tracheotomy followed by a formal laryngotracheal reconstruction at a later date.

Subglottic Hemangioma

Hemangiomas represent malformation of vasoformative tissue. Hemangioma in the airway usually occurs in the submucosa of the subglottic region; it increases in size over 6 to 18 months, followed by involution (40). Hemangioma may extend beyond the airway into the mediastinum. Approximately 50% of infants with airway hemangioma have cutaneous hemangioma in the head and neck region.

Infants with subglottic hemangioma present with inspiratory stridor, hoarseness, barking cough, and airway obstruction. Airway film shows soft tissue swelling in the subglottis, which is often asymmetric. Endoscopy shows a lesion that is localized to the posterior subglottis and is soft and compressible. Biopsy is usually not necessary unless diagnosis is in question, and the endoscopist should be prepared to manage possible hemorrhage into the airway. Treatment of subglottic hemangioma depends on the degree of airway obstruction and the extent of airway involved by the hemangioma. Treatment options include tracheotomy followed by expectant waiting for involution of the hemangioma, corticosteroids, and laser excision. More recently, interferon- α 2a administration has been introduced as a treatment for airway hemangiomas (41).

Tracheal Obstruction

Tracheal Stenosis

Tracheal stenosis may be secondary to mucosal webs of variable thickness without any gross deformity of the underlying cartilage. Stenosis of the trachea can also be caused by complete tracheal rings of variable length. The segment with complete tracheal rings lacks the posterior membranous portion of the trachea.

Symptoms of airway obstruction from tracheal stenosis depends on the diameter of the narrowed airway lumen. Neonates with tracheal stenosis can present with persistent cough, respiratory distress, expiratory stridor, and wheezing. Symptoms tend to worsen following an upper respiratory infection, and sudden and complete obstruction can occur from mucus plugging of the narrowed segment. Many patients also tend to have feeding difficulties.

P.1104

The diagnosis is suggested by history, airway films, and fluoroscopy; however, a definitive diagnosis is made by endoscopic evaluation. Mucosal web may respond to dilation alone. Short segments of tracheal stenosis are resected with end-to-end anastomosis (42). Long segments of stenosis require tracheoplasty using pericardial and/or cartilage grafts (43). These surgical procedures are associated with high morbidity and mortality rates.

Tracheomalacia

In tracheomalacia there is increased flaccidity of the tracheal walls, which leads to anterior-posterior collapse of the airway and obstruction (44). Primary tracheomalacia is an isolated finding that usually resolves by age 2 years. Secondary tracheomalacia is seen in neonates with tracheoesophageal fistula (TEF) or external vascular compression. In primary tracheomalacia and in secondary tracheomalacia associated with TEF, deficiency in the tracheal cartilage may cause the abnormal collapse of the trachea (44,45).

Clinical symptoms of tracheomalacia range from mild to severe. Common features of severe cases include inspiratory and/or expiratory stridor, wheezing, persistent coughing, recurrent respiratory infections, reflex apnea, and difficulty with clearing airway secretions. Reflex apnea describes a respiratory arrest that can progress to a cardiac arrest and is seen in patients with tracheobronchial compression (46). Diagnosis of tracheomalacia can be suggested by fluoroscopy, but a definitive diagnosis can only be made by endoscopic examination of the airway under spontaneous ventilation. Widened semicircular cartilages, ballooning of the posterior membranous wall, and collapse of tracheal lumen are seen. In severe cases tracheotomy is required until the condition resolves. The use of positive airway pressure through the tracheotomy tube may be necessary to maintain patency of the airway below the tracheotomy tube (47).

Vascular Compression

Innominate artery compression of the trachea can occur when there is an anomalous distal origin of the innominate artery from the aortic arch. The innominate artery crosses the trachea in a left-inferior-to-right-superior direction and causes compression of the trachea. Infants with this condition present with stridor, recurrent respiratory infections, feeding difficulties, and reflex apnea. Diagnosis is best made by endoscopy and MRI. Surgery is necessary only in infants with severe stridor or reflex apnea. Suspension of the innominate artery through thoracotomy or median sternotomy and reimplantation of the innominate artery are available surgical options (48).

Other less common vascular anomalies causing airway obstruction include double aortic arch, right aortic arch with left ligamentum arteriosum, and pulmonary artery sling. Evaluation of these conditions includes chest radiographs, MRI, and endoscopy. In symptomatic infants, the appropriate surgical procedure should be undertaken by a cardiothoracic surgeon.

THORACIC LESIONS CAUSING RESPIRATORY DISTRESS

Congenital Lobar Emphysema

Congenital lobar emphysema can be severe or life-threatening as a result of hyperexpansion of a single lobe of the lung. Air is permitted into the involved lobe but denied egress. The lobe becomes emphysematous, resulting in compression of adjacent pulmonary parenchyma and mediastinal displacement. Symptoms may appear shortly after birth and invariably develop before 4 months of age (49). The cause is unknown. An inherent, cartilaginous defect in the bronchus has been postulated, but the bronchial abnormality is not always recognizable in the resected specimen.

A chest radiograph is characteristic, showing hyperaeration of the involved lobe with mediastinal shift away from the affected side. The lobar distribution of the hyperaeration can be appreciated, and adjacent pulmonary parenchyma is compressed. The upper lobes are most frequently involved, but the condition may be seen in the

middle lobe. Rarely, the lesion is bilateral (50).

Treatment is surgical, and prompt thoracotomy and lobectomy are undertaken after the diagnosis is made. An infant may remain compensated for some weeks and then deteriorate rapidly from acute hyperinflation of the involved lobe. There is no place for expectant management of congenital lobar emphysema.

An identical clinical picture may be seen in the neonate who has been ventilated for a prolonged time and develops a large pneumatocele as a result of respiratory tract barotrauma. It is often difficult for the physician to determine whether respiratory distress is caused by the pneumatocele or by generalized pulmonary parenchymal disease. Surgical excision of the pneumatocele is indicated if the lesion is enlarging and the respiratory status is worsening without another apparent cause.

Cystic Adenomatoid Malformation

Cystic adenomatoid malformation (CAM) is a pulmonary maldevelopment that presents with cystic replacement of pulmonary parenchyma. If the cysts are small (i.e., microcystic CAM) and constitute a small portion of one lung, the child may be asymptomatic. If the lesion is microcystic and replaces a large portion of the lung, the fetus may develop hydrops, and the prognosis is poor (51). If the cysts are macroscopic and the child is in respiratory distress at birth, the problem may be misdiagnosed as congenital diaphragmatic hernia. Appropriate therapy for the symptomatic neonate with CAM is thoracotomy and resection of the involved lung. Postoperative support with extracorporeal membrane oxygenation (ECMO) has been necessary for

P.1105

infants developing severe persistent pulmonary hypertension after CAM excision (52).

Bronchogenic Cyst

Bronchogenic cyst is another lung bud anomaly in which the normal bronchiole-to-bronchiole communication is absent or atretic, resulting in a mucus-producing cyst that may obstruct the trachea, bronchus, or esophagus. This seldom causes severe problems in the neonate, but it must be considered if a space-occupying lesion is detected on a chest x-ray film obtained for investigation of respiratory distress. Excision of the bronchogenic cyst is the preferred treatment.

Iatrogenic Airway Injury

As aggressive management of the pulmonary disease of newborns has developed, there has been a concurrent increase in injury to the airway or pulmonary parenchyma. Long-term intubation and high peak inspiratory pressure settings on the ventilator place these children at an increased risk of airway injury. It has been known since 1976 that perforation of bronchi, particularly the bronchus of the right lower lobe, can be prevented by careful measurement of suction catheters so that they do not extend more than 1 cm beyond the carina (53). The development of a bronchopulmonary fistula after chest tube evacuation of a pneumothorax can be life-threatening and may require surgical closure of the fistula, although some children have been successfully treated nonoperatively (54).

Complications of high-pressure ventilation include development of interstitial emphysema and bronchopulmonary dysplasia. The interstitial emphysema is usually self-limited, although some infants may benefit from a surgical approach to the problem (55). Surgery can be curative for granulomas within the airway of chronically intubated neonates, particularly if the lesions contribute to air trapping or stenosis. The best management for iatrogenic airway injury is prevention, and although not totally avoidable, careful attention to ventilator management and suction techniques should reduce the incidence and severity of these problems.

Diaphragmatic Hernia

Development of the diaphragm is generally complete the 12th week of gestation, by which time the bowel has returned to the abdominal cavity. Failure of the development of the posterolateral portion of the diaphragm results in persistence of the pleuroperitoneal canal or foramen of Bochdalek, which allows the viscera to occupy the chest cavity, and the abdomen is underdeveloped and scaphoid. Both lungs are hypoplastic, more so on the side of the hernia. Bronchial branching, lung weight, and lung volume are decreased. The pulmonary arteries are hypoplastic (56,57). The lesion occurs in one of every 3,000 live births, with equal frequency in male and female infants. Sporadic occurrence is the rule, but a familial pattern has been reported (58,59).

The prenatal diagnosis of congenital diaphragmatic hernia (CDH) can be made using fetal sonography as early as 15 weeks of gestation (60). Sonographic findings include herniated abdominal viscera, abnormal anatomy of the upper abdomen, and mediastinal shift away from the herniated viscera (61). The high-risk fetus is identified by a diagnosis early in gestation, a dilated stomach in the chest, low lung-to-thorax ratio, low lung-to-head ratio, and polyhydramnios. Amniocentesis with a fetal karyotype identifies chromosomal defects; trisomy 18 and 21 are most common. More than 40% of newborns with CDH have associated anomalies of the heart, brain, limbs, genitourinary system, or craniofacial region (62).

