The clinical presentation of Hirschsprung's disease (i.e., aganglionic megacolon) may be subtle and go unrecognized for months or years until the classic symptoms of constipation and abdominal distension are unmistakable. However, the history of constipation goes back to the early days of life in most patients with Hirschsprung's disease. The consequences of aganglionosis can be life-threatening in the newborn period (129). The absence of ganglion cells modifies neuromuscular conduction and prevents proper evacuation of the bowel. Abdominal distension or debilitating enterocolitis brings the infant to the surgeon's attention.

Failure of an infant to pass meconium in the first 36 hours of life should alert the pediatrician to the possibility of Hirschsprung's disease. Retention of a meconium plug requiring mechanical assistance for its evacuation is another presumptive sign that the colon may be aganglionic. A positive barium enema, even in a newborn, can be a reliable indication of Hirschsprung's disease (130). The characteristic terminal narrow segment, with transition to dilated bowel in the area of the rectosigmoid, is a classic finding in older children but may not be present in neonates. Anal dilation produced by a rectal examination may confuse the findings. A normal barium enema in the neonate does not exclude the diagnosis of aganglionosis, and confirmatory evidence must be obtained by rectal biopsy.

Several techniques of biopsy have been described, but any one that provides an adequate specimen of the rectal wall can establish the diagnosis. The absence of ganglion cells in the submucosal or muscular plexus confirms the diagnosis. Experienced pathologists can interpret the more superficial biopsies, which include only the submucosal tissue. The advantage of partial-thickness biopsy is that there is less intramural scarring to complicate the definitive surgical procedure for correction of Hirschsprung disease. A suction biopsy technique is available that is readily adapted for use in infants (131). This bedside procedure provides adequate submucosal tissue for interpretation by an experienced pediatric pathologist. A histochemical technique estimating acetylcholinesterase activity has been helpful in establishing the diagnosis in some centers and has the added advantage of requiring only tiny fragments of bowel tissue (132).

The clinical presentation of Hirschsprung disease varies. Intestinal obstruction is not always typical. Enterocolitis is often the presenting complaint in a newborn, and this may be confused with NEC, seen primarily in premature infants with respiratory distress. The effects of enterocolitis associated with Hirschsprung disease can be devastating unless recognized and treated appropriately (133). Enterocolitis often presents with diarrhea and signs of collapse. Sepsis may be fatal if not promptly recognized and treated. The enterocolitis can sometimes be controlled by careful rectal lavage with normal saline. It is vital that the volume of solutions instilled be recovered during the lavage.

Whether the symptoms are those of obstruction or enterocolitis, after the infant has been resuscitated, the safest course of action is the performance of a colostomy in an area of bowel containing ganglion cells. Most babies have a transition somewhere in the rectosigmoid, and a high sigmoid colostomy usually ensures normal innervation (134). The presence of ganglion cells at the site of the colostomy should be verified by biopsy at the time of colostomy formation. In desperately ill infants, the condition may preclude a controlled laparotomy with frozen-section confirmation of the transition area. In these babies, a right transverse colostomy ensures that ganglionic bowel has been exteriorized in 98%. The few remaining infants have total colonic aganglionosis or aganglionic small bowel and present special problems in management. In

these infants, barium enema is helpful, showing marked foreshortening of the entire colon. The basic surgical

principle is to achieve exteriorization of the most distal normally innervated bowel.

Definitive surgical therapy is deferred until the infants are managed through the initial crisis and have achieved a weight of about 7 to 9 kg. At that time, the ganglionic intestine is transposed to the anus by one of the several pull-through techniques now available. These include the classic operation described by Swenson (135) and the modification popularized by Duhamel (136). Many centers favor the endorectal pull-through procedure of Soave (137). Several centers have advocated surgery in the newborn period with a pull-through operation and no colostomy (138). The early results are promising, but the follow-up period has been too short to allow proper scrutiny.

If the physician suspects Hirschsprung disease, the diagnosis is made early. The outlook for these infants is favorable because currently available operations have now become standardized (139). Minor constipation is the most frequent sequela of surgery. Most babies with congenital megacolon achieve excellent functional results (140).

Necrotizing Enterocolitis

Necrotizing enterocolitis is a condition predominantly seen in premature infants. It is characterized by partial- or full-thickness intestinal ischemia, usually involving the terminal ileum. The cause is unknown, but the common pathway appears to be a combination of factors that leads to intestinal ischemia (141). Studies suggest that the combination of ischemia and reperfusion injury may be a factor in the development of NEC (142). Known risk factors include prematurity, neonatal stress, formula feedings, and surgery in the newborn period. Other factors considered to increase the risk of NEC are umbilical artery catheterization, infection with certain types of bacteria, and hypoalbuminemia (143).

Although the cause is uncertain, the histopathology is well established. Initially, the disease begins as mucosal ischemia, with resultant sloughing of this layer. As the disease progresses, gas develops within the muscular layers (Fig. 44-15) and may be seen on x-ray films as pneumatosis cystoides intestinalis. If full-thickness necrosis occurs, perforation and peritonitis develop. The rapidity of disease progression differs in each patient, but those who perforate usually do so within the first few days of the disease.

The diagnosis of NEC is based on clinical assessment and x-ray studies. The earliest signs are often an intolerance of feedings with vomiting. In about one-half of the patients, the vomitus is bile stained. Abdominal distension is a common early finding. Hematest-positive stools help confirm the diagnosis, but blood may be absent or a late finding. Abdominal wall erythema and a palpable abdominal mass are commonly late findings and signify more extensive disease. The use of paracentesis to choose surgical candidates has been advocated by Kosloske (144) and Ricketts (145).

Figure 44-15 Operative photograph of a loop of intestine affected by necrotizing enterocolitis. The gas in the seromuscular layer distorts the segment of intestine. Normal loops of uninvolvement are evident.

Radiographic findings in early NEC may show only separated loops of distended intestine, suggesting bowel wall thickening. Pneumatosis cystoides intestinalis is pathognomonic for NEC and may be present early in the disease process. A persistent large loop of intestine seen on a series of x-ray films has been used by some as an indication for surgery, but in our experience, many children with persistent loops have been successfully treated medically.

Hepatic portal venous gas usually implies a particularly severe or extensive form of the disease, and more than 80% of children with this finding required surgery. Free intraperitoneal air is an absolute indication for surgery, although pneumoperitoneum from air dissecting down from the chest in the ventilator-dependent child must be ruled out so that an unnecessary laparotomy is not performed (dissecting air — PO_2 of air in abdomen = FiO_2 provided to infant by the ventilator; pneumoperitoneum — PO_2 of air in abdomen = 21 torr).

Initial management of the child with NEC without pneumoperitoneum is standardized. The child receives nothing orally, the stomach is decompressed with a gastric sump tube, and intravenous antibiotics are begun. Antibiotics must cover gram-negative and gram-positive aerobic organisms, but anaerobic bacteria coverage is less necessary (146). Fungal infection is common after surgical treatment of NEC, and oral nystatin (Mycostatin) is recommended postoperatively (147). The best method of determining which babies require surgery consists of repeated physical examinations by the same examiner; flat and left lateral decubitus abdominal radiographs every 4 to 6 hours for detection of pneumoperitoneum; careful monitoring of the respiratory status and acid-base balance; and monitoring of the leukocyte and platelet counts for signs of sepsis.

In our experience, indications for surgery include pneumoperitoneum, persistent metabolic acidosis (i.e., pH less than 7.2), rapidly worsening pulmonary status, and unremitting neutropenia or thrombocytopenia (148). Because many of our patients with hepatoportal venous gas come to surgery, we operate on these children if they

P.1122

do not improve promptly on medical therapy. Our experience is similar to that of others in that mortality is higher in patients who have perforated before surgery, and it is therefore better to operate before perforation has occurred.

Surgery in these infants should be expeditious and conservative. The frankly necrotic or perforated intestine should be removed, and ileostomies formed. Although routine primary anastomosis in NEC has been advocated by some, most surgeons prefer ileostomy formation in almost all patients (149). When massive resection is necessary, the chance for the child's survival is limited, but the premature infant's intestine still has potential for growth and adaptation, and rarely is the entire intestine involved in the disease. Drainage of the peritoneum under local anesthesia in the infant weighing under 1,500 g has been advocated for perforated NEC by Ein and colleagues, although many babies managed by this method eventually require formal laparotomy (150).

If ileostomy is performed, the mucous fistula should be exteriorized close to the functioning ileostomy, and closure should be planned when the child is large enough (i.e., approximately 2 kg) and at a sufficient time after the event (i.e., at least 4 to 6 weeks) to minimize the possibility of recurrence (151). Because of a 20% incidence of stricture after medical or surgical treatment of NEC in our patients, barium enema is performed in all our surgical patients before ileostomy closure and in any medical patients with feeding difficulties. Other physicians have advocated a UGI study for all babies with medically treated NEC before feeding (152).

The children are not fed orally for at least 2 to 3 weeks after the onset of NEC, and it frequently takes more than 1 month for those patients successfully treated medically to attain adequate oral caloric intake.

Hyperalimentation is mandatory in these children as soon as NEC is diagnosed, and we prefer central intravenous alimentation for most children with NEC.

The long-term success rate for treatment for NEC has been good despite long hospitalization for GI adaptation when massive resection is necessary. The quoted survival rate for children with medically treated NEC is now more than 80%, and the survival rate for those requiring surgery is approximately 50%. At CNMC, the survival rate for NEC has steadily increased since 1980 and is 80% for the surgical and medical groups combined (148). Successful medical treatment may be followed by late-onset intestinal obstruction as a result of scarring, and an interesting long-term complication of ileocolic anastomosis in infancy is the development of anastomotic ulcers. These ulcers present as painless rectal bleeding or melena years after the NEC surgery (153). Necrotizing enterocolitis is discussed in more detail in Chapter 40.

Imperforate Anus

Imperforate anus affects male and female infants with equal frequency and occurs in approximately one of every 20,000 live births. The lesion results from a failure of differentiation of the urogenital sinus and cloaca. Associated anomalies include urogenital, cardiac, spinal cord, and esophageal malformations, especially esophageal atresia and tracheoesophageal fistula. The latter lesion occurs in 10% of patients with imperforate anus (154).

Imperforate anus can be broadly classified as high or low, depending on the relationship of the distal rectal pouch to the levator complex. High imperforate anus in either gender implies that the rectal pouch is above the sphincter muscle complex. Low imperforate anus implies that the rectum has descended past this level, with an abnormal location in the perineum. Because the levator musculature is actually funnel shaped, these associations are somewhat approximate and should be considered as guidelines. Infants with low imperforate anus can be expected to have rectal continence after repair. The sphincter muscle complex must be precisely located and preserved in infants with high imperforate anus, and a normal relationship to the rectum established surgically for continence to be achieved.

Eighty percent of girls with imperforate anus have the low type. Usually, the rectum terminates by means of a fistula anterior to the normal location of the anus on the perineum (Fig. 44-16A), on the vaginal fourchette (Fig. 44-16B), or low in the vagina. Because the termination of the colon is accessible and colostomy is not necessary, early therapy can be directed at decompression of the bowel by catheter irrigation and dilation of the fistula.

It is possible to transpose the anus from the posterior vagina or perineum to its normal position in the newborn period. This is not always necessary if the bowel is easily decompressed or the baby can stool spontaneously through the fistula. A judicious interval is appropriate to allow the baby to grow before surgery is carried out. Definitive repair usually can be accomplished by means of perineal operation because the rectum is properly related to the muscles of continence. In instances in which the fistula cannot be identified, it is usually high in the vagina and not accessible to dilation or surgical revision in the newborn period. In this 20% of female infants, a colostomy is necessary. Definitive therapy for high imperforate anus in the female infant is deferred until the baby weighs 7 to 9 kg.

In boys, the incidences of high and low imperforate anus are equal. Approximately one-half of the babies present with a fistula placed ectopically on the perineum, anterior to the normal location of the anus. The fistula can terminate as far forward as the penoscrotal junction. At birth, the opening of the fistula is not always apparent, and an interval of 12 to 24 hours may be required until the bowel fills with air or meconium reaches the most distal point in the GI tract (Fig. 44-17A). When a spot of meconium or beads of mucus can be identified on the perineum, there is assurance that the rectal pouch is low, implying that the rectum has traversed the sphincter muscle complex, and continence is expected after repair. In babies with these findings, a perineal anoplasty in the newborn period accomplishes decompression of the bowel, and no colostomy is needed.

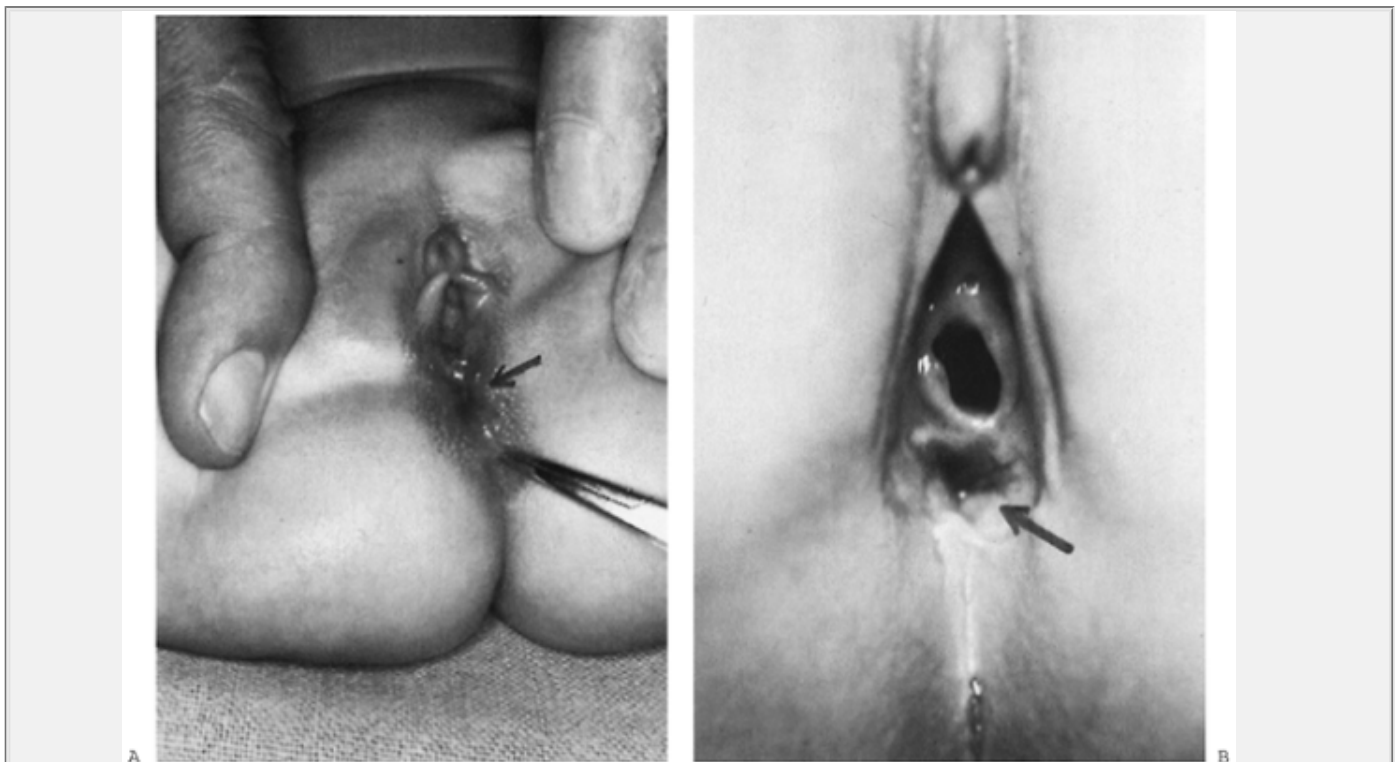

Figure 44-16 A: Female infant with an imperforate anus. The arrow demonstrates the opening of the perineal fistula. The clamp is at the point where a normal anus would open. **B:** Close-up photograph of imperforate anus and an introital fistula just inside the labia minora and immediately beneath the hymenal ring. This is the most common form of fistulous opening in a female imperforate anus.

If no fistula is visible on the perineum, the male infant can be presumed to have a high imperforate anus. The fistula usually communicates with the posterior urethra. A colostomy is needed for decompression, and the definitive pull-through operation is generally deferred until the baby is about 1 year of age. Improved results in children with high imperforate anus are being reported with the use of the posterior sagittal anoplasty, described by Pena and DeVries, at approximately 1 year of age (155).

The value of an x-ray film with the infant in the upside-down position (i.e., Wangenstein-Rice position) is limited in the diagnosis of the level of imperforate anus (Fig. 44-17B) and is primarily of historic interest (156). Although it may help when it shows the rectal pouch at or near the perineum, it can also be misleading if the distal rectum is filled with meconium that prevents air from reaching the most distal aspect of this pouch, and complete reliance on this view for the selection of therapy is ill advised. Ultrasonography may be helpful in locating the rectal pouch.

Needle aspiration for detecting meconium in the blind perineum, with or without injection of contrast material, has been advocated by some physicians but should be performed only by the pediatric surgeon responsible for the child's care (157). If there is no fistula, and a low imperforate anus cannot be diagnosed with certainty, a colostomy is advised. Risk of a colostomy performed for a low imperforate anus is preferable to prejudicing the chances of a successful pull-through procedure by an ill-advised perineal exploration in the newborn period. With realization of the importance of the accurate transposition of the rectal pouch to the perineum, successful functional restoration has become the rule.

DISORDERS OF THE GENITALIA

Vaginal and Uterine Anomalies

Anomalies of the female reproductive tract range from simple imperforate hymen to complex forms of vaginal atresia and uterine malformations (158). These anatomic abnormalities result from errors in müllerian duct or urogenital sinus development. In the newborn, because of

P.1124

obstruction and accumulation of reproductive tract secretions, these conditions usually present during physical exam with either an abnormal perineum or a pelvic mass. In babies with imperforate hymen, the bulging hymen is easily identified, and hymenectomy or hymenotomy via a perineal approach provides relief of the distal vaginal obstruction. More proximal anomalies require additional ultrasonographic, radiographic, or endoscopic investigation to determine the location of the obstruction. The subsequent surgical strategy depends on the severity of the defect and may include a combined abdominal and perineal approach with complex reconstructive techniques. In children with vaginal agenesis, a neovagina is created from a segment of colon.

A

B

Figure 44-17 A: Imperforate anus and partly covered perineal fistula that opens on the scrotum always occurs with a low pouch. The rectum has traversed the levator sling musculature properly. **B:** Upside-down radiographic technique of Wangenstein-Rice using a metal marker at the anus shows the distance between the rectal pouch and the anal skin. It is clearly above a line drawn between the pubis and lower border of the sacrum. There is a second gas-containing space anterior to the rectum. This indicates the presence of a rectourethral fistula with air trapped in the bladder.

Ovarian Masses

The use of prenatal ultrasound has led to the increased detection of ovarian cysts in newborns (159). Formed in response to maternal hormones, presumably many of these cysts will resolve spontaneously following birth. For simple cysts, the decision regarding treatment, therefore, lies in the increased risk of ovarian torsion. Small cysts, less than 5 cm in size, should be followed with serial ultrasound examinations. Larger cysts and all complex ovarian masses should be excised, with care taken to preserve ipsilateral ovarian tissue.

Ambiguous Genitalia

Disruption of the orderly molecular and biochemical events in sexual differentiation lead to incomplete anatomic differentiation and clinically manifest as intersex abnormalities. These may be classified as true hermaphroditism (ovarian and testicular tissue present), male pseudohermaphroditism (testicular feminization), female pseudohermaphroditism (congenital adrenal hyperplasia), and mixed gonadal dysgenesis (160).

Optimal care of the infant born with ambiguous genitalia requires a team approach with input from parents, neonatologists, endocrinologists, and pediatric surgeons. When a newborn presents with ambiguous genitalia, the diagnostic and therapeutic goals include immediate determination of the type of abnormality based on physical examination of the gonads and cytologic analysis (Table 44-1), prompt gender assignment based on the type of abnormality and external anatomic considerations, and early medical management of congenital adrenal hyperplasia. These goals should be accomplished if possible within the first 24 hours of life. Genetically female infants should be assigned the female gender regardless of the degree of virilization. For genetically male babies, assignment depends largely on the size of the phallus because satisfactory surgical techniques do not exist to reconstruct an adequate phallus.

P.1125

However, follow-up studies have indicated a high incidence of emotional problems among genetic males assigned as females.

TABLE 44-1 DIAGNOSIS OF INTERSEX ABNORMALITY BASED ON CHROMOSOME ANALYSIS AND GONAD PHYSICAL EXAMINATION

	Symmetric Gonads	Asymmetric Gonads
XY	Male pseudohermaphroditism (testicular feminization)	Gonadal dysgenesis
XX	Female pseudohermaphroditism (congenital adrenal hyperplasia)	True hermaphroditism

The timing or type of surgical intervention is determined by gender assignment and subsequent radiographic or endoscopic investigations. Gonads associated with gonadal dysgenesis or inconsistent with gender assignment are excised to prevent malignant degeneration and contradictory hormone secretion, respectively.

Reconstructive procedures such as clitoroplasty and vaginoplasty must take into account preservation of sensation and function and the location and division of a urethrovaginal fistula. Infants assigned the male gender require hypospadias repair.

OBSTRUCTIVE JAUNDICE

A variety of neonatal cholestatic syndromes overlap in presentation with obstructive jaundice from biliary atresia. Many conditions causing direct hyperbilirubinemia have been grouped under the term "neonatal hepatitis." To some extent, this is misleading because hepatitis implies an inflammatory process within the liver. It is preferable to separate the infants into one group with cholestatic syndromes and another group with extrahepatic obstruction, such as biliary atresia. In the former group, specific disease entities are further identified by serologic testing or metabolic screening (see Chapters 35 and 40). A common metabolic condition that causes neonatal jaundice is α 1-antitrypsin deficiency. Screening for this inherited disorder is recommended for all infants with conjugated hyperbilirubinemia. Infants with cystic fibrosis may present with obstructive jaundice that mimics biliary atresia, and infants receiving intravenous hyperalimentation for weeks or months may develop cholestatic jaundice.

Advances in hepatobiliary imaging using ^{99m}Tc scans have made it possible to differentiate cholestatic from obstructive jaundice with a high degree of accuracy, particularly after administration of phenobarbital for 5 days before the scan (161). Numerous diagnostic blood tests have been recommended, but none is completely reliable, and most represent unnecessary procrastination. The infant who has an obstructive profile on liver function tests and hepatic scan, with a negative evaluation for cystic fibrosis and α 1-antitrypsin deficiency, should be evaluated with an abdominal ultrasound to identify the gallbladder and extrahepatic biliary ducts and with a percutaneous liver biopsy. Absence of the extrahepatic duct on ultrasound and the finding of extrahepatic cholestasis on biopsy mandate surgical exploration.

An initial exploration is made through a limited right subcostal incision. If a normal gallbladder is seen, a trans-cholecystic cholangiogram is obtained. If the extrahepatic biliary tree appears normal, a liver biopsy is obtained, and the incision is closed.

If the gallbladder is atretic, or the liver is obviously cirrhotic, suggesting an obstructive process, the incision is enlarged so that the extrahepatic biliary system can be formally explored. Any remnant of the gallbladder or extrahepatic biliary duct through which a cholangiogram can be performed is used. In the infant with extrahepatic biliary atresia, only thread-like remnants of the biliary tree are identified. The atretic ducts are transected at their confluence, deep into the porta hepatis, and an anastomosis is created to a segment of the small intestine. This procedure is called a portoenterostomy (Kasai procedure). When the operation is performed in infants younger than 3 months of age, there is reasonable expectation that bile will drain into the intestine (162). Children who fail to drain bile after the portoenterostomy may be rescued by liver transplantation before 1 year of age, although the complication rate in these infants is higher than in older children with liver transplants (163).

Other causes of jaundice that can be relieved surgically are choledochal cysts, common duct stones, and inspissated sludge in the bile ducts. True choledochal cysts are rarely encountered in the newborn period but should be treated by cyst excision and intestinal drainage of the hepatic duct, using a technique similar to the Kasai procedure. Bile peritonitis after spontaneous rupture of the bile duct may resemble a choledochal cyst to the unwary surgeon. These babies require only drainage of the area, with anticipation that the perforation will heal spontaneously although the infant is maintained on antibiotics (164,165).

Biliary hypoplasia is a descriptive term for the radiologic finding of a diminutive extrahepatic ductal system. This may be a secondary condition resulting from intrahepatic cholestasis. Biliary hypoplasia has been associated with intrahepatic disease conditions, such as the cholestasis seen in α 1-antitrypsin deficiency (166). A cholangiogram confirms the patency of these structures and their narrow caliber. Liver biopsy invariably shows cholestasis, and there is often a paucity of intrahepatic bile ducts. Speculation that there is an inflammatory component associated with biliary hypoplasia and that it represents a phase of a dynamic process, leading perhaps to total biliary obstruction, has prompted the use of corticosteroids for treatment. In some instances of steroid therapy, the jaundice resolved, and subsequent biopsies reverted to normal.

With the increased use of abdominal ultrasonography, cholelithiasis has been diagnosed in infants with increasing

frequency, particularly in infants with ileal resection or long-term intravenous hyperalimentation (167). In the asymptomatic baby, observation often is rewarded with spontaneous disappearance of the gallstones, although symptomatic cholelithiasis should be managed by cholecystectomy (168). Obstructive jaundice is discussed in more detail in Chapters 35 and 40.

HERNIA AND HYDROCELE

Inguinal hernia and hydrocele occur commonly, especially in male infants. They result from the persistence of a patent processus vaginalis, a finger-like projection of the peritoneum accompanying the testicle as it descends into the scrotum. In the female infant, the peritoneal extension accompanies the round ligament and can remain patent, becoming a potential hernia sac. A hydrocele is often associated with an inguinal hernia, or it may be an isolated finding. The fluid may be in communication with the peritoneal cavity, and the hydrocele may therefore wax and wane in size, or it may be separated and completely isolated in the scrotum, in the inguinal canal, or, in female infants, the canal of Nuck. A hydrocele presents a smooth, cylindrical contour, with the superior margin generally distinct. It is not tender and is often asymptomatic. The hernia is often large enough that it is easily appreciated as a swelling in the groin or scrotum. The mass can usually be reduced back into the abdominal cavity.

The special anatomic associations of infants puts them at particular risk for incarceration of a hernia. The internal inguinal ring is narrow, and intestine finding its way into the hernia sac in the inguinal canal can become trapped and be reduced only with great difficulty. The incidence of inguinal hernia is dramatically increased in children born earlier than 36 weeks of gestation, with as many as 35% of them developing hernias.

In premature infants in our neonatal unit, we repair the hernias before discharge. If the premature infant has a hernia that freely moves in and out of the inguinal canal, has no history of incarceration, and is first seen as an outpatient, we prefer to delay elective repair until the baby is at least 46 weeks of gestation to minimize postoperative apnea (6), especially in the anemic child (169). If a troublesome hernia in a premature infant must be repaired earlier than the elective 46 weeks of gestational age, we prefer to use spinal anesthesia rather than general anesthesia to minimize the risk of postoperative apnea (6).

If there is diagnostic confusion between an incarcerated hernia and a hydrocele, a rectal examination with bimanual palpation of the internal inguinal ring delineates the structures passing through the ring into the inguinal canal. The vas deferens is a constant reference point, and the intestine adjacent to the vas and between the examining fingers confirms the diagnosis of a hernia. Surgical repair is indicated in all cases of inguinal hernia.

If incarceration of a hernia occurs, moderate bimanual pressure, applied by compressing the sac from below although providing a gentle downward counterforce with the hand above the inguinal ring, usually achieves reduction. Occasionally, these hernias reduce spontaneously after sedation is given and struggling and crying are terminated. If the hernia fails to reduce, or if there is obvious intestinal obstruction and systemic toxicity, emergency surgical reduction and repair are necessary.

An inguinal hernia in a female infant is often diagnosed by palpation of a nontender ovoid mass in the groin. The mass represents an ovary herniated into the open sac. Although the gonad can usually be reduced back into the abdomen, it often prolapses in and out until surgical repair is carried out. If the inguinal hernia is apparent unilaterally, the opposite side is routinely explored in all children younger than 1 year of age because the incidence of bilateral hernias in these children is approximately 50%.

ABNORMALITIES OF THE UMBILICUS AND ABDOMINAL WALL

Umbilical Hernia

Umbilical hernia is a common condition of the newborn, presenting as a central fascial defect beneath the umbilicus. Incarceration is a rare complication in patients with umbilical hernia, but it occurs more commonly in patients with smaller defects of the fascia, such as those seen in the neonate. Umbilical hernias are more common in African-Americans, in premature infants, and in patients with congenital deficiencies of thyroid hormone.

Most babies with umbilical hernia require no surgical treatment because the hernia disappears spontaneously up to 9 years of age. With persistence of the hernia until 4 years of age, repair is indicated. In a few patients, there is progressive enlargement of the skin of the umbilicus until a prominent proboscis is produced. Surgical repair is indicated early. A simple repair suffices for all these patients and can be accomplished through a small semilunar incision made in the curve of the umbilicus. Complicated fascial flap repairs, such as may be required in adults, are unnecessary and contraindicated in young patients. The umbilicus is never excised.

Adhesive dressings with coins and metallic or plastic objects have no place in the management of umbilical hernia because they are ineffective and merely cover the defect at the expense of irritating the surrounding skin.

Primary Infection of the Umbilicus

With the advent of prenatal care, the incidence of infection around the umbilicus (i.e., omphalitis) has been markedly reduced. Potentially serious complications can result from infections in this area. Cellulitis of the abdominal wall, with direct spread into the peritoneal cavity and resultant peritonitis of the newborn, has been recorded. The most serious consequence is ascending infection along the umbilical vein to the portal system and liver. Before antibiotics,

P.1127

the resultant multiple hepatic abscesses were often fatal. A more common sequela is portal vein thrombosis, which is a major cause of portal hypertension in children. In the past, this was a significant cause of esophageal varices in young patients, and although this condition now occurs less often, it must be avoided by prompt local and systemic antibiotic treatment of suspected infections in and around the umbilicus.

UMBILICAL GRANULOMA

The formation of weeping granulation tissue at the umbilicus is common in the newborn. Failure of the umbilical epithelium to grow over the severed stump of the umbilicus results in a persistent crusting mass of granulomatous tissue. Cauterization with silver nitrate is diagnostic and therapeutic. Applications of silver nitrate twice weekly for 1 month clear most umbilical granulations. With persistence of fluid at the umbilicus, a patent omphalomesenteric duct or patent urachus should be considered.

Patent Omphalomesenteric Duct

During fetal development, the omphalomesenteric duct forms a connection from the intestinal tract to the placenta. If this duct fails to involute, a tubular attachment persists between the ileum and the abdominal wall (Fig. 44-18). Liquid ileal content refluxes out of this duct.

Figure 44-18 A probe indicates that the umbilical opening which connects with the intestinal tract (i.e., patent omphalomesenteric duct).

Diagnosis of a congenital fistula at the umbilicus is made by inspection, sonography, and probing of the tract. The introduction of radiopaque material into the ostium at the umbilicus demonstrates a connection to the intestinal lumen on lateral x-ray films of the abdomen.