Typically, babies with congenital Bochdalek hernia present dramatically with cyanosis (See Color Plate) and severe respiratory distress immediately after birth. Because the abdominal viscera are dislocated through the defect into the chest, the abdominal contour is scaphoid. Breath sounds are diminished or absent, and because the mediastinal structures have been displaced, the heart sounds are heard in the right chest. As the bowel fills with gas, respiration and cardiac action are further compromised, hypoxia and respiratory acidosis are increased, and death is inevitable unless appropriate intervention is undertaken. Congenital diaphragmatic hernia is no longer considered a surgical emergency unless the viability of the herniated bowel is in question. In some instances, the infants remain relatively asymptomatic in the early hours and days of life, and rarely, a diaphragmatic hernia is an incidental finding in an older child. The respiratory symptoms demand an immediate x-ray film, which is diagnostic. The hernia is on the left side in 90% of these infants, and the air-filled bowel is seen occupying the left hemithorax, with resultant displacement of the mediastinum to the right (Fig. 44-4). The abdomen is gasless. Additional x-ray films are unnecessary, and contrast studies for additional confirmation are contraindicated.

Many newborns with CDH have respiratory failure within minutes of birth, and urgent stabilization is mandatory to reverse hypoxia, hypercarbia, and metabolic acidosis. Prompt and aggressive preoperative care is essential (63,64). This generally includes mechanical ventilation with 100% oxygen, sedation with narcotics, muscle paralysis, controlled alkalosis with hyperventilation and intravenous sodium bicarbonate, and vasopressors. Permissive hypercarbia and gentle ventilation have proven effective in a number of centers. Regardless of the mode of therapy, the goal is to reverse the baby's persistent pulmonary hypertension with right-to-left shunting of oxygen-poor blood across the open foramen ovale and the ductus arteriosus.

Some infants do not improve despite aggressive therapy, and many centers use ECMO before hernia repair to stabilize these desperately ill infants (65,66). Venovenous or venoarterial bypass is used, depending on the infant's hemodynamic stability. Bypass is continued until the pulmonary hypertension is reversed and lung function is

P.1106

improved. Most infants respond within 7 to 10 days, but some require up to 3 weeks of support. Newborns who have not improved after this time probably have such severe pulmonary hypoplasia that further extracorporeal life support is futile.

Figure 44-4 X-ray film of left diaphragmatic hernia with loops of bowel well up into the chest. Although most diaphragmatic hernias do not have a sac, the smooth curve of the sac in this instance is visible. Notice that the heart is displaced to the border of the right chest.

There are no absolute respiratory criteria that exclude newborns with CDH from consideration for ECMO support (67,68). Approximately 60% of infants with CDH who are supported by ECMO are expected to survive (see Chap. 32).

The surgical findings are usually those of a posterolateral defect in the left diaphragm, with most or all of the abdominal viscera in the chest. The surgeon reduces the hernia gently by withdrawing the viscera from the chest. If a sac is present, it is delivered and excised. There may be adequate diaphragmatic tissue to accomplish direct suture repair. If a significant portion of the diaphragm is lacking, prosthetic material is used to close the defect. Before completion of the repair, a small chest tube may be placed in the left hemithorax and brought out through an intercostal space.

The temptation to expand the compressed lung at the time of initial surgery must be resisted. Aggressive attempts at expansion can result in pneumothorax on the contralateral side, which, if unrecognized, is a disastrous complication.

The abdominal viscera have been located in the thorax throughout most of the developmental period of the fetus; thus, there is insufficient room within the abdomen to accommodate the intestine without dangerously increasing the intraabdominal pressure, compressing the vena cava, and compromising respirations by elevating the diaphragm. To avoid these potential problems, the surgeon may omit anatomic closure of the abdominal wall. Skin flaps are quickly mobilized, and only the skin is closed, or the abdomen is closed by creating a silastic silo as for gastroschisis or a large omphalocele. The ventral pouch created accommodates the intraabdominal organs; diaphragmatic action and venous return are unimpeded. The ventral hernia is repaired after the infant has been weaned off the ventilator and is in stable clinical condition.

Ten percent of infants with Bochdalek hernias present with the defect on the right side. The difference in incidence on the two sides may be explained by the presence of the liver, which partially blocks the pleuroperitoneal canal and limits the amount of bowel that can herniate into the chest. Symptoms in babies with right-sided hernias may be less severe, but when a right diaphragmatic hernia of Bochdalek presents as an emergency, it is managed as described.

After CDH repair and removal from ECMO, ventilation is continued with ventilation rates and oxygen concentrations necessary to maintain adequate oxygenation. Continuous transcutaneous oxygen monitoring of upper and lower body areas is useful. To avoid relapse into pulmonary hypertension, weaning from the ventilator should be achieved by making small incremental changes in the inspired oxygen and ventilator rate.

New modalities being investigated may offer an increased chance of survival for infants with CDH. These include

surfactant replacement therapy, liquid ventilation, intratracheal pulmonary ventilation, and pulmonary lobar transplantation (69,70). Prenatal repair of the diaphragmatic hernia has been abandoned, as there was no improvement in survival or morbidity in a randomized trial. Current prenatal therapy of CDH is directed at occluding the trachea, which results in enlargement of the lungs with retained fluid. The baby is then delivered by planned cesarean section, at which time the trachea is repaired or intubated, with the baby remaining on placental support. Initial discouraging results with this technique have been improved with recent modifications; however, fetal tracheal plugging remains an experimental procedure that is being evaluated in a limited number of centers (71,72).

Babies who present after the first day of life with signs and symptoms prompting a diagnosis of diaphragmatic hernia are almost always hardier patients and have greater pulmonary reserve, and they can be expected to make a satisfactory recovery.

The anterior retrosternal hernia of Morgagni is rarely encountered in the newborn. The diagnosis is confirmed by chest radiograph in the lateral projection. The standard treatment is surgical reconstruction, beginning with an abdominal approach through a thoracoabdominal

P.1107

incision. The prognosis is usually favorable, and these lesions are not associated with the severe cardiopulmonary complications seen with Bochdalek hernias in the neonatal period.

Eventration of the Diaphragm

Eventration of the diaphragm may be congenital or acquired. The congenital presentation may mimic that of a congenital diaphragmatic hernia with a sac. The acquired lesion results from paralysis of the diaphragm, most commonly caused by operative trauma or birth injury (73).

Large eventrations and diaphragmatic paralysis are poorly tolerated by infants (74). Paradoxical cephalad motion of the diaphragm on inspiration produces a shift of the mobile, neonatal mediastinum that limits the function of the contralateral lung. Moderate or severe respiratory distress is evident; many newborns with eventration require ventilatory support.

Diagnosis is suggested by a marked elevation of a hemidiaphragm on a chest radiograph. Fluoroscopic examination identifies paradoxical movement of the diaphragm. Treatment is plication of the diaphragm with nonabsorbable sutures that reef up or overlap the diaphragm. The taut diaphragm results in less abnormal motion and improved ventilation.

LESIONS OF THE ESOPHAGUS

Esophageal Atresia and Associated Anomalies

The success story of the management of infants born with esophageal atresia and tracheoesophageal fistula is one of the most dramatic and satisfying that the pediatric surgeon, the neonatologist, and the pediatrician can point to. In the early 1900s, virtually all babies born with esophageal atresia and tracheoesophageal fistula died. In 1941, Haight and Towsley were the first to bring an infant with esophageal atresia and tracheoesophageal fistula successfully through the rigors of primary transthoracic reconstruction (75). This landmark accomplishment occurred before antibiotics, respiratory support, or sophisticated intravenous nutrition were available. This surgical approach formed the basis of modern operative and postoperative care of infants born with this anomaly. Fifty years after the first survivor was announced, every baby born with atresia of the esophagus who is spared coexisting fatal abnormalities and is offered appropriate care has an excellent chance of leading a normal life.

Embryologic and Genetic Considerations

The cause of esophageal atresia is unknown, but it is related to the common origin of the esophagus and trachea (76). The embryonic trachea and esophagus are first recognized as a ventral diverticulum of the foregut approximately 22 or 23 days after fertilization (77). As the diverticulum elongates, a proliferation of endodermal cells appears on the lateral walls. These cell masses become ridges of tissue that ultimately divide the foregut into tracheal and esophageal channels. The division into separate tubes is completed between 34 and 36 days after fertilization. Many embryologic studies indicate that interruption of development in the fourth fetal week

allows persistence of fistulas and clefts between the esophagus and trachea and permits incomplete development of the esophagus.

There are reports of familial occurrences of esophageal atresia, which raises the possibility of a heritable genetic factor. Numerous accounts of twins and siblings with esophageal atresia have been reported (78). Conversely, certain commonly coexistent anomalies, such as the VACTERL (i.e., vertebral, anal, cardiac, tracheal, esophageal, renal, and limb anomalies) association (see Chapter 38) and other malformations, strongly suggest that the developing fetus is affected by a teratogen or defect of embryogenesis (79).

In many babies with esophageal atresia, it is the associated anomalies that alter treatment and affect survival. Congenital heart defects and chromosomal abnormalities are the most worrisome. Major anomalies that may seriously affect the infant but that are not usually fatal include imperforate anus and other congenital obstructions of the gut. Grosfeld and Ballantine found that 31 (37%) of 84 infants had cardiac anomalies; 18 (21.4%) had GI malformations, of whom 11 (13%) had imperforate anus; and six (7%) had the VACTERL association (80). A ventricular septal defect is the most common cardiac lesion, followed in frequency by patent ductus arteriosus and tetralogy of Fallot. Piekarski and Stephens suggest that the high incidence of coexisting anomalies is a reflection of generalized damage to the mesenchymal tissue in the fourth week of gestation (81).

Esophageal Atresia with Tracheoesophageal Fistula

Esophageal atresia occurs in approximately one of 3,000 to 4,500 births. In the most common form of esophageal anomaly (86% of patients), the blind-ending upper esophageal segment usually extends into the upper portion of the thorax, and the lower portion of the esophagus is connected to the trachea at or just above the tracheal carina (Fig. 44-5) (82). This connection is 3 to 5 mm in diameter and easily admits inspired air or, in a retrograde fashion, acidic gastric secretions. The earliest clinical sign of esophageal atresia is excessive oral secretions or regurgitation of saliva. The saliva pools in the blind-ending esophagus and then accumulates until it is apparent around the lips as excessive mucus. The first feeding is followed by choking, coughing, and regurgitation. Abdominal distension is a prominent feature, occurring as inspired air is transmitted through the fistula and distal esophagus into the stomach. Gastric juice may pass upward in the distal esophagus, traversing the tracheoesophageal fistula and spilling into the trachea and lungs, leading to chemical

P.1108

pneumonia. Pulmonary difficulties are compounded by atelectasis and diaphragmatic elevation secondary to gastric distension.

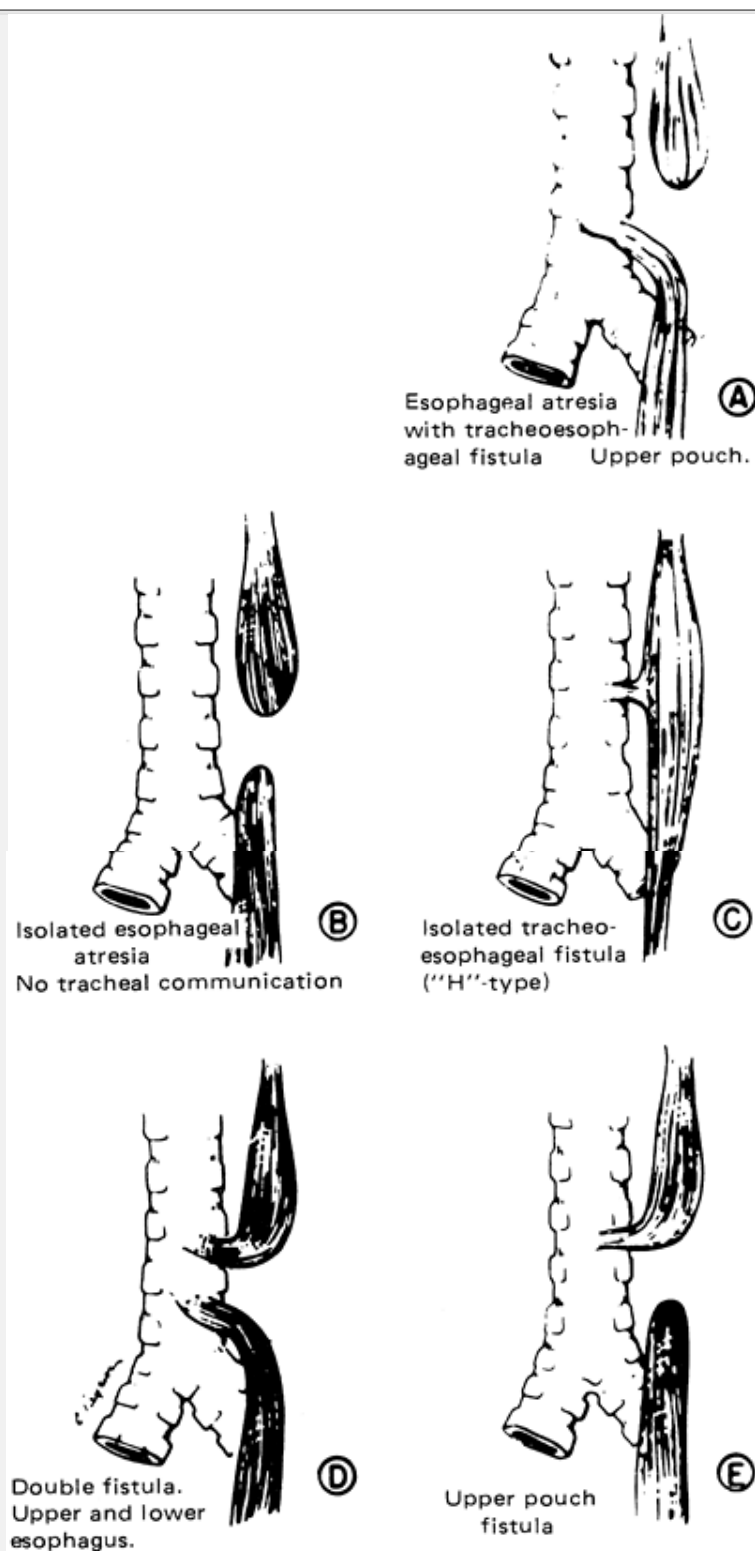

Figure 44-5 The various forms of esophageal malformations are shown in the order of the frequency in which they occur. From Nardi GL, Zuidema GD. *Surgery*, 3rd ed. Boston: Little, Brown, 1972, with permission.

Diagnosis

The diagnosis of many infants with esophageal atresia is made prenatally. Polyhydramnios is the most frequent finding, particularly in infants with pure esophageal atresia. Those with a tracheoesophageal fistula may not develop polyhydramnios if the communication is large enough to permit swallowing of the amniotic fluid through the fistula. An additional finding on a prenatal ultrasound is failure to identify the fetal stomach, which should raise the suspicion for esophageal atresia. The prenatal diagnosis of esophageal atresia permits the search for other anatomic anomalies and possible chromosomal defects. Appropriate prenatal counseling and preparation of the family can be initiated, specifically with arrangement for postnatal correction, unless contraindicated by coexistent abnormalities.

Once the infant is born, attentive members of the nursing staff who are feeding the baby are often the first to suspect the esophageal blockage. Esophageal atresia may not be obvious on the initial newborn examination unless an attempt is made to pass a tube into the stomach. Thin, flexible feeding catheters should be avoided because they may coil up in the esophagus and give the misleading impression that they have passed into the stomach. A larger, stiffer catheter carefully advanced will meet the obstruction. Occasionally, a tube dissects into the wall of a normal esophagus, leading to a misdiagnosis of esophageal atresia, particularly in a premature infant. A contrast x-ray film rules this out and confirms the diagnosis of atresia; a lateral projection with 1 mL of dilute barium or an isoosmolar contrast agent (e.g., metrizamide) shows the length of the upper pouch, defines its precise extension into the chest, and demonstrates the rare upper pouch fistula (Fig. 44-6A,B). Air seen in the bowel confirms the presence of a tracheo-esophageal fistula. The existence of pneumonia or atelectasis also can be demonstrated on the initial radiographs.

Evaluation of the heart and great vessels with echocardi-ography is important to identify potential cardiac anomalies and verify the aortic arch position. A right-sided arch may alter the surgical approach and exposure. Bronchoscopy is useful to identify the level of the fistula and to exclude upper pouch fistulas and laryngotracheoesophageal clefts.

Management

After the diagnosis is secure, the following measures should be instituted promptly:

- Basic supportive measures, such as an infant warmer.
- Place the infant in a 30- to 40-degree head-up position.
- Give nothing orally.
- Provide intravenous antibiotics for possible aspiration.
- Place a sump suction catheter in the upper pouch to remove the excess secretions (Fig. 44-7).
- Consult with the appropriate pediatric surgical service.

The traditional approach to the timing of surgical repair was based on the increased risk of operating on infants with low birth weight and pneumonia. However neonatal care has evolved to the point that neither low birth weight nor the presence of pneumonia is a risk factor for poor survival (83). Severe anomalies and their consequences are now the crucial determinants of survival. Therefore, at Children's National Medical Center (CNMC), each baby admitted with esophageal atresia is managed according to

P.1109

his or her physiologic status alone (84). If the infant is stable, immediate primary repair is undertaken. If unstable, surgery is delayed until the clinical status is stabilized, the impact of associated anomalies is determined, and the infant can be anesthetized and operated on safely.

Figure 44-6 **A:** Lateral radiograph of a baby with esophageal atresia and tracheoesophageal fistula reveals a small meniscus of barium in the upper pouch. Gas is present in the stomach and intestinal tract because of the fistulous connection to the trachea. In this radiograph, some air in the lower esophageal segment can be seen in the posterior mediastinum. **B:** In a radiograph of a patient with isolated esophageal atresia, the upper pouch is outlined by barium. There is no air below the diaphragm. **C:** In a barium swallow in a patient with H-type isolated tracheoesophageal fistula, a normal-sized lumen of the esophagus is seen. Dye has spilled into the trachea, outlining the upper trachea and larynx. The fistula is at the level of the clavicle.

Of historic interest, a classification developed by Waterston and colleagues in 1962 was useful in the stratification of patients for different management plans and the comparison of outcomes (85). The infants were classified as follows:

-
-
-

- Category A: Birth weight over 2.5 kg (5.5 lb) and otherwise well
- Category B: Birth weight of 1.8 to 2.5 kg and well, or higher birth weight but moderate pneumonia and other congenital anomalies
- Category C: Birth weight under 1.8 kg, or higher birth weight but severe pneumonia and severe congenital anomaly.