Treatment for patent omphalomesenteric duct is elective abdominal exploration with division and closure of the fistula at its origin in the ileum and total excision of the fistula, including its attachment to the undersurface of the umbilicus. This procedure must not be postponed because there is a potential for intestinal volvulus to occur around the postlike attachment between the umbilicus and the ileum.

In rare instances, if the patent omphalomesenteric duct opening is large, the peristaltic activity of the bowel can result in eversion of proximal intestine, as in intussusception, through the opening onto the abdominal wall. Clinically, this appears as a mucosa-covered extrusion, and the resulting mass is easily confused with a small ruptured omphalocele. Careful inspection of the neck of the defect at the border of the abdominal skin discloses the true nature of the lesion. The bowel has in effect turned inside out and prolapsed through the patent omphalomesenteric duct. Immediate operation, with reduction and repair, is indicated.

Patent Urachus

During embryologic development, there is free communication between the urinary bladder and the abdominal wall. Persistence of this tract establishes a communication between the urinary bladder and the umbilicus through which urine may pass. Although this passage is small, the umbilicus is constantly wet. The first sign of a patent urachus may be urinary infection. In some patients, a portion of the urachus has obliterated with only a partially patent remnant or cyst remaining beneath the umbilicus. Urachal cysts may present after the newborn period as an infected infraumbilical mass caused by colonization with skin organisms from the umbilicus; sonography reveals this anatomy.

In the diagnostic workup of a newborn suspected of having a patent urachus, the cystogram in lateral projection demonstrates the abnormal tract. Another diagnostic technique is the introduction of a colored dye into the bladder through the urethral catheter. The appearance of dye on the abdominal wall confirms the connection between the umbilicus and the bladder. Extraperitoneal surgical exploration of the infraumbilical area allows complete excision of the urachal tract and closure of the bladder. Partial urachal remnants, sinus tracts, and cysts are easily excised.

Omphalocele

Developmental arrest of those somites that form the peritoneal, muscular, and ectodermal layers of the abdominal wall results in a central defect called an omphalocele. The

P.1128

defect is covered by a translucent membrane overlying the bowel and solid viscera and may vary in size from a small hernia of the cord that is 1 or 2 cm in diameter to a huge mass containing essentially all the abdominal viscera (Fig. 44-19). Usually, the sac remains intact, but it is occasionally ruptured during delivery.

Figure 44-19 Large omphalocele. Notice the covering of the sac and its relation to the umbilicus, which protrudes from the lower portion.

The diagnosis of this lesion is made entirely by inspection because it is readily apparent immediately after delivery of the baby. The abdomen is wrapped carefully with well-padded, saline-soaked gauze and an outer dry layer in preparation for transport. Placement of a nasogastric tube to decompress the stomach and attention to maintenance of a normal core temperature are essential initial maneuvers. No pressure is placed on the omphalocele in an attempt to reduce it. This is hazardous to the integrity of the sac, may interfere with venous return, and may impede the infant's respiratory efforts.

Small omphaloceles are usually amenable to complete one-stage surgical repair. For larger omphaloceles (6

cm), a sheet of Silastic with interwoven Marlex can be sewn around the edge of the defect to envelop the omphalocele (170,171). Steady pressure on the prosthesis and a reduction in size over several days bring about gradual reduction of the omphalocele so that surgical closure can be accomplished. Irrigation with povidone-iodine (Betadine) solution or coverage with a layer of silver sulfadiazine (Silvadene) has been effective in reducing surface contamination throughout the time for which the prosthesis is required.

Coexisting anomalies, such as exstrophy of the cloaca or congenital heart disease, may make surgical closure inappropriate. Painting the omphalocele sac with 4% mercurochrome promotes a firm, strong crust to cover the defect. This protection serves until the natural process of epithelialization occurs. Although success with a plastic prosthesis has obviated the need for the painting method, it is still a useful treatment in rare instances; mercury toxicity is possible.

Congenital malrotation of the colon usually occurs in patients born with omphalocele. Although it is in itself not a serious defect, the anomaly can lead to midgut volvulus, and symptoms of intestinal obstruction in a baby who has previously recovered from treatment of omphalocele must be considered a dire emergency.

Gastroschisis

Originally confused as a type of omphalocele, gastroschisis is now recognized as a separate entity. It differs embryologically in that the abdominal wall has completed its development but a defect remains at the base of the umbilical stalk, through which a portion of the intestinal tract has escaped. Gastroschisis always occurs as a defect lateral to the base of the umbilicus, and the defect may represent an isolated congenital defect in the abdominal wall. An alternative theory of the embryogenesis of gastroschisis holds that closure of the celomic cavity has been completed although a portion of the intestinal tract remained trapped outside the abdomen in the base of the umbilical cord. It is postulated that this hernia of the cord then ruptures, allowing the intestine to float freely in the amnion although the umbilical arteries and vein remain attached to the baby.

The escape of the intestine into the amniotic cavity can occur at different times in fetal development. This conclusion follows the observation that in some infants the intestines are glistening and normal looking, as if they had escaped a celomic envelope just before birth. Many infants with gastroschisis, however, are born with edematous and matted intestinal loops that appear to have been exposed to the amniotic fluid for many weeks (Fig. 44-20).

Immediate treatment in the delivery room consists of wrapping the baby and the exteriorized intestine in saline-soaked gauze and dry sterile dressings. Prompt surgical repair is undertaken. In about one-half of the patients, the viscera can be returned to the abdomen and secure closure obtained. In favorable cases, peristalsis returns in a few days, and normal bowel function can be expected. If the

P.1129

bowel is matted and edematous, it may take many weeks before intestinal function recovers. Nutrition can be successfully supported during this interval by intravenous hyperalimentation. Previously, many of these babies died of malnutrition before intestinal function returned.

Figure 44-20 Patient with gastroschisis. The edematous, matted bowel is the result of the intestines floating freely in the amniotic fluid. Remarkably, these distorted viscera ultimately fit back into the abdominal cavity and assume normal appearance and function.

If the abdominal wall cannot be closed without undue tension, which interferes with respiration and venous return, an extraabdominal prosthetic compartment must be fashioned. As in staged omphalocele repair, Silastic-covered Marlex is well suited for this purpose because its surface is inert and does not adhere to the bowel. After the prosthesis is fastened to the fascial margins, the capacity of the plastic compartment is gradually reduced until complete surgical closure is possible, usually within 7 to 10 days. This staged maneuver, coupled with intravenous alimentation, has resulted in an increased percentage of survivors from a previously lethal anomaly (172). Intestinal atresia occurs in about 10% of patients with gastroschisis. In these babies, the clinical course is one of early complete obstruction, which requires abdominal exploration if the lesion has been inadvertently overlooked at the time of initial repair of the gastroschisis.

Congenital Deficiency of the Abdominal Muscle

The prune-belly syndrome consists of three major anomalies:

- Deficiency of the abdominal musculature
- Dilation of the urinary collecting system
- Bilateral cryptorchidism.

By definition, all patients with this syndrome are male, but a similar condition has been reported in female patients. In severely affected infants, there is marked wrinkling of the skin of the abdomen and no muscular substance beneath (Fig. 44-21). Lower abdominal musculature is most frequently and severely involved.

The bladder is characteristically large, and the ureters are dilated and tortuous. The kidneys may be hypoplastic, but usually there is enough renal parenchyma for adequate function from at least one side. There is an increased incidence of patent urachus, particularly if the renal function is poor.

Figure 44-21 An infant with congenital deficiency of the abdominal musculature shows the typical prune-belly appearance.

The cause of the condition is unknown. It has been proposed that all these infants have some degree of urethral obstruction, with resultant overdistension of the bladder and abnormal pressure on the developing muscular somites (173). Others have suggested that the primary deficiency is in the abdominal musculature, allowing overdistension of the bladder with secondary changes in the urinary collecting system. It is probable that neither of these explanations is completely valid and that some more comprehensive explanation exists for the coexistence of the unusual abdominal deficiency and the distortion of the collecting system.

The treatment of these infants is conservative and nonoperative if their renal function is good (174). If the renal function is poor, urinary diversion may be necessary in the neonatal period to eliminate pressure in the collecting system. Abdominal wall reconstruction and bilateral orchiopexy can be performed between 1 and 2 years of age if the renal function is stable. Reconstruction of the abdominal wall is best performed through a low

transverse incision so that the use of normal upper abdominal musculature is maximized (175).

SACROCOCCYGEAL TERATOMA

A sacrococcygeal teratoma is an unusual tumor that is usually detected in the newborn or neonate (176). Most teratomas present as a large mass arising from the coccyx. The mass is made of mature and immature elements of different cell types. The mass may be several centimeters in diameter, or it may rival the size of the newborn infant (177). In the newborn period, the tumor is usually benign; however, when it is discovered later, the incidence of malignancy rises (178).

The diagnosis is frequently made at the time of prenatal ultrasound (179). A large solid or cystic mass is observed in the sacral region. The maternal serum alpha-fetoprotein level may be elevated. Occasionally, the blood flow through the tumor is large enough to produce heart failure and hydrops in the fetus (180). Langer and colleagues proposed using a large mass and heart failure as an indication for fetal surgery to arrest the tumor growth (181). If a sacrococcygeal teratoma is diagnosed prenatally, a multidisciplinary approach to the pregnancy and delivery is indicated (182).

The key to the management of an infant born with a sacrococcygeal teratoma is an expeditious surgical resection. The infant is stabilized, with careful attention to high-output cardiac failure. Hypothermia can be a major problem in the nursery and the operating room because of the large surface area of the mass. After a search for coexisting anomalies, and after appropriate resuscitation, the mass is resected. Complete resection is usually possible without long-term sequelae, although bowel continence can be a

P.1130

problem if the sphincter mechanism is disturbed by the tumor or the surgery. It is important to remove the coccyx to prevent recurrence. The tumors are rarely malignant in the newborn period, and complete surgical resection is curative.

VASCULAR ACCESS

An excellent text, *Atlas of Procedures in Neonatology*, is recommended for an in-depth review of vascular access techniques in the infant (183). The traditional method of maintaining vascular access in the neonate for blood sampling, medications, and parenteral nutrition has been to use an umbilical vessel catheter. When the umbilical vessel catheter must be maintained for an extended period of time, the risk of complications, such as emboli, thrombosis, and infections, becomes prohibitive, and the line must be removed. The use of transcutaneous pulse oximetry has reduced the need for arterial umbilical lines in neonates with pulmonary problems. When arterial access is re-quired, the right radial artery is a useful alternative because its preductal location accurately reflects intracerebral blood oxygenation.

Even in the smallest babies, a radial artery line can be placed by cutdown with optical magnification. Placing an arterial line percutaneously is preferable to the cutdown technique, with the aim of maintaining future arterial patency. However, multiple attempts to access the radial artery percutaneously should be discouraged to avoid damage to the artery, preventing access by cutdown. The posterior tibial artery is an alternate site for arterial lines in neonates. More proximal arterial lines in the brachial artery have been used in selected patients, although the risk of extremity ischemia is substantial with this location. Access via the femoral artery is contraindicated.

Establishing reliable venous access in the preterm infant has become one of the most common procedures done by pediatric surgeons. The placement of a catheter into the central venous circulation allows the use of more concentrated intravenous solutions and eliminates the risk of subcutaneous infiltration of solutions and resultant skin sloughs. In the past, central venous catheters were placed predominantly by a percutaneous approach; this is now restricted to larger neonates, using a Seldinger technique. In preterm infants, a Silastic catheter is placed by cutdown, with a Dacron cuff attached to the catheter placed beneath the skin to prevent catheter infection and accidental removal. A percutaneous ultrathin Silastic catheter that can be threaded from a peripheral vein to the central venous system is used with increasing frequency at the CNMC, but many children continue to require the cutdown technique.

The site of venous catheter placement depends on patient anatomy, disease, location of previous catheters, and surgeon preference. The sites of choice are the external jugular or facial vein to avoid damage to the internal jugular vein. In the infant weighing less than 1,000 g, the internal jugular vein may be the only one of adequate size, and its use unilaterally should not cause serious problems. When the line is placed in the neck, the tip of

the catheter should be in the superior vena cava just cephalad to the right atrium. Silastic catheters within the atrium may cause atrial thrombus formation, atrial perforation, or dysrhythmias.

If the superior vena caval system cannot be used, the saphenous vein, at its junction with the femoral vein, can usually be cannulated, even in infants weighing less than 1,000 g. If the saphenous vein is used, it is best to keep the catheter tip caudad to the renal veins (i.e., below the level of L1 to L2).

Central venous catheters in neonates are plagued with complications. Infection remains the most common complication, occurring in approximately 10% of infants. Although catheter infection can be successfully treated with intravenous antibiotics, it is better to remove the catheter, give intravenous medications and nutrition temporarily through a peripheral intravenous line, and replace the central line, if still needed, after all cultures are free of infection. Most of the organisms that contaminate central venous lines originate from the infant's skin or from careless decontamination of the connecting tubing before line changes or the administration of medication.

Central vein thrombosis is a serious problem that may lead to superior vena caval syndrome, which includes head and arm swelling and pleural effusions as a result of obstruction of the thoracic duct drainage. Babies weighing less than 1,000 g are at particularly high risk of developing thrombus (184). Management of vena caval thrombosis with thrombolytic agents, such as urokinase, may be beneficial, but the risk of systemic anticoagulation must always be considered. Some reduction in the risk of thrombosis may be achieved by the use of 1 U of heparin per 1 mL of intravenous solution.

Chapter 45

Immunology of the Fetus and Newborn

Joseph A. Bellanti

Barbara J. Zeligs

Yung-Hao Pung

Immunology has come a long way since 1905, when the Russian biologist Eli Metchnikoff prophetically wrote, "Within a very short period, immunity has been placed in possession not only of a host of medical ideas of the highest importance, but also of effective means of combating a whole series of maladies of the most formidable nature in man and the domestic animal. Science is far from having said its last word, but the advances already made are amply sufficient to dispel pessimism in so far as this has been suggested by the fetal diseases and the feeling that we are powerless to struggle against them" (1).

Once the branch of medicine that dealt exclusively with the study of protection of the host against microorganisms, immunology now enjoys a much broader biologic scope and is concerned with the host processes that recognize and eliminate foreignness. Immunologic responses serve three functions: defense, i.e., resistance to infection by microorganisms, homeostasis, i.e., removal of worn-out host cells, and surveillance, i.e., perception and destruction of mutant cells (2). Although not fully developed, the cells of the immunologic system of the fetus and neonate manifest a striking capacity for response to the environment. However, the fetus and newborn appear to be particularly vulnerable to injury caused directly by immunologic mechanisms or inflicted by infectious agents that take advantage of the relatively immature and inexperienced immune system. Immaturity refers to the genetically programmed low response or lack of response of the fetal and newborn immune system. Inexperience refers to the fact that the newborn immune system has not yet had its first immunologic encounter. Those who care for newborns must understand these processes because they form the basis for the prevention, diagnosis, and treatment of many diseases that afflict these patients (Table 45-1).

DEVELOPMENT OF THE IMMUNE SYSTEM

Role of the Environment

The development of the immune response may be visualized as a series of adaptive cellular responses to an ever-changing and potentially hostile environment. Development can be considered at several levels: the species, the individual, or the cell (Table 45-2). From an evolutionary standpoint, the effect of a hostile macroenvironment provided the selective pressures leading to the survival of those life forms within the species that were best adapted to that environment (i.e., phylogeny). Within the developing fetus, the microenvironment in which undifferentiated progenitor cells exist (e.g., thymus, bursa of Fabricius) provides yet another type of inductive environment, permitting the full expression of immunity within the developing infant. The immunologically mature person may be considered as the best-selected form resulting from this type of development (i.e., ontogeny). The molecular environment (i.e., antigen) in which immunologically reactive cells

exist provides the best-studied inductive stimulus leading to the proliferative and differentiating events commonly associated with cellular immune responses. Memory cells may be considered the best-adapted form for this environment. Fetal and neonatal development of the immunologic system is best understood in terms of the developing host responding to his environment. The cells and functions that constitute the immune system appear early in fetal life, but at least some of them are fully activated only after birth, after interaction of the neonate with his environment. Under certain circumstances (e.g., intrauterine infections), the environment of the developing fetus may be so altered that the immune system begins activation *in utero*. The neonatologist and others entrusted with the care of the newborn must be concerned

P.1136

with the deleterious effect of factors introduced to the fetus from the ever-changing and complex external environment. Threatening agents that may gain access to the fetus during prenatal development include maternal drugs, infecting organisms, and antibiotics. The obstetrician and the neonatologist, who have already made significant contributions to the understanding of teratogenic effects of these agents, must be made aware of their effects on the developing immunologic system.

TABLE 45-1 APPLICATONS OF IMMUNOLOGY FOR THE NEONATOLOGIST

Type	Example of Immunologic Procedure	Disease
Prevention	Rhogam	Hemolytic disease of the newborn
Diagnosis	Elevated IgM globulins in cord serum	Intrauterine infections
Therapy	Fresh blood transfusions	Acute sepsis of the newborn

The glucocorticoids, toxic agents which are frequently administered to human fetuses and newborns for prevention of respiratory distress syndrome, also act on their immune system. Glucocorticoid administration results in the inhibition of several cellular and humoral systems including cytokine production and T-cell activation, both of which are already significantly decreased in the newborn. Additionally, neonatal immune cells are more sensitive to glucocorticoids than adult immune cells (3). Further, it has long been noted that sex hormones appear to play a significant role in modulation of immune function (4). It has been repeatedly observed in studies of serious bacterial infections in infants, i.e., sepsis, pneumonia, and meningitis, that a preponderance of male infants exists over females (5,6,7,8). There are variety of humoral and cellular deficiencies compared to the adult levels which may contribute to this susceptibility including the following: lower numbers of white blood cells and polymorphonuclear neutrophil leukocytes (PMN) in males (9); lower numbers of CD3 and CD4 cells and higher numbers of CD8 and natural killer (NK) cells in males (10); higher immunoglobulin M (IgM) levels in females (11); and greater antimicrobial antibody responses which have longer duration persist in females (12).

Development Of Components

For ease of discussion, the immunologic system may be considered under two major headings. The innate immune system, which functions primarily during inflammatory responses, includes the phagocytic cell system, i.e., PMNs, mononuclear phagocytes, i.e., monocytes and macro-phages, and several amplification systems, including complement, coagulation, and kinin systems. The adaptive immune system consists of cell-mediated, i.e., T-cell and humoral, i.e., B-cell systems. It is important to stress that the innate and adaptive systems are intimately interrelated and interdependent. For example, the activation of the complement system by immunoglobulins, i.e., IgM and immunoglobulin G [IgG] or the production of chemotactic factors and other cytokines plays a significant role in the whole inflammatory response. The monocyte or macrophage may function in inflammatory responses and play a significant role in the processing of antigen, steps that are essential to the induction of the specific immune response. The macrophage forms part of the innate and adaptive immune systems and is important to the afferent and efferent limbs of the immune response. The cytokines are other products secreted by cells that play a role in innate and adaptive immune mechanisms. Several abnormalities of innate immunity may affect the newborn infant, including abnormalities of quantitative and qualitative factors of cellular function (e.g., neutrophils, mononuclear phagocytes) and humoral factors (e.g., specific antibody, complement, fibronectin) (13,14,15). The quantitative cellular abnormalities are related to size and ability to regenerate mature cells for the storage pools of phagocytic cells in the fetal liver, neonatal spleen, bone marrow, and local sites such

P.1137

as lung and skin. The qualitative cellular abnormalities are related to the adherence and directed migration, i.e., chemotaxis of phagocytic cells in response to and toward a chemoattractant that is exogenous, e.g., bacterial proteins or endogenous, e.g., cellular or plasma products, the attachment and internalization, i.e., phagocytosis of the source of the inflammation after its precoating, i.e., opsonization by specific plasma factors such as antibody or complement, and the inactivation, i.e., microbicidal activity and digestion, i.e., antigen processing of the phagocytosed material. The deficiencies in the neonatal phagocytic cell system that may predispose to infection are summarized in Table 45-3.

TABLE 45-2 EFFECT OF ENVIRONMENT ON THE DEVELOPMENT OF THE IMMUNE RESPONSE

Target	Inductive Environment	Process	Selected Form
Species	Macroenvironment	Phylogeny	Existing life forms
Individual	Microenvironment	Ontogeny	Immunologically mature
Individual Cell	Molecular environment (antigen)	Induction of immune response	"Memory" cells

TABLE 45-3 DEFICIENCIES IN NEONATAL HOST DEFENSES PREDISPOSING TO INFECTION

Anatomic barriers

Injuries during delivery (e.g. skin abrasions)
Invasive procedures in the nursery (e.g. umbilical artery catheters, endotracheal tubes)

Phagocytic cells

Small polymorphonuclear leukocyte storage pool
Decreased polymorphonuclear leukocyte adherence
Decreased polymorphonuclear leukocyte and monocyte chemotaxis
Decreased polymorphonuclear leukocyte intracellular killing in stressed neonates
Decreased phagocytosis in stressed neonates

Complement

Decreased levels of complement
Decreased expression of complement receptors

Cytokines

Decreased levels of cytokines, particularly IFN- γ , TNF- α and IL-12

Cellular immunity

Maturational deficiencies in T-cell immunoregulation, i.e., Th2 skewing, and antigen presenting system

Humoral immunity

Decreased IgA, IgM
Decreased IgG in premature neonates
Impaired antibody function
Decreased levels of fibronectin
Decreased levels of cytokine (e.g. IFN- γ , TNF)

INFLAMMATORY RESPONSE

After tissue injury or invasion by microorganisms, a cascade of systemic and local events is triggered. This generalized response to injury is referred to as an inflammatory response. The febrile response is believed to reflect enhanced metabolic activity and to be related to the release of endogenous pyrogens (i.e., cytokines interleukin-1 [IL-1] and tumor necrosis factor alpha [TNF α]) from the host's leukocytes, which then trigger a hypothalamic response (16). Because these pathways are not particularly well developed in the neonate, fever is not a valuable sign of infection in this age group. Similarly, leukocytosis and an increased rate of sedimentation, commonly associated with bacterial infections in the older infant and child, are not particularly useful predictive markers of inflammation in neonates. However, other parameters in the inflammatory response, such as the increase in α - and β -globulins with the elevation of C-reactive protein, occur in the neonatal period and are commonly used in the diagnosis of infectious diseases in the neonate. An elevation in total neutrophil count is an inconsistent and unreliable index of neonatal sepsis; neutropenia during sepsis is more common in the neonate. If neutropenia reflects storage pool exhaustion, it is a poor prognostic sign, even with appropriate antibiotic therapy (17,18,19). An important event accompanying innate immune responses in the newborn is the activation of the coagulation system, with disseminated intravascular coagulation, as seen in bacterial sepsis. The measurement of clotting factors and fibrin split products may provide another marker for

infection.

CELLULAR COMPONENTS

The cellular responses are carried out primarily by phagocytic cells, such as PMNs, monocytes, and macrophages, and secondarily by eosinophils and lymphocytes. The storage pool size and the function of PMNs play a critical role in the inflammatory response.

POLYMORPHONUCLEAR

Polymorphonuclear Leukocyte Storage Pools

Leukocytes are first produced in the liver at about 2 months of gestation. By 5 months of gestation, the bone marrow has become the primary hematopoietic center, and liver production has diminished (20). PMN storage pools are considerably smaller per kilogram of body weight in the premature and full-term newborn than in adults (21,22). Neonates are less capable of increasing their PMN numbers because the proliferative rate of their progenitor cells is already near maximum compared with adults (23).

Polymorphonuclear Leukocyte Adherence, Mobility, and Chemotaxis

The skin of the newborn is relatively deficient in expressions of innate immunity. After introduction of a foreign substance into the skin, several inflammatory cells begin to adhere to the wall of vessels near the substance and move in a directed fashion toward it in response to a chemical released from the foreign material or surrounding tissue. This adherence phenomenon is now recognized to occur through the action of cell surface receptors that function as adhesion molecules (i.e. adhesins) which include integrins, immunoglobulin superfamily, selectins and other adhesion molecules which are described below. Normally circulating

P.1138

PMNs express certain glycoproteins on their surfaces which function as adhesion molecules, i.e., I-selectins. During the initial inflammatory response, soluble mediators including the cytokines, i.e., TNF-alpha (TNF- α) and IL-1, induce the expression of molecules on the surface of endothelial cells i.e., E-selectins, which serve as a counteracting receptor for certain blood group antigens, i.e., sialyl Lewis X and Lewis X found on PMNS. This interaction aided by the I-selectins on PMNs results in "leukocyte rolling," a phenomenon in which loose PMN-endothelial cell adhesions are made and broken permitting loose cell associations resulting in rotation of the PMN along the endothelial surface. As further activation occurs, intercellular adhesion molecule-1 (ICAM-1) is expressed on the endothelial cells together with the β 2 integrin adhesion receptor on PMNs. This results in a high avidity spreading of the PMNs and the release of their I-selectins, which initiates their transendothelial migration.

An absence of leukocyte adhesins is seen in an autosomal recessive disorder, the leukocyte adhesion deficiency-1 (LAD-1). This is associated with a mutation of the gene on chromosome 21q22.3 encoding CD18, the 95kD β 2 integrin subunit, which occurs on PMNs, monocytes, macrophages, and certain lymphocytes and is associated with impaired cell adhesion. It is clinically seen in infants with delayed separation of the umbilical cord, and in

recurrent bacterial and fungal life-threatening infections. In the adult inflammatory response, a prominent PMN infiltration occurs during the first 4 to 12 hours, followed by a predominant mononuclear response consisting of macrophages and lymphocytes. In the newborn, the shift from a PMN response to a mononuclear cell response is slower and less intense than in the adult, reflecting maturational deficiency. In some studies, a curiously high percentage of eosinophils is observed in the 2- and 4-hour exudate of newborns older than 24 hours but not in those younger than 24 hours. Although the precise mechanisms for this eosinophilic response are unknown, it is of interest that the lesions of erythema toxicum, well known to neonatologists, consist primarily of eosinophilic leukocytes. Mobility or movement encompasses a series of cellular events that are decreased in the neonate and include cell responsiveness to chemoattractants (24,25,26,27,28). The latter reflects expression of cell surface receptors (particularly complement receptor [CR]) (3), adherence, deformability, and aggregation, all of which are necessary for normal chemotaxis (29,30,31,32,33,34,35,36). Chemotaxis does not appear to reach adult levels until 16 years of age (37). Neonatal PMNs exhibit less chemotactic activity than do adult cells because of deficiencies of intrinsic cellular factors and extrinsic humoral factors. The primary deficient humoral factors are complement components C5 (38).

PHAGOCYTOSIS

Once mobilized, the phagocytic cells mount an attack on their target by a process of phagocytosis. In the adult, many foreign substances, such as damaged tissue or nonvirulent organisms, may be ingested by phagocytic cells through unenhanced processes involving cell receptors (e.g., integrins, fibronectin), nonspecific plasma, and tissue factors. More virulent organisms require opsonization by a specific antibody or complement. The newborn may have compromised cellular and humoral factors involved in phagocytosis. Of the immunoglobulins, only IgG globulins are transmitted across the placenta. The complement factors do not cross the placenta (39). Complement and fibronectin levels are deficient in the neonate (40). Several investigations of phagocytosis in the neonate have had conflicting results. In some studies, phagocytosis by neonatal leukocytes is abnormal when they are suspended in neonatal serum. Normal activity is restored when the same cells are resuspended in adult serum. However, under certain in vitro and in vivo conditions, neonatal PMNs are deficient in phagocytic capacity compared with the adult PMN (41). For example, if the concentration of adult serum is varied or if phagocytes are taken from sick full-term infants, phagocytic activity is deficient relative to that in normal full-term neonates. The decreased phagocytic activity may be related to the decreased expression of the complement receptor CR3 in the newborn, which is reported to reach only 60% to 70% of adult levels during stimulation. This receptor is important for complement-dependent adherence, surface adherence with albumin and fibronectin, and penetration of PMN into tissues. Decreased expression of C3 may contribute to the relatively poor adherence and chemotaxis of neonatal cells. Further, the reported deficiency in the newborn of IL-1 and TNF- α (42), critical in the expression of E-selectins on endothelial cells and the β 2 integrin adhesion receptors on PMNs, could also contribute to the relatively poor adherence and chemotaxis of neonatal cells.

Microbicidal and Metabolic Activity

After particle uptake by phagocytes, there is an increase in oxygen consumption and in glucose use by the hexose monophosphate pathway (HMP), events that are collectively referred to as the "respiratory burst." The formation of hydrogen peroxide, the result of

increased HMP activity, is considered to be of major importance in the killing of many bacteria by the oxygen-dependent antimicrobial system. A second antimicrobial system, which is oxygen-independent and granule associated, plays an important role in phagocytic cell function.

Oxygen-Dependent Systems

Phagocytic leukocytes, such as PMNs, respond to a particulate or soluble stimulus with a respiratory burst of increased oxygen consumption and the production of toxic microbicidal oxygen radicals, including superoxide (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radicals. When the cell membrane is stimulated, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, i.e., membrane-

P.1139

associated oxidative enzymatic system, which consists of the oxidase and nonmitochondrial flavoprotein and cytochrome components, is activated and transfers electrons to molecular oxygen, reducing it to the free-radical superoxide anion (43). Chronic granulomatous disease (CGD) is a genetic disorder in which the PMNs and monocytes are incapable of generating the oxidative burst necessary to produce the antimicrobial oxygen metabolites, i.e., hydrogen peroxide and related compounds. This is the result of a deficiency of one of the components of the NADPH oxidase complex. The consequent loss of the important antibacterial mechanisms of the human host defense is the basis for recurrent bacterial and fungal infections in these children. There has been marked clinical improvement in CGD patients treated with interferon- γ (IFN- γ). The production of high-energy oxygen radicals and superoxide by the newborn's PMNs is evaluated differently by various researchers. The O_2^- generation system seems to be efficient in the normal newborn and human fetus (44,45). There is some evidence that the NADPH oxidase system in granulocytes generating O_2^- is completely developed during fetal life, but triggering mechanisms are probably deficient. The release by fetal and newborn bone marrow of many immature phagocytic cells with significantly reduced phagocytic function into the peripheral blood and the relatively rapid exhaustion of this cell reservoir may explain the defect in granulocyte function observed in stressed and infected newborns (46).