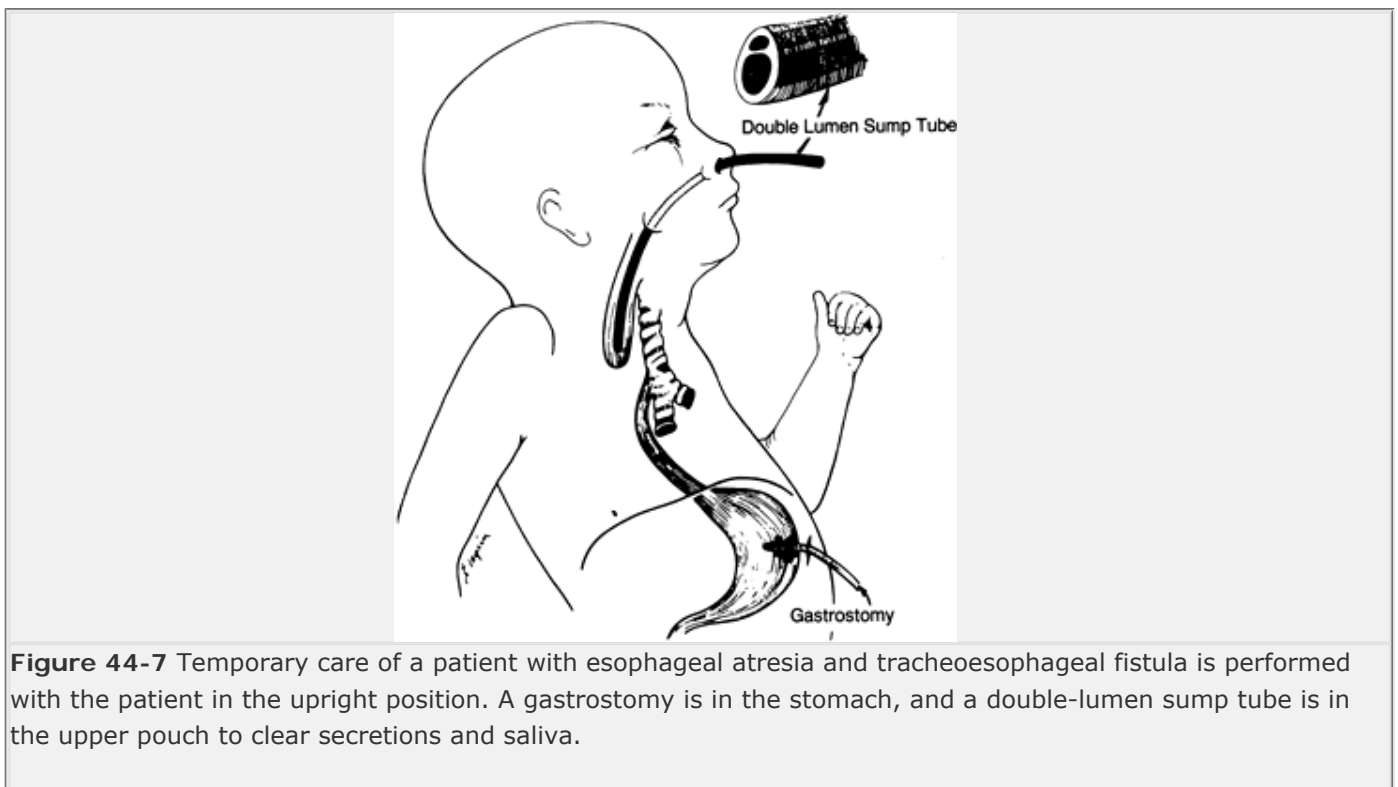

Figure 44-7 Temporary care of a patient with esophageal atresia and tracheoesophageal fistula is performed with the patient in the upright position. A gastrostomy is in the stomach, and a double-lumen sump tube is in the upper pouch to clear secretions and saliva.

Immediate Operative Repair

A thoracic incision provides exposure of the upper pouch and tracheoesophageal fistula. A right thoracotomy is standard unless the aortic arch is on the right, which would interfere with the dissection. A retropleural approach affords protection of the lung by maintaining its pleural envelope. If an anastomotic leak occurs, it will not communicate with the pleural cavity but can be drained posteriorly from the mediastinum with less morbidity.

The fistula is identified and carefully divided from the trachea. The tracheal opening is closed with several sutures, with care to avoid narrowing the tracheal lumen. Although some centers have advocated simple ligation of the fistula, this procedure is rarely performed because it is associated with an unacceptably high rate of

recurrence (86).

The circumference of the lower esophageal fistula is usually small and is enlarged by trimming and spatulating its open end. The tip of the upper pouch is mobilized extensively and cut across to expose the lumen. Most surgeons employ a single-layer circumferential anastomosis to approximate the two ends instead of the classic two-layer Haight anastomosis (87).

Avoiding undue tension on the repair and averting compromise of the blood supply to the two ends are key factors in obtaining good results. The upper pouch is more amenable to mobilization than the distal fistula because the blood supply comes submucosally from the neck. The blood supply to the distal fistula is more easily compromised because it derives from tiny branches off the aorta. If the ends do not come together easily, there are surgical techniques available for extending the length of the upper pouch (88).

Although once routine, gastrostomy is now rarely used in stable infants. Postoperatively, infants are maintained on intravenous nutrition. Some surgeons employ a transanastomotic feeding tube so that early enteral feedings can be initiated. A chest tube is placed to drain the mediastinum and pleural space if necessary. The chest tube is connected to suction and monitored for evidence of air leak, blood loss, or saliva, which indicate an anastomotic leak. Postoperative management requires meticulous care to avoid potential disruption of the tracheal suture line, particularly if suctioning or reintubation is required. A contrast swallow is usually obtained on the fifth or sixth postoperative day. If all looks well, and there is no leak, feedings are begun and quickly advanced. Some surgeons routinely dilate the esophagus of all infants before discharge to prevent potential stricture formation.

Delayed Primary Repair and Staged Repair

If the infant is unstable, an intermediate plan allows correction of minor difficulties before repair. This plan involves delay of the surgical repair for several days. Management of these babies includes upper pouch suction with a Replogle tube, head-up position, antibiotics, and parenteral nutrition. These maneuvers provide for stabilization, improvement of pulmonary status, and diagnosis and management of certain higher-priority malformations, particularly cardiac lesions. Primary retropleural repair, as described previously, is undertaken when the infant's condition is stable and the risk of surgery has been reduced.

Unstable infants with serious coexisting anomalies or severe prematurity have diminished chances for survival. For these infants, a gastrostomy is placed, and repair is postponed. This approach uses early retropleural fistula division without anastomosis, gastrostomy feedings, and continuous sump suction of the upper pouch. Division of the fistula is important to prevent reflux of gastric contents. In some premature infants with noncompliant lungs, division of the fistula is required to allow adequate ventilation, in essence closing off the lower-resistance pathway through the fistula and stomach. Immediate closure of the fistula may be lifesaving in these instances.

Gastrostomy and fistula division without anastomosis requires constant, intensive nursing care, but it can be safely maintained for many weeks. Coupled with the holding pattern provided by suction of the upper pouch and gastrostomy drainage, infants with esophageal atresia and

P.1111

tracheoesophageal fistula can be maintained indefinitely by intravenous nutrition although weight and pulmonary status are improved and other congenital anomalies are studied and corrected. Later, the definitive transthoracic operation is performed, and the esophageal anastomosis is accomplished electively.

Results

At the CNMC in Washington, D.C., over 150 patients with a blind upper esophageal pouch and a fistula arising from the bifurcation of the trachea were treated between 1966 and 1997. Approximately 90% of these patients survived. Since 1982, the physiologic status of the infant has been the sole guide to therapy. The survival for infants who were classified as stable and had primary repair is 100%. Survival in the unstable group who had staged repair is 60%. The deaths were from associated anomalies, including congenital diaphragmatic hernia and hypoplastic left heart. As a result of this experience with high-risk infants, we concluded that a staged procedure, even one that abandons the esophagus, is preferable to primary repair for selected infants in the highest-risk group. This decision is controversial. Most pediatric surgeons eschew the staged approach, preferring primary repair in most infants with esophageal atresia and tracheoesophageal fistula.

Complications

Complications are not uncommon and require scrupulous diagnostic evaluation. Strictures, gastroesophageal reflux, poor motility, recurrent fistula, and tracheomalacia produce similar respiratory symptoms and may be difficult to differentiate.

Gastroesophageal reflux after repair of esophageal atresia has become increasingly recognized as a clinical problem because of more sensitive diagnostic tools, such as 24-hour potential of hydrogen (pH) monitoring. Werlin and co-workers showed that all of the 14 postoperative esophageal atresia patients they studied exhibited severe esophageal motor dysfunction. Only five of the 14 had a swallowing problem (89). In 1980, Jolley and others studied 25 young patients between 3 and 83 months after repair of esophageal atresia and tracheoesophageal fistula. Seventeen of 25 had significant gastroesophageal reflux demonstrated by prolonged pH monitoring, and 12 of these patients had significant symptoms in the form of vomiting, respiratory difficulty, or esophagitis (90). Wheatley and Coran concluded that esophageal dysmotility and gastroesophageal reflux were serious problems in combination and recommended fundoplication in selected patients (91).

Esophageal stricture is a common complication (31% in our series) after the anastomosis of the esophagus. Stricture may present early with an inability to swallow, choking, or failure to thrive, but symptoms may develop later, particularly at the time of transition to solid foods. In most infants esophageal dilation is successful, but some require repetitive dilations as often as every 2 weeks for 1 year. Occasionally, a recalcitrant stricture requires operative resection.

Anastomotic disruption with leakage of saliva, gastric juice, and swallowed liquid into the mediastinum or thoracic space was once a dreaded complication after surgery. It is no longer universally fatal because of improvements in nutrition and antibiotics. The leak may be identified on a contrast study obtained before feeding or by an increase in the output from the chest tube or the drainage of saliva through the chest tube. If the operative repair has been accomplished with a retropleural approach and the pleura remains intact, external drainage posteriorly from the mediastinum is a relatively simple matter. If transthoracic repair is followed by esophageal disruption, the leak is best treated by extensive drainage, parenteral nutrition, and delayed surgical intervention. If the baby is deteriorating, it may be wise to abandon the esophagus and create a diverting cervical esophagostomy.