Oxygen-Independent Systems

The oxygen-independent microbicidal system is demonstrated by the ability of phagocytic cells to kill organisms in anaerobic conditions and by non- O_2 -dependent microbicidal activity of the cells from patients with CGD. The active components of the O_2 -independent system reside in the phagocytic cell granules. In the PMN, the primary (i.e., azurophilic) granules contain acid hydrolases, neutral proteases, lysozyme, bactericidal cationic protein, and myeloperoxidase, a critical component in the O_2 -dependent system, which catalyses the generation of toxic oxyhalide ($HOCl^-$) from H_2O_2 . The specific granules contain vitamin B12-binding protein, phospholipase-A2, collagenase, more lysozyme, and lactoferrin, which has an important role in OH generation by the O_2 -dependent system. The secondary granules contain stores of cell receptors for complement components (e.g., CR3) and chemoattractant. It is clear from the contents of the granules that degranulation plays a key role in both microbicidal systems and that deficiencies in granule population could result in a poor inflammatory response. This is particularly demonstrated by the role that the first

granules to be released play in the amplification of the complement cascade, generation of chemoattractant C5a, release of a monocyte chemoattractant, and promotion of PMN adherence to endothelial cells (47). The granule complement is established early in cell differentiation. Primary granules appear in the promyelocyte stage and secondary granules in the myelocyte stage. Except under extreme conditions, when very immature cells are released from the bone marrow (e.g., severe neonatal sepsis), the granule content of neonatal phagocytes is similar to that of the adult. The results obtained in studies of bactericidal activity of neonatal PMNs are similar to those found in studies of phagocytosis; results obtained under apparently normal conditions differ from those obtained under stress. A deficient bactericidal activity has been shown in PMNs from neonates with a variety of clinical abnormalities, including sepsis, meconium aspiration, respiratory distress syndrome, hyperbilirubinemia, and premature rupture of the membranes (48). When subjected to the demands of adjustment to extrauterine life, relative deficiencies of the bactericidal activities of PMNs contribute significantly to the compromised host defense mechanisms of the neonate.

MONOCYTES AND MACROPHAGES

The other major phagocyte system involved in immunologic processes is the mononuclear phagocyte system, which consists of circulatory monocytes and tissue macrophages. Tissue macrophages comprise a wide network of phagocytic cells, including alveolar and gastrointestinal tract macrophages important for initial defense at major portals of entry and dendritic cells important in antigen processing and presentation of antigen at local sites (i.e., Langerhans cells in the skin). Liver (i.e., Kupffer cells) and spleen macrophages are vital for the systemic clearance of microorganisms, cellular debris, and immunocomplexes. Monocytes-macrophages perform a variety of functions, from microbicidal activity to secreting over 100 molecules important in inflammatory regulation (49). These secretory products include cytokines, growth factors, eicosanoids, enzymes, enzyme inhibitors, clotting factors, complement components, plasma-binding proteins, and low-molecular-weight reactive oxygen and nitrogen products.

Macrophages play a vital role in angiogenesis and wound healing. Inflammation, which is a vital part of the immune defense, is marked by the rapid movement of monocytes out of the circulation in response to several factors, including bacterial protein, complement components, fibrinopeptides, and several cytokines (e.g., transforming growth factor [TGF], platelet-derived growth factor [PDGF], IL-1, TNF, IL-2). During this inflammatory response, the monocytes may be further primed by cytokines (e.g., IFN- γ), IL-2, granulocyte-macrophage colony-stimulating factor [GM-CSF]). Interferon- γ activated macrophages are more bactericidal, tumoricidal, and express more major histocompatibility complex class II (MHC II) molecules on their surface. They are enabled to present antigens to lymphocytes and are primed to release cytokines (e.g., TNF- α). Monocytes-macrophages can express several plasma membrane receptors, such as those for immunoglobulin (i.e., Fc receptor [FcR]) and complement components (i.e., CR1 and CR3), that enhance their function, and carbohydrate receptors (e.g., MMR on resident macrophages only).

P.1140

Although studies of Fc and C3b receptors on newborn monocytes reflect a level similar to those in adult cells, cord blood monocytes are less efficient in the phagocytosis of group B streptococci and intracellular killing of *Staphylococcus aureus* and group B streptococci (50). The reason for this defective intracellular killing is unknown, but the characteristic susceptibility of the newborn to group B streptococcal (GBS) infections may depend, in part,

on the immunologic immaturity of the mononuclear phagocyte system. Monocytes, particularly cytokine-activated macrophages, are the first and the most important defense against many intracellular microorganisms (e.g., *Toxoplasma gondii*). Although the antibacterial activity of the newborn's monocytes is comparable to that of the adult, these cells probably have only an initial role in limiting infection. The high incidence (65%) of congenital toxoplasmosis after maternal infection during the third trimester and the significant incidence of serious tissue damage in the fetus may result from a deficient activation of the fetal tissue macrophages. Decreased generation by neonatal lymphocytes of IFN- γ , which is necessary for killing of intracellular pathogens, for the increased expression of MHC II and cytokine production, and for normal inflammatory response and antigen presentation, may facilitate the survival and replication of *T. gondii* in fetal tissues (51,52). Macrophage function is deficient in the neonate (53). This may be related to decreased cytokine production. Investigation has focused on the functional capabilities of monocytes in neonates, including chemotaxis, phagocytosis, microbial killing, and antibody-dependent cellular cytotoxicity (ADCC). Only chemotaxis has been shown to be primarily deficient, although the total number and the function of alveolar macrophages has been reported to be deficient in the neonatal period (54). This observation may partially explain the newborn's susceptibility to GBS pneumonia.

HUMORAL COMPONENT

Complement System

The complement system is a key component in the production of innate or natural resistance to infection in vertebrates. Deficiencies of complement components can contribute to the susceptibility of the neonatal host to infection. Despite its significant biologic role, relatively little is known about the complement system in the neonate, except that it is deficient in this period and the components do not cross the placenta from mother to fetus (39). The third component of complement, C3, can be synthesized in different tissues in the human conceptus, beginning as early as 290 days of gestation (55). The sites of synthesis for C3 appear to be the fibroblast, the lymphoid cell, and the macrophage. There is some evidence that the liver is the major producer of C3 in adults. Serum concentration of C3 in the fetus rises almost exponentially, from 1.9 mg/dL at 5.5 weeks of gestation to between 52 and 167 mg/dL at 28 to 41 weeks. The mean level in cord blood is approximately 90 mg/dL, one-half the maternal levels. Studies of C3 phenotypes indicate that C3 is synthesized in utero. The concentration of complement in the newborn falls slightly after birth and recovers before the infant is 3 weeks of age. By 6 months of age, C3 reaches adult levels. Phagocytosis of bacterial products enhances production of complement components. It can be deduced that antigen stimulation after birth may play a role in the induction of complement synthesis. Complement components C3, C4, and C5 are deficient in premature and full-term infants compared with maternal and adult standards. Propp and colleagues found that C1q, C3, C4, and C5 in cord blood from full-term neonates were approximately 50% of the respective maternal levels (56). Low levels of properdin, factor B(C3PA), C1, C2, C3, and C4 also have been reported in cord blood. Levels of C1q, C2, C3, C4, C5, factor B (C3PA), properdin, and total hemolytic complement are lower in the neonatal period. Most of the biologic effects of complement, including opsonization, immune adherence, complement-dependent viral neutralization, generation of anaphylactic and chemotactic factors, and production of cell membrane lesions, require only the first five complement components. Because the fetus can synthesize each of these components in biologically active form within the first trimester of

development, but in smaller quantities than the adult, all these immunologic functions could be affected to some degree by complement levels. There is a decreased expression of CR3, the receptor for the complement component C3bi on neonatal PMNs, which is important in a variety of adhesion reactions, such as cell adherence, mobility, and phagocytosis.

FIBRONECTIN AND ADHESION MOLECULES

Fibronectin is a nonimmune opsonin that exists in an insoluble form on most cells and in a soluble form in plasma and interstitial fluid. Newborn infants have fibronectin levels in the plasma that are one-third to one-half those found in the adult. These levels are further reduced in premature infants and under various pathologic conditions in the newborn (e.g., sepsis, malnutrition, re-spiratory distress syndrome, asphyxia) (57). Fibronectin is a glycoprotein with a molecular weight of 450,000 that promotes the clearance by phagocytic cells of fibrin, platelets, immune complexes, and collagenous debris. Fibronectin is also an important opsonic factor for numerous pathogenic microorganisms, including *Staphylococcus aureus*, *Streptococcus* sp., and some gram-negative bacteria. It functions as a chemoattractant for phagocytic cells alone, as for macrophages, or by increasing the response in PMNs. Fibronectin induces the expression of the complement receptors, i.e., CR1 and CR3, amplifying functions of the phagocytic cell system. Low levels of fibronectin may contribute to hypofunction of the neonatal phagocytic cell

P.1141

system, predisposing to the development of sepsis. Adhesion molecules are a group of glycoproteins on cells that mediate cell-to-cell or cell-to-matrix (e.g., fibronectin, basement membrane) attachments. These include four groups of adhesion molecules, i.e., integrins, immunoglobulin superfamily molecules, selectins and other adhesion molecules. The attachment occurs through ligand-receptor interaction, as with ICAM-1, vascular cell adhesion molecule-1 (VCAM-1), and endothelial leukocyte adhesion molecule-1 (ELAM-1) on endothelial cells with the integrins LFA-1 (CD11a/CD18), Mac-1 (CD11b/CD18), p150,95 (CD11c/CD18), VLA-4, and slex integrin-adhesion molecules on phagocytic cell plasma membranes. This binding facilitates recruitment of these cells into inflammatory sites. Activation of phagocytic cells by a variety of events, including adherence, and by cytokines such as TNF- α and IL-1, induces the expression of the adhesion molecules. If the cytokine production is deficient, the adhesion molecule expression may also be reduced. Deficient cytokine production may be responsible for the decreased inflammatory response seen in newborns.

CYTOKINES

There are a group of hormonelike proteins, or glycoproteins, secreted primarily by lymphocytes and macrophages and a variety of other cells, that act as mediators of systemic inflammatory and immune responses by being molecular messengers between participating cells. Some of these were previously referred to as lymphokines or monokines, based on their cellular origin, but they are all generically referred to as cytokines. A summary of the major cytokines appears in Table 45-4, listing their primary cell sources and principal functions. In the neonatal period, there are deficiencies in two very important cytokines that may be key in the age-dependent susceptibility of the infant to viral and bacterial infections. These include IFN- γ and TNF- α , both of which display reduced mRNA expression and protein production (58,59). The primary deficiency appears to result from an immaturity in T-cell

function, particularly in the production of IFN- γ in the neonate, which is reported to be 10-fold less than in the adult. Interferon- has antiviral effects and is an important immune cell modulator. It increases MHCII expression and the cellular functions, particularly of NK cells, PMNs, and microbicidal activity of macrophages. It induces T-cell differentiation and IgG and TNF production, which augments antimicrobial activity of phagocytic cells. In the neonate, the T-cell production of TNF is 50% less than in the adult, and IFN- γ -enhanced mononuclear phagocyte production of TNF is 7% less than adult levels. Tumor necrosis factor plays a major role in enhancing phagocytic cell function and inducing a variety of other antimicrobial, inflammatory, and immune functions, such as the expression of adhesion molecules (i.e., integrins ICAM-1, VCAM-1, ELAM-1 on endothelial cells and phagocytic cells) alone or by inducing the production of other cytokines. A study has reported that both IL-12 mRNA expression by cord blood mononuclear cells and IL-12 production are greatly reduced compared to adult levels. IL-12 is an important cytokine in the regulation of NK and T-cell function. It is hypothesized that the impaired capacity of IL-12 production in the neonate may contribute to the decreased production of IFN- γ and NK cytotoxicity (60). Further, Zola and associates (61) have reported significantly lower expression of some of the cytokine receptors on CD4 and CD8 T lymphocytes and on B lymphocytes. These include the following, decreased IL-2(p55) and TNFR(p75) on CD4, CD8 T cells, and on B cells; decreased IL-2 (p75) on CD4 and CD8 T cells; decreased IL-6 and IL-7 on CD4 T cells; decreased IFN- γ on CD8T cells and decreased IL-4 on B cells (62). Collectively, these deficiencies in the neonatal cytokine repertoire may, in part, contribute to the immaturity of the immune response of the newborn and may play a major role in their increased susceptibility to infections.

ANTIBODIES

Antibodies react with antigens, and they appear to play a significant role in events mediating inflammatory responses, such as phagocytosis, chemotaxis, and the release of mediators. The extent to which the antibodies affect these functions in the fetus and newborn depends on the permeability of the placenta to a given antibody and maturation of the antibody-producing system. Silverstein and colleagues studied the maturation of immunologic capability and lymphoid tissues in the normal fetal lamb in utero (Fig. 45-1) (63). They established the sequence of the antibody response to different antigens. Bacteriophage OX174 given on day 37 elicited the earliest antibody response, at 41 days

P.1142

P.1143

of gestation. This is a remarkable observation, because the fetal sheep has little organized lymphoid tissue at this stage. At approximately 66 days of gestation, the fetus becomes able to respond to the protein ferritin, but not until 125 days of gestation can it respond to egg albumin. Antibodies against Salmonella typhi or bacillus Calmette-Guerin appear only after birth. The researchers were unable to induce tolerance until the lamb reached the age at which it was able to recognize the antigen and produce antibody. It is possible to draw an analogy between this phenomenon and the poor response of human newborn infants to the polysaccharide antigens. These phenomena must be understood

P.1144

in the human if adequate immunization techniques are to be developed and allergic diseases are to be prevented (Table 45-5).

Figure 45-1 Comparison of immunologic and lymphoid development in the fetal lamb. Numbers on the upper horizontal axis show the earliest times at which antibody responses and graft rejection could be detected. The order in which lymphocytes appear in different tissues is as follows: bacteriophage (X Φ), horse ferritin (Fer); snail hemocyanin (Hcy); hen albumin (Oval); diphtheria toxoid (Dip Tox). (Adapted from Silverstein A, Prendergast R. The maturation of lymphoid tissue structure and function in ontogeny. From Lindahl-Kiessling K, Alm G, Hanna MG Jr, eds. *Morphological and functional aspects of immunity*. New York, Plenum Press, 1971, with permission.)

TABLE 45-4 CHARACTERISTICS OF MAJOR CYTOKINES

Cytokine	Primary Cell Source	Activity	Principal Effects
IL-1	Macrophages, NK and B cells, Endothelial cells	Immunoaugmentation: activates T cells by enhancing production of IL-2 and expression of IL-2 receptors; augments B cell proliferation and Ig synthesis; activates macrophages	Inflammation, immunostimulatory, fever
IL-2	T lymphocytes and large granular lymphocytes (LGL)	T, B and NK cell growth factor	Activates cytotoxic T cells, B cells, NK cells and macrophages
IL-3	T lymphocytes	Hematopoietic growth factor	Promotes growth of early myeloid progenitor cells
IL-4	T helper lymphocytes, eosinophils, basophils, possibly mast cells	T and B cell growth factor; promotes IgE production	Enhances antigen-presenting capacity of B cells; Promotes immunoglobulin switch from IgM to IgE; influences T lymphocytes growth, differentiation and survival; drives naive T-helper cells towards a Th2 phenotype
IL-5	Th cells	B cells and eosinophil growth factor and stimulator	Promotes IgA switch and eosinophilia
IL-6	Polyclonal Monocytes, macrophages, T and B cells, Fibroblasts, endothelial cells, hepatocytes	Hybridoma growth factor; augments inflammation	Mediates T cell activation, growth and differentiation; Growth factor for B cells and immunoglobulin production; Induces fever and production of acute-phase proteins; Inhibits IL-1 and TNF synthesis
IL-7	Stromal cells	Lymphopoietin	Growth factor for B and T cell precursors
IL-8	Monocytes, macrophages, endothelial and epithelial cells	Most important chemoattractant for neutrophils, activates PMN, chemoattractant for lymphocytes	Regulates lymphocyte homing and neutrophil infiltration

IL-9	Eosinophils and Th2 lymphocytes	T and B cell growth factor; Mast cell growth factor; stimulation of hematopoiesis	Together with IL-2 increases fetal thymocyte proliferation; stimulates erythroid precursor cell proliferation; synergistic with IL-4 to produce IgE, synergistic with IL-5 to enhance production of eosinophils
IL-10	Monocytes, B and T lymphocytes (Th1 and Th2) and thymocytes	Proliferation of cytotoxic T-cells, B-cells and mast cells; inhibition of cytokine synthesis by Th1 cells; inhibition of cytokine synthesis by Th2 cells; inhibition of IFN- γ and TNF by NK cells; IL-10 shows homology with EBV proteins	Inhibits cytokines associated with cellular immunity and allergic inflammation and stimulates humoral and cytotoxic immune responses; down-regulates production of pro-inflammatory cytokines
IL-11	Bone marrow stroma cells, stromal fibroblasts	Functions as cofactor in hematopoiesis; B cell regulator of stem cell cycle; has stimulatory function on connective tissue cells; cytoprotective for skin, bowel mucosa and joint inflammation	Synergistic with other growth factors to produce erythrocytes, platelets and mast cells; stimulates Ig synthesis in the presence of T cells; contributes to lymphoid production in bone marrow
IL-12	Monocytes, macrophages, B cells and others	Activates NK cells, induces CD4 T cell differentiation to Th1-like cells; induces proliferation of T helper and cytotoxic lymphocytes	Induces IFN- γ secretion, activates macrophages, enhances cell mediated cytotoxicity
IL-13	T cells	B cell growth and inhibits macrophage inflammatory cytokine production	Homologous to IL-4; Promotes T cell growth and proliferation; stimulates B cell growth and differentiation; promotes IgE production
IL-14	B cell of non Hodgkin's lymphoma	B cell growth factor (BCGF)	Stimulates rapid proliferation of non-Hodgkin's lymphoma B cell; inhibits Ig synthesis

IL-15	Monocytes, macrophages, neutrophils, fibroblasts, epithelium	IL-2 like, stimulates growth of intestinal epithelium and modulates epithelial changes in celiac disease	Stimulates T and B cell growth and proliferation; chemotactic for T cells; differentiation of NK cells
IL-16	CD8+ T cells, mast cells, respiratory epithelial cells, CD4+ T cells, eosinophils	Potent chemoattractant for CD4+ T cells, monocytes and eosinophils	Chemoattractant; modulator of T cell activation; inhibitor of HIV replication, induces IL-2 receptors in CD4+ cells
IL-17	Activated CD4+ T cells, eosinophils	Stimulates macrophages, fibroblasts and stromal cells to produce PGE ₂ , cytokines (IL-6, IL-8, IL-11, G-CSF) and nitric oxide	Stimulates cytokine production and induces expression of ICAM-1
IL-18	Stromal cells, activated macrophages	Growth factor and stimulator of Th1 proliferation	Synergistic with IL-12 to induce IFN- γ and GM-CSF in activated T cells, upregulates cytokine receptors
IL-19	Monocytes	Member of the IL-10 family	Can be induced by LPS and GM-CSF
IL-20	Keratinocytes	Member of the IL-10 family	Overexpressed in psoriasis
IL-21	Activated T lymphocytes	Homologous to IL-2 and IL-15	Activates NK cells; promotes proliferation of B and T lymphocytes
IL-22	T cells, mast cells	Member of the IL-10 family	Induced by IL-9 and LPS; induces acute phase response
IL-23	Activated dendritic cells	Homologous with an IL-12 subunit	Induces IFN- γ ; contributes to Th1-like differentiation
IL-24	Th2 lymphocytes	Member of the IL-10 family	Induced by IL-4
IL-25	Th2-like lymphocytes	Contributes to IgE secretion	Stimulates release of IL-4 and IL-13
G-CSF	Monocytes, T cells, endothelium and fibroblasts	Myeloid growth factor	Generates neutrophils
M-CSF	Monocytes, fibroblasts, endothelium	Macrophage growth factor	Generates macrophages
GM-CSF	T cells and others (endothelium, fibroblasts, monocytes)	Monomyelocytic growth factor	Myelopoiesis

IFN- α	Monocytes, macrophages, B lymphocytes and NK cells	Antiviral, antiproliferative and immunomodulating, mediation of antitumor activity	Stimulates NK and phagocytic cells, upregulates MHC class I antigens
IFN- β	Fibroblasts	Antiviral, antiproliferative and immunomodulating, mediation of antitumor activity	Stimulates NK and phagocytic cells, upregulates MHC class I antigens
IFN- γ	Th lymphocytes, NK cells and macrophages	Immunomodulating, antiproliferative	Induce cell membrane antigen expression (i.e., MHC class I and II); primary cytokine responsible for cell-mediated immunity; inhibits IL-4 or IL-13 induced IgE production
TNF- α	Mononuclear phagocytes	Inflammatory, immunoenhancing and tumoricida	Induces anti-tumor immune responses; induces expression of adhesion molecules; potent activator of neutrophils; responsible for severe cachexia; causes vascular thromboses, tumor necrosis and enhances phagocytic cell function, induces apoptosis of many cells; induces secondary production of cytokines by stromal cells
TNF- β = LT	T lymphocytes	Stimulates antitumor immunity	Induces anti-tumor immune responses; induces expression of adhesion molecules
TGF- β	Chondrocytes, osteocytes, fibroblasts, platelets, monocytes and some T cells	Anti-inflammatory; induces formation of extracellular matrix; causes immunosuppression by inhibiting B and T cells	Wound healing, scar formation and bone remodeling; supports IgA isotype class switch; plays major role in immune nonresponsiveness (tolerance) in the gut

B, bursal dependent; EBV, Epstein-Barr virus; G-CSF, granulocyte-colony-stimulating factor; GM-CSF, granulocyte- macrophage-colony-stimulating factor; IL, interleukin; IFN, interferon; LGL, large granular lymphocytes; M-CSF, macrophage-colony-stimulating factor; MHC, major histocompatibility complex; NK, natural killer; T, thymus derived; TGF, transforming growth factor; TH, thymic; TNF, tumor necrosis factor.

TABLE 45-5 DEVELOPMENT OF THE IMMUNE SYSTEM IN THE FETUS

Gestation (Wk)	Findings
4	First blood centers appear in yolk sac
5.5	Synthesis of complement is detected
7	Lymphocytes appear in peripheral blood, about 1000/mm ³
7-9	Lymphocytes appear in thymus
11	CD2 receptors (i.e., E rosette) develop in thymus lymphocytes; B-cell maturation occurs in liver and spleen, with IgG, IgA, IgM, and IgD surface markers; serum IgM levels can be detected
12	Antigen recognition is demonstratable
13	Graft-versus host reactivity is present
14	Phytohemagglutinin responses by thymus lymphocytes occurs
17	Serum IgM levels can be detected
20	Secondary lymphoid complex is present
20-25	Lymphocytes in blood number about 10,000/mm ³
22	Complement levels detectable in serum
30	IgA level detectable in serum

Adapted from Cauchi MN. Immunological aspects of pregnancy and the newborn. In: Cauchi MN, Gilbert GL, Brown JB, eds. *The clinical pathology of pregnancy and the newborn infant*. London: Edward Arnold Publishers, 1984:325, with permission.

OPSONIC CAPACITY

The opsonic capacity of blood refers to the enhancement of phagocytosis and includes the activities of antibodies, complement, and other proteins that are not well defined. IgM appears to have the greatest opsonic activity. Full-term and premature human newborns appear to be relatively deficient in opsonic activity toward a variety of agents. The degree of deficiency varies with different agents and probably particularly involves antibodies of the IgM type. This deficiency of antibodies may account for the susceptibility of the newborn to gram-negative infections, because IgM antibodies do not traverse the placenta. However, Miller observed that addition of purified IgM to neonatal sera does not enhance opsonization of yeast particles. Complement and other heat-labile factors amplify the opsonic activity of IgM to a much greater extent than they amplify IgG opsonic activity. The deficit in opsonic activity derives from deficiencies of complement, particularly of components C3, C5, and C3PA. In the premature infant, lowered levels of IgG may play a role in the opsonic deficiency (64). Rigorously controlled studies of the opsonic capacity of the fetus and newborn are needed so that the usefulness of potentially harmful treatments, such as fresh plasma transfusion in the septicemic neonate, can be determined. One of the important clinical sequelae of deficient antimicrobial antibody is seen in GBS infection of the newborn. The increased susceptibility of newborns to GBS infection has been correlated with deficiency of maternal antibody directed against the type-specific polysaccharides of the organism.

ADAPTIVE IMMUNE MECHANISMS

The maturation of adaptive immune responses in the human begins in utero between 8 and 12 weeks of gestation. The differentiation of cells destined to perform these functions appears to arise from a population of progenitor cells, referred to as stem cells, that are located within the yolk sac, fetal liver, and bone marrow of the developing embryo (Fig. 45-2). Depending on the type of microchemical environment surrounding these cells, differentiation occurs along at least two avenues: hematopoietic and lymphopoietic.

HEMATOPOIETIC DIFFERENTIATION

One type of microchemical environment leads to the proliferation and differentiation of stem cells into myeloid, erythroid, and megakaryocyte precursors. The products of these cell lines are the monocytes, granulocytes, erythrocytes, and platelets of the circulation. In the human, granulocytic cells are first observed in the liver of the fetus in the second month of gestation. Leukocyte production by the fetal liver declines at about the fifth month of gestation, when the bone marrow activity increases.

LYMPHOPOIETIC DIFFERENTIATION

Classically, the lymphoid system develops along two independent pathways leading to morphologically and functionally distinct populations of immune lymphocytes: the thymus-derived system of cell-mediated immunity (CMI), whose principal effector cells are the T lymphocytes, and the bursal-dependent system of antibody-mediated immunity, which is effected by the B lymphocytes. The T lymphocyte is commonly identified by the T-cell receptor-CD3 (TCR-CD3) complex or CD2 surface marker (i.e., binding site for sheep erythrocytes). The B lymphocyte is recognized primarily by its surface CD19 or CD20 markers or immunoglobulin.

The immune system of the human derives from gut-associated tissue in the embryo. The first appearance of pluripotential hematopoietic stem cells in the yolk sac is at 2.5 to 3 wk of gestational age and these cells migrate to the fetal liver at 5 wk of gestation; later, they reside in the bone marrow, in which they remain throughout life. The lymphoid stem cells develop from these precursor cells and depending on the organs or tissues to which the stem cells traffic, differentiate into T, B, or NK cells. During the middle

P.1145

of the first trimester of gestation, primary lymphoid organ (thymus and bone marrow) development begins and proceeds rapidly, followed by secondary lymphoid organ (spleen, lymph nodes, tonsils, Peyer patches, and lamina propria) development. Throughout life these organs continue to serve as sites of differentiation of T, B, and NK lymphocytes from stem cells. Both the initial organogenesis and the continued cell differentiation occur as a consequence of the interaction of a vast array of lymphocytic and microenvironmental cell surface molecules and proteins secreted by the involved cells. The complexity and number of such cell surface molecules led to the development of an international nomenclature and classification of these differentiation antigens, which are now referred to as clusters of differentiation (CD) (65) (Table 45-6).

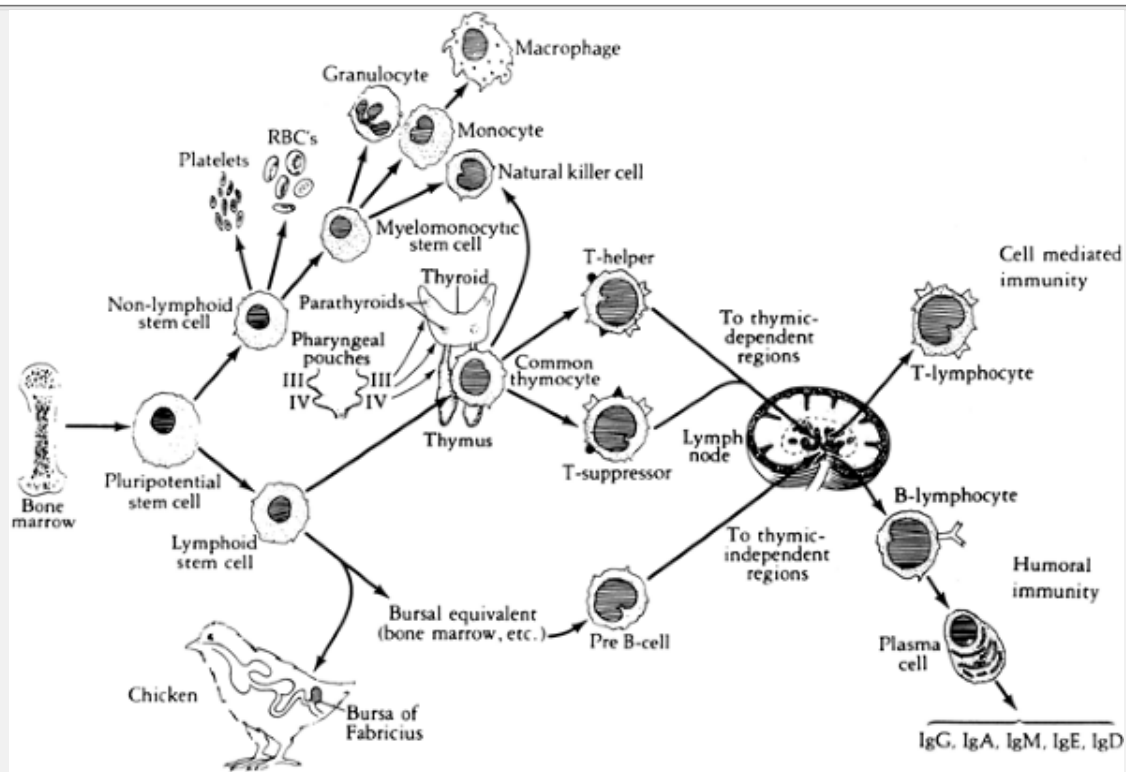

Figure 45-2 Ontogeny of immune response, showing differentiation of progenitor cells into hematopoietic and immunocompetent cells. From Bellanti JA. *Immunology III*. Philadelphia, WB Saunders, 1985:48, with permission.

T-CELL SYSTEM

The basic cell type differentiates into lymphoid cells when the progenitor cells are influenced by certain microchemical environments. The first is the thymus, which leads to the differentiation of T cells (66,67). The thymus gland is derived from the epithelium of the third and fourth pharyngeal pouches at about the sixth week of fetal life. The parathyroid glands also begin their development at about this time from the same pouches. With further differentiation, a caudal migration of epithelium occurs, and beginning in the eighth week, blood-borne stem cells enter the gland and begin lymphoid differentiation. With further development, the thymus is infiltrated with lymphocytes and is differentiated into a dense cortex containing many small lymphocytes and a less dense, central medulla with relatively more epithelial elements. Thymocyte precursors are probably derived from multipotential hematopoietic precursors in the fetal liver and later in the bone marrow (68,69,70). Under the influence of thymic epithelium-derived chemoattractants, pro-T cells initially localize to the thymic corticomedullary junction. These CD4-negative, CD8-negative T-cell precursors undergo extensive gene rearrangement, phenotypic alteration, and biochemical modification to yield the population of thymocytes that undergoes intrathymic selection. First, precursor T cells with affinity for self MHC (i.e., usually CD4-positive and CD8-positive) are positively selected in the cortex of the thymus. Subsequently, in the medulla, they undergo negative selection, and those that recognize self-antigens are deleted. More than 95% of the thymocytes, which include cells that have not been positively selected and those that have been negatively selected, proceed to programmed cell death, a process called apoptosis. The selected mature thymocytes, usually bearing mature TCRs with CD8 or CD4 molecules (i.e., single positive), seed the peripheral lymphoid tissue. In the developing thymus, there exists a dynamic interplay of cytokines that act in a coordinated and temporal manner to control the passage of the precursor cell through different stages of development in the thymus (Fig. 45-3). In particular, IL-1, IL-2, IL-4, and IL-7 may play central roles in precursor proliferation and differentiation (71). T-cell differentiation within

P.1146

the thymus appears to be regulated by several factors synthesized by the thymic epithelial cells. Several peptides have been described, and they share some properties that may result from their relative impurity (72). One of the best characterized of these thymic hormones is thymopoietin (molecular weight, 5562), which promotes prothymocyte to thymocyte differentiation, as demonstrated in the appearance of typical T-cell surface markers (73). Some synthetic polypeptide molecules that seem to have all the differentiation-inducing

properties of the original molecule are being evaluated. Although the characterization of hormones is preliminary, the use of thymosin has intriguing applications in clinical medicine as a replacement therapy for immunoincompetence. The clinical importance of the simultaneous embryogenesis of the parathyroid and thymus is seen in one of the immunologic deficiency disorders of infancy, the DiGeorge anomaly. The DiGeorge anomaly is a developmental defect in which derivatives of pharyngeal pouches III and IV do not arise, usually because of inadequate neural crest contributions resulting in congenital aplasia of the thymus and the parathyroids. The condition presents in the early newborn period with hypocalcemic tetany, characteristic facies and cardiovascular defects and a propensity to infections which result from T cell deficiency, e.g., candidiasis. Recently, a spectrum of disorders resembling the DiGeorge syndrome has been described all associated with a deletion of the long arm of the 22 chromosome (74). This gamut of disorders has been referred to as the Catch 22 and include a cluster of developmental anomalies including velocardiofacial (VCF) or Shprintzen syndrome, conotruncal atresia and the DiGeorge syndrome. There is no known feature that uniformly occurs, and the diagnosis of DiGeorge anomaly is usually based on two or more of the following: (a) typical facies (e.g., hypoplastic mandible, short philtrum, hypertelorism, ears low set or malformed or both) (b) characteristic heart lesion (e.g., conotruncal malformation, usually interrupted aortic arch [IAA] type B) (c) persistent hypocalcemia with onset in the first month of life (d) documented inability to identify the thymus at surgery or autopsy (e) decrease in T-cell response to mitogens (f) decrease in T-cell number (75,76). Two rare conotruncal anomalies, type B IAA and truncus arteriosus, account for over one-half of the cardiac lesions seen in DiGeorge anomaly. Of all patients with IAA type B, 68% had DiGeorge anomaly; of all patients with truncus arteriosus,

P.1147

33% had DiGeorge anomaly. Failure of descent of the thymus is extremely common in DiGeorge anomaly, but immunodeficiency that requires correction occurs in only approximately 25% of the patients. The term, complete DiGeorge anomaly, should be reserved for patients with complete absence of the thymus and parathyroids who are in need of reconstitution of the immune system without which life is incompatible. The physician can identify patients requiring treatment of the thymic defect by T-cell enumeration and in vitro proliferation assays. Two alternatives for therapy are thymus transplantation and bone marrow transplantation from a HLA-matched sibling. After emigration of the T cells from the thymus, they circulate through the lymphatic and vascular systems as the long-lived lymphocytes (i.e., the recirculating pool), which then populate certain restricted regions of the lymph nodes, the thymic-dependent subcortical areas, and the periarteriolar regions of the spleen. Removal of the thymus in neonatal mice renders them deficient in the number of circulating T cells and leads to depletion of the thymic-dependent areas in lymphoid tissue. The long-lived nature of these lymphocytes and the degree of competence in the human may explain in part why, after thymectomy, immediate deficits are not usually seen in the newborn period, although they may become apparent later in life. After birth, the thymus plays a continually changing role in relation to body size. It is largest compared with body size during fetal life, and at birth, it weighs 10 to 15 g. The gland continues to increase in size, reaching a maximum of 30 to 40 g at puberty, after which involution occurs. The increased incidence of autoimmunity and malignancy with aging has been associated with senescence of thymic function.

TABLE 45-6 CLASSIFICATION OF LYMPHOCYTE SURFACE MOLECULES; CLUSTERS OF DIFFERENTIATION (CD)

CD Number	Other Names	Tissue/Lineage	Function
CD1	T6	Cortical thymocytes; Langerhans cells	Antigen presentation to TCR $\gamma\delta$ cells
CD2	SRBC receptor	T and NK cells	Alternative pathway of T cell activation; binds LFA-3 (CD58)
CD3	T3, Leu 4	T cells	Transduces signals from TCR (TCR-associated)
CD4	T4, Leu3a	Helper T cell subset	Receptor for HLA class II antigens; associated with p56 <i>lck</i> tyrosine kinase
CD7	3A1, Leu 9	T and NK cells and their precursors	Co-mitogenic for T lymphocytes
CD8	T8, Leu2a	Cytotoxic T cell subset; also on 30% of NK cells	Receptor for HLA class I antigens; associated with p56 <i>lck</i> tyrosine kinase
CD10	cALLA	B cell progenitors	Peptide cleavage
CD11a	LFA-1a α chain	T, B, and NK cells	Ligand for ICMAS 1,2, and 3 with CD 18
CD11b, c	MAC-1, CR3; CR4 γ	NK cells	With CD18, receptors for C3bi
CD16	FcR III	NK cells	FcR for IgG
CD19	B4	B cells	Regulates B cell activation
CD20	B1	B cells	Mediates B cell activation
CD21	B2	B cells	C3d and the EBV receptor; CR2
CD34	My10	Precursor cells	Unknown
CD40	CD40	B cells and monocytes	Initiates isotype switching when ligated
CD45	Leukocyte common antigen, T200	All leukocytes	Tyrosine phosphatase that regulates lymphocyte activation; CD45R0 isoform on memory T cells, CD45RA isoform on naive T cells
CD56	N-CAM; NKH-1	NK cells	Mediates NK homotypic adhesion
CD154	CD40 ligand, gp39	Activated CD4 T cells	Ligates CD40 on B cells and initiates isotype switching

T CELLS

The stages in the life history of T cells are marked by the gradual appearance of a variety of membrane-bound glycoproteins (Fig. 45-4). Many of them have been identified by employing monoclonal antibodies. Immature thymocytes are characterized by the expression of some surface markers acquired during intrathymic development, such as transferrin receptor (CD71), CD1, CD2, CD4, CD8, and the CD3/TCR complex. After the T cells enter the circulation, they lose the transferrin receptor and CD1 molecule. In the peripheral blood, approximately 70% of T cells express the CD4 marker, and CD8 is found on approximately 30%. T cells that acquire helper activity characteristically express CD4, and suppressor T cells have CD8 but not CD4 on their surface. The CD4 receptor with

P.1148

antigen-specific TCR/CD3 complex allows the helper T cell to recognize antigens combined with antigen-presenting cell surface MHC II molecules. Helper T cells are induced to undergo blast transformation and cell division after interaction with antigen and MHC II molecules on the macrophage and other antigen-presenting cells. T-cell activation leads to the production of a variety of cytokines (e.g., IL-2, IL-3, IL-4, IL-5, IL-6, GM-CSF, IFN- γ , TNF), cell proliferation, and increased cell surface receptor expression (e.g., CD71, IL-2 receptor). Significantly decreased production of IL-4 and IFN- γ by neonatal T cells has been observed after activation (77). T helper cell populations have been further subdivided into Th1 and Th2 subsets. These subsets are identified by their different patterns of cytokine production: Th1 produces IFN- γ , IL-2, TNF- β Th2 produces IL-4, IL-5, IL-6, IL-9, IL-10, IL-13 (78). The functions of Th1 and Th2 cells appear to correlate with their distinctive cytokine production, i.e., Th1 cells are involved in cell-mediated immune reactions and delayed type hypersensitivity; Th2 cells are involved in antibody production and atopic disease (79).

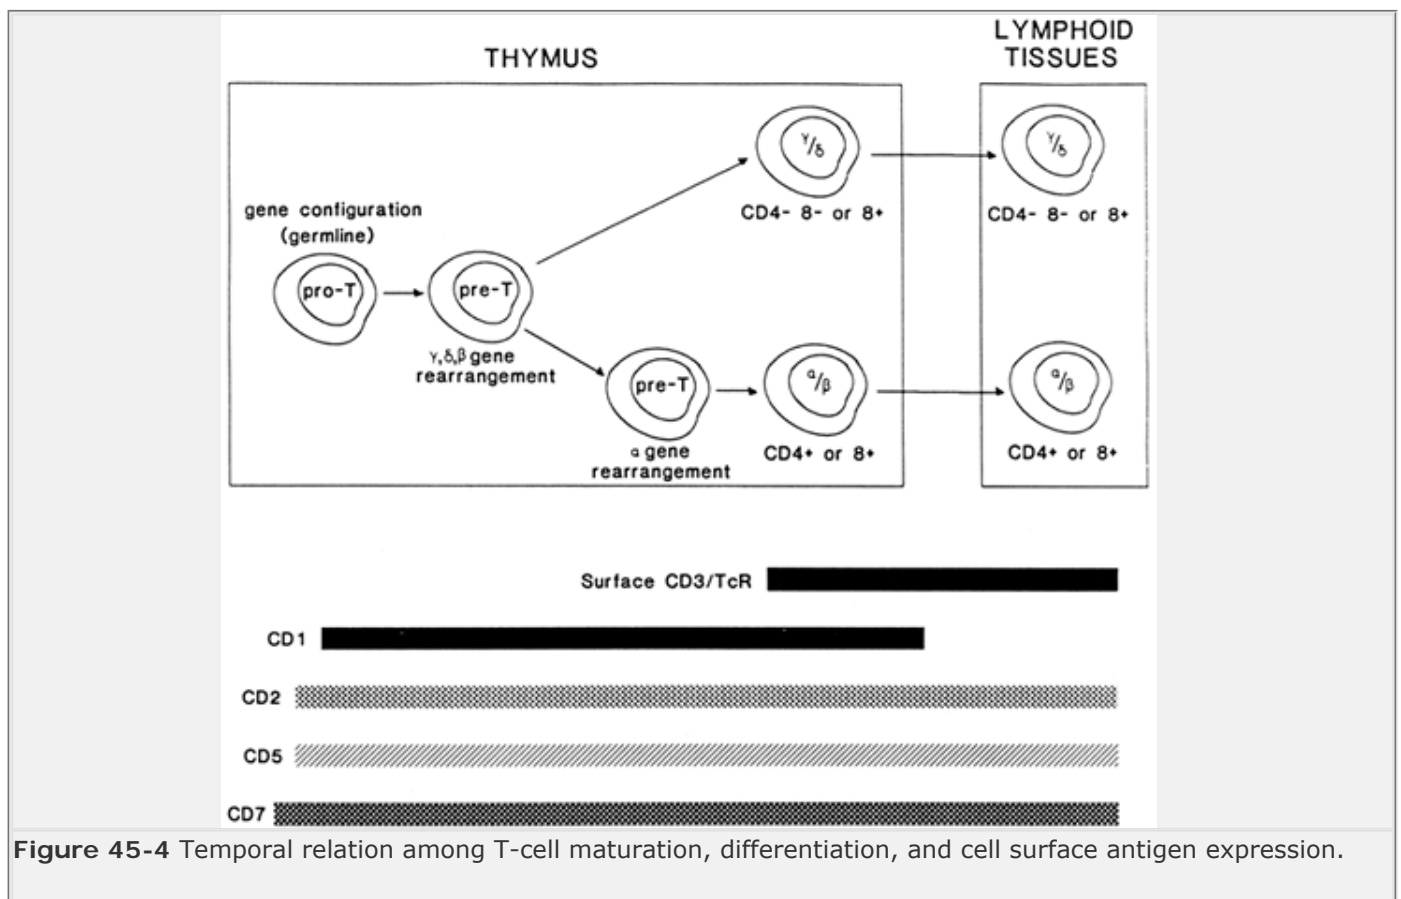

Figure 45-4 Temporal relation among T-cell maturation, differentiation, and cell surface antigen expression.

The T cell population in the cord blood of newborns is skewed largely toward a Th2 phenotype (80). This is the result of the production of Th2 stimulating factors from the placenta that leads to the induction of the cytokines IL-4, IL-5, IL-13, and the reduced production of IFN- γ . The decreased Th1 function during pregnancy is consistent with the survival advantage imparted to the fetus during his/her intrauterine existence. At birth, the lymphocyte system of the neonate is primarily dominated by cells with a Th2 phenotype that results in a suppression of cell-mediated responses. In the early postnatal period, the normal infant continues to show a Th2 skewing, but by the end of the first year (81) there is a shift to Th1 predominance (Fig. 45-5).

Consequently 60% to 70% of normal children exhibit no reactivity to allergens by the age of five years. In

contrast, the allergic infant continues to show a prominent Th2 skewing with a delayed acquisition of Th1 function (82) (Fig. 45-5). Studies of cord blood mononuclear cells (CBPM) showed that T cells produce a minimal Th1-like response (83). Further, the diminished capacity of the infant's T cells to produce IFN- γ is not primarily caused by an intrinsic cellular defect. The ability of allergens to induce specific proliferative responses by cord blood mononuclear cells at birth indicates that intrauterine lymphocyte "priming" has occurred. This does not indicate that all newborns who have come into contact with allergens during the prenatal period, and have mounted a specific Th2 immune response, subsequently will become atopic infants. Thus the presence of a specific allergen mediated proliferative response at birth cannot necessarily be considered a predictive marker for the subsequent appearance of allergic illnesses. A study by Prescott and associates (84), showed that future atopics have paradoxically lower values in all types of Th2 cytokines. This suggests that maintenance of a Th2 cytokine pattern would require either the presence of Th2-enhancing stimuli that have a booster effect and/or the lack of down-regulating

P.1149

stimuli capable of shifting the immune system toward the production of a predominate Th1 type cytokine pattern (85) (Fig. 45-5).

Figure 45-5 Schematic representation of hypothetical changes in Th1 and Th2 values in the normal infant during postnatal development showing the Th2 skewing in early infancy and the acquisition of normal Th1. In contrast, the atopic infant shows the Th2 skewing in early infancy but a delayed acquisition of normal Th1 values. Adapted from Bellanti JA, Malka-Rais J, Castro HJ, Mendez de Inocencio J, Sabra A. Developmental immunology: clinical application to allergy-immunology. *Ann Allergy Asthma Immunol* 2003;90:2, with permission.

The mechanisms that favor "immune shifting" are not well known. The progressive maturation of the antigen presenting cells, especially dendritic cells, which are immature at birth may play a role. The Th2 skewing in the newborn (86) may in part be the result of the diminished capacity of antigen presenting cells to produce IL-12 at the time of antigen presentation which is necessary to induce T cells to favor their differentiation toward a Th1 phenotype, and NK cells to produce IFN- γ (87). This may result in a production of predominant Th2 cell clones when antigens are presented to the antigen presenting cell system during the immature phase. Subsequent contact with these antigens may predispose to a Th2 response in the first few months of life (Fig. 45-5).

Increase in Atopic Diseases and the Role of Decreased Infection in Industrialized Countries: the Hygiene Hypothesis

In recent years there has been an alarming increase in the prevalence of the atopic diseases, i.e., those which are characterized by a familial predilection and increased IgE production and which include allergic rhinitis, asthma and infantile (atopic) eczema. Although no satisfactory explanation has been found, at least two hypotheses have been offered to explain this increase (88). These include: (a) a change in nutritional patterns or increased exposure to environmental pollutants as a result of our modern technologies and industrialization;

and (b) changes in lifestyle in affluent developed countries in which as a result of improved sanitation there has been a reduction in the Th1 inductive influences as a result of minimized exposure to infectious agents or their byproducts, e.g., endotoxin. One of the earliest observations that supported an antiallergic effect by some infections came from reports suggesting a reduction in allergic disease in children with tuberculosis and following bacillus Calmette-Guérin (BCG) immunization. In a study by Shirakawa and associates (89), an inverse correlation between asthma, allergic symptoms, IgE levels and Th2 cytokine production was found with positive tuberculin tests in children at 6 and 12 years of age. Others have been unable to find a beneficial effect of measles or BCG (90,91). It has been reported that exposure to some viral infections very early in life appears to offer some protection against asthma (92), atopic sensitization within the first 12 months of life and children who come from large sibships also are reported to have a decrease in allergies at school (93,94, 95). It has been suggested that in the affluent Western societies, in which infectious disease has decreased, that the Th1-promoting effect of these infections has been lost. This theory is known as the "hygiene hypothesis" and has been proposed to explain the remarkable increases in atopic diseases in these societies (96).

Another important factor that has been identified is bacterial endotoxin, which is a potent stimulator of IL-12 production. In turn, IL-12 elicits IFN- γ production and evokes a Th1 response from naïve helper T cells (97,98). Further evidence for the atopy preventing Th1 favoring effects of endotoxin exposure was shown in a study which reported lower prevalence of atopy in farm-residing children compared with nonfarm-residing children in Germany, Austria and Switzerland (99,100). Additionally, it has been reported that children living in homes, during the first year of life, with 2 or more dogs or cats, known sources of endotoxin, have a decreased risk of atopic sensitization at age 6 to 7 years (101). Thus, in addition to factors

P.1150

which influence the maturation of the antigen presenting cell system in early childhood there are other inductive influences may be responsible for establishing a mature Th1 response and in protecting against early allergic sensitization.

T-cell helper function in newborns is quite low, but it develops almost to adult levels by 6 months of age. T-cell-mediated suppression of immune responsiveness is somewhat higher in the infant than in the adult. The percentage of putative suppressors with the CD8 phenotype is lower in cord blood than in adult blood (102). However, in functional assays, neonatal T cells elicit increased spontaneous suppressor activity compared with adult T cells. Moreover, suppressor T cells exert a strong cytostatic effect on adult B- and T-cell proliferation, probably to prevent graft-vs.-host (GVH) reaction by maternal cells transferred to the fetus. Natural killer CD3-negative CD56-positive cell activity is extremely low in the neonatal period, and it reaches the adult level by between 1 to 5 months of age. Although the percentage of NK cells in the peripheral mononuclear cell population is decreased in neonates, the absolute number of these cytotoxic NK cells is high in infancy and even higher from 1 month to 4 years of age compared with that in adults (103). The increased number of NK cells with adequate cytotoxic abilities present from 1 month to 4 years of age indicates the predominance of NK immunity during infancy to early childhood, in the presence of immaturity in other aspects of immunologic system. In the neonatal period, the decreased NK cell activity predisposes to increased severity of viral infections. As a general rule, T cells acquire immunocompetence (i.e., strong proliferation in mixed lymphocyte culture [MLC] and antigen binding) early during fetal life, even though their functional capacities are not always comparable to those of the adult. Newborns, particularly premature infants, have a significantly lower rate and degree of skin sensitization to dinitrochlorobenzene (DNCB), and rejection of skin allografts is slower in newborns than in normal adults. Delayed hypersensitivity can be induced in newborns during the first month of life. The newborn's inconsistency in this capacity appears to be caused more by a decreased inflammatory response and macrophage function than by depressed T-cell activity. A depressed T-cell function may be a consequence of neonatal viral infection, hyperbilirubinemia, corticosteroid therapy, or maternal medications taken late during pregnancy. Specific T-cell immunity can result from antigenic exposure in utero to certain antigens such as penicillin, mumps virus, Escherichia coli, diphtheria and tetanus toxoid, and dental plaque in the mother. There are some suggestions that specific CMI can be acquired from the ingestion of T cells contained in colostrum or breast milk or transferred through the placenta. The proliferative capabilities of immature lymphocytes are well developed early in gestation and, at the time of birth, are equal to or may exceed those of adult lymphocytes; the inflammatory response and macrophage functions, however, appear to be impaired in the newborn period.

B-CELL SYSTEM

If the progenitor cells fall under the influence of a second type of microchemical environment, differentiation produces a population of lymphocytes and plasma cells concerned with humoral immunity or antibody synthesis (see Fig. 45-2). This B-cells population comes under the influence of the bursa of Fabricius in birds (104). In

humans, bone marrow constitutes one of the equivalents of the bursa, but all available evidence indicates that the human fetal liver is the analog of the bursa of Fabricius in humans. The process of B-cell differentiation from a multipotent stem cell begins in fetal liver between 8 and 9 weeks of gestation, with the appearance of pre-B cells. Pre-B cells have MHC II antigens on their surface and the CD19 receptors (i.e., pan-B cell marker) shown in Fig. 45-6. These cells begin to synthesize the cytoplasmic, the heavy chain of IgM, that later becomes the surface IgM that appears on "baby" or immature B cells. CD21, which is the receptor for complement C3d and Epstein-Barr virus (EBV), also begins to appear on the immature B-cell surface. Although these cells continue to express surface IgM, they begin to express one of the surface immunoglobulins (i.e., IgA, IgG, IgD) shown in Fig. 45-7.

Recently, a new molecular ligand has been described which governs the IgM-IgG isotype class switch referred to as the CD40 receptor (CD40-R) found on the T cells which binds to a CD40 ligand on B cells. A deficiency of the CD40 ligand has been described in hyperimmunoglobulin M syndrome. The CD40 ligand is deficient developmentally in the newborn and accounts for the prominent IgM responses of the fetus and newborn as described below (105,106). After stimulation by antigen, and helper T cells through CD40/CD40 ligand, the immature cells become mature plasma cells or memory cells (107). As in T-cell development, B-cell development involves several cytokines, such as IL-3, IL-4, IL-5, IL-6, and IL-7. These cytokines influence B-cell growth and differentiation but also regulate, with CD40/CD40 ligand interaction, the immunoglobulin class switch and secretion. The cytokines that are responsible for isotype switching from IgM have been partially elucidated; IL-10 induces the switch to IgG1 or IgG3; transforming growth factor induces the switch to IgA1 or IgA2 and IL-4 associated with IL-13 induces the

P.1151

switch to IgE and IgG4 (108). IL-6 induces the committed B cells to become a mature immunoglobulin-secreting plasma cell. The first surface immunoglobulin expressed by a B cell is an IgM; at 13 weeks of fetal life, most B cells express IgM and IgD. In the next differentiation step, B-cell clones start to express IgG (i.e., subclasses 1, 2, 3, 4), IgA (i.e., subclasses 1, 2), or IgE. Full-term babies probably have a complete repertoire of B-cell clones, and they can theoretically synthesize each type of immunoglobulin. However, human newborns fail to respond efficiently to all antigens; for example, they are unable to mount an antibody response to polysaccharide antigens. Infants respond to protein antigens (i.e., T-dependent antigens), mainly with IgM production and a slow progression, compared with that of the adult, to IgG response. Children younger than 18 months fail to respond with an IgG2 production to Hemophilus influenzae type b capsular antigen (Hib); this deficient synthesis of IgG2, which is the predominant subclass of antibody against *H. influenzae*, may explain the frequent appearance of *H. influenzae* infections in young children. The acquisition of adult levels of immunoglobulins is achieved by approximately 1 year of age for IgM, at 5 to 7 years for IgG, and at 10 to 14 years for immunoglobulin A (IgA) (109). The reasons for this defective antibody response are believed to be related in part to diminished expression of CD40 ligand (CD40L) by activated neonatal T cells and decreased production of cytokines. Additionally, the expression of CD40L is a function of age; reduced at birth, increasing during the first few months and reaching a plateau in the second decade. This is reportedly as a result of maturation of the CD4+ subset and has been correlated with expression of CD45RO antigen. Excessive suppressor T-cell activity in newborn blood, defective regulatory cytokine production, and a partial immaturity of the B cell have been suggested as limiting factors in the perinatal response (110,111). The relative deficiency of antibody responses of infants less than 2 years of age to polysaccharide antigens has been overcome by vaccines which utilize carrier proteins with the polysaccharide antigen, e.g., Hib vaccine. The fetal liver occupies the central role in B-cell development, as it probably does in T-cell development. The B cells constitute a much smaller part of the recirculating pool of lymphocytes than the T cells and populate the thymic-independent regions of the lymphoid tissue, including the germinal centers of lymph nodes. Removal of the bursa or its mammalian equivalent leads to a profound deficiency of γ -globulin with little or no effect on CMI (112). Antibody provides a major defense against

P.1152

encapsulated high-grade pyogenic pathogens including *Streptococcus pneumoniae*, *H. influenzae*, and *Neisseria meningitidis*. The development of immunity in the fetus and the newborn must not be considered separate from maternal influences.

Figure 45-6 Temporal relation among B-cell maturation, differentiation, and cell surface marker or antigen expression, with permission.

Figure 45-7 Mammalian B-cell differentiation model. B cells differentiate from a stem cell to a rapidly dividing pre-B cell lacking functional antibody receptors. These cells initially synthesize cytoplasmic IgM that later becomes surface IgM (i.e., baby B cells). These baby B cells can easily be made tolerant and are pivotal for further differentiation of immunoglobulin-producing cells. While they continue to express surface IgM, they begin to express one of the surface IgG subclasses or IgA, followed later by the appearance of surface IgD. When these double or triple cells are triggered by antigen, helper T cells, or B-cell mitogens, they become mature plasma cells or memory cells (not illustrated in this figure). The antigen-dependent T-cell-driven stage requires the presence of surface IgD that is lost after antigenic stimulation. (LPS, lipopolysaccharide). Adapted from Cooper MD, Seligmann M. In: Bellanti JA, ed. *Immunology III*. Philadelphia: WB Saunders, 1985, with permission.

The Mucosa-Associated Lymphoid Tissues: Anatomic Organization

It is now generally recognized that there exists in the human, a highly integrated and finely regulated common mucosal immune system referred to as the mucosa-associated lymphoid tissues (MALT), which consists of an extensive network of cells and cell products found on the vast domain of mucosal surfaces which interface with the external environment and which protect us from entry of foreign substances. Although originally conceived

of as a "local" immune system only found at body surfaces, separate and distinct from a "peripheral" immune system, it is now clear that the MALT is but one component of a broader unified immune system. The mucosa-associated lymphoid tissues performs immune exclusion by inhibiting colonization of pathogens and penetration of harmful soluble antigens. The neonatal period is particularly critical because the newborn is immediately exposed to a large number of microorganisms, foreign proteins and chemicals.

Shown in Fig. 45-8 is a schematic representation of the unique features of the MALT and its relationship to the total immunologic system. Immunologically activated T and B lymphocytes derived from the generalized lymphatic drainage are comingled in the lymph with counterpart T and B lymphocytes derived from stimulation at mucosal and skin sites and enter the blood through the thoracic duct. From there, this collection of lymphocytes forms a recirculating pool which can "home" back to their original mucosal sites of sensitization or to other mucosal sites. This recirculating pool of sensitized T and B lymphocytes in the blood can also percolate back into the lymph in primary lymphoid tissues in lymph nodes and other secondary lymphoid tissues at mucosal sites through unique structures called postcapillary venules. Thus, lymphocytes enter the lymph through both the vascular and the lymphatic channels and form a continuously recirculating pool of lymphocytes prepared to function at internal sites and at mucosal surfaces.

Included within MALT are the mucosal surfaces of the gastrointestinal, respiratory and genitourinary systems

P.1153

and all tissues that interface with the external environment (Fig. 45-8). For ease of discussion, the various components of MALT have been classified into clusters of anatomically organized sites shown in Fig. 45-8 and which include: (a) the gut-associated lymphoid tissues (GALT); (b) the skin-associated lymphoid tissues (SALT); the mammary-associated lymphoid tissues; (c) other mucous gland-secreting tissues, e.g., lacrimal, genitourinary systems; and (d) the bronchus-associated lymphoid tissues (BALT) and the nasopharyngeal-associated lymphoid tissues (NALT).

Figure 45-8 Schematic representation of the unique features of the mucosa-associated lymphoid tissues (MALT) and its relationship to the total immunologic system. Reproduced with permission from Bellanti JA, Sabra A, Zeligs BJ, et al. *Gastrointestinal Immunopathology. Ann Allergy Asthma Immunol* 2004; 93:26-32.

The Enteromammary Circulation

Lactating mammary glands are another part of the mucosal immune system and in the human participate in a set of remarkable immunologic events which links the inductive sites of the GALT, BALT, and mammary-associated lymphoid tissues of the mother with the effector sites of gut and the upper airways of the breast fed infant (113) (Fig. 45-9).

After initial sensitization to food antigens or microflora found in the GALT and BALT of the mother, primed B and T lymphocytes from Peyer's patches or peribronchial lymphoid tissues leave these sites via lymph and peripheral

blood and home to the lactating mammary gland in which local production of secretory antibodies (secretory IgA [sIgA] and secretory IgM [sIgM]) specific for these antigens occurs. Breast milk, therefore, contains a boutique of specialized antibodies resulting from antigenic stimulation in the inductive sites of MALT both in gut and airways of the mother. This has been documented by showing that sIgA from breast milk exhibits antibody specificity for a wide range of common intestinal and respiratory pathogens. The secretory antibodies are thus highly targeted against infectious agents in the mother's environment, which are those likely to be encountered by the infant during its first weeks of life. In addition to its role in infectious disease the benefits of breast feeding in prevention of allergic disease in the infant are well documented. Thus, breast-feeding represents a unique immunological integration of the mucosal immunologic systems of the mother and child, which has biologic significance both in the protection afforded the breast fed infant against infectious disease and in the prevention of allergic disease.