Recurrent fistulas may develop in a few infants (92). Usually, there is a history of a perioperative leak. The symptoms are often those of recurrent respiratory problems, such as bronchitis or pneumonia, related to silent aspiration. Reoperation is required to divide the fistula.

Tracheomalacia is an uncommon complication, but it is difficult to manage. It may be related to a congenital weakness of the trachea or operative injury. The spectrum of presentation ranges from complete collapse of the airway, with an inability to ventilate without positive pressure, to mild tracheal compromise. Bronchoscopy reveals the level and degree of collapse. In severe cases, operative suspension of the aorta and trachea is curative.

Esophageal Atresia without Fistula

Esophageal atresia may occur without a fistulous connection to the respiratory tract. This variant accounts for approximately 8% of esophageal malformations. As with other forms of esophageal atresia, these babies cannot swallow food or saliva. Because there is no tracheo-esophageal fistula, air is absent from the GI tract, and the abdomen is noticeably scaphoid. The radiologic findings of a blind upper pouch coupled with the absence of air below the diaphragm are pathognomonic of isolated esophageal atresia.

For many years, the standard treatment of isolated esophageal atresia included cervical esophagostomy and gastrostomy. At a later time, a feeding pathway would be created with a segment of small bowel or colon or with construction of a reversed gastric tube. This time-proven practice still has a place in the treatment of pure esophageal atresia. Since the mid-1970s, new methods for bridging the gap between the disparate esophageal segments have evolved. Howard and Myers reported a technique for elongating the blind upper pouch using daily stretching by bougie dilators, allowing the two esophageal ends to be successfully united after several months (93). Mechanical stretching of the pouches may not be necessary. Natural growth in the first months of life produces

impressive elongation of the esophageal pouches. During the interval, meticulous nursing care is required to prevent aspiration of saliva and ensure adequate nutrition. In many infants, the wisest course may still be

cervical esophagostomy and gastrostomy, with later esophageal replacement (94). This course is even more appropriate for the premature infant, especially if respiratory distress proves troublesome.

The decision to preserve or abandon the esophagus rests on the patient's weight, pulmonary status, presence of other serious anomalies, and general hardiness during the early diagnostic and sustaining maneuvers. Our experience has led us to treat the last 20 consecutive infants who presented with isolated atresia of the esophagus by cervical esophagostomy and gastrostomy, reconstructing the esophagus at 1 year of age using a reversed gastric tube. The latter is a tube created from the greater curve of the stomach, brought up through the chest, and anastomosed to the upper esophageal segment. Nineteen of the 20 infants survived and are growing well.

Isolated Tracheoesophageal Fistula

Isolated (i.e., H-type) tracheoesophageal fistula is a rare lesion, representing approximately 4% of esophageal anomalies. Although congenital tracheoesophageal communication without atresia may be found at any level, most of these fistulas occur in the upper portion of the trachea and the esophagus, at or above the level of the second thoracic vertebra (95). Larger fistulas and communications extending throughout the length of the trachea have been seen, defects appropriately called laryngotracheoesophageal clefts.

The infant suffering from congenital tracheoesophageal fistula usually chokes and coughs with feeding. Prompt relief may be achieved by gavage feeding. Frequently the diagnosis is not made in infancy because the symptoms can be subtle. Pneumonitis often develops in the early days of life and recurs frequently as patchy bronchopneumonia. With continued aspiration through the fistula, a constant state of bronchopneumonia supervenes, attended by all of the manifestations of chronic infection. For any child with recurrent pneumonia, a wide variety of disease entities must be considered, but the list should include H-type tracheoesophageal fistula.

A contrast esophageal swallow with a dilute or isoosmolar medium may reveal the fistula (see Fig. 44-6C). Tracheobronchoscopy is usually successful in demonstrating this anomaly, but simultaneous esophagoscopy may be required. The fistula can be exposed through a cervical collar incision in most instances. A thoracic approach is necessary in 10% to 15% of patients. Surgery produces complete cures for most patients.

Laryngotracheoesophageal Cleft

Although once uniformly fatal, laryngotracheoesophageal clefts can now be repaired with good results. Early diagnosis is essential to prevent repeated aspiration through the communication between the trachea and esophagus below the vocal cords. Bronchoscopy allows identification of the cleft and its severity. Defects range from those involving only the upper trachea to those extending the entire length and beyond the carina. Management involves tracheostomy and an antireflux procedure to prevent aspiration, with later repair of the defect (96).

Gastroesophageal Reflux

In 1947, Berenberg and Neuhauser defined a condition they called "chalasia," or abnormal relaxation of the gastroesophageal junction (97). The affected babies manifest relentless regurgitation that may present as spitting, mild vomiting, or vigorous vomiting after every feeding. The deleterious effects of gastroesophageal reflux in infants have been recognized with increasing frequency (98,99 and 100). The spectrum of symptoms caused by gastroesophageal reflux in the infant is distinctly different from that seen in the adult. In infants, the main symptoms of gastro-esophageal reflux are regurgitation, significant growth retardation, aspiration pneumonia, apneic spells, stridor, and esophagitis (91,92,101,102). The abnormality is the absence of a normal valvular mechanism at the gastro-esophageal junction that allows unimpeded reflux of gastric content. Associated medical conditions affect many infants. Congenital or acquired central nervous system disorders are most frequent, including severe asphyxia, cerebral palsy, chromosomal anomalies, and microcephaly.

Infants with repaired esophageal atresia and tracheo-esophageal fistula may have reflux that leads to anastomotic strictures, poor weight gain, or aspiration pneumonias.

Most infants with gastroesophageal reflux have some form of vomiting from birth. In some babies, the vomiting suggests the diagnosis of pyloric stenosis. Retardation of growth and development is the second most common presenting symptom, occurring in approximately 50% of our patients. These babies rank below the tenth percentile on their growth chart or show a marked falling off of growth progression. Recurrent aspiration with pneumonia occurs in approximately one-third of infants with pernicious gastroesophageal reflux. Reflux may

also be the underlying cause of severe apnea in some infants (100).

A barium swallow demonstrates reflux in about 75% of symptomatic patients. However, reflux can also be shown in many otherwise normal, healthy infants, and radiologists have understandable difficulty in defining gastro-esophageal reflux that is pathologic. Gastroesophageal reflux can be documented and quantified with radionuclide material. This examination permits an accurate appraisal of the pathophysiologic effects of reflux in most patients. It has proved adaptable to infants, and when serial observations are extended over several hours, normal reflux can usually be differentiated from pathologic reflux. Gastric emptying is also measured by this scan.

Monitoring of pH at different levels of the esophagus can demonstrate gastric acid reflux. With timed studies,

P.1113

physicians can now chart reflux in relation to sleeping, various body positions, and during eating, documenting episodes that lead to characteristic symptoms or life-threatening incidents (103). Esophagoscopy helps physicians to document the presence of esophagitis in selected infants.

Every effort should be made to reverse the consequences of pernicious gastroesophageal reflux by conservative therapy. Medical therapy of symptomatic infants with gastro-esophageal reflux consists of maintaining a semiupright posture and small frequent feedings of thickened material. Bethanechol has yielded little or no benefit, but metaclopramide, which increases the tone and amplitude of gastric contraction, relaxes the pyloric sphincter, and accelerates gastric emptying, has proved more helpful.

In rare instances, the extent of a baby's nutritional depletion or chronic pneumonitis may demand hospitalization. In infants sick enough to be hospitalized, 3 weeks is an ample period to determine whether their symptoms can be controlled by intensive medical measures. Infants less severely affected should be evaluated in an outpatient setting over 2 to 4 months. If symptoms are controlled by medical means, reflux usually disappears by 15 months, coincident with the development of upright posture. In our experience, medical therapy fails for approximately 15% of patients.

With worsening or protraction of symptoms despite adherence to conservative treatment, surgical correction is recommended if the infant fails to gain weight and grow adequately, has recurrent pneumonitis, has life-threatening apnea spells, or has esophagitis. Prompt operative correction is thought appropriate without medical trial for those patients with thoracic translocation of a significant portion of the stomach and esophageal stricture.

Surgical intervention is undertaken to place the gastro-esophageal junction well below the diaphragm (i.e., lengthen the intraabdominal esophagus), recreate an acute angle of His, and create a valve-like mechanism to force the fundus of the stomach against the esophagus. The Nissen fundoplication involves wrapping the fundus of the stomach completely around the esophagogastric junction (Fig. 44-8). In the Thal procedure, the wrap is partial (i.e., 210 to 270 degrees). Postoperative problems such as dysphagia and inability to burp and vomit (i.e., gas-bloat syndrome) appear less likely with the Thal procedure (102). Gastroesophageal reflux is discussed in more detail in Chapter 37.

ABDOMINAL SURGERY

The indications for abdominal surgery are distension and bilious vomiting. To these should be added the scaphoid contour seen if there is high intestinal obstruction or the abdominal viscera are in an ectopic location, as in infants with congenital diaphragmatic hernia. Extreme degrees of abdominal distension are associated with intestinal and gastric perforation. Tenderness signifying peritoneal irritation can be elicited by careful examination. A tender erythematous abdominal wall is a reliable sign of an intraabdominal catastrophe with resultant peritonitis and ischemic intestine. Reliance on bowel sounds can be misleading. Peristalsis can exist despite peritonitis or be absent when intestinal distension is caused by mechanical obstruction.