MATERNAL, FETAL, AND NEONATAL INTERACTIONS

In the human, the predominant transfer of antibody occurs by way of the passage of the IgG immunoglobulins from the maternal circulation to that of the fetus. This is accomplished by means of an active transport of this immunoglobulin molecule by virtue of a receptor located on one portion of the molecule referred to as the Fc fragment. In this manner, the fetus receives a library of preformed antibody from his or her mother, reflecting most of her experiences with infectious agents. The sIgA immunoglobulins found in breast milk also

P.1154

provide local protection of the mucous membranes of the gastrointestinal tract. Although these antibodies are not absorbed, their unique structure renders them more effective in these sites and may explain the lower incidence of enteric infections seen in breast-fed infants. It has been shown that as much as 11 g of sIgA may be delivered initially to the breast-fed newborn infant in 24 hours, based on total output in the early colostrum. Subsequently, total sIgA output appears to decrease significantly, and between 3 and 50 days postpartum, as much as 3 g of sIgA may be delivered to the breast-fed infant (114). The fate of ingested sIgA has not been clearly defined. A small amount may be absorbed from the intestine and appear in the circulation within the first 24 hours of life (115). Significant numbers of granulocytes, macrophages, and B and T lymphocytes appear in breast milk (116). The B lymphocytes in human milk can produce IgA antibodies. Secretory antibodies in milk are directed against antigens occurring in the gastrointestinal tract: *Escherichia coli*, *O.* and *K.* antigens, *Shigella O* antigen, *Vibrio cholerae O* antigen, *E. coli* and *V. cholerae* enterotoxins, poliovirus, and rotavirus. There appears to be a direct relation between the extent of intestinal antigenic exposure and the level of specific secretory antibodies in milk. It is possible that, after antigenic stimulation, the lymphoid cells from the Peyer patches of the gastrointestinal tract home by way of the mesenteric lymph nodes and the blood to the mammary gland tissue and appear in the milk. As a result of this homing mechanism, human milk contains secretory IgA antibodies against many microorganisms harbored in the maternal intestine at the time of lactation (i.e., microorganisms that the baby is most likely to be exposed to after birth). Because of the same homing mechanism, human milk contains IgA antibodies to many food protein antigens (e.g., cow-milk proteins). It is possible, particularly in infants with atopic predisposition, that the frequency and magnitude of food allergy may be decreased by a prolonged period of breast-feeding (117). In the early period of life, when the infant's own secretory IgA system is maturationally deficient, breast-feeding may provide the infant with antibodies that support the local immune defense system. Decreasing the antigenic exposure or influencing the infant immune response by prolonged breast-feeding may prevent or delay the development of atopic disease. Other protective factors are present in human milk, such as lactoferrin, lactoperoxidase, Lacto bacillus bifidus factor, complement components, and leukocytes. Necrotizing enterocolitis, a disease seen primarily in premature infants who have suffered severe perinatal stress, affects predominantly formula-fed infants. Neonatal rats subjected daily to a short period of hypoxia developed a reproducible model of the disease. All animals died as a result of necrotizing enterocolitis if they were formula-fed, but not if breast-fed. The viable macrophages in their breast-feedings appear to have afforded the survivors protection and to have prevented the mortality seen in control animals. However, studies carried out after naturally acquired maternal cytomegalovirus infection or other viral and bacterial infections have demonstrated acquisition of neonatal infections in breast-feeding babies of infected mothers (118). Occasionally, fetal cells or other proteins may gain access to the maternal circulation and actively immunize the mother to the paternal allotypes found on these substances. This process, referred to as isoimmunization, may lead to serious disease in the infant, such as hemolytic disease of the newborn, thrombocytopenia, and leukopenia. The development of serum immunoglobulins during intrauterine life and postnatally is shown in Fig. 45-10. The amount and type

P.1155

of γ -globulin found in the blood of the newborn at birth is higher than those of the mother and are made up almost exclusively of the IgG immunoglobulins. There are few or no IgA and IgM globulins in cord sera because the fetus is usually protected in utero from antigenic stimuli. If challenged *in utero* as a consequence of immunization of the mother with Salmonella vaccine or infection (e.g., congenital rubella, cytomegalic inclusion disease, toxoplasmosis), the fetus responds with antibody production, largely of the IgM variety. The exclusion of other classes of antibody is beneficial to the fetus in many cases. For example, the exclusion of the IgM isohemagglutinins, leukoagglutinins, or the IgE antibodies of allergy prevents disease that may be produced by these antibodies. However, it also prevents the passage of other maternal antibodies that would be beneficial to the newborn, such as the IgM antibodies important in bacterial defense (e.g., opsonins, agglutinins, bactericidal antibodies) against gram-negative bacteria. This may explain the increased susceptibility of the newborn to infection with gram-negative organisms such as *E. coli*. There is great variability in the types of antibodies that are obtained transplacentally by the fetus (Table 45-7). This reflects the quantity of antibodies in the maternal circulation and of their molecular sizes. For example, low-molecular-weight IgG antibodies (e.g., rubeola antibody), present in high concentrations in maternal serum, are readily transferred. IgG antibodies in lower concentrations (e.g., Bordetella pertussis) are poorly transferred, and macroglobulin antibodies (e.g., Wasser mann antibody) are completely excluded. Because the IgG immunoglobulins are passively transferred, they have a finite half-life, between 20 and 30 days, and their concentration in serum falls rapidly within the first few months of life, reaching its lowest level between the second and fourth months. This period is referred to as physiologic hypogammaglobulinemia. During the course of the first few years, the levels of globulin increase because of exposure of the maturing infant to antigens in the environment. There appears to be a sequential development in the γ -globulins at different rates. The IgM globulins attain adult levels by 1 year of age. Under physiologic conditions, little or no IgA synthesis is observed *in utero*. Plasma cells appear in the intestinal lamina propria of the neonate shortly after birth. IgA is not detectable in the serum or in the secretions during the first 2 to 3 days of life, although IgA is frequently present in the secretions after the fourth day of life. The secretory IgA concentration matures rapidly, reaching adult levels by 4 to 6 weeks of life. Serum IgA levels rise more slowly, and adult levels are observed after 10 to 14 years. This pattern of appearance of immunoglobulins recapitulates that seen in phylogeny and appears to parallel that seen after antigenic exposure during the primary immune response. In addition to providing protection to the newborn, passively acquired IgG antibodies may interfere with active antibody synthesis after immunization procedures. Several studies have confirmed that passively acquired antibody to diphtheria and to pertussis may actually inhibit active antibody formation after active immunization. This occurs in the case of killed vaccines, appears to be dose related, and can be overcome by increasing the inoculum size. In the case of immunization with live virus vaccines, the effect of passively acquired antibody is to neutralize the vaccine virus, inhibiting successful immunization with parenteral live vaccines. Immunization at 2 to 3 months of age with killed vaccines (e.g., diphtheria, pertussis, tetanus) does not appear to be appreciably inhibited by this passive antibody. Live virus immunization procedures are usually delayed until the end of the first year of life because of the inhibitory effect of the passive antibody. Another situation in which passive acquired antibody may interfere with active antibody synthesis is the natural immunity acquired by the newborn infant from breast milk. IgA in breast milk may interfere with successful immunization with live poliovirus vaccines by neutralizing virus in the gastrointestinal tract.

P.1156

Poliovirus immunizations are not usually delayed, even in breast-fed infants, because active immunization follows sequential poliovirus administration according to recommended immunization schedules for infants and children. Maternal antibodies can have harmful effects, as shown in Table 45-8.

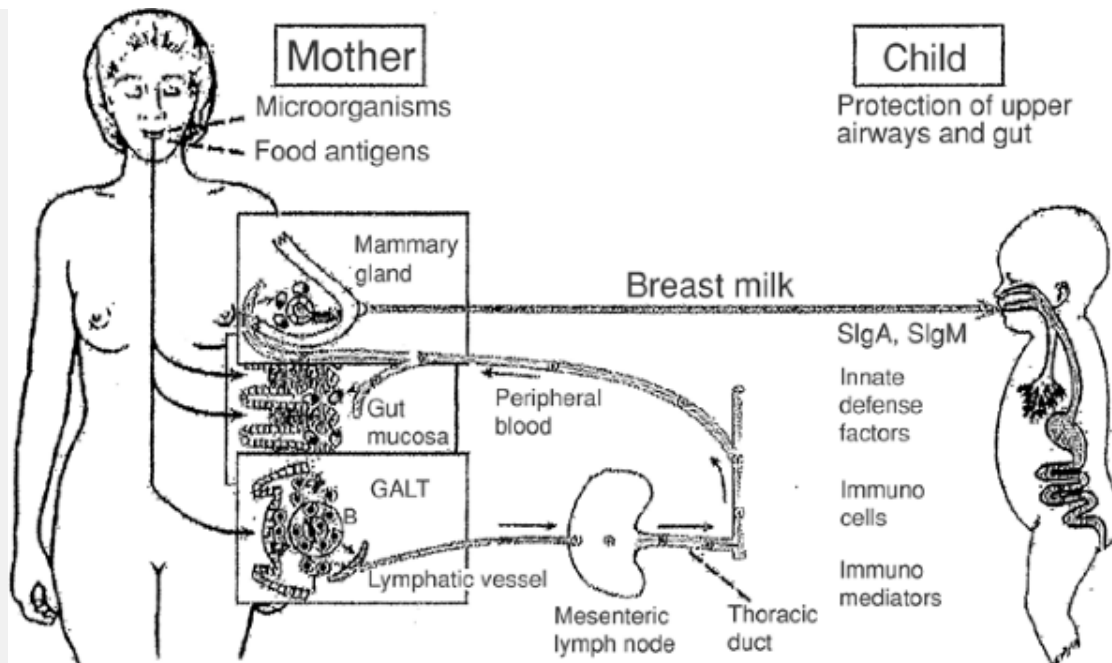

Figure 45-9 Integration of mucosal immunity between mother and the newborn, showing the linkage of the mucosal immunologic systems of the mother and child. After initial sensitization to the food antigens and microflora found in the GI tract of the mother, primed B and T lymphocytes from Peyer's patches leave via lymph and peripheral blood to the lactating mammary gland in which local production of secretory antibodies (SIgA and SIgM) specific for enteric antigens (microorganisms and food proteins) occurs. By this mechanism, the breast-fed infant receives relevant secretory antibodies directed against the antigens found in the maternal GI tract reflecting her intestinal microenvironment and hence the infant is better protected both in the gut and in the upper airways in the same way as the mother's gut mucosa is protected by similar antibodies. Reproduced with permission from Brandtzaeg P. Mucosal immunity: integration between mother and the breast-fed infant. *Vaccine*. 2003;21:3382-3388, with permission.

TABLE 45-7 RELATION OF ANTIBODY TYPE AND TRANSPLACENTAL TRANSFER

Good Passive Transfer	Poor Passive Transfer	No Passive Transfer
Diphtheria antitoxin	<i>Hemophilus influenzae</i>	Enteric somatic (i.e., O)
Tetanus antitoxin	<i>Bacillus pertussis</i>	antibodies (Salmonella sp.,
Antierythrocytic toxin	Dysentery	Shigella sp., Escherichia coli)
Antistaphylococcal antibody	Streptococcus MG	Skin-sensitizing antibody
		Heterophile antibody
Salmonella flagella (H) antibody		Wasserman antibody
Antistreptolysin		
All the antiviral antibodies Present in maternal circulation (e.g., rubeola, rubella, mumps, poliovirus)		
VDRL antibodies		
VDRL, venereal disease research laboratory.		

Maternal Disease	Antibodies	Effect on Infant
Hyperthyroidism	LATS	Transient hyperthyroidism
Idiopathic Thrombocytopenia	Platelet antibodies	Transient thrombocytopenia
Isoimmunization (e.g., platelets, neutrophils, red blood cells)	Platelet, neutrophil, isohemagglutinins, Rh ₀ (D)	Transient thrombocytopenia, neutropenia, anemia
Lupus erythematosus	antibodies	Transient LE-cell phenomenon, neutropenia, thrombocytopenia,
Myasthenia gravis	Autoantibodies to blood elements (e.g., LE-cell factor, Coombs test, platelets)	congenital heart disease (i.e., AV block)
	Cholinergic receptor antibody	Transient neonatal myasthenia gravis

AV, atrioventricular; LATS, long-acting thyroid stimulator; LE, lupus erythematosus

Preliminary studies have reported that nucleotides added to human formulas at concentrations similar to that in human milk enhanced the development of the immune system during infancy. (119). Responses to vaccines were evaluated in full term healthy infants receiving milk based control formula with or without nucleotides added and compared with infants fed human milk. The nucleotide group had significantly higher antibody titers to Haemophilus influenzae type b polysaccharide and diphtheria toxoid immunization but responses to tetanus toxoid or oral polio virus immunization were not enhanced.

IMMUNOLOGIC CONSEQUENCES OF INTRAUTERINE INFECTIONS

The possibility of intrauterine infection should be suspected in a newborn infant if there is a known exposure of the mother to an infectious disease during pregnancy or if the infant is small for gestational age or fails to thrive. Manifestations of intrauterine infection include petechiae, hepatosplenomegaly, congenital malformation, inguinal hernia, thrombocytopenia, and unusual skin rash (see Chapter 47). An IgM concentration greater than 20 mg/dL in the cord blood or in the infant serum is considered abnormal. It should be pointed out that an elevated IgM level may be the result of leakage of maternal blood into the fetus; under these circumstances, the infant's IgA level usually exceeds the IgM level, reflecting the IgA-IgM ratio in maternal blood. IgM concentration test repeated after 3 to 4 days disclose a significant fall in the case of maternal transfusion, but the amount of IgM actively synthesized by the newborn will have increased. Congenital infections frequently become chronic and persist for weeks or years with signs and symptoms that are not seen in children or adults with the same infection. The agents that produce persistent infection of the human fetus exhibit a predilection for the reticuloendothelial system. Impaired function of reticuloendothelial cells may be associated with the development of immunodeficiency. In the congenital rubella syndrome, infection results from transmission of the virus from the pregnant mother to the fetus in the first 5 months of gestation. The infection of the child continues after birth for 6 months to 3 years, despite passive antibody acquired from the mother and active antibody synthesis by the infant. After birth, the child may continue to shed virus while making antibody. A variety of abnormal antibody responses have been reported in children with congenital rubella, including increased levels of IgM with low IgG and absent IgA and low levels of IgM with low levels of IgG and absent IgA

(120,121). Reports have appeared of poor antibody responses in patients with congenital rubella as determined by delayed appearance of isohemagglutinins, suboptimal vaccine responses, immune paresis with no response to tetanus or Salmonella typhi vaccines, and impaired CMI as demonstrated by impaired lymphoproliferative responses to phytohemagglutinin and decreased lymphocytotoxicity (122,123,124). These abnormal responses have been associated with an increased frequency of infections. Many of the alterations reverted to normal responses later, when the child was no longer excreting virus (125). This could represent a form of immunologic blockade while the child is shedding virus, reversal of which may be linked to the maturity of the immunologic systems. Cytomegalovirus and herpesviruses produce infections that persist for years or throughout life, when infection is acquired in utero. Cell-mediated immunity appears to be particularly important in these infections. In one study, eight infants with congenital cytomegalovirus infection and six of their mothers showed decreased specific CMI (126). The decreased CMI in the mothers may have contributed to the transmission of the infection to the infant. The earlier the infection, the more

P.1157

devastating is the effect on the ontogeny of the immune system. If an insult occurs to the thymus in the first trimester, the normal development of T-cell function is affected; if the insult occurs in the third trimester, no resulting damage should be expected. Viral infection of the fetus may be limited by the degree of cellular immune competence, as exemplified by the infants with proven congenital infection and intact cellular responses who are no longer shedding virus at birth. The cellular competence of the fetus may also modulate the manifestations of intrauterine infection. Intrauterine syphilis, for example, presents in late pregnancy, at which time the body mounts a brisk cellular immune response to the spirochete. Infection occurring early in gestation may go unnoticed because the spirochete has neither a toxic nor a teratogenic effect on the fetus. The spirochete is teratogenic only when the immune response to the organism is activated. In contrast, rubella in very early gestation has primarily teratogenic effects (e.g., congenital defects). In later pregnancy (2-4 months), a primarily inflammatory effect is seen (e.g., hepatitis, iridocyclitis, meningitis). These differences may result from an intact cellular immune response characteristic of the older fetus, but in some cases, the immune response of the child may fail to limit or clear these infections.

IMMUNOLOGIC EVALUATION

The functional significance of the two-compartment system is important in clinical medicine. It provides a useful basis on which understanding of the primary immunodeficiency disorders rests and a framework for a more logical approach to the management of maturational deficiencies in the newborn period. Selective deficiencies of the thymic-independent B system (i.e., agammaglobulinemias) pre-sent with recurrent bacterial infections. Selective deficiencies of the thymic-dependent tissues are associated with fungal and viral infections. Patients with combined B- and T-cell defects have the most serious of all the immunodeficiency syndromes, with profound deficiencies in cell-mediated and antibody-mediated functions; they present with a diversity of infections. Evaluation of the immune system during the perinatal period is not an easy task. The evaluator must take into consideration the dynamic, rapidly growing, and adaptive parameters of the immune function in response to a changing internal and external environment. Table 45-9 shows some of the major classes of immunodeficiencies that can be diagnosed in the newborn period, with their time of onset and associated infections. A detailed history, with emphasis on family background and a careful physical examination, should offer a solid foundation for interpretation of clinical and research laboratory data. Table 45-10 presents some suggestions for the clinical evaluation of the newborn. Table 45-11 lists some of the pertinent clinical and historic information that could be useful in the diagnosis of immunodeficiency disorders in the newborn period. Although most immunologic defects are not clinically apparent until postnatal life, it is not unlikely that in certain instances the result of immunologic deficiency may be intrauterine infection with a resultant damaged baby at birth or an aborted conceptus. Cohen and Zuelzer and others have shown maternal blood-formed elements in fetal circulation (127). Theoretically, early passage of immunologically active mononuclear cells from the mother to the fetus could be responsible for GVH reaction. Although direct proof of GVH reactions in the fetus is lacking, several clinical situations suggest that such processes may occur in the newborn and fetus. Among these can be cited the report of an XX/XY chimerism in a 12-week-old abortus of a mother who had several repeated spontaneous abortions (128). A case was reported by Naiman and colleagues, in which, after three exchange transfusions, the infant developed jaundice, aplastic anemia, and marked histiocytosis (129). This infant also showed chimerism of the mononuclear cells, with one line representing donor cells.

NEONATAL IMMUNE RESPONSE TO HUMAN IMMUNODEFICIENCY VIRUS

The immune response to human immunodeficiency virus (HIV) infection in neonates is described in greater detail in Chapter 47. The complexity of the immune response to HIV infection seen in the adult is equal or greater in the newborn. Human immunodeficiency virus has a tropism for human CD4-positive T cells and bone-marrow-derived dendritic cells, megakaryocytes, cells of monocyte-macrophage lineage, and the macrophage-microglial and endothelial cells of the central nervous system. A characteristic depletion of CD4-positive cell numbers is seen in HIV infections, after which there is a continuous but variable rate of decline of CD4 cells. In adults there is acute loss of CD4-positive T cells around the time of seroconversion and in the late symptomatic phase of disease. There are several proposed mechanisms to explain the depletion of CD4 cells, because infection of the cell is not necessarily cytopathic. One possible mechanism is that discharge of virions may be vigorous enough to disrupt the cell and cause death, depleting cell numbers. Alternatively, expression of viral antigens on the cell surface can result in CMI cytotoxicity. These losses may be compounded by the inability of the bone marrow to respond appropriately to replenish CD4 cells. Because CD4 cells play a pivotal role in many immunoregulatory functions, the loss in these cells is responsible for a reduction in their helper-inducer function and a decrease in other T-cell, B-cell, and monocyte activities, resulting in wide-ranging functional defects in cellular and humoral immunity. Immune dysregulation and innate immune activation are features of HIV disease. Generalized immune activation evidenced by polyclonal hypergammaglobulinemia and elevated activation markers (e.g., β 2-microglobulin, neopterin) is recognized, and the levels of these activation markers are used to predict disease progression. Human immunodeficiency virus encoding a superantigen

P.1158

has been suggested; this may play a role in the generalized polyclonal activation and subsequent clonal deletion of T cells. One of the most perplexing clinical problems for the pediatrician and neonatologist is the diagnosis of acquired immunodeficiency syndrome in children younger than 15 months of age, because maternal IgG antibody to HIV is passively transferred across the placenta and may persist until 15 to 18 months of age in uninfected infants. Detection of HIV antibody is therefore not reliable for infants younger than 15 months of age. Moreover, viral culture and P24 antigen assays have a low sensitivity (i.e., viral culture detects approximately 50% of infected neonates). Although potentially useful, polymerase chain reaction (PCR) assay is limited by the high false positives as a result of contamination or carryover during testing, the complexity of the test and required laboratory facilities, and the cost. With improved quality control, PCR can identify as many as 50% of asymptomatic perinatally infected infants at birth. Viral-specific IgA antibody (i.e., HIV-IgA) immunoblot assay has a high sensitivity (99.4%) and high specificity (99.7%) for children older than 3 months of age but a much lower sensitivity in neonates. As a practical

P.1159

approach, identification of the infected infant relies on identification of the infected mother, followed by careful clinical and laboratory monitoring of the infant throughout the first year of life. Suggested laboratory tests include serial HIV antibody testing (i.e., ELISA and immunoblot); serial P24 antigen testing; HIV culture; immunoglobulin levels; T-cell numbers and subsets, remembering that neonates have significantly higher T-cell numbers than older children; and one or more other diagnostic techniques (e.g., PCR, HIV-IgA, immunoblot assay). The aim is to diagnose HIV infection before the onset of severe opportunistic infection, especially *Pneumocystis carinii* pneumonia.

TABLE 45-9 IMMUNODEFICIENCY DISORDERS THAT CAN BE DIAGNOSED IN THE NEONATAL PERIOD

Disorder	Example	Genetics	Time of Onset	Type of Infection
Phagocytic Cell Disorders				
Quantitative	Neutropenia	Variable	At birth	Virulent bacteria
	Congenital asplenia	Variable	At birth or later	Gram-negative
Qualitative	Chronic granulomatous disease	X-linked, autosomal recessive	At birth, delayed	Less virulent bacteria
	Leukocyte adhesion deficiency	Mutation of gene on 21q22.3	separation of umbilical cord	Virulent bacteria, fungal
Disorders of antibody-forming cells				
	Agammaglobulinemia	Variable	>6 mo of age, earlier if infant is premature or small for dates	Virulent bacteria
Disorders of T-cells and/or B-cells				
T-cell immunodeficiency (i.e., cell-mediated or delayed hypersensitivity)	Catch 22 (Congenital aplasia of thymus), i.e., DiGeorge syndrome, VCFS, conotruncal anomaly	Variable	At birth	Fungal, viral
	Chronic mucocutaneous candidiasis	Sporadic forms, autosomal recessive		Fungal
	Pediatric acquired immunodeficiency syndrome	None	At birth or later	Bacterial, fungal, protozoal, viral, <i>Pneumocystis Carinii</i>
Combined B- and T-cell immunodeficiency	Severe combined immunodeficiency	X-linked recessive, autosomal recessive, sporadic forms	6 mo	Bacterial, fungal, viral, <i>Pneumocystis carinii</i>
	Cellular immunodeficiency with abnormal immunoglobulins (i.e., Nezelof syndrome)	Variable	Variable	Bacterial, viral, fungal
Complex (i.e., multisystem) immunodeficiencies	Immunodeficiency with ataxia and telangiectasia	Autosomal recessive	>6 mo	Bacterial, viral, fungal
	Immunodeficiency with eczema and thrombocytopenia (i.e., Wiskott-Aldrich syndrome)	X-linked Recessive	>6 mo	Bacterial, fungal, viral, <i>Pneumocystis carinii</i>
Disorders of early and late components of complements				
	Deficiency of C1, C2, C4 and later components of complement have been described	Variable	At birth	Gram-negative

TABLE 45-10 CLINICAL EVALUATION OF THE IMMUNE SYSTEM IN NEONATES

History

Previous newborn deaths in the family; history of immune diseases

Previous isoimmunization in mother (e.g., due to pregnancy or transfusions [Rh, ABO] or to - globulin administration)

Previous diseases in the mother (e.g., autoimmune diseases: SLE, thyroiditis, myasthenia gravis, idiopathic thrombocytopenic purpura)

History of medications in mother (e.g., quinine, quinidine, Sedormid, chlorpromazine)

History of infections during pregnancy (e.g., rubella, cytomegalic inclusion diseases, toxoplasmosis, syphilis, herpes simplex, UTI, vaginal infections, TB)

Physical Examination

General appearance (i.e., assess degree of activity: if there is hyperactivity, consider hyperthyroidism, passive transfer of LATS; if there is hypoactivity or muscle weakness, consider myasthenia gravis with transfer of antibodies to muscle; if there is purpura, consider thrombocytopenia due to the passive transfer of antibodies to platelets)

Skin (e.g., jaundice in first 24 h of life, petechiae are characteristic of isoimmunization such as erythroblastosis fetalis)

Eyes (e.g., exophthalmos due to LATS)

Chest (e.g., pneumonitis seen in many intrauterine infections)

Cardiovascular (e.g., evaluate for congenital heart disease, congenital heart block in infants of mothers with SLE)

Abdomen (e.g., hepatosplenomegaly seen in severe erythroblastosis fetalis, in congenital intrauterine infections, in GVH reactions, and in the absence of spleen)

Extremities (e.g., deformities and other birth defects)

Neurologic (e.g., convulsions, weakness)

GVH, graft-versus host; LATS, long-acting thyroid stimulator; SLE, systemic lupus erythematosus; TB, tuberculosis; UTI, urinary tract infection. From Bellanti JA, ed. Immunology III. Philadelphia: WB Saunders, 1985:578, with permission.

EVALUATION OF THE HUMORAL IMMUNE SYSTEM

Table 45-12 summarizes the evaluation of the humoral immune system. Pure humoral immunodeficiency syndromes are not clinically manifested in the prenatal period because of the protective effect of maternal IgG. However, very premature infants, particularly those born at less than 32 weeks of gestation, may have IgG serum levels below 400 mg/dL. Small-for-gestational-age infants also have decreased IgG, some impairment of specific antibody responses (e.g., to attenuated polio virus), reduction in specific IgG secretory antibody responses, and an increased incidence of antibodies to food (130). Another factor to be considered is hypogammaglobulinemia in the mother, which, although rare, can lead to inadequate levels of IgG in the newborn.

TABLE 45-11 DIAGNOSTIC CLUES FOR IMMUNODEFICIENCY DISORDERS IN NEONATES

Findings	Comments
Hypocalcemic tetany Absence of thymic shadow Candidiasis	Catch 22, DiGeorge syndrome—characteristic features are in vitro lymphocyte stimulation with phytohemagglutinin and MLR
History of immunodeficiency in other family members	Most immunologic defects genetically determined; gender-linked most common
Agammaglobulinemia	Quantitative immunoglobulins not useful because of passive transfer of IgG; determination after 2 to 4 mo helpful in establishing diagnosis; allotypes helpful; B-cell (CD19) enumeration
Chronic granulomatous Disease	NBT helpful as screening test only because there may be nonspecific elevation; tests of bactericidal function fail to reach normal values in presence of adult sera
Poor growth, splenomegaly, hepatomegaly, diffuse dermatitis, diarrhea	GVH-laboratory findings include anemia, decrease in serum complement, histiocytic infiltration of bone marrow, and erythrophagocytosis; skin biopsy shows mummified cells

Howell-Jolly bodies in peripheral smear, absence of spleen, shadow in x-ray film	Congenital absence of spleen and other associated Malformations
Seborrheic dermatitis	C5 deficiency (i.e., Leiner disease)
Chronic diarrhea	Defect in phagocytosis of baker's yeast particles secondary to failure of sera to opsonize yeast
GVH, graft-versus host; MLR, mixed lymphocyte reaction; NBT, nitroblue tetrazine	

EVALUATION OF THE CELL-MEDIATED IMMUNE SYSTEM

Table 45-13 summarizes the evaluation of the CMI system of the newborn. Evaluation of the CMI system begins with a total and differential leukocyte count. Lymphopenia is seen in most of the CMI deficiencies, but the lymphocyte count may be normal in some patients. The number of T

P.1160

cells, B cells, CD4 helper cells, and CD8 suppressor cells can be ascertained by flow cytometry, using specific monoclonal antibody for individual cell markers (e. g., CD3 for T cells, CD19 or CD20 for B cells). In vitro lymphoblastogenic responses of T cells to specific antigens also are informative for host CMI, provided the antigens have been encountered previously (e.g., *Candida* for a baby with history of thrush). Tests of lymphoproliferative responses should be performed with different concentrations of T-cell mitogens, such as concanavalin A and phytohemagglutinin. Newborn lymphocytes seem to respond better than those of adults at low dosages of mitogens; at higher concentrations, they are less responsive than adult lymphocytes (131). Mixed lymphocyte culture reactions may be helpful in diagnosing CMI deficiencies. A dissociation of low phytohemagglutinin, with normal MLC, can be seen in some patients with CMI deficiency. On the basis of phylogeny and ontogeny, it can be speculated that such a defect originates at a higher level of T-cell differentiation. Lack of MLC responses suggests a defect occurring earlier in ontogenic development. Determinations of enzymes, such as adenine deaminase and nucleoside phosphorylase, may help clarify some of the cases of severe combined immunodeficiency and motivate the clinician to investigate enzyme replacement therapy or possible gene therapy. Skin testing with fungal, bacterial, and viral antigens for delayed hypersensitivity has not proved useful in the newborn. Skin testing with PHA is claimed to be somewhat more sensitive (132). Contact sensitization to DNCB offers advantages over intradermal testing. Dinitrochlorobenzene is positive in 90% of normal persons. Viral infections sometimes depress CMI, and some of the patients who are referred to us may

show energy because of persistent viral infections. In these cases, sound medical judgment, patience, and repeated studies are necessary. Fetal growth retardation and malnutrition also depress CMI and humoral re-sponses for several months after birth (Error! Bookmark not defined.). Evaluation of the innate immune responses in the newborn is almost limited to testing PMN function with the Rebeck skin-window technique (Table 45-14), which has not yet been standardized for the newborn. The nitroblue tetrazine test may be used as a screening test for CGD; the results should be confirmed by bactericidal assay. Lowered numbers of complement components have been described in the prenatal and cord blood. The extent to which these reflect actual functional abnormalities of complements is uncertain. Phagocytic tests should include evaluation of influences of C3 and C5. Separate evaluation of the complement effects on phagocytosis, chemotaxis, and bactericidal activities must be made. A functional deficiency of C5 activity has been described in Leiner disease. Monocyte function, although important, is not usually clinically evaluated because of a lack of adequate methods. Poplack and colleagues have shown that in humans, ADCC activity

P.1161

against erythrocytes depends only on the monocyte (133). It is hoped that this test will prove significant in the evaluation of the monocyte in the fetus and newborn infant.

TABLE 45-12 DIAGNOSTIC TESTS FOR EVALUATION OF THE HUMORAL IMMUNE FUNCTION IN NEONATES

Test	Comment
Practical	
Quantitative measurement Of immunoglobulins	May reveal elevated IgM or IgA; does not distinguish maternal from fetally produced IgG
IgG subclass determination	IgG3 increases in prenatal period and reaches adult levels after 3 months; IgG1, IgG2, IgG4 close to adult levels many months (years) later
Determinations of total number B and T cells by CD markers	Does not necessarily correlate with decreased Ig synthesis; helpful to elucidate level of B cell defect
Specialized	

Specific antibody responses de novo sensitization (e.g., Salmonella)
Regional lymph node biopsy after immunization

O antigen induces IgM; H antigen induces IgG
Helpful for humoral as well as CMI

TABLE 45-13 DIAGNOSTIC TESTS FOR EVALUATION OF CELL-MEDIATED IMMUNITY IN NEONATES

Test	Comments
Practical	
WBC and differential	Normal lymphocyte count does not rule out CMI deficiency; low count compatible but not diagnostic
Determination of absolute number of T cell by CD2/CD3 marker; T cell subsets by CD4 and CD8	No functional test but correlates well with CMI status
Mitogen stimulation of lymphocytes, e.g., PHA and/or measurement of cytokine production	Optimal, suboptimal, and overoptimal concentrations of PHA should be used
Specific antigen stimulation of lymphocytes and/or measurement of cytokine production	Previously known exposure required (e.g. Candida)
Specialized	
Skin testing with DNCB	Positive result practically rules out CMI deficiency
Lymph node biopsy after stimulation with de novo organism	To determine whether dependent areas are normal
Biopsy of thymus	To be performed in patients with obvious CMI; helps elucidate different types of CMI deficiencies that could orient new therapeutic measures
MHC I and MHC II antigen expression	Such as bare lymphocyte syndrome (i.e., MHC II deficiency)

TABLE 45-14 DIAGNOSTIC TESTS FOR POLYMORPHONUCLEAR LEUKOCYTE FUNCTION IN NEONATES

--

Test	Comment
Peripheral blood count and differential	Often of help, count important (e.g., neutropenia); morphology of cells important (e.g., Chediak-Higashi syndrome)
Rebuck skin window	May give general clue to defect of inflammatory function, particularly ability to marshal leukocytes to site of infection
Phagocytosis	Results vary with assay used; particle being phagocytized critical; assay used must distinguish humoral and cellular components of process
Chemotaxis	Decreased in cellular and humoral activity during neonatal period
Quantitative NBT	Screening test; if normal or high, does not rule out CGD
Flow cytometry for cell surface markers	Can detect absence of CD11 for diagnosis of LAD1 or absence of CD15 for LAD2; can detect CGD by employing rhodamine dye assay
Bactericidal activity	Measured by direct killing assay; CGD can be diagnosed during neonatal period
Measurement of specific leukocyte Enzymes	Not done routinely

IMMUNOLOGIC THERAPY

Because newborn infants are less immunologically competent than adults and premature infants are even more susceptible to serious infections than full-term infants, several replacement therapies have been tried with variable results.

PREVENTION OF INFECTION IN LOW BIRTH WEIGHT INFANTS

There is little transport of maternal IgG to the fetus before 32 weeks of gestation, and endogenous synthesis does not begin until about 24 weeks after birth (134,135,136,137). In low-birth-weight infants, serum IgG levels by 3 months of age are only 60 to 150 mg/dL, compared with 100 to 350 mg/dL for infants born at term (138,139,140). It is reasonable to consider intravenous immunoglobulin

(IVIG) prophylaxis in premature infants. Some pilot studies indicated a lower rate of severe infection in IVIG-treated low birth weight infants compared with placebo-treated patients (141,142,143,144). In a randomized, double-blind, placebo-controlled trial involving 588 infants with birth weights of 500 to 1750 g, mortality was not significantly reduced among IVIG recipients (145). However, the number of infections was significantly reduced among IVIG recipients. There was some evidence that the beneficial effect may vary by birth-weight category, and significantly more placebo patients were small for gestational age. Information about long-term results (less than 56 days) is not available from this trial. Preliminary analysis of other trials indicates no significant differences in infection rates between IVIG recipients and placebo recipients (146,147). Another multicenter, randomized, controlled trial, involving more than 2000 neonates with birth weights between 500 and 1500 g, has been completed (148). Intravenous immunoglobulin was initiated at less than 72 hours of age, and continued every 2 weeks until hospital discharge or a weight of 1.8 kg. No significant difference was seen in the rate of nosocomial infection or in the mortality rate between control and treated groups.

The disparity in these results may be as a result of several variables. For instance, these studies are complicated by the fact that multiple factors contribute to the predisposition to infection in premature neonates and that different predominant pathogens occur in different nurseries. There are differences in the titers of antibodies to various pathogens, especially GBS infection, in different lots of IVIG preparations. Moreover, differences in the study design and IVIG dosage and schedule make direct comparison of the various trials difficult. At this time, IVIG cannot be recommended as standard prophylaxis for low-birth-weight infants.

TREATMENT OF PRESUMED NEONATAL INFECTION

Small trials using primarily historic controls have yielded mixed results. Questions remain concerning dose, schedule, and patient selection. Sidiropoulos and colleagues treated successively admitted infants suspected of neonatal sepsis with antibiotics or antibiotics plus IVIG (0.5-1.0 g/day for 6 days) (149). A reduction of mortality was found. Two of 20 infants treated with antibiotics plus IVIG died, compared with 4 of 15 infants treated with antibiotics alone (10% vs. 26%; $p=0.16$). Among premature infants weighing less than 2500 g, IVIG made a significant difference. Four (44%) of 9 patients who received antibiotics alone died, compared with 1 (9%) of the 11 who received antibiotics plus IVIG ($p<0.05$). Haque and associates studied 60 preterm infants of 28-37 weeks of gestation who were suspected of having bacterial sepsis (150). One-half of the group was treated with antibiotics alone and one-half was treated with antibiotics plus IgM-enriched IVIG. The doses were 190 mg/kg/day of IgG and 30 mg/kg/day of IgM for 4 days. Six (20%) of the 30 infants who received antibiotics alone died,

compared with 1 (3.3%) of the 30 who received antibiotics plus IVIG, a statistically significant difference.

Christensen and associates used IVIG plus antibiotics in neonates with clinical signs of sepsis. They found IVIG recipients to have a more rapid correction of neutropenia, a more rapid appearance of immature neutrophils in the peripheral circulation suggesting release of neutrophils from marrow storage pools, and an increase in arterial oxygen tension compared with control infants receiving albumin (151). There were no deaths in either group, and no difference in mortality rates were observed. These studies suggest, but do not prove, that IVIG is a valuable form of therapy in septic premature newborns.

GROUP B STREPTOCOCCAL INFECTION

Group B streptococcal infection is one of the serious diseases in the newborn period. The use of IVIG in this condition has been addressed by Fischer (152,153,154) and Santos (155). Some of these preparations are opsonic for multiple strains of group B streptococci in vitro and protect animals against experimental GBS disease. Such passively administered IgG could ensure that premature infants who are at high risk of infection or already ill are protected by antibody to group B streptococci, even if little of it has been obtained transplacentally. However, not all GBS strains are uniformly susceptible to opsonization by antibody to group B streptococci. Lot-to-lot variation in antibody activity to group B streptococci has been observed. To ensure that an appropriate quantity of antibody is administered, screening of immunoglobulin lots for functional activity and pharmacokinetic studies in neonates are necessary. Studies by Hill and colleagues indicated that administration of IVIG in neonatal rats improved the outcome of GBS pneumonia and sepsis by increasing opsonization and by enhancing PMN migration (156). The mechanisms of these actions are unclear, but antibody may prevent neutrophil depletion by localizing bacteria to the lung in which they can be phagocytized by pulmonary leukocytes and may generate inflammatory mediators, causing the release of PMNs from the marrow (157,158). Combined use of other plasma factors may provide even better protection against bacterial pathogens. Neonatal rats with GBS infection had significantly lower mortality rates if given IVIG and fibronectin than if given fibronectin alone. If IVIG is used, it seems reasonable to normalize the IgG level to between 700 and 1000 mg/dL, using frequent infusions and determination of IgG levels. A dose of 100 mg/kg usually raises serum IgG by about 100 mg/dL.

An alternative method of transferring specific GBS antibody to the newborn by maternal immunization in late gestation (30-32 weeks) has been extensively investigated by Baker, Rench, and McInnes (159) who found that a GBS-tetanus-conjugate vaccine elicited good levels of functional antibody in mothers and their infants in whom levels persisted for at least 2 months. Recently, although the

commonly used practice of intrapartum antimicrobial prophylaxis has been successful in lowering the incidence of early onset GBS sepsis, there are concerns that this prophylactic use of antibiotics may raise the incidence of non-GBS antimicrobial-resistant infection (160).

SPECIFIC ANTIBODY REPLACEMENT THERAPY

Variability in IVIG preparations and lots creates several difficulties in predicting results of treatment for specific organisms. There is a potential role for directed preparations containing specific antibodies. Intravenous immunoglobulin apparently has minimal short-term side effects or complications. Nevertheless, large, multicenter studies must be completed before possible long-term problems such as hepatitis or inhibition of subsequent antibody synthesis can be identified or ruled out. The fact that IVIG has known immunomodulating properties should be kept in mind when one is considering its use in persons without antibody deficiency (161). Passively administered antibodies are potent antigen-specific immunosuppressive agents, as illustrated by the high degree of efficacy of Rho(D) immune globulin (RhoGAM) in preventing sensitization of Rh-negative women to the Rh-D antigen on the erythrocytes of their Rh-positive fetuses. Recent studies in patients with systemic vasculitis demonstrated a 51% decrease in antineutrophil cytoplasm antibodies after high-dose therapy with IVIG, and this decrease was maintained during follow-up (162). Although there are no controlled clinical studies of the suppression of immune responses to other antigens by passively administered antibody, there is no reason to believe that antibodies to the Rh-D and neutrophil cytoplasm antigens are unique in this regard. There is evidence from animal and in vitro studies that IVIG can suppress antibody formation, T-cell proliferation and the activity of NK cells (163,164,165,166,167). In addition to the masking of antigens, IVIG has many potential mechanisms for suppressing the immune response, including interaction with Fc receptors on the membranes of various cells of the immune system and the combination of antiidiotypic antibodies with antibody-producing cells or secreted antibodies (168). Antiidiotypic antibodies in IVIG could impair the capacity of B cells from even immune hosts to secrete antibody. Blockade of the Fc receptor by high doses of IVIG, as in the treatment of idiopathic thrombocytopenic purpura, or by the formation of immune complexes of IVIG with antigens could also impair the normal clearance of opsonized infectious agents and lead to overwhelming infection. There are many reasons not to administer IVIG unless there is a demonstrated broad antibody-deficiency state or other accepted clinical indications. Furthermore, studies in neonatal animals have shown that, in some situations, survival rates are reduced with high concentrations of IVIG plus antibiotic compared with antibiotic alone. The routine use of IVIG as adjuvant therapy of neonatal infections cannot be recommended at this time (169).

SUMMARY OF RECENT CONSIDERATIONS CONCERNING THE USE OF INTRAVENOUS IMMUNOGLOBULIN IN NEONATAL SEPSIS

A review of studies of IVIG therapy by Weisman and associates (170) reports that although it is safe, the studies do not prove efficacy in treatment or prevention of neonatal bacterial infection. It suggests that pathogen-specific antibody IVIG products are required and larger and more careful trials need to be performed. In support of this, a more recent report of the safety and efficacy of monthly prophylaxis with respiratory syncytial virus immune globulin (RSV-IVIG) showed positive results. This was a randomized study of 510 children with bronchopulmonary dysplasia and/or prematurity. The children received 750 mg/kg of RSV-IVIG or placebo intravenously every 30 days. The results suggest that monthly administration was safe well tolerated and reduced the hospitalization by 41% in children receiving RSV-IVIG treatment (171). Following this study the use of RSV-IVIG was approved by the FDA for prevention of severe RSV infections in infants younger than 24 months with bronchopulmonary dysplasia or history of premature birth (172).

ACTIVE IMMUNIZATION OF PREGNANT WOMEN

Although the results of specific antibody replacement therapies seems promising, the availability and delay of the initiation of therapy (i.e., using it only when the condition is clinically suspected) are of concern. If pregnant women could be safely immunized at the beginning of the third trimester, producing high levels of protective antibody which then cross the placental barrier, this would probably give protection to neonates early enough to significantly decrease the incidence of the infection. Group B streptococcal sepsis develops in approximately 3 neonates per 1000 live births, resulting in approximately 11,000 cases annually in the United States. Mortality and morbidity from these infections continue to be substantial (173,174, 175,176). Because human immunity to group B streptococci correlates with type-specific anticapsular antibodies and low levels of these antibodies predict susceptibility to invasive disease, to actively immunize women with capsular polysaccharide antigens of group B streptococci to stimulate production of type-specific, IgG antibody for transplacental protection of the fetus might be a valuable therapeutic or prophylactic approach (177,178, 179,180). Baker and associates immunized 40 pregnant women, at a mean gestation of 31 weeks, with a single 50 g dose of the type III capsular polysaccharide of group B streptococci (181). Twenty-five women (63%) responded to the vaccine. Of the infants born to these women, 80% continued to have protective levels of antibody (e.g., IgG-specific antibody, 2 g/mL) at 1 month of age, and 64% had protective levels at 3 months. Serum samples from infants with 2 g/mL of antibody to type

III group B streptococci uniformly promoted efficient opsonization, phagocytosis, and bacterial killing in vitro of type III strains. This effect may be mediated exclusively by the alternative complement pathway. Although this vaccine, with an overall response rate of 63%, is not optimally immunogenic, this study suggests that maternal immunization is feasible and can provide passive immunity against systemic infection with type III group B streptococci in most newborns. Larger trials with better vaccines are required to evaluate the safety and clinical effectiveness of this strategy.

USE OF RECOMBINANT HUMAN GRANULOCYTE-COLONY STIMULATING FACTOR OR GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR

Recently several studies have investigated the use of recombinant human granulocyte-colony stimulating factor (rh G-CSF) or recombinant human granulocyte-macrophage colony-stimulating factor (rh GM-CSF) in newborn infants with presumed sepsis. This is based on the reported lower levels of these cytokines in the premature infant and an inability of the mononuclear cells of the neonate to produce significant amounts after stimulation (182,183). The first study consisted of 42 newborn infants 26 to 40 weeks of age with presumed bacterial sepsis within 3 days of life which were randomized to receive either placebo or varying doses of rh G-CSF, i.e., 1, 5, or 10 micrograms/Kg every 24 hours or 5 or 10 micrograms/Kg every 12 hours. The results showed that rh G-CSF was well-tolerated and induced a significant dose dependent increase in peripheral blood and bone marrow absolute neutrophil concentration and in C3bi expression. A 2-year follow-up of neonates treated with rh G-CSF showed that there were no associated long term adverse effects (184). In a second study, 20 very low birth weight (VLBW) neonates 72 hours old were randomized to receive either placebo or rh GM-CSF at varying doses intravenously per day. The results revealed that in infants receiving rh GM-CSF there was a significant increase in the circulating absolute neutrophil count and their C3bi receptor expression and monocyte count. In addition there was a significant increase in bone marrow absolute neutrophil concentration. One important consideration for the use of G-CSF or GM-CSF in the prevention of neonatal infection is that the use of these cytokines alone only stimulates an increase in phagocytic cell numbers. This may not be sufficient, and prevention may require the use of antimicrobial specific antibody and/or complement, e.g. fresh plasma, as a source of opsonins. A recent review of clinical trials employing G-CSF and GM-CSF for treatment or prevention of neonatal infections by Carr, Modi and Dore, although promising, concluded that there is currently insufficient evidence to support the introduction of either modality into neonatal practice (185).

PLASMA COMPONENT TRANSFUSION

Neonates have significant impairment in humoral and cellular immune factors. Augmentation of deficient humoral factors by transfusion of transfer factor, fresh frozen plasma, antibody, or whole blood has been protective in humans or neonatal animals with infection (186,187,188,189,190,191,192,193,194). Because of the extensive interaction between cellular and humoral factors, the positive effect of these therapies is thought to be produced, at least partially, by their improvement of neonatal neutrophil function. One study showed that replacement of humoral factors and PMNs is superior to replacement of humoral factors alone. Transfer factor is a dialyzable extract from human leukocytes with chemoattractant activity. The results of its use in patients with chemotactic defects vary. Some investigators found that transfer factor corrected the PMN chemotactic defect in patients with candidiasis and the hyper-IgE syndrome, but others found that it suppressed PMN function in several patients with the hyper-IgE syndrome. Fresh frozen plasma contains antibody, complement, fibronectin, and other proteins that help protect against infection and have been found to be deficient in the neonate, especially the premature infant (195,196,197). Fresh frozen plasma infusions are commonly given to neonates with hypotension and are well tolerated. A preliminary study suggests that fresh frozen plasma transfusions improve PMN chemotaxis in newborn infants. Whether this improvement results in decreased morbidity or mortality from infection is unknown.

PNEUTROPHIL TRANSFUSION THERAPY

Bone marrow reserve for PMN in neonates is limited, and bone marrow pool exhaustion during neonatal infection is common. The most direct way to correct the impairment in neonatal PMN function and reserve is to transfuse adult PMNs into newborn infants. Several studies of the efficacy of the use of transfused adult PMNs in human neonates with sepsis have produced varying results (198,199,200,201,202,203). The first clinical trial of PMN transfusion in human neonates was carried out by Laurenti and associates. In this nonrandomized study, the mortality rate was 10% in the transfused group and 72% in the nontransfused group. No untoward effects of the transfusions were observed. The striking improvement in morbidity and mortality rates in the transfused group suggested that PMN transfusions could benefit septic newborns. Christensen and colleagues carried out a prospective trial of adult PMN transfusion in 26 septic neutropenic neonates. Ten neonates with moderate or no depletion of their marrow PMN reserve did not receive PMN transfusion, and none died. Eight (89%) of 9 neonates with severe depletion of marrow PMN reserve who did not receive

PMN transfusion died. These data indicate that septic neutropenic neonates with normal marrow PMN reserve who are given standard antibiotic and supportive care are likely to survive without PMN transfusion. In contrast, septic neutropenic neonates with severe marrow PMN depletion have a high mortality rate despite antibiotics and supportive care and can probably benefit from adult PMN transfusions. Two studies of the use of transfusion of PMNs from whole blood buffy coat layers failed to demonstrate a beneficial effect in septic neonates. Baley and associates conducted a prospective, randomized, controlled trial of PMN transfusions for septic neonates that failed to demonstrate any improvement in survival. Several researchers have recommended bone marrow examination before neonatal PMN transfusion to detect bone marrow exhaustion. Neonates with marrow exhaustion have a poor prognosis and may benefit most from PMN transfusion. Because this procedure is invasive and delays delivery of PMNs to neonates with fulminant infection, a rapid, accurate, and easily performed test to document marrow exhaustion would be useful. There are several potential problems associated with PMN transfusion. Polymorphonuclear leukocyte sequestration in the lung, resulting in pulmonary decompensation (e.g., decreased PaO₂), occurs in adults and children (204,205). Graft vs. host disease has been reported after PMN transfusion in the immunocompromised host (206). Irradiation of leukocytes with minimum of 3000 cGy should be sufficient to impair lymphocyte function and prevent GVH disease without altering PMN number and function. Human immunodeficiency virus transmission from PMN transfusion is another potential concern. Although minimized with current antibody screening programs, an estimated 1 in 100,000 to 1,000,000 units of antibody-negative blood may contain transmissible virus as a result of recent HIV infection in the donor (207). It is unknown if the risk of HIV transmission is greater with PMN transfusion than with whole blood or packed cell transfusions. Cytomegalovirus, EBV, and hepatitis virus are other infectious agents that may be transmitted by PMN transfusion. Use of one of the recipient's parents, preferably the mother, as the PMN donor minimizes the risk of viral transmission. Although the results of studies of PMN transfusion in neonates appear promising, large prospective randomized trials must be carried out before it can be concluded that the potential benefits of PMN transfusion outweigh the risks. Polymorphonuclear leukocyte transfusion cannot be recommended for routine adjunctive therapy of neonatal sepsis at this time (208). Polymorpho-nuclear leukocyte transfusion can be considered for the subgroup of septic neonates with neutrophil storage pool depletion, because this group of high-risk infants appear to be the most likely to benefit. Although the use of granulocyte transfusions has been hampered by limitation in collecting adequate quantities of leucocytes, recently the potential use of G-CSF to stimulate normal donor production of granulocytes has stimulated renewed interest and may address this drawback (209).

Anemias

Erythroid Development

Early hematopoietic cells originate in the yolk sac. By the eighth week of gestation, more definitive fetal erythropoiesis is taking place in the liver. The liver remains the primary site of erythroid production throughout the early fetal period. By 6 months of gestation, the bone marrow becomes the principal site of erythroid cell development. Later during gestation, a switch occurs in the type of hemoglobin being formed, with adult hemoglobin (HbA) re-placing fetal hemoglobin (HbF). The site of production of erythropoietin (EPO) switches from the less sensitive hepatic to the more sensitive renal site (1).

The earliest characterized erythroid precursor is the burst-forming unit (BFU-E), which gives rise to colony-forming units (CFU-E). These are identified by their growth characteristics in culture. Neonatal BFU-E and CFU-E are as sensitive as their adult counterparts to EPO stimulation (2,3). Earlier development is a function of other factors, including interleukin-3 and stem cell factor. The numbers of BFU-E progressively decline along the series of fetal blood, cord blood, adult bone marrow, and adult blood. More than 40 times the number of BFU-E can be cultured from fetal blood as from an equivalent volume of adult blood (1). Measurement of the peripheral blood pool does not indicate the size of the total body pool, so it cannot be inferred that the fetus has a markedly greater erythropoietic potential than an adult does (4). It is probably at least comparable.

The major difference between fetal and adult erythropoiesis is in the response to EPO. Erythropoiesis is controlled by a feedback loop involving EPO. A decrease in erythrocyte mass is reflected by an increase in EPO, which drives erythropoiesis to increase erythrocyte mass and diminish EPO production. The expected correlation between EPO and measures of oxygen delivery (e.g., hemoglobin level, mixed venous oxygen tension, and available oxygen) can be detected in premature neonates, providing evidence that the same feedback loop exists (5-,6 and 7). The measured levels of EPO are much lower than those of older children and adults with corresponding degrees of anemia. Brown and colleagues (7) presented evidence that the magnitude of the EPO response was lowest in the least mature infant (27 to 31 weeks of gestation). Forestier and associates (8) found low EPO values in cordocentesis samples from infants between 18 and 37 weeks of gestation. Surprisingly, there was no correlation between gestational age and EPO level. This poor EPO response persists through the neonatal period, resulting in a reduced erythropoietic stimulus and lower hemoglobin levels in premature infants.

Normal Hemoglobin Levels

In the newborn period, the hemoglobin concentration is undergoing constant physiologic change. A clear definition of the normal hemoglobin range is therefore important for proper evaluation and management.

Normal hemoglobin values at birth have been determined through measurement of levels in cord blood of newborn infants. In a review of normal blood values in the newborn, Oski and Naiman (9) cited a range of 13.7 to 20.1 g/dL, with a mean of 16.8 g/dL. Blanchette and Zipursky (10) obtained similar results in studies of healthy newborns, yielding cord hemoglobin values (mean \pm 1 SD) of 16.9 ± 1.6 g/dL in full-term infants and 15.9 ± 2.4 g/dL in premature infants. Definitive values for premature infants are known as a result of cordocentesis sampling. Data from Forestier and colleagues (8) for 18 to 29 weeks of fetal life and our data for fetuses older than 36 weeks of gestation are given in Table 46-1. Based on these data, cord hemoglobin levels less than 13.0 g/dL should be considered abnormal in term and premature (<36 weeks of gestation) neonates. In the very premature infant (<26 weeks of gestation), values as low as 12.0 g/dL may be acceptable. If anemia is confirmed, a prompt and careful search for the cause should be initiated.

One factor that can significantly influence the hemoglobin level in newborn infants is the amount of placental transfusion. At birth, blood is rapidly transferred from the placenta to the infant, with one-fourth of the placental transfusion occurring within 15 seconds of birth and one-half by the end of the first minute (11). The placental

P.1170

vessels contain 75 to 125 mL of blood at birth.(12) Usher and associates (13) demonstrated that the blood volume of an infant could be increased by as much as 61% by delayed cord clamping. In that study, the average erythrocyte mass in a group of infants with delayed cord clamping was 49 mL/kg at 72 hours of age compared with 31 mL/kg in a group in whom the cord was clamped immediately after birth. Although infants delivered after delayed cord clamping have higher hemoglobin values, it should be recognized that the placental

transfusion may be markedly reduced or prevented if the infant is held above the level of the placenta at the time of delivery; in this situation, it is possible for an infant to lose blood into the placenta and be born anemic (14).

TABLE 46-1 NORMAL ERYTHROCYTE VALUES DURING GESTATION^a

Weeks of Gestation	Erythrocytes ($\times 10^{12}/L$)	Hemoglobin (g/dL)	Hematocrit (%)	Mean Corpuscular Volume (fL)
18–21	2.85 \pm 0.36	11.7 \pm 1.3	37.3 \pm 4.3	131.11 \pm 10.97
22–25	3.09 \pm 0.34	12.2 \pm 1.6	38.6 \pm 3.9	125.1 \pm 7.84
26–29	3.46 \pm 0.41	12.9 \pm 1.4	40.9 \pm 4.4	118.5 \pm 7.96
>36	4.7 \pm 0.4	16.5 \pm 1.5	51.0 \pm 4.5	108 \pm 5

^a Values are means \pm 1 standard deviation.

Anemia in the Newborn Period

Anemia at birth or appearing during the first few weeks of life can be broadly categorized into three major groups. The anemia may be the result of blood loss, hemolysis, or underproduction of erythrocytes.

Physiological Anemia and the Anemia of Prematurity

The hemoglobin concentration of healthy full-term and premature infants undergoes typical changes during the first weeks of life (15,16,17 and 18). After birth, there is a transient increase in hemoglobin concentration as plasma moves extravascularly to compensate for the placental transfusion and an increase in circulating erythrocyte volume that occurs at the time of delivery (19). Thereafter, the hemoglobin concentration gradually falls, to reach minimal levels of 11.4 \pm 0.9 g/dL in term infants by 8 to 12 weeks of age and 7.0 to 10.0 g/dL in premature infants by 6 weeks of age (Fig. 46-1) (18).

There are several reasons for the fall in hemoglobin. The first is the decline in erythrocyte production that occurs in the first few days of life and is evidenced by a fall in reticulocyte counts during that time (Fig. 46-2).

Normally, reticulocyte counts may be elevated during the first 1 or 2 days of life (200 to 300 $\times 10^9/L$) but then fall to low levels (in the order of 50 $\times 10^9/L$) through the remainder of the neonatal period. This diminution of erythropoiesis is probably related to decreased EPO production. The reduced EPO response persists until approximately 6 weeks of age, at which time erythrocyte production increases, as evidenced by a sharp rise in reticulocyte numbers in the blood and an increase in total body hemoglobin (Fig. 46-2). Other factors that contribute to the physiologic anemia in newborns, particularly the more profound anemia in premature infants, are the shortened survival of neonatal erythrocytes and rapid body growth (Fig. 46-2) (20,21).

The effect of rapid body growth on hemoglobin levels is unique to neonates and deserves special mention. Healthy premature infants are in a phase of rapid growth when

P.1171

active erythropoiesis, as evidenced by a mild reticulocytosis, resumes at 6 to 8 weeks of age. Associated with this rapid gain in body weight is an obligatory increase in the total circulating blood volume. The resultant hemodilution may cause a peripheral hemoglobin concentration that is static or even falls slightly. The apparent paradox of a stable or falling hemoglobin concentration despite active erythropoiesis (i.e., mild reticulocytosis and an increasing erythrocyte mass) gradually corrects, and the peripheral hemoglobin concentration increases (see Fig. 46-2). Failure to recognize the important effect of rapid body growth on the peripheral hemoglobin concentration may lead to inappropriate investigation and treatment of apparent anemia (16,22).

Figure 46-1 Hemoglobin values of 178 normal premature infants ≤ 36 weeks of gestation. Data at the first point, day 0, are cord blood values. Subsequent points represent data from capillary blood samples on 1, 5, 7, 14, and 28 days of life. The dark line represents the mean value, and the shaded area includes 95% of all values.

Figure 46-2 Changes in total body hemoglobin, blood hemoglobin concentration, reticulocyte count, and body weight in a representative premature infant. The vertical bars represent the infant's body weight. During the first 6 weeks of life, the blood hemoglobin concentration and total body hemoglobin fall as a result of decreased erythrocyte production, as evidenced by the low reticulocyte count. The more rapid decline in blood hemoglobin concentration from the third to the sixth week is the result of the increasing body size and dilution of the hemoglobin mass. After 6 weeks of age, hemoglobin production increases, as evidenced by the increased reticulocyte count and the rapid increase in total body hemoglobin. The blood hemoglobin concentration during that period may rise slightly, or not at all, because the total body size increases at approximately the same rate as the total hemoglobin mass.

The signs and symptoms of this early anemia in premature infants are nonspecific and reflect changes in metabolic rate or cardiorespiratory function and perfusion. Controversy exists about whether tachycardia, tachypnea, periodic breathing, and apnea are reliable indicators of anemia (23,24,25,26,27,28 and 29). Stockman and Clark (30) demonstrated an improvement in weight gain after transfusion in premature infants in infants with poor weight gain. Others have not confirmed these observations (27,28 and 29). Lactate measurements and cardiac output can be shown to decrease following transfusion, but neither measurement on its own can be considered a surrogate for diagnosing anemia (27,31).

Trials of folate, iron, and vitamin E have not shown any evidence of benefit in preventing the physiological anemia of infancy (32). Optimal protein supplementation is important for maintaining good hematopoiesis (33,34,35,36,37 and 38).

Several groups have tested blood transfusion as therapy for the anemia of prematurity. Blank and associates (39) and Meyer and associates (40) were unable to demonstrate clinical benefit in transfused versus nontransfused neonates other than an improved hematocrit. In both studies several children were transfused for tachycardia, apnea, bradycardia, or other clinical signs interpreted as signs and symptoms of anemia. Others have shown benefit in these clinical parameters from transfusion in selected asymptomatic infants (41,42 and 43), although hemoglobin values are not necessarily the best indicator of need (41). Surveys of blood product use in neonatal units show that most transfusion practices are based on a preset hemoglobin value or what the clinician interprets as signs and symptoms of anemia (apnea, poor weight gain, etc.) (44). Similar clinical criteria have been incorporated into guidelines for the transfusion of premature infants (45). Trials of transfusion therapy at arbitrary values have not demonstrated clear benefit and may expose infants to infectious agents (e. g., cytomegalovirus [CMV], hepatitis, human immunodeficiency virus [HIV]) (46) and other risks from blood products (e.g., graft-versus-host disease). Future trials of transfusion therapy for anemia in premature infants

require better defined end points before they can yield definitive results. Prevention of anemia would be a better strategy.

The desire to avoid the use of blood products coupled with the need to treat symptomatic anemia has led to trials of recombinant EPO in premature newborns. Low plasma EPO levels are a major contributing factor in the pathogenesis of anemia of prematurity. This is caused by reduced responsiveness of the liver compared to the kidney to tissue hypoxia and increased clearance of EPO in premature infants (1). When plated in clonogenic assays, erythroid progenitors from neonates demonstrate good responsiveness to EPO with an increase in BFU-E and CFU-E colonies (2,3). Furthermore, EPO in sufficient doses combined with adequate iron and protein supplements can induce an increase in the hemoglobin concentration in neonates. However, it remains unclear if these findings can be translated into a clinically meaningful reduction in the need for red blood cell (RBC) transfusions in premature neonates. In clinical trials reported to date, EPO has been started either early (within the first week of life) (47,48,49,50,51,52 and 53) or late (about 3 weeks of age) (34,36,54,55,56,57,58,59,60 and 61). In general, infants receiving larger EPO doses at both time points have shown improvement in reticulocyte counts and hemoglobin levels and a decrease in the number of transfusions per infant. Of importance, however, early initiation of EPO therapy was not associated with a significant reduction in the number of infants transfused, and in groups treated later most red blood cell exposures occurred before the start of EPO therapy.

In a recent meta-analysis Vamuakas and Strauss (62) analyzed 21 prospective controlled trials of EPO in newborn

P.1172

infants published during the period 1990 through 1999. The clinically relevant end points were a reduction in the number and volume of RBC transfusions. The investigators found that treatment with EPO reduced RBC transfusions by an average of 11ml/kg, a value that was statistically significant ($p < 0.001$). However, there was extreme variation among trials. The variability in the studies included birth weight of study subjects, postnatal age at study entry, frequency and dose of EPO, use of iron supplementation, and triggers for RBC transfusion. Unfortunately, even among studies in which these variables were similar there were differences in results.

In another meta-analysis by Garcia and associates (63) the authors analyzed 8 randomized placebo-controlled studies that administered EPO or placebo after the first week of life and focused on erythrocyte transfusion needs after the third week of life ("late" transfusions). In this specific group of patients they found that neonates in the EPO group received significantly fewer transfusions proportional to the dose of EPO administered. Based on these two analyses, it remains unclear whether EPO treatment should be universally recommended for all premature babies as a means to prevent clinically significant anemia that will require RBC transfusion. It is also unclear whether the cost of the RBC transfusions that are avoided by treatment with EPO is higher than the cost of EPO. Furthermore, although no adverse effects of EPO could be demonstrated by 1 year of age (53) the long term side effects of EPO in premature infants is unknown. Recently development of neutralizing antierythropoietin antibodies was demonstrated in patients with chronic renal failure who developed pure red cell aplasia following treatment with EPO. These patients were adults who received EPO treatment for 3 to 67 months. The condition resolved several months after cessation of EPO treatment during which time the patients required multiple RBC transfusions. Whether neonates who are treated with EPO for less than 3 months can develop neutralizing antibodies remains to be determined (64), and this potential complication of EPO therapy should be taken into consideration when assessing the risk:benefit of EPO therapy in newborn infants (65).