Figure 44-8 A successful method for the surgical correction of gastroesophageal reflux employs gastric fundoplication as described by Nissen.

Pertinent radiologic studies to be obtained in all cases of suspected intraabdominal surgical lesions are the flat and upright views of the abdomen. The left lateral decubitus radiograph may be substituted for the upright radiograph if pneumoperitoneum is suspected. Intestinal obstruction can be diagnosed and the level of obstruction determined by the configuration of the air-fluid levels. Pneumoperitoneum is usually readily appreciated on abdominal x-ray films. Supine radiographs may show the football sign produced by superimposition of the falciform ligament on a large bubble of free air (Fig. 44-9). The bowel wall may be outlined by air outside and inside the bowel lumen. The left lateral decubitus radiograph may show air around the liver. Not infrequently, the findings on radiographs may be subtle and require an alert physician to make the diagnosis. Distended bowel and the absence of air-fluid levels in intestinal loops of various sizes suggest obstruction secondary to meconium ileus. Calcifications scattered within the abdomen indicate intrauterine perforation with meconium peritonitis.

Figure 44-9 Supine abdominal x-ray film demonstrates a massive intraperitoneal air collection. The air is seen as a large central bubble on which is superimposed a dense linear opacity produced by the falciform ligament. The falciform ligament forms the lace for the football sign.

Unless precluded by a deteriorating clinical condition, a contrast enema, usually of isoosmotic Gastrografin initially, requires only a short delay that is usually justified by the information obtained. The enema need not be an elaborate study in these precarious subjects.

The diagnosis of malrotation is most accurately made with a small amount of contrast placed into the stomach to confirm the position of the ligament of Treitz. Incomplete obstructions of the GI tract, such as those caused by congenital stenosis or intraluminal web, are often the most difficult congenital lesions to diagnose and require contrast studies of the upper GI (UGI) tract with careful attention to every centimeter of intestine on fluoroscopy.

Pneumoperitoneum: Gastric Perforation

Spontaneous perforation of a hollow viscus is most frequently seen in distressed neonates who have undergone resuscitation immediately after birth. The presence of free air in the peritoneal cavity may be secondary to perforation anywhere in the GI tract and is a surgical emergency. The surgeon approaching the infant with pneumoperitoneum must be prepared to investigate systematically the entire GI tract and anticipate problems such as Hirschsprung disease, gastric perforation, necrotizing enterocolitis (NEC), or other ischemic insults to the intestine resulting in perforation (104,105,106).

After perforation, egress of air into the peritoneal cavity usually leads to impressive abdominal distension. Elevation of the diaphragm occurs with potential embarrassment of the infant's respiratory dynamics. A temporary but lifesaving maneuver is needle aspiration of the peritoneal cavity, which diminishes air under pressure, allowing the diaphragm to return to a more normal position. There is usually dramatic relief of abdominal distension and respiratory distress. It is not hazardous to insert a needle adapted to a 50-mL syringe through the anterior abdominal wall. The bowel is usually compressed against the posterior parietes and is not likely to be injured by this maneuver.

Surgical intervention must be prompt. When massive distension of the abdomen occurs, a gastric perforation can be anticipated. Typically, the rent occurs high on the greater curvature of the stomach. Because the perforation may be located on the posterior wall, thorough exploration of relatively inaccessible areas of the stomach must be carried out. Although it has been suggested that perforation of the stomach results from congenital deficiency of musculature in the gastric wall, this explanation is questionable. The apparent absence of musculature at the margin of the perforation probably represents retraction of the muscles of an overdistended stomach, with a ballooning of mucosa between the muscle fibers.

Repair is accomplished by primary closure in two layers after debridement of the margins of the perforation. A gastrostomy tube, inserted through a noninvolved area of the stomach, is advisable to ensure postoperative decompression. The subsequent course of the infant is usually uncomplicated if the underlying problem for which resuscitation was required is controlled. Cautious feedings can be started within a few days of surgical repair. For diagnosis and management of perforations occurring elsewhere in the GI tract, see Meconium Peritonitis and Necrotizing Enterocolitis.

Temporary Diversion of the Intestinal Tract

Newborn intestinal emergencies often demand a temporary vent or enterostomy. Although not as desirable as an end-to-end union of the bowel, these measures may be lifesaving in fragile infants who are critically ill as the result of intestinal obstruction or peritonitis or who are threatened by serious congenital defects. An abdominal stoma in the infant does not carry the same implications as in the adult; the physician must stress this fact to allay the fears and doubts of a worried parent. Most enterostomies are temporary, and the outlook for restoration of complete intestinal continuity is good.

Gastrostomy

The stomach requires venting for two reasons. First, decompression of the GI tract is necessary in the face of

P.1115

any abdominal catastrophe. Placement of the gastrostomy obviates the need for a nasogastric tube. It is more efficient and eliminates the danger of pressure necrosis of the alar cartilage of the infant's nose and the respiratory hazards that attend nasogastric tubes. Second, the gastrostomy tube provides access for feeding a depleted neonate.

Gastrostomy can be performed under local anesthesia, although it is usually done under general anesthesia. Frequently, the procedure complements a primary abdominal operation. A simple Stamm gastrostomy is preferred, and it is not difficult to remove or replace the tube as an office procedure. If the gastrostomy tube is to be maintained for a long time, it may be replaced after 1 month with a gastrostomy button, which is easier

for the parents to care for at home (107).

Ileostomy

Temporary ileostomy is less desirable than primary union of the bowel, but there are clinical circumstances in which its creation as a temporary diverting procedure is prudent, including inflammatory necrosis of the distal small bowel with intraperitoneal soiling and peritonitis, ischemic insult with marginal viability of the bowel, and marked disparity in lumen size, as in intestinal atresia or meconium ileus.

A properly performed ileostomy is usually well tolerated and rarely causes skin breakdown. With appropriate supportive care, weight gain and healing proceed, and intestinal reconstruction can be carried out electively with greater safety for the infant. We recommend closure of the ileostomy when the infants weigh 2.5 to 3.0 kg to minimize fluid and electrolyte imbalances that these babies may develop (108).

In very sick infants or in babies with other underlying conditions such as meconium ileus, the double-barrel enterostomy of Mikulicz has proved valuable. The common wall that has been created is gradually crushed with a special clamp, partly reestablishing intestinal continuity. Complete closure of the bowel can be achieved without reentering the peritoneal cavity. Another effective technique of intestinal venting that permits access to the distal GI tract is the end-to-side enteroenterostomy described by Bishop and Koop (109). This technique has particular application for lesions in the proximal GI tract, such as jejunal and high ileal atresia.

Colostomy

The four usual indications for colostomy in the neonate are impending or actual perforation of the colon, colonic atresia with huge disparity of the bowel lumen, Hirschsprung's disease, and high imperforate anus. The loop colostomy has the advantage of simplicity and speed in critically ill babies. An end-colostomy is mechanically sound, easily managed, and avoids spillage into the distal loop, which is an advantage in treating Hirschsprung disease and imperforate anus. A diaper neatly covers the colostomy during the early months of life, until definitive surgical correction of the primary problem is accomplished and the colostomy can be closed (see Chapter 37).

Rotational Abnormalities

Malrotation

In the developing embryo, the elongating intestine must undergo rotation as it returns to the celomic cavity so that it can be accommodated within the confines of the abdominal cavity. The proximal small intestine assumes the characteristic C-shaped contour, and the duodenum is fixed to the left of the midline at the ligament of Treitz. The cecum takes a counterclockwise rotation, reaching its final location in the right lower abdomen (110). Incomplete intestinal rotation with consequent inadequate fixation of the intestinal mesentery may be an asymptomatic occurrence, may give rise to subtle symptoms difficult to diagnose, or may present as a life-threatening intraabdominal catastrophe. An understanding of the mechanism by which the lesion becomes symptomatic is necessary if the physician is to recognize and prevent the devastating complications that can accompany midgut volvulus.

If rotation is abnormal, bands are formed between the ectopic cecum, located in the right upper quadrant, and the right lateral abdominal wall. As these bands course from the cecum to the abdominal wall, they traverse the duodenum and can cause intermittent, incomplete duodenal obstruction. Symptoms of partial duodenal obstruction are often baffling. The infant may experience intervals of normal feeding pattern that are interspersed with exasperating episodes of vomiting. Because the obstruction is high in the GI tract, abdominal distension does not occur. The telltale sign of an underlying mechanical problem is bile in the vomitus. This lesion, more than any other, supports the contention that bile-stained vomitus in an infant necessitates a thorough diagnostic workup to detect a malrotation and subsequent midgut volvulus. More than 50% of babies present with symptoms before 1 week of age, but 10% remain asymptomatic until after 1 year of age (111).

The most reliable diagnostic study is a UGI series for localization of the ligament of Treitz. Surgical correction of malrotation of the colon prevents a future volvulus of the midgut and relieves the partial duodenal obstruction. The bands binding the cecum to the right abdominal wall are lysed, and the large bowel is freed and transposed to the left side of the abdomen. The duodenum is mobilized on its medial aspect, in which the narrow mesentery is intimately associated with the superior mesenteric artery. As the mesentery of the small bowel is freed

medially, it assumes a broad position over the posterior abdominal wall. With the mesentery splayed, the potential for torsion is eliminated. It is unnecessary to fix the intestine in its new position with sutures (112). The appendix, because it now lies on the left side of the abdomen, is usually removed or inverted. Operative correction of malrotation in this manner is known as the Ladd procedure.

Malrotation with Midgut Volvulus

If fixation of the mesentery of the small bowel has not occurred normally, the intestine is subject to torsion on the axis of the superior mesenteric artery. This mechanism of obstruction must be considered for an infant with bile-stained vomiting, especially if there is no abdominal distension. Abdominal tenderness is an ominous finding.