In summary, the overall incremental benefit of EPO therapy in neonates in the setting of rigorous transfusion guidelines and effective strategies to minimize iatrogenic (phlebotomy) blood losses, plus appropriate iron and protein supplementation is not clear and requires further study in carefully designed prospective clinical trials. Alternative transfusion strategies, discussed in detail later in this chapter, may be equally effective in preventing multiple donor exposure and may be more cost-effective. Currently, the most prudent approach is for individual neonatal units to assess the impact of newer transfusion strategies in their population before implementing routine EPO therapy (66).

If a decision is made to administer recombinant EPO to decrease RBC transfusions to ill extremely low birth weight infants (birth weight $<1,000$ g) Calhoun and colleagues have recommended that a dose of 200 U/kg/day of EPO plus iron supplementation be given for two weeks; if the goal is to decrease or possibly eliminate the need for late transfusions to very low birth weight infants (birth weight $<1,500$ g) with the anemia of prematurity or the late anemia of Rhesus hemolytic disease the investigators recommend giving 400 U/kg of EPO three times per week subcutaneously for 2 weeks with added iron (67).

Anemia Caused by Blood Loss

Blood loss resulting in anemia may occur prenatally, at the time of delivery, or postnatally. Blood loss may be the result of occult hemorrhage before birth, obstetric accidents, internal hemorrhages, or excessive blood sampling for diagnostic studies (Table 46-2). Faxelius and colleagues (68) associated a low erythrocyte volume with a maternal history of bleeding in the late third trimester, placenta previa, abruptio placentae, nonelective cesarean section, deliveries associated with cord compression, Apgar scores less than 6, an early central venous hematocrit less than 45%, and a mean arterial pressure less than 30 mm Hg.

Occult Hemorrhage Before Birth

Occult hemorrhage before birth may be caused by bleeding of the fetus into the maternal circulation or by the bleeding of one fetus into another in multiple pregnancies. In approximately 50% of all pregnancies, some fetal cells can

P.1173

be demonstrated in the maternal circulation (69). In about 8% of pregnancies, from 0.5 to 40.0 mL of blood is transferred from the fetus to the mother at birth, and in 1% of pregnancies, the blood loss exceeds 40 mL. Fetomaternal hemorrhages are more common after traumatic diagnostic amniocentesis or external cephalic version.

TABLE 46-2 TYPES OF HEMORRHAGE IN THE NEONATE

Occult hemorrhage before birth
Fetomaternal
Traumatic amniocentesis
Spontaneous
After external cephalic version
Twin-to-twin
Obstetric accidents, malformations of the placenta and cord
Nuchal cord with placental blood trapping
Rupture of a normal umbilical cord
Precipitous delivery
Entanglement
Hematoma of the cord or placenta
Rupture of an abnormal umbilical cord
Varices
Aneurysm
Rupture of anomalous vessels
Aberrant vessel
Velamentous insertion
Communicating vessels in multilobed placenta
Incision of placenta during cesarean section
Placenta previa
Abruptio placentae
Internal hemorrhage
Intracranial
Giant cephalhematoma
Subgaleal
Retroperitoneal
Laceration of the liver
Ruptured spleen
Pulmonary

Fetomaternal Hemorrhage

The clinical manifestations of a fetomaternal hemorrhage depend on the volume of the hemorrhage and the

rapidity with which it has occurred. A sudden and unexpected decrease in fetal movements may be a warning sign of an acute, massive fetomaternal hemorrhage (70). The prognosis for such cases is poor and may be improved by prompt delivery and a neonatal transfusion, or if the fetus is premature by cord sampling and an intrauterine transfusion (71,72 and 73). If the hemorrhage has been prolonged or repeated during the course of the pregnancy anemia develops slowly giving the fetus an opportunity to develop hemodynamic compensation. These infants may manifest only pallor at birth. After acute hemorrhage just before delivery, the infant may be pale and sluggish, with gasping respirations and signs of circulatory shock.

The degree of anemia varies. Usually, the hemoglobin is less than 12.0 g/dL before the physician recognizes signs and symptoms of anemia. Hemoglobin values as low as 3.0 to 4.0 g/dL have been recorded in infants who were born alive and survived. If the hemorrhage has been acute, and particularly in hypovolemic shock, the hemoglobin value may not reflect the magnitude of the blood loss. Several hours may elapse before hemodilution occurs and the magnitude of the hemorrhage is appreciated. In general, a loss of 20% of the blood volume acutely is sufficient to produce signs of shock and is reflected in a fall in hemoglobin concentration within 3 hours of the event.

In acute and chronic hemorrhage, the erythrocytes usually appear normochromic and normocytic. Rarely in chronic hemorrhage, the cells appear hypochromic and microcytic, indicating fetal iron deficiency anemia (74).

If anemia is a direct result of a fetomaternal hemorrhage, the Coombs test is negative, and the infant is not jaundiced. Infants with anemia secondary to blood loss generally have lower than average bilirubin values throughout the neonatal period as a consequence of their reduced erythrocyte mass.

The diagnosis of a fetomaternal hemorrhage great enough to result in anemia at birth can be made with certainty only by the demonstration of fetal cells in the maternal circulation. The Kleihauer technique of acid elution is the simplest and most commonly employed method for the detection of fetal cells (75). The test is based on the property of HbF to resist elution from the cell in an acid medium. The acid elution technique can be relied on with certainty for diagnosis only when other conditions capable of producing elevations in maternal HbF levels are absent. These include maternal thalassemia minor, sickle-cell anemia, hereditary persistence of HbF, and in some normal women, a pregnancy-induced rise in HbF production (76). In these conditions, the appearance of the Kleihauer test, with many cells containing variable amounts of HbF, is easily differentiated from that of a true transplacental hemorrhage, in which the fetal cells containing high concentrations of HbF are readily differentiated from the maternal cells containing no HbF.

The diagnosis of a fetomaternal hemorrhage may be missed in situations in which the mother and infant are incompatible in the ABO blood group system. In such instances, the infant's A or B cells are rapidly cleared from the maternal circulation by the maternal anti-A or anti-B and may not be seen in the Kleihauer preparation.

Twin-to-twin Transfusion

Twin-to-twin transfusion is observed in 13% to 33% of monozygotic multiple births with monochorial placentas (77). In approximately 70% of monozygotic twin pregnancies, a monochorial placenta exists. Blood exchange between twins may produce anemia in the donor and polycythemia in the recipient. If a significant hemorrhage has occurred, the difference in hemoglobin between the twins exceeds 5.0 g/dL. There is a maximal discrepancy of 3.3 g/dL in cord blood hemoglobin concentration in dizygotic twins. The anemic twin may develop congestive heart failure and hydrops, and the plethoric twin may manifest symptoms and signs of the hyperviscosity syndrome, disseminated intravascular coagulation (DIC) and hyperbilirubinemia.

The hemorrhage may be acute or chronic. Tan and associates (77), on the basis of a review of 482 twin pairs in which 35 were found to have the transfusion syndrome, pointed out how the difference in weight of the twins could be used to establish the timing of the hemorrhage. If the weight difference exceeded 20% of the weight of the larger twin, the transfusion was chronic, and the smaller infant was invariably the donor. The anemic, smaller twin displayed reticulocytosis. If the difference in the weight of the twins did not exceed 20% of the weight of the larger twin, the larger twin was the donor in almost 50% of cases. In these presumably acute transfusions around the time of birth, significant reticulocytosis was not observed in the anemic donor.

If twin-to-twin transfusion is suspected, attempts to confirm it by placental examination should be made. The placentas of all multiple pregnancies should be routinely examined for purposes of genetic counseling. If hematologic evidence has not been obtained, and the infants have died, other findings may suggest the diagnosis, including polyhydramnios of the recipient's amniotic sac and oligohydramnios of the donor and marked differences in the size and organ weights of the twins.

With the advent of accurate ultrasound assessment of the fetus, the diagnosis of twin-to-twin transfusion in utero has become possible, and a careful assessment of chorionicity in twins undergoing first trimester ultrasound scanning is recommended (78). The early detection of monochorionic twins identifies a high-risk pregnancy that should be managed in obstetric centers experienced in dealing with such cases. In cases of severe twin to twin transfusion, the

P.1174

donor (anemic) twin is smaller, and there is associated oligohydramnios; the recipient (polycythemic, hypervolemic) twin is larger, and there is associated polyhydramnios. Intrauterine diagnosis is therefore dependent on identification of same sex, size difference, oligohydramnios/polyhydramnios, and a monochorionic placenta. When diagnosed in utero, twin-to-twin transfusion syndrome can be classified into five discreet stages (79). Stage I is defined by the finding of isolated discrepancy in amniotic fluid volumes between fetuses; absence of a urine filled bladder in the donor fetus defines Stage II, absent or reversed end-diastolic flow in the umbilical artery of the donor fetus or abnormal venous Doppler pattern in the recipient, such as reversed flow in the ductus venosus or pulsatile umbilical venous flow Stage III, hydrops fetalis Stage IV and demise of one or both fetuses Stage V. Perinatal outcomes correlate with disease severity as assessed by the stage at presentation and gestational age at delivery; overall the perinatal mortality rate for the twin-to-twin transfusion syndrome is 30% to 50% (80). Therapy has included repeated amniocentesis to reduce polyhydramnios, photocoagulation of placental vascular anastomoses, amniotic septostomy, and selected feticide by cord occlusion (78).

Obstetric Accidents and Complications

Obstetric accidents and malformations of the placenta and cord may be responsible for major blood loss at the time of delivery. These accidents may be unreported to the pediatrician and may result in diagnostic confusion about the cause of shock in the early hours of life or the presence of pallor and unexplained anemia during the second or third day of life.

The obstetric conditions that can produce neonatal hemorrhage are listed in Table 46-2. Severe and often fatal fetal hemorrhage may accompany placenta previa, abruptio placentae, or accidental incision of the placenta or umbilical cord during a cesarean section. A tight nuchal cord may cause venous obstruction leading to excessive blood trapping in the placenta and resulting in severe hypovolemia (81) and anemia (82). A prospective study of red cell mass suggested that babies born with a tight nuchal cord had a significantly lower red cell mass than controls (83).

In women with late-third-trimester bleeding, Clayton and associates (84) were able to anticipate the birth of a possible anemic infant by examining the vaginal blood for the presence of fetal erythrocytes, employing the acid elution technique of Kleihauer (75,84).

It is good pediatric practice to obtain a hemoglobin measurement routinely at the time of delivery of all babies born of women with late third-trimester bleeding. This determination should be repeated in 6 to 12 hours to observe the expected fall in hemoglobin resulting from the hemodilution that follows recent blood loss.

Severe bleeding as a result of an obstetric accident or complication of delivery often results in the birth of a pale, limp infant. Respirations, which usually commence spontaneously, are often irregular and gasping. They are not associated with retraction, as in conditions accompanied by primary pulmonary disease. Cyanosis is minimal, and the infant's pale color is not improved by oxygen administration. The peripheral pulses are weak or absent, and the blood pressure is reduced. The venous pressure measured after the insertion of an umbilical catheter is found to be extremely low.

Internal Hemorrhage

Anemia that appears in the first 24 to 72 hours of life and is not associated with significant jaundice is commonly caused by hemorrhage at the time of birth or by a postnatal internal hemorrhage. Traumatic deliveries may result in subdural or subarachnoid hemorrhages or cephalhematomas of sufficient magnitude to produce anemia. Subaponeurotic or subgaleal hemorrhages are relatively common after vacuum extraction and may lead to significant neonatal anemia.

Breech deliveries may be associated with hemorrhage into the adrenals, kidney, spleen, or retroperitoneal area. Rupture of the liver or subcapsular hemorrhage into the liver may occur more commonly than is clinically recognized (85,86 and 87). An infant with a ruptured liver may appear well for the first 24 to 48 hours of life

and then suddenly go into shock. The abdomen may appear distended, and a mass contiguous with the liver is often palpable. Shifting dullness on abdominal percussion can often be demonstrated, and an elevation of the right hemidiaphragm may be seen on the radiograph. Splenic rupture may occur after a difficult delivery or as a result of the extreme distension of the spleen that is often seen in babies with severe erythroblastosis fetalis. The physician should always suspect a rupture of the spleen when an anemic, and often hydropic, infant with erythroblastosis is found to have a low initial venous pressure at the time of exchange transfusion. The diagnosis of intraabdominal hemorrhage is readily made with ultrasonography.

In infants with birth weights less than 1,500 g, bleeding into the cerebral ventricles, subarachnoid space, and parenchyma can also produce significant decreases in hemoglobin concentration.

Iatrogenic Anemia due to Blood Sampling

Anemia appearing during the first week of life is often caused by blood removal for diagnostic studies required for the frequent monitoring of critically ill infants. Removal of more than 20% of a subject's blood volume produces anemia. In an infant of 1,500 g, this represents a blood loss of only 25 mL. If frequent blood sampling is necessary, a flow sheet should be used to record the amount removed at any given time. This simple technique often converts a diagnosis of idiopathic anemia to one of iatrogenic anemia.

Despite the use of micromethods using small volumes of blood by most laboratories, cumulative blood losses through sampling for laboratory monitoring are often surprisingly large in small infants. Blanchette and Zipursky

P.1175

(88) reported an average blood loss of 22.9 mL of packed cells from 59 premature infants studied through the first 6 weeks of life. Forty-six % (26 of 57) of the infants studied had cumulative losses that exceeded their circulating erythrocyte mass at birth (Fig. 46-3); in a few cases, losses were equivalent to two or three times the infants' initial circulating erythrocyte masses. Because these losses must be replaced, at least in part, by erythrocyte transfusions, some infants had the equivalent of a double- or triple-volume exchange transfusion simply as a result of blood sampling for laboratory tests. Approximately 10% of all blood loss during sampling for laboratory monitoring was hidden and represented blood on cotton swabs or in the dead space of syringes or tubing of butterfly sets used to collect blood samples (89).

There is a strong correlation between the volume of blood sampled and that transfused (Fig. 46-4), suggesting that much of the erythrocyte transfusion requirements of ill, premature infants is a direct consequence of blood loss for essential laboratory monitoring (88). In the study by Blanchette and Zipursky (88), significantly more blood was sampled from infants judged to be clinically ill than from healthy premature infants. Iatrogenic blood loss through sampling was significant in both groups (mean \pm 1 SD = 26.9 \pm 9 and 14.6 \pm 5 mL, respectively). These comparative volumes may not appear large, but the actual values must be compared with a total erythrocyte mass that varies between 32.3 and 45.5 mL/kg (90,91,92,93 and 94). The removal of 1 mL of blood from a 1-kg infant is equivalent to removing 70 mL of blood from an average adult, and it is therefore not surprising that repeated blood sampling, even with capillary samples, can have a profound effect on the hemoglobin concentration of small, premature infants. Ballin and colleagues have demonstrated that, if the erythrocytes that are discarded from samples drawn in which only the plasma was used were instead reinfused, the fall in hemoglobin concentration could be substantially reduced (95).

Figure 46-3 Cumulative blood losses through sampling in premature infants, expressed as a percentage of their erythrocyte mass at birth. Infants were studied during the first 6 weeks of life, and each vertical bar represents a single infant.

Figure 46-4 Relation during the first 6 weeks of life between the cumulative volumes of blood sampled from and transfused into 57 premature infants who had birth weights less than 1,500 g. Volumes represent milliliters of packed erythrocytes (r , correlation coefficient).

Treatment of Anemia Secondary to Blood Loss

The treatment of anemia secondary to blood loss depends on the degree of anemia and the acuteness of the hemorrhage. For acute hemorrhage, the following measures must be employed:

- If the infant is pale and limp at birth, clear the airway, administer oxygen, and intubate if necessary.
- Obtain venous access immediately. In some circumstances, this may best be achieved by the insertion of an umbilical venous line. Blood specimens for hematologic determinations and crossmatching should be

drawn. If an umbilical line is placed, it may be possible to measure a central venous pressure.

- As soon as it is apparent that pallor is a result of hypovolemic shock or profound anemia and not a consequence of asphyxia, administer 15 to 20 mL/kg, in order of preference and depending on ready availability, of O Rh-negative packed RBCs, plasma, 5% albumin, or isotonic saline. Infants with acute external blood loss usually demonstrate dramatic improvement after such a procedure. Infants with massive internal hemorrhages show less evidence of response.
- A repeat injection of 10 to 20 mL/kg of whole blood or reconstituted whole blood (packed RBCs plus fresh frozen plasma [FFP]) may be appropriate after the first transfusion, particularly if whole blood was not administered initially and the venous pressure and arterial pressure have not returned to normal.

After resuscitating the infant, make efforts to determine the cause of blood loss. Examine the placenta and cord for evidence of abnormalities. Obtain a blood sample from the

P.1176

mother for the detection of a fetomaternal hemorrhage. The infant who is mildly anemic at birth as a consequence of chronic blood loss and who is in no distress may not require transfusion.

For anemic infants still requiring intensive support, especially mechanical ventilation, it is probably appropriate to treat anemia with blood transfusion. The decision to transfuse must be based on the hemoglobin level and on the clinical condition of the baby.

Hemolytic Anemia

Anemia as a consequence of a hemolytic process is common in the newborn period and has multiple causes. Hemolysis is almost always associated with elevation of the serum indirect bilirubin value to 170 $\mu\text{mol/L}$ (10 mg/dL) or greater. In general, a hemolytic process is first detected during the investigation of jaundice occurring during the first week of life.

Difficulties in Diagnosing Hemolytic Disease in Newborn Infants

Detection and diagnosis of hemolytic disease in newborn infants may be difficult because many of the tests used in older children and in adults are of little value during the first days of life. Hemolytic disease in adults is diagnosed if there is evidence of a rapidly falling hemoglobin concentration, increased erythrocyte production in the absence of hemorrhage, abnormal erythrocyte morphology, and increased erythrocyte destruction within the bloodstream with the release of free hemoglobin or within the reticuloendothelial system with production of bilirubin. In the newborn infant, these signs of a hemolytic process are of limited value and require additional interpretation.

Figure 46-5 The three-dimensional appearance of erythrocytes as seen by scanning electron microscopy (A) and by light microscopy (B) of glutaraldehyde-fixed cells. (1, discocytes; 2, bowls; 3, spherocytes; 4, echinocytes; 5, acanthocytes; 6, dacrocytes; 7, keratocytes; 8, schizocytes; 9, knizocytes; 10, immature erythrocytes).

Evidence of Increased Erythrocyte Production

In adults, an increased reticulocyte count with a stable or falling hemoglobin concentration is evidence of increased erythrocyte production and, in the absence of hemorrhage, is diagnostic of a hemolytic process. The reticulocyte count in normal newborns has a wide range, limiting its value except in severe hemolytic disease.

Erythrocyte Morphology

The shape of erythrocytes in newborns differs from that in adults. Abnormally shaped cells are frequently seen in blood smears of newborn infants, particularly premature infants. The various abnormally shaped cells in full-term and premature infants are shown in Fig. 46-5 and their percentages are detailed in Table 46-3.

Accordingly, erythrocytes in newborns can have distorted morphology without any pathological hemolysis.

TABLE 46-3 ERYTHROCYTE DIFFERENTIAL COUNTS IN ADULTS AND NEONATES

Erythrocytes	Adults	Median (5%–95%) ^a	
		Full-Term Infants ^b	Premature Infants ^c
Number studied	53	31	52
Disks	78 (42–94)	43 (18–62)	39.5 (18–57)
Bowls	18 (4–50)	40 (14–58)	29 (13–53)
Ratio of disks to bowls	2 (0–4)	2 (0–5)	3 (0–10)
Spherocytes	0 (0–0)	0 (0–1)	0 (0–3)
Echinocytes	0 (0–3)	1 (0–4)	5.5 (1–23)
Acanthocytes	0 (0–1)	1 (0–2)	0 (0–2)
Dacrocytes	0 (0–1)	1 (0–3)	1 (0–5)
Keratocytes	0 (0–1)	2 (0–5)	3 (0–7)
Schizocytes	0 (0–1)	0 (0–2)	2 (0–5)
Knizocytes	1 (0–4)	3 (0–8)	1 (0–6)
Others	1 (0–4)	3 (0–7)	4 (1–11)

^a All values are expressed as a median plus the 5% to 95% range, because the distribution of most values was nongaussian.

Evidence of Erythrocyte Destruction

The catabolism of erythrocytes results in the equimolar production of bilirubin and carboxyhemoglobin (96,97). A rapid increase in the degree of hyperbilirubinemia is a cardinal sign of erythrocyte destruction. The measurement of blood carboxyhemoglobin or in the rate of carbon monoxide excretion (98) also correlates with hemolysis (99,100 and 101).

In adults and children, intravascular hemolysis is evidenced by increased levels of hemoglobin in the plasma (i. e., hemoglobinemia), a fall in serum haptoglobin, and the appearance of hemoglobinuria and methemalbuminemia. In the normal newborn, haptoglobin levels may be zero, and plasma hemoglobin levels are above those found in adults. Gross elevations in plasma hemoglobin and hemoglobinuria are evidence of intravascular hemolysis, but the value of these tests in detecting mild hemolysis in newborn infants is limited.

When erythrocytes are destroyed in the reticuloendothelial system, bilirubin is produced, with elevation of indirect bilirubin in the blood. In the newborn, there are many other causes of hyperbilirubinemia (see Chapter 35). In newborns, unlike adults, indirect hyperbilirubinemia is not a specific sign of hemolytic disease. Unusually rapid appearance of jaundice, particularly in the first 24 hours, suggests hemolytic disease. Because there are many causes of indirect hyperbilirubinemia, all newborns with abnormally high indirect bilirubin levels must be studied for evidence of hemolytic disease.

Alloimmune Hemolytic Disease

Hemolytic disease in the newborn as a consequence of alloimmunization of the mother is caused by the passage of fetal erythrocytes into the maternal circulation, in which they stimulate the production of antibody. Antibodies of the IgG class return to the fetal circulation, attach to antigenic sites on the surface of the erythrocyte, and cause its rapid removal by the fetal reticuloendothelial system. The incidence and clinical manifestations of alloimmunization depend on the type of blood group incompatibility between the mother and fetus. This topic has been the subject of many comprehensive reviews (102,103,104 and 105).

Rh Hemolytic Disease.

The incidence of Rh incompatibility in a population depends, in large part, on the prevalence of the Rh-negative antigens. The prevalence of the Rh-negative genotype ranges from approximately zero in Japanese, Chinese, and North American Indian populations to 5.5% among African-Americans and 15% among American Caucasians (106,107 and 108). Among Caucasian women, it has been estimated that in approximately 9% of all pregnancies, an Rh-negative woman carries an Rh-positive fetus. In 6% of pregnancies at risk, alloimmunization of the mother occurs if there is no immunoprophylaxis.

The severity of Rh hemolytic disease varies greatly from infant to infant. It is estimated that, without antenatal diagnosis and treatment, the perinatal mortality in this disease would be approximately 17.5%, with stillbirths accounting for about 14% of deaths (105). The degree of hemolytic disease tends to be more severe in subsequent pregnancies than in the initial one in which sensitization has occurred.

Pathogenesis.

The entry of fetal cells into the maternal circulation is the cause of Rh isoimmunization. As few as 0.05

P.1178

to 0.1 mL of cells, particularly if transferred repeatedly, are sufficient to produce immunization. Rh immunization tends to occur more frequently in pregnancies that have been complicated by toxemia, cesarean section, or manual removal of the placenta, because transplacental hemorrhages occur with greater frequency and in greater volume under these circumstances. It is estimated that 1% of Rh-negative women develop antibodies as a consequence of these transplacental hemorrhages before the delivery of their first child. An additional 7.5%

manifest evidence of sensitization within 6 months of the delivery of their first child, and another 7.5% show no evidence of immunization 6 months after delivery but develop antibodies during their next pregnancy if their fetus is Rh-positive, presumably as a consequence of a sensitization during the first pregnancy.

Destruction of Fetal Erythrocytes by Anti-D.

The transfer of antibody from the mother into the fetal circulation is responsible for the clinical manifestations of the hemolytic process. The erythrocyte, coated with an antibody of the IgG class, is removed primarily in the spleen of the fetus. The rate of destruction is generally proportional to the amount of antibody on the cell. At very high levels of antibody, the cell may be destroyed by intravascular hemolysis and splenic sequestration.

Before birth, the chief danger of excess erythrocyte destruction is profound anemia. After birth, the infant is primarily at risk from the toxic products of erythrocyte breakdown, such as bilirubin. In utero, the infant responds to the increased breakdown of cells by increasing the rate of erythrocyte production. This is reflected by an elevation of reticulocyte count and the presence of nucleated erythrocytes in the peripheral circulation. This accelerated demand for erythrocytes results in active erythropoiesis in non-marrow sites such as the liver, spleen, and lung. A major portion of the hepatosplenomegaly observed in infants with hemolytic disease is a result of this extramedullary erythropoiesis.

In infants with severe Rh incompatibility, the liver and pancreas exhibit pathologic changes. Islet cell hyperplasia can be observed in the pancreas, and focal cellular necrosis with cholestasis may be seen in the liver.

The most severely affected infants manifest hydrops fetalis. This massive edema with pleural effusions and ascites is not strictly related to the hemoglobin level of the infant. Other factors play a role in the development of hydrops, including intrauterine hypoxia, hypoproteinemia, and a lowering of the nonprotein oncotic pressure of the plasma. Hydrops fetalis has been observed in a variety of other conditions (Table 46-4).

Clinical Manifestations.

The main signs of hemolytic disease in the newborn are jaundice, pallor, and enlargement of the liver and spleen. Jaundice usually becomes evident during the first 24 hours of life, frequently within the first 4 to 5 hours of life, and becomes maximal by the third or fourth day. Jaundice and the metabolism of bilirubin are extensively discussed in Chapter 35.

TABLE 46-4 SOME CAUSES OF HYDROPS FETALIS

Severe chronic anemia in utero
Parvovirus infection
Erythroblastosis fetalis
Homozygous alpha-thalassemia
Chronic fetomaternal transfusion or twin-to-twin transfusion
Glucose-6-phosphate dehydrogenase deficiency (rarely)
Cardiac failure
Severe congenital cardiomyopathy or myocarditis
Premature closure of foramen ovale
Large arteriovenous malformation (e.g., hemangioma)
Intrauterine arrhythmias
Hypoproteinemia
Renal disease
Congenital nephrosis
Renal vein thrombosis
Congenital hepatitis
Intrauterine infections
Syphilis
Toxoplasmosis
Cytomegalovirus
Miscellaneous
Maternal diabetes mellitus

Parabiotic syndrome of multiple pregnancies
Sublethal umbilical or chorionic vein thrombosis
Fetal neuroblastoma
Cystic adenomatoid malformation of the lung
Pulmonary lymphangiectasia
Chorioangioma of the placenta
Transient leukemia of Down syndrome

The degree of anemia reflects the severity of the hemolytic process and the infant's capacity to respond to it with increased erythrocyte production. Late anemia may develop in infants with Rh alloimmunization. This is observed in two clinical settings. In one, the infant does not become sufficiently jaundiced in the initial newborn period to require exchange transfusion. This is more common since the advent of phototherapy, which may control the jaundice even though the hemolytic process continues. Continued erythrocyte destruction occurs, and the infant can develop severe or fatal anemia between 7 and 21 days of life. The other, more common situation occurs in infants who have had exchange transfusions. In these infants, a gradual fall in hemoglobin may be observed, with hemoglobin values of 5 to 6 g/dL being reached by 4 to 6 weeks of life. This results from the continued presence of IgG anti-D in the neonatal circulation with destruction of residual and newly formed Rh-positive cells. Spontaneous correction can be expected by 6 to 8 weeks of age.

Petechiae and purpura may be observed in infants with severe anemia as a result of thrombocytopenia and a disturbance in the intrinsic system of coagulation. This disturbance may result from DIC or from hepatic dysfunction with consequent inability to synthesize the vitamin K-dependent factors (109,110).

P.1179

Laboratory Findings.

Decreased hemoglobin concentration, increased reticulocyte count, and increased numbers of nucleated erythrocytes in the peripheral blood reflect the presence of the hemolytic process. Hemoglobin determinations performed on venous samples most accurately reflect the severity of the hemolytic process. Values less than 13 g/dL in the cord blood should be regarded as abnormal. The reticulocyte count is usually greater than 6% and may reach 30% to 40%. In the peripheral blood, nucleated erythrocytes may be observed in addition to some degree of polychromasia and anisocytosis. Spherocytes are not found in patients with Rh hemolytic disease.

The erythrocytes of infants with Rh hemolytic disease test positive on direct Coombs testing, indicating the presence of maternal IgG on the erythrocyte surface. An eluate obtained from cord red blood cells, if available, should confirm presence of anti-D. Of note, affected infants may type as Rh-negative at birth as a result of maternal anti-D blocking the Rh antigen on cord or neonatal red blood cells reacting with the Rh typing reagent.

Prevention.

The prevention of Rh hemolytic disease focuses primarily on the administration of anti-D immune globulin to the mother in the antenatal period, usually at the 28th week of gestation and in some countries at the 34th week of gestation, and after delivery, abortion, and invasive procedures. For immunized women the focus is on the prevention of fetal hydrops and death by intrauterine transfusion until safe delivery can be assured, usually at the 36th week of gestation. Some recent reviews are worth noting (111,112 and 113).

The early proposals for the use of anti-Rh immunoglobulin were based on the observation that ABO incompatibility offered protection against the development of Rh sensitization, probably by allowing destruction of the fetal erythrocytes in the mother before they could stimulate Rh antibody formation. Because most major transfers of fetal erythrocytes occur at the time of delivery, efforts were undertaken to destroy such cells soon after delivery. The development of a human immunoglobulin concentrate of anti-D (WinRho) greatly facilitated application of this means of prevention. Prevention of Rh sensitization is now about 90% effective with the use of anti-D immune globulin at the time of delivery. Failures may reflect fetomaternal transfusions that occur before term, or massive transfusions that occur at the time of delivery in which the amount of anti-D immunoglobulin administered is inadequate to destroy the large numbers of fetal cells that have entered the circulation, or because of prior sensitization of the mother following transfusion of Rh positive RBCs. Prior sensitization of a Rh negative mother caused by maternal-fetal transfusion from her Rh positive mother has been reported. The physician can detect massive hemorrhages at delivery by examining maternal blood for fetal erythrocytes by the Kleihauer technique. It has been estimated that approximately one in 250 deliveries

involves a transplacental hemorrhage of more than 30 mL (105). In such instances, a larger dose of anti-D immunoglobulin should be given, and is based on the volume of fetal blood detected by the Kleihauer test.

Immunization before delivery occurs in approximately 1% of women at risk (105) and can be prevented by the antenatal administration of anti-D immunoglobulin at week 28 or 34 of gestation (111,112,113 and 114). It has been suggested that this may not be cost-effective therapy; however, it is the recommendation of some experts that all Rh-negative women with Rh-positive partners should be treated antenatally with anti-D immunoglobulin to prevent Rh immunization (115).