Roentgenographic abnormalities are often characteristic, with evidence of duodenal obstruction and scanty gas distributed through the remainder of the bowel. The air-fluid levels typical of intestinal obstruction elsewhere in the GI tract are not usually associated with this malrotation. An airless abdomen is an ominous sign and usually indicates that infarction of the intestine has already taken place. Bloody stools imply that significant compromise to the intestinal vasculature has occurred. A UGI series shows a corkscrew-like constriction of the third portion of the duodenum.

If midgut volvulus is diagnosed or suspected as the underlying mechanism for the infant's illness, emergency surgical exploration is undertaken. If the findings are favorable and the bowel is viable, the torsion is reduced by counterclockwise rotation, and a Ladd procedure is carried out as described for the treatment of malrotation without volvulus. The prognosis is favorable as long as the viability of the intestine is not in question. However, if the diagnosis has been delayed or the volvulus has been an intrauterine event, intestinal ischemia, infarction, or both may be encountered in the distribution of the superior mesenteric artery. Initial judgments regarding the viability of the intestine are not easy; intestinal resection at the time of initial exploration is contraindicated. The ischemic intestine must be given every opportunity to recover after the torsion has been reduced. The first operation consists of untwisting the small bowel and establishing a gastrostomy.

Reexploration is undertaken 24 to 36 hours later, and areas of obvious infarction are identified. These are resected, and appropriate enterostomies are brought out to the abdominal wall; anastomosis is contraindicated. Any intestine of marginal viability is retained in hope that it will recover. Reexploration to determine recovery or further loss of small bowel is repeated after another interval of 36 to 48 hours. After the full extent of intestinal loss has been established and the margins of viable bowel exteriorized, the surgeon is faced with the management of a desperately ill infant at risk from sepsis, disseminated intravascular coagulation, and the inevitable nutritional crisis attending a short-bowel syndrome.

A central venous catheter for total parenteral alimentation is established, and nourishment is provided by this technique throughout the early postoperative weeks. After the infant has achieved positive nitrogen balance and the reestablishment of intestinal continuity is complete, there is then a difficult period of weaning from parenteral onto oral feedings. About 40 cm of residual small intestine seems to be required for successful adaptation of the intestine in full-term infants, although adaptation has been reported for children with considerably less than 40 cm of intestine (113). If the distal ileum and ileocecal valve are intact, slightly less bowel may be tolerated. Infant formulas that are fat-free and contain monosaccharides and hydrolyzed protein should be used to feed these babies because these formulas require only a minimal absorptive surface and little enzyme activity for assimilation. Gradually, the volume and concentration of these substances may be increased until all calories are taken orally. The process of weaning the infant from total intravenous to total oral alimentation may take months. This underscores the devastating complications of a midgut volvulus and indicates the need for vigilance by pediatrician and surgeon in the pursuit of the diagnosis of malrotation.

Hypertrophic Pyloric Stenosis

Pyloric stenosis occurs in approximately one of 300 to 1,000 live births. Its cause is obscure. Boys are affected about four times as frequently as girls, and the disease seems to have a predilection for the first-born child. There is a familial tendency, with a 2.5% to 20% incidence of pyloric stenosis in children of affected parents; the variation in incidence depends on the genders of the affected parent and child (114). It has been speculated that hypertrophy of the circular muscles of the pylorus results from propulsion of milk curds against the spastic pyloric canal, producing edema, additional spasm, and subsequent hypertrophy of the musculature, leading to complete obstruction. Some researchers have postulated that the muscle hypertrophy is a response to vagal stimulation. This is somewhat substantiated by the observation that infants undergoing surgery for esophageal

atresia and tracheoesophageal fistula seem to have a higher incidence of pyloric stenosis, a result perhaps of vagal nerve irritation in the operative field. No infectious agent has been isolated despite the apparent seasonal incidence of the disease. The clinical onset of bile-free projectile vomiting at 2 to 8 weeks of age in a first-born boy strongly suggests the diagnosis of congenital hypertrophic pyloric stenosis. Occasionally, the onset is insidious, and these babies can present to the pediatrician as perplexing feeding problems. A typical history reveals intermittent vomiting that gradually increases in frequency and intensity over a week, until the baby vomits most ingested feedings with impressive force.

Abdominal examination is carried out with the stomach empty. If the infant has not just vomited, the physician may need to use a nasogastric tube to ensure an adequate examination. The baby can be given a pacifier for relaxation. Visible peristalsis may be observed moving across the upper abdomen. The examiner stands to the left, elevating the baby's feet with his left hand to relax the abdominal muscles and then palpates gently in the right upper quadrant. The pyloric olive is palpable to the experienced examiner in 90% of patients, and radiographic studies are usually not needed. If pyloric stenosis is suspected but the olive cannot be palpated, the diagnostic procedure of choice is abdominal ultrasonography, which is more than

P.1117

90% accurate in centers experienced with this technique (115). A UGI series is usually reserved for those patients with vomiting but a normal ultrasonographic examination, in whom another cause of obstruction is suspected. Hyperbilirubinemia is seen in 8% of babies with pyloric stenosis. Almost all the bilirubin is of an indirect type and may be related to a decreased level of hepatic glucuronyl transferase (116). Jaundice clears after pyloromyotomy.

Infants with pyloric stenosis are conveniently grouped according to their clinical condition at the time they are seen by the surgeon. About one-half are well hydrated and in a satisfactory nutritional state. Serum electrolytes are normal, and the urine, although concentrated, is of adequate volume. These babies can undergo surgical correction without preoperative preparation. For the remaining infants, preparation before surgery is necessary. The typical pattern of electrolyte disturbance is that of mild or moderate metabolic alkalosis. The hypokalemia may not be reflected in the serum electrolytes, but potassium supplements must be provided before the alkalosis can be corrected. Salt-losing adrenogenital syndrome can present with symptoms identical to pyloric stenosis. However, this condition is characterized by an elevated serum potassium and metabolic acidosis.

These moderately dehydrated infants usually can be corrected within 12 hours with 5% dextrose-half-normal saline solution at a rate half to twice that of maintenance. After urine production is certain, potassium should be replaced at 2 mEq/kg for the 12-hour period of therapy.

A few infants present with severe dehydration and malnutrition and are often well below their birth weight. In this group, extensive rehydration is mandatory before surgery. The infants are profoundly alkalotic and potassium deficient. Their protein stores are depleted, urine is scanty, and they may be anemic. Intensive therapy for 2 to 3 days is required to bring these infants into metabolic balance. Fluids, electrolytes, colloid, and even blood may be necessary. Fortunately, it is rare to see such children today.

A Ramstedt-Fredet pyloromyotomy is usually performed through a transverse skin incision placed in the right upper quadrant of the abdomen. However, a circumbilical incision or laparoscopic approach have gained popularity. This short, safe, surgical procedure accomplishes division of the hypertrophic circular muscles of the gastric outlet and reestablishes patency of the pyloric channel (Fig. 44-10). In most cases, glucose water feedings can be reinstated 6 to 8 hours postoperatively. If the child tolerates the first feeding, slow advancement of the volume of his regular formula is encouraged. The infant commonly vomits a few times postoperatively, but this should not alter his feeding advancement. Explanation to the parents that this vomiting is common can allay their anxiety. The child is generally ready for discharge on the second or third postoperative day, when he attains adequate oral intake. Typically, the babies enjoy a growth spurt in the immediate postoperative weeks, much to the satisfaction of the parents.

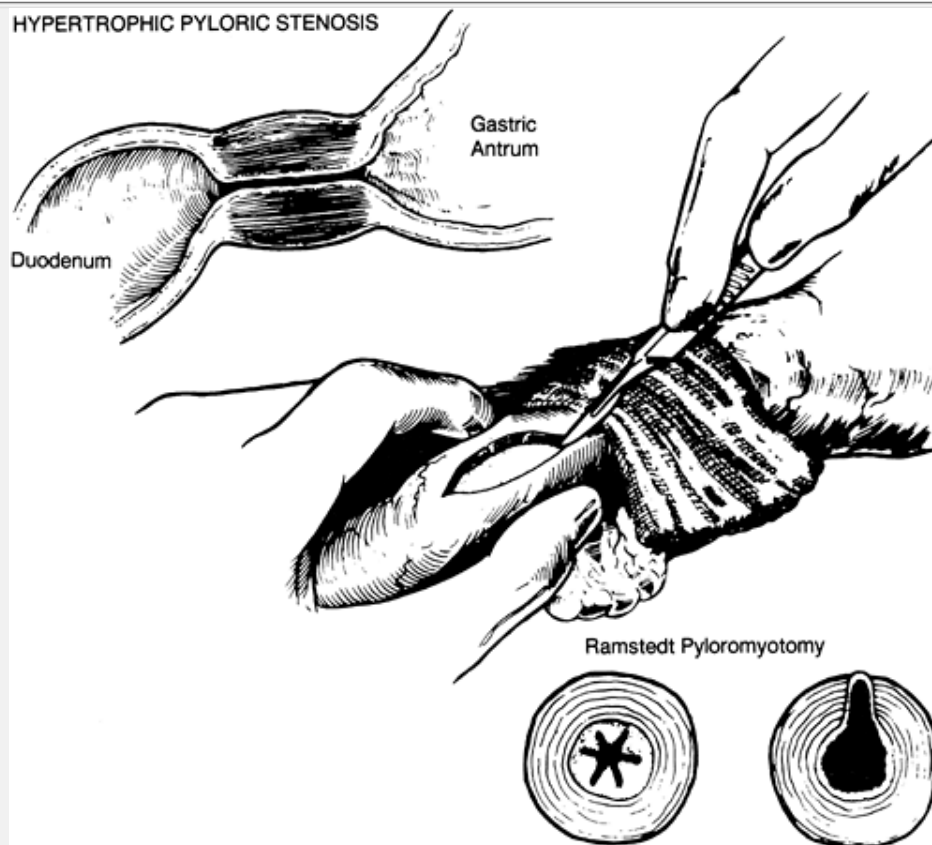

Figure 44-10 A Ramstedt pyloromyotomy is made through all layers of the pylorus except the mucosa. The cross section demonstrates how the mucosa of the pylorus expands into the defect created, enlarging the cross-sectional diameter of the pyloric channel.

Duodenal Atresia, Stenosis, and Annular Pancreas

Duodenal obstruction may be complete or partial and results from intrinsic causes or external compression (117). An intraluminal diaphragm can cause partial, intermittent obstruction that is difficult to recognize. Only a carefully performed UGI series outlines an intraluminal web and determines the site of obstruction. Annular pancreas, duodenal stenosis, and congenital bands are other causes of partial duodenal obstruction in which the need for early surgical intervention is more apparent.

Duodenal atresia results in complete obstruction. In instances of complete duodenal obstruction, swallowed air is prevented from passing beyond the duodenum, and the middle and lower abdomen are scaphoid. The characteristic x-ray finding is that of a double bubble of ingested air filling the stomach and blind-ending duodenum (Fig. 44-11). Duodenal atresia is often associated with trisomy 21.

Unless the underlying cause of obstruction is related to malrotation, an initial period of nasogastric drainage and resuscitation with intravenous fluids and electrolytes is appropriate before duodenal obstruction is surgically corrected. Surgical therapy is tailored to the particular lesion encountered. The intraluminal web can be resected through a transduodenal approach. It may be necessary for the surgeon to perform a gastrotomy or duodenotomy, through which a Foley catheter with the balloon minimally inflated is passed, to identify the site at which the web is attached.

Some stenotic lesions can be managed by local duodenoplasty, but obstruction from duodenal atresia requires bypass for relief. Obstruction secondary to duodenal atresia or annular pancreas is best treated by creating a

P.1118

duodenoduodenostomy (118). A duodenojejunostomy is an alternative method to establish intestinal continuity.

Figure 44-11 Characteristic double bubble of congenital duodenal obstruction.

Jejunoileal Atresia

Atresia of the bowel probably results from an ischemic insult to the intestine during its development (119). The atresia may be discrete, involving only a short segment of jejunum or ileum (Fig. 44-12), or it may involve the intestine over many centimeters (120). Atretic areas are sometimes multiple, and although the intervening bowel is normal, considerable length may be missing. Abdominal distension and bile-stained vomitus are the usual presenting symptoms. Radiographs show air-fluid levels distributed throughout the abdomen (Fig. 44-13). In cases of distal ileal obstruction, the contrast enema adds confirmation, showing the typical microcolon.

Figure 44-12 In this patient with jejunal atresia, a dilated proximal segment and a narrow distal jejunum are evident.

Figure 44-13 An upright abdominal x-ray film of a patient with jejunal atresia shows gastric distension and approximately three loops of bowel with no gas beyond the obstruction.

A short period of restoration with fluids, electrolytes, and colloid may be necessary, but this should never exceed a few hours. The method of surgical correction depends on the intraoperative findings. If the intestinal length is normal, the dilated proximal end is excised back to near-normal-caliber bowel, and an end-to-back anastomosis is performed. In the infant with a large-gap atresia, the proximal end is tapered, and anastomosis is then accomplished (121,122). The end-to-side reconstruction, described by Bishop and Koop, has proved safe and effective and has the added advantage of providing access to the GI tract for irrigations postoperatively (109). This type of repair is particularly helpful if there is a major disparity in the size of the ends of the intestine. A Mikulicz enterostomy or simple end-enterostomy may be lifesaving in critically ill, depleted newborns with distal bowel obstruction.

Incomplete obstruction resulting from stenosis of the bowel can be puzzling and hazardous because there is a confusing clinical picture. The infants feed poorly, occasionally vomit, or become distended without pattern. These symptoms continue despite changes in the formula.

P.1119

The pediatrician may consider food allergies, nonspecific failure to thrive, and even a nervous mother as underlying causes. The obstruction finally becomes complete, or the bowel perforates. Surgical exploration may be needed to confirm a diagnosis of ileal stenosis, and this approach is considered even if x-ray examinations of the intestine have been normal when the clinical course of the infant suggests this diagnosis. Cure is achieved by appropriate intestinal tailoring procedures such as a Y-V plasty or longitudinal incision and transverse closure (i.e., Heineke-Mikulicz principle).

Meconium Plug Syndrome

The meconium plug syndrome is a benign form of colon obstruction in the neonate caused by a firm white plug of mucus. These babies usually present with abdominal distension. Abdominal x-ray films reveal distended loops of bowel. A barium enema shows a long radiolucency within the descending colon. The plug is passed after the barium enema or a saline rectal irrigation. Although meconium plug syndrome is found in otherwise completely normal infants, it can be difficult to differentiate from Hirschsprung disease and to rule out cystic fibrosis, so many surgeons routinely perform a rectal biopsy and obtain a sweat chloride test in infants with meconium plug syndrome.

Meconium Peritonitis

Meconium peritonitis usually follows antenatal intestinal obstruction and perforation of the bowel above the obstruction in conditions such as bowel atresia, volvulus, meconium ileus, and neonatal Hirschsprung's disease. If it occurs early in gestation, the perforation may have sealed off, but the chemical peritonitis gives rise to tiny scattered foreign-body reactions that may become calcified and be visible radiographically. If the perforation occurs closer to birth, calcifications are usually not seen on radiographs, and chemical peritonitis may be followed by bacterial peritonitis. More frequently, the presenting signs are those of intestinal obstruction.

Meconium Ileus

Intestinal obstruction resulting from viscid meconium impacted in the terminal ileum is seen as the earliest manifestation of cystic fibrosis. This problem affects about 10% of the cystic fibrosis population. Infants with meconium ileus subsequently develop other complications of their underlying disease, but the later respiratory sequelae are not necessarily more severe (123).

The clinical presentation of meconium ileus is not unlike that seen with other forms of distal intestinal obstruction. Abdominal distension and bile-stained vomitus are characteristic. The upright radiograph of the abdomen is especially helpful in this form of intestinal obstruction in the newborn. The characteristic soap bubble mass in the right lower abdomen and a paucity of air-fluid levels despite the presence of many gas-filled loops of intestine is pathognomonic (Fig. 44-14). The air-fluid levels characteristic of obstruction do not develop because air is trapped by the tenacious meconium, and a clear interface is not produced. The contrast enema shows a microcolon, unused because of the distal ileal obstruction. Concretions of meconium in the terminal ileum immediately proximal to the ileocecal valve are often seen.

Figure 44-14 An x-ray film of a newborn infant with meconium ileus reveals many gas-filled loops, but little fluid is seen. The right lower quadrant is filled with a large loop of intestine distended by meconium. Gas trapped in the meconium gives the typical ground-glass appearance.

Surgical intervention may be required for relief of obstruction, but enemas of Gastrografin often eliminate the obstructing mass of meconium (124). At our institution, the Gastrografin is diluted 1:4 with saline so that the complications of a hyperosmolar fluid enema are avoided. This radiopaque contrast material contains a wetting agent (Tween 80) in which the thick meconium is soluble. If the Gastrografin can be successfully advanced through the microcolon and into the obstructed distal ileum, there is reasonable expectation that meconium will be passed spontaneously with relief of obstruction (125). When the first attempt moves some meconium out, but the infant's obstruction is not completely relieved, a second enema is justified several hours later. Complete removal of the meconium may take several Gastrografin enemas over a few days. If these maneuvers fail to relieve the obstruction, or if meconium peritonitis is present, surgical exploration is the only acceptable treatment.

P.1120

If surgical correction is necessary, technical problems associated with evacuating the tar-like meconium from the distended ileum and establishing intestinal continuity between the dilated proximal intestine and the distal microcolon have been solved in various ways. Irrigation through an ileostomy with dilute acetylcysteine has proved effective in some infants. A rapid and safe anastomosis involving the Bishop-Koop technique is well suited for this problem (109). A Mikulicz enterostomy has the virtue of speed although providing decompression and establishment of continuity. These techniques allow access to the distal intestine for postoperative irrigations with acetylcysteine. With use, the colon has the potential to function normally, and the vent established by the Mikulicz or Bishop-Koop procedure is closed surgically. In selected infants, resection and primary anastomosis can be performed at the first operation. In the postoperative period, the infant is subject to respiratory difficulty secondary to impacted secretions. These may require tracheal suctioning or bronchoscopy for relief. When oral feedings are instituted, exogenous pancreatic supplements are provided so that digestion

and use of calories are ensured.

Duplications

An uncommon cause of intestinal obstruction in the newborn is that arising secondary to duplications of the bowel. These can exist at any level of the intestine and may cause obstruction when the lumen is compromised by the gradually expanding duplication or by the duplication acting as a focus for segmental intestinal volvulus. Because they occur on the mesenteric aspect of the bowel, duplications are intimately involved with the blood supply to the normal intestine. Small, cystic duplications are easily resected with a segment of the adjacent bowel (126). However, extensive fusiform or intramural duplications may tax the surgeon's ingenuity. In these instances, resection of the common wall, with creation of a single conduit, may enable the surgeon to preserve an extensive segment of normal intestine (127). Gastric mucosa can exist within a duplication and result in GI hemorrhage (128). This cause of GI bleeding is considered in the evaluation of a baby with melena.

Hirschsprung's Disease