Stillbirths are prevented by intrauterine transfusions or by the early termination of pregnancy. The pregnant woman at risk for delivery of an infant with Rh(D) hemolytic disease is one who is Rh (D)-negative, has an Rh (D)-positive partner, and has anti-D antibodies in her serum. All such women must be followed carefully during pregnancy (102,116).

Intrauterine Diagnosis and Treatment.

The most accurate assessment of severity of disease in the at-risk fetus is the estimation of amniotic fluid bilirubin levels. Amniotic fluid is normally clear and colorless. It acquires a yellow pigmentation in cases of severe hemolytic disease because of the passage of bilirubin into it. The amount of bile pigment in the amniotic fluid more accurately reflects the degree of fetal involvement than does the maternal antibody titer. The concentration of bilirubin pigments, usually measured by spectrophotometry of amniotic fluid, is approximately 350 to 700 nm. Normal amniotic fluid, when plotted on a logarithmic scale, describes a straight line, but when a pigment is present, a bulge appears at approximately 450 nm. This can be measured, and the change in optical density (OD) as a function of gestational age can be employed to gauge the severity of the hemolytic process (116,117). Women who should be considered for amniocentesis are those with a history of hemolytic disease in previous infants and those whose anti-D titers are greater than 0.125 by the indirect Coombs test, remembering that titers may vary from laboratory to laboratory.

Fetal Rh(D) typing using DNA extracted from amniotic fluid cells can identify the fetus at risk (118) and thus avoid the need for fetal blood sampling to determine the Rh status of the fetus. At-risk pregnant women determined to be carrying an Rh-negative fetus can then be referred back to the care of local physicians/obstetricians for routine antenatal monitoring.

For the Rh positive fetus, analysis of the amniotic fluid indicates whether the fetus is suffering from severe disease, and this is used as a guide to management, which may include continued observation with amniocentesis at 2-week intervals, premature induction after 33 weeks of gestation, or intrauterine blood transfusion. Measurement of medial cerebral artery velocity using Doppler ultrasound may be used as an indicator of anemia (119,120).

P.1180

In severely affected cases, allogenic blood should be made available (i.e., on hand) at the time of delivery to transfuse immediately if needed. Also, if hydrops is present, platelets should be available for transfusion because splenic platelet sequestration can cause significant thrombocytopenia (platelet count <50,000 μ L).

The treatment of severe hemolytic disease in utero has been by intrauterine transfusions into the peritoneum of the fetus. The preferred method now is direct intrauterine transfusion through the umbilical vein. With intrauterine diagnosis (e.g., amniotic fluid, fetal DNA genotyping, or fetal blood analyses), most fetuses with severe Rh disease can be salvaged. Those who reach 36 weeks of gestation can be induced prematurely, and the survival rate is expected to be the same as for a full-term infant with Rh disease. For those with more severe disease who would not survive to 36 weeks of gestation, intrauterine transfusion beginning at 20 to 22 weeks of gestation results in salvage of as many as 87% of patients (121).

Blood for intrauterine transfusion should be O negative, fresh (<7 days old) and CMV safe. Before transfusion a fetal hemoglobin level should be obtained, a direct Coomb's test performed and the fetal red blood cell antigen status confirmed. The amount of blood to be transfused is then calculated and the fetal hemoglobin level rechecked at the midway point of the placental transfusion; additional blood is then transfused as appropriate given the final target hemoglobin level (122,123). For the fetus with hydrops fetalis and severe anemia the transfusion is often split over a few days with the first transfusion calculated to increase the hemoglobin level to 100 g/L.

Management.

Newborns with Rh hemolytic disease are at risk of death or neurological damage, primarily from anemia or hyperbilirubinemia. As soon as the infant has been delivered and respirations have been established, the infant should be carefully examined and an assessment of pallor, organomegaly, petechiae, edema, ascites, respiratory rate, pulse, and blood pressure made in an attempt to judge the severity of the hemolytic process. Cord blood samples should be analyzed for hemoglobin concentration, reticulocyte count, nucleated erythrocyte count, blood type, direct Coombs reaction, and serum bilirubin concentration, conjugated and unconjugated.

In the infant with a positive-reacting Coombs test, the major initial decision is whether to perform an immediate exchange transfusion or to observe the infant's clinical status. In many instances, the outcome of previous pregnancies and the result of amniocentesis during the current pregnancy provide valuable information about what to anticipate in the way of severity. Except for the obviously pale or edematous child, the decision to perform an immediate exchange transfusion is based on laboratory findings.

It has been suggested that a cord hemoglobin less than 11.0 g/dL or a cord bilirubin higher than 4.5 mg/dL is an indication for immediate exchange transfusion (121). The value of immediate transfusion is that it is more efficient to remove a "potential bilirubin load" (i.e., antibody-coated erythrocytes) than to allow hemolysis to occur, with distribution of bilirubin throughout the tissues, from which it is removed with greater difficulty by exchange transfusion.

For less severely affected infants, exchange transfusion is indicated if it becomes apparent that the rate of bilirubin rise is such that total indirect bilirubin will exceed 20 mg/dL (330 μ mol/L) in otherwise healthy full-term infants (124). The physician needs to use lower maximal bilirubin levels in sick or premature infants (see Chapter 35).

The potential role of high dose intravenous immunoglobulin G (IVIG) therapy in infants with Rh(D) hemolytic disease merits discussion. In a multicenter controlled trial of IVIG therapy to reduce the need for exchange transfusions in neonates with Rh hemolytic disease, Rubo and associates (125) randomly assigned 34 patients with Rh incompatibility to receive conventional treatment including phototherapy, with or without IVIG therapy (dose 500 mg/kg). They found that 12.5% of the children in the IVIG group required exchange transfusions compared to 69% of the control group ($p < 0.005$). No side effects of IVIG were observed. Gottstein and Cooke (126) reviewed randomized and quasi-randomized controlled trials comparing IVIG and phototherapy with phototherapy alone in neonates with Rh and/or ABO incompatibility. They found that significantly fewer infants required exchange transfusion in the IVIG treated group. The duration of phototherapy and of hospitalization were also significantly reduced. Therefore, it seems that IVIG therapy reduces serum bilirubin levels and the need for blood exchange transfusions in children with alloimmune hemolytic disease.

ABO Hemolytic Disease.

ABO hemolytic disease results from the action of maternal anti-A or anti-B antibodies on fetal erythrocytes of the corresponding blood group. Although approximately 20% of all pregnancies are associated with ABO incompatibility between the mother and fetus, the incidence of severe hemolytic disease is low. Anti-A and anti-B antibodies are found in the IgA, IgM, and IgG fractions of plasma. Only the IgG antibodies cross the placenta and are responsible for the production of disease. These naturally occurring antibodies result from continuous immune stimulation by A and B substances that exist in foods and gram-negative bacteria. Anti-A and anti-B titers are low or absent in most pregnancies and it is not understood why some women develop high anti-A or anti-B titers. They may be the result of repeated, asymptomatic bacterial infections. ABO hemolytic disease tends to occur in the newborns of mothers with high levels of IgG anti-A or anti-B titers.

Fewer A or B antigenic sites are present on the erythrocytes of the newborn, which is responsible for the weakly reactive Coombs test in infants with ABO hemolytic disease. The sparse distribution of A and B sites on the erythrocytes of the newborn also explains why the erythrocyte life span

P.1181

in ABO hemolytic disease is only slightly shortened. Adult group A erythrocytes transfused into a baby with maternally acquired anti-A antibody are rapidly destroyed and may produce severe intravascular hemolysis. For this reason group O RBCs are used for transfusion support of infants with severe ABO hemolytic disease of the newborn. Another factor that explains the low incidence of severe ABO hemolytic disease in neonates is the fact that fetal and newborn blood contains soluble blood group A and B substances that neutralize transplacentally acquired antibodies.

The diagnosis of ABO hemolytic disease is often difficult and may first require the exclusion of other causes of hyperbilirubinemia. Usually, the diagnosis is suspected when hyperbilirubinemia appears in the group A or B baby of a blood group O mother. The disease is more common and more severe in infants of African descent. Jaundice appearing in the first 24 hours (icterus praecox) is particularly characteristic of ABO hemolytic disease. Anemia may be mild or may not be present. Evidence of alloimmunization is difficult to interpret because the Coombs test may be negative or only weakly positive. It has been observed that one-third of all A or B babies of O mothers have a positive direct Coombs test (127); in approximately two-thirds of these babies, an elution test demonstrated anti-A or anti-B on the surfaces of their erythrocytes (127). However, the Coombs and elution tests are not specific for ABO hemolytic disease because these tests are frequently positive in infants who are not affected with disease.

The diagnosis of ABO hemolytic disease is supported by the finding of increased numbers of spherocytes; these are best detected by evaluating the three-dimensional shape of the erythrocyte (Fig. 46-6). Increased erythrocyte production is also demonstrated by an increased reticulocyte count. The diagnosis of ABO hemolytic disease is supported by the following tests and findings:

- Indirect (unconjugated) hyperbilirubinemia.
- Jaundice appearing during the first 24 hours of life.
- A Group A or B baby of a Group O mother.
- Increased numbers of spherocytes in the blood.
- Increased erythrocyte production evidenced by reticulocytosis or an elevated carboxyhemoglobin concentration.
- The presence of IgG, anti-A, or anti-B in cord plasma or serum.

Figure 46-6 The erythrocytes of a patient with hereditary spherocytosis, as seen on a stained blood smear (A) and by three-dimensional viewing (B) of glutaraldehyde-fixed cells.

The levels of IgG anti-A, or anti-B in the mothers of babies with ABO hemolytic disease are significantly higher than those in mothers whose infants do not have the disease. These tests are often not available and, unfortunately, are not high in specificity or sensitivity in the diagnosis of ABO hemolytic disease.

Treatment of this disease is directed primarily toward the prevention of hyperbilirubinemia. Phototherapy reduces the need for exchange transfusion (128). Prophylactic phototherapy may be beneficial when the cord bilirubin is at least 4 mg/dl (129).

Hemolytic Disease Resulting From Minor Blood Group Incompatibility.

Hemolytic disease related to maternal erythrocyte antibodies other than anti-D, anti-A, or anti-B is relatively uncommon. In one study, minor group antibodies were found in 121 (0.08%) of 142,800 pregnant women (130). The principal antibodies found were anti-E, anti-c, and anti-K (Kell). In a report of 30 cases of hemolytic disease of the newborn, the following antibodies were responsible: 14 anti-c, nine anti-E, two anti-Ce, two anti-K, one anti-Fy^a, one anti-Jk^a, and one anti-U (131). Anti-K antibodies may cause severe hemolytic disease in newborn infants, including hydrops fetalis and neonatal death (132). Of interest, the severity of hemolytic disease of the newborn does not correlate with the anti-K titre (133). These antibodies are known to inhibit fetal erythropoiesis (134,135). Based on the above it is recommended that all pregnant women should have their blood screened for antibodies at least once during pregnancy before week 34 of gestation.

Inherited Defects of the Erythrocyte

Inherited defects of erythrocyte metabolism, membrane function, and hemoglobin synthesis all may manifest themselves in the newborn period. Defects of erythrocyte metabolism include glucose-6-phosphate dehydrogenase (G6PD) deficiency and less common disorders such as pyruvate kinase deficiency.

Glucose-6-Phosphate Dehydrogenase Deficiency.

The major function of the erythrocyte is the delivery of oxygen to the tissues. The cell is constantly exposed to oxygen, and the erythrocyte membrane and cytoplasm are subjected to oxidative damage. Oxidation causes the formation of precipitates of denatured hemoglobin (Heinz bodies), which appear to be associated with a shortened erythrocyte life span in vivo (Fig. 46-7). The erythrocyte has a metabolic system that can prevent oxidative damage (Fig. 46-8). Glucose-6-phosphate dehydrogenase is an enzyme in this system; if it is absent, there is a risk of oxidative damage to the erythrocyte, particularly if the

P.1182

cell is stressed by chemicals or drugs capable of oxidative damage (Table 46-5).

Figure 46-7 Heinz bodies in a newborn who developed hemolytic anemia after exposure to naphthalene in mothballs.

Glucose-6-phosphate dehydrogenase deficiency is a common genetic disorder affecting millions of people in the world (136). There are three major types of deficiency, all of which are inherited as a gender-linked recessive disorder. The most severe deficiency occurs rarely and is associated with a chronic hemolytic anemia. With this type of deficiency, the person has a mild or moderate anemia throughout life and may have severe hemolytic disease as a newborn. The second type affects Asians (e.g., 5.5% of Chinese) and many populations in the Middle East and Mediterranean region (e.g., 0.7% to 3% of Greeks, with the highest incidence of 53% among Kurds). These persons are healthy but are at risk of developing hemolytic anemia when exposed to oxidative drugs or chemicals (e.g., sulfa drugs, fava beans). The anemia may be of sudden onset and may be severe. In the absence of fava beans or drug exposure, hemoglobin levels are normal, although there is evidence that the erythrocyte life span is slightly shorter than normal. The third type of deficiency affects individuals of African

descent (e.g., 10% to 14% of African Americans), in whom the severity of the defect usually is not as great as in those with the other two types. Anemia appears only with drug exposure, is less severe than that of the Asian-Mediterranean type, and tends to be self-limited.

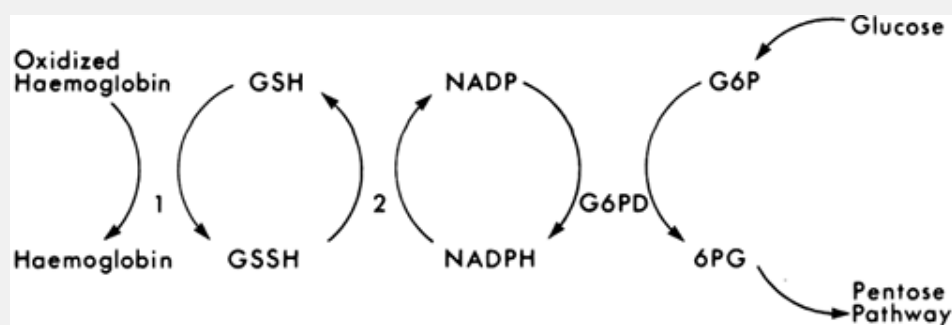

Figure 46-8 Protection against oxidative stress in erythrocytes. The erythrocyte is constantly exposed to oxygen; as a result, there is formation of hydrogen peroxide (H_2O_2), lipid peroxides in the membrane, and oxidized products of hemoglobin such as methemoglobin and Heinz bodies. To prevent the formation of, and to reduce, the levels of these oxidized products, the erythrocyte has a system by which a series of enzyme steps link the metabolism of glucose through the pentose pathway to the reduction of oxidized products (1, glutathione peroxidase; 2, glutathione reductase; G6PD, glucose-6-phosphate dehydrogenase; 6PG, 6-phosphogluconate; G6P, glucose-6-phosphate; GSH, reduced glutathione; GSSH, oxidized glutathione; NADP, nicotinamide-adenine dinucleotide phosphate; NADPH, nicotinamide-adenine dinucleotide phosphate, reduced)

Glucose-6-Phosphate Dehydrogenase Deficiency and Neonatal Jaundice.

Because their erythrocytes have a diminished capacity to deal with oxidative stress as a result of lower levels of glutathione peroxidase and catalase and a relative deficiency of vitamin E, newborn infants with G6PD deficiency

P.1183

are at greater risk of developing hemolytic anemia than are adults. It appears that G6PD deficiency is associated with an increased incidence of neonatal hyperbilirubinemia, especially in the more severe type affecting the Asian and Mediterranean groups. Hyperbilirubinemia in G6PD-deficient boys has been reported in newborns in Greece, Italy, Singapore, and Thailand (137,138). Full-term African American infants with G6PD deficiency do not develop hyperbilirubinemia more frequently than normal infants do, although the incidence in premature infants may be slightly higher (139). It has been reported, however, that male infants of African descent with G6PD deficiency have a significantly higher incidence of hyperbilirubinemia than do controls (140). Although the hyperbilirubinemia is associated with G6PD deficiency, there is a tendency for the jaundice to occur more frequently in particular families and communities, indicating that genetic and environmental factors must influence the incidence of the disease.

In this group of patients, jaundice may be severe and may lead to kernicterus (101,141,142 and 143). In most cases, however, hemoglobin and reticulocyte counts are normal, although in some affected infants the cord blood contains increased bilirubin and decreased hemoglobin levels, suggesting the presence of a mild hemolytic process in utero. There is no evidence of intravascular hemolysis in most of these patients. Slusher and associates (144) demonstrated elevated carboxyhemoglobin (a sensitive indicator of hemolysis) values in Nigerian children with G6PD deficiency and hyperbilirubinemia. Studies of Sephardic-Jewish neonates have yielded opposite results, with no elevation of carboxyhemoglobin values over nonjaundiced G6PD-deficient controls (145,146). The latter observation has been coupled with data suggesting deficient hepatic bilirubin conjugation in neonates with G6PD deficiency (147).

Clinical Manifestations.

The jaundice that occurs in these infants usually appears to be an accentuation of the physiologic jaundice of newborns with a late peak (around 5-6 days), although jaundice may appear in some during the first 24 hours of life. There is seldom evidence of a hemolytic process. Abnormal erythrocyte morphology has been documented during hemolytic episodes in adults, but this is seldom described in newborns. However, a more severe hemolytic anemia may appear, with evidence of abnormal erythrocyte morphology, Heinz bodies in the

peripheral blood, and intravascular hemolysis. This may be the result of infection or exposure to drugs or chemicals (e.g., naphthalene in mothballs) (148). However, it is unusual to elicit the latter from the perinatal history.

Diagnosis.

The presence of unexplained hyperbilirubinemia in an infant of a high-risk (racial intermarriage must be taken into account) population may suggest G6PD deficiency. The enzyme defect can be detected by one of many screening tests (149,150), based on changes in either fluorescence or color resulting from the activity of NADPH, thus indirectly measuring the activity of G6PD. Current screening tests are very effective, yielding good sensitivity and specificity, but an abnormal result should be followed up with a definitive measurement of G6PD activity based on spectrophotometric measurement of the reduction of NADP⁺ to NADPH (151). A false normal screen result can occur in infants with significant hemolysis, which destroys the older, more G6PD-deficient red blood cells.

The finding of G6PD deficiency in a jaundiced infant does not in itself prove that the jaundice was caused by the enzyme defect. Other causes of jaundice must be excluded. In a study on Sephardic-Jewish neonates, neonates with both ABO incompatibility and G6PD deficiency showed no increased evidence of hemolysis when compared with neonates with only ABO incompatibility (152). Glucose-6-phosphate dehydrogenase deficiency is most severe and frequent in male infants because it is a recessive gender-linked disorder. However, female infants may be affected because they have two populations of erythrocytes, one with normal and one with low levels of G6PD, in keeping with the Lyon hypothesis. Given the high gene frequency, it is also possible for a female infant to be homozygous for the deficiency.

Treatment.

Treatment is the same as that for hyperbilirubinemia described in Chapter 35. Drugs and chemicals likely to produce hemolytic anemia (Table 46-5) should be avoided by these patients.

Other Glycolytic Enzyme Defects of the Erythrocyte.

Other abnormalities are far less common than G6PD deficiency and are unusual causes of a hemolytic process during the newborn period. Virtually all of the recognized defects have been associated with jaundice and anemia in neonates. Of this group, erythrocyte pyruvate kinase deficiency appears to be most commonly responsible for a severe hemolytic process during the first week of life. These disorders are usually characterized by the presence of a normal osmotic fragility of unincubated blood, few or no spherocytes in the peripheral blood smear, and failure of splenectomy in later life to correct the hemolytic process. Unless the infant is a member of a high-risk group (the Amish population in the United States), it is practical to defer diagnosis of these infants until approximately 3 months of life, after it has been established that the hemolytic process observed in the neonatal period is chronic and that the more common reasons for it have been excluded.

Abnormalities of the Erythrocyte Membrane

Hereditary Spherocytosis.

In approximately 50% of patients with hereditary spherocytosis, a history of neonatal jaundice can be obtained. Hyperbilirubinemia may require exchange transfusions. Untreated hyperbilirubinemia has resulted in kernicterus in infants with hereditary spherocytosis.

Although most patients with hereditary spherocytosis are anemic, the degree of anemia, reticulocytosis, and

P.1184

hyperbilirubinemia is quite variable. The hemoglobin may fall rapidly during the first several weeks of life, reaching values of 5.0 to 7.0 g/dL by 1 month of age. Neither the hematologic values observed during the immediate newborn period nor the values observed during the first several months of life are reliable indicators of the eventual severity of the disease. Hemoglobin levels of 4.0 to 7.0 g/dL during the first several months of life may subsequently stabilize in the range of 7.0 to 10.0 g/dL. Repeated transfusions are then rarely needed except during the course of infections or aplastic crises. Splenectomy, if indicated, should be deferred if possible, until at least 5 or 6 years of age so that the risk of postsplenectomy infections is minimized.

Hereditary spherocytosis can be diagnosed during the newborn period. Examination of the peripheral blood reveals characteristic microspherocytes, and the osmotic fragility of erythrocytes is increased. The osmotic fragility of the erythrocytes of normal newborn infants is lower than that of adults' erythrocytes, and if an infant is suspected of having spherocytosis, the osmotic fragility should be compared with normal newborn standards. The osmotic fragility test should be deferred, if possible, until the child can readily spare the necessary blood volume for the test. Family studies are extremely useful in confirming the diagnosis, although an affected parent is identified in only approximately 70% of cases.

Hereditary Elliptocytosis.

Hereditary elliptocytosis may manifest in the newborn period as a hemolytic anemia. Only 12% to 15% of newborns with this morphologic abnormality have a shortened erythrocyte survival in later life, but many more appear to have a hemolytic anemia during the first several weeks or months of life. In the newborn period, hereditary elliptocytosis may manifest as hyperbilirubinemia and anemia associated with the presence of fragmented and deformed erythrocytes in the circulation. This is referred to as neonatal poikilocytosis. The erythrocytes of these infants are unusually susceptible to fragmentation after heating. This defect disappears within the first few months of life, and the erythrocytes assume an elliptic appearance, usually with no or minimal evidence of hemolytic disease. As in hereditary spherocytosis, demonstration of an affected parent or sibling helps to establish the diagnosis.

Most patients do not require treatment, although an exchange transfusion may be required for infants with hyperbilirubinemia. For patients with persistent hemolytic anemia, splenectomy has proved beneficial, but as in hereditary spherocytosis, it should be deferred, if possible, until the patient is at least 5 or 6 years of age.

Disorders of Hemoglobin Synthesis.

The predominant hemoglobin in the newborn infant is HbF ($\alpha_2\gamma_2$); therefore, it is not surprising that abnormalities in β -chain production (e.g., sickle-cell disease, β -thalassemia) do not manifest during the first month of life. Thalassemia has been diagnosed as early as the second month of life (153). Patients with sickle-cell disease are usually found to be anemic by 3 months of age, but cases of jaundice and systemic signs during the neonatal period have been reported (154).

Early identification of infants with severe sickle cell syndromes e.g. homozygous sickle cell disease, sickle β -thalassemia through universal newborn screening programs are strongly recommended because morbidity and mortality from sepsis in infants in sickle cell disease can be substantially reduced by early identification of affected infants, enrollment in comprehensive care and prophylactic treatment with penicillin (155,156, and 157). Red blood cell transfusion before sampling as part of a newborn screening program can impair detection of sickle cell disease and it is therefore recommended that repeat screening be performed in such infants 120 days following the last transfusion (158).

Abnormalities in γ -chain production have been described during the first month of life, although most of these are not clinically significant. Heinz body hemolytic anemia with an unstable γ -chain abnormality has been reported (159). Cases of microcytic anemia in newborns with reduced γ -chain synthesis have been described as part of a γ - β -thalassemia syndrome (160,161,162 and 163).

Alpha-chain disorders occur frequently in the newborn period. Most are clinically insignificant although some forms of α -thalassemia that manifest in the newborn period can be serious. The α -thalassemia group of diseases represents abnormalities in the synthesis of the α -chains of hemoglobin. Synthesis of these chains is determined by two pairs of α -genes. A deletion of one or more of these four α -genes results in one of the α -thalassemia disorders. The severity of the disease in the newborn and in the adult depends on the number of genes deleted. If one gene is lacking, the patient is hematologically normal unless he or she is a newborn, in which case there is a slight elevation of Bart hemoglobin (γ_4). If two genes are absent (i.e., two missing from one chromosome or one missing from each of the two chromosomes), the patient has α -thalassemia trait, which manifests as microcytosis in the newborn (mean corpuscular volume $<95 \mu\text{m}^3/\text{cell}$) and elevation of Bart hemoglobin. If three genes are deleted, the patient has hemoglobin H (HbH; β_4) disease, a lifelong hemolytic anemia that manifests in the newborn as jaundice and anemia. If all four genes are absent, the patient can form no α -chains and cannot form HbA or HbF. As a result, the infant is usually born dead or severely hydropic, with death occurring several hours after birth. There are now several examples of such children being maintained on transfusion therapy (164). The hemoglobin of these infants is predominantly Bart hemoglobin.

In patients with HbH disease, one parent is lacking one α -gene (i.e., a silent carrier), and the other is lacking two α -genes on one chromosome (i.e., α -thalassemia trait). In the patient with homozygous α -thalassemia, each parent is lacking two genes on one chromosome. It is now thought that the α -thalassemia trait that is found in 2% to 10% of individuals of African descent is in the trans form in which one

P.1185

abnormal gene is present on each of the two chromosomes (i.e., $-\alpha, -\alpha$), and that the cis form ($-\alpha, \alpha$) does not occur in such individuals but does occur with various frequencies in populations in Southeast Asia and the Mediterranean region. This is the reason homozygous α -thalassemia and HbH disease are not found in individuals of African descent.

The incidence of α -thalassemia can be determined through measurement of levels of Bart hemoglobin in newborns. Silent carriers (i.e., $-\alpha, \alpha\alpha$) have as much as 2% of Bart hemoglobin. Those with α -thalassemia trait ($-\alpha, \alpha\alpha$ or $-\alpha, -\alpha$) have 2% to 9% Bart hemoglobin. Those with HbH disease ($-\alpha, -$) have up to 20% of Bart hemoglobin.

Acquired Defects of the Erythrocyte

Infections.

Infections can induce a hemolytic anemia in the newborn infant who has no underlying inherited defect of erythrocyte metabolism. Such cases manifest with hyperbilirubinemia, which initially may be indirect and subsequently include direct hyperbilirubinemia. Severe hemolytic anemia infrequently complicates sepsis. One exception is *Clostridium welchii* sepsis, in which anemia is associated with microspherocytosis.

Congenital syphilis, toxoplasmosis, cytomegalic inclusion disease, rubella, generalized coxsackie B infections, and *Escherichia coli* septicemia are examples of infections in which anemia and jaundice are common. Some of the nonhematologic manifestations of these diseases (e.g., rash, chorioretinitis, purpura, and hepatosplenomegaly) are useful in differentiating these disorders from alloimmunization or other primary erythrocyte abnormalities.

Drugs.

The erythrocytes of the newborn infant are particularly sensitive to the toxic effects of oxidant drugs. Those, particularly of premature babies, demonstrate increased numbers of Heinz bodies, marked glutathione instability, and an increased tendency to develop methemoglobinemia when incubated with acetylphenylhydrazine or menadione. In many respects, the cells of these infants mimic the metabolic abnormalities observed in cells from patients with G6PD deficiency. Severe Heinz body hemolytic anemia (Fig. 46-7), which occurs in infants with severe G6PD deficiency, is also seen in normal newborns who are exposed to oxidant drugs. The best and most frequent example of this is naphthalene-induced hemolytic anemia caused by exposure to mothballs. This disease is associated with a severe hemolytic anemia, hemoglobinuria, and the presence of fragmented erythrocytes and spherocytes in the circulation. If these are detected, a careful search for exposure to naphthalene or other oxidant drugs (Table 46-5) should be carried out. This increased susceptibility to oxidative damage may be related to the low levels of antioxidants, including glutathione peroxidase, catalase, and vitamin E, in the newborn infant. Idiopathic Heinz body hemolytic anemia probably reflects a similar mechanism, resulting in hyperbilirubinemia and anemia with Heinz bodies present, but the infant has normal G6PD levels, a normal hemoglobin electrophoresis, and a negative heat test for the presence of unstable hemoglobins (165). Evaluation of the family yields no evidence of an inherited disorder, and in the affected neonate, the disorder appears to be self-limited, disappearing within the first several months of life. Vitamin C supplementation may be a factor in the etiology of idiopathic Heinz body hemolytic anemia; however, a randomized controlled trial of vitamin C in small premature newborns was unable to demonstrate hemolysis in supplemented infants (166).

Anemia Caused by Impaired Erythrocyte Production

Diamond-Blackfan Syndrome

Inherited impaired erythrocyte production is a rare cause of anemia in the newborn. The most common cause is

the Diamond-Blackfan syndrome, also known as congenital hypoplastic anemia or pure red cell aplasia. The incidence is 4 to 7 cases per million live births. In approximately one-third of infants with this abnormality, anemia is detected at birth (167), and most patients are diagnosed in the first year of life. The leukocyte count and platelet count are usually normal. In 15 to 20% of cases there is a positive family history consistent with either recessive (autosomal or possibly X-linked) or autosomal dominant inheritance (168). In 25% of cases the disease is associated with mutations in the *RPS19* gene on chromosome 19q13.2, and in about 40% the disease is associated with an as yet unidentified gene on 8p23 (169).

Low birth weight affects about 10% of these patients. Physical anomalies are found in about one third of patients. Anomalies apparent at birth include microcephaly, cleft palate, eye defects, web neck, and abnormalities of the thumb including absent or triphalangeal thumbs (170).

The diagnosis may be established by demonstrating anemia, reticulocytopenia, and a marked decrease in the bone marrow erythroid-myeloid ratio in an otherwise healthy newborn. Erythroid to myeloid ratios range from 1:6 to more than 1:200. Clonogenic assays show decreased CFU-E and BFU-E progenitors (171). Molecular diagnosis based on the finding of mutations for the *RPS19* gene is available, but will identify only one quarter of all affected patients.

Spontaneous remissions are rare and unpredictable and most patients require treatment for severe anemia. The majority of the patients will respond to prednisone, which is the recommended initial treatment. Response, reflected by a reticulocytosis and a rise in the hemoglobin level, often occurs within 2 weeks. After the hemoglobin has reached its maximum, the medication is reduced to the lowest dose necessary to maintain a hemoglobin level in the acceptable range. Unfortunately, only about 30 to 40% of the patients remain responsive to prednisone and can be maintained on acceptably low doses. Most patients require a lifelong transfusion program. Hematopoietic stem cell transplantation from a matched sibling donor is successful in up to 80% of the patients (172). There is a slightly increased risk of myelodysplasia, leukemia and solid tumors (173,174).

P.1186

Congenital Sideroblastic Anemia

Sideroblastic anemias are inherited or acquired disorders of mitochondrial iron utilization resulting in accumulation of iron in the mitochondria of red blood cell precursors. This can be diagnosed by Perl's Prussian-blue iron staining showing greater than 10% cells with circular or ringed staining around the nucleus. Among the inherited sideroblastic anemias are X-linked sideroblastic anemia (associated with the *ALAS2* gene) (175,176); X-linked sideroblastic anemia with ataxia (associated with the *ABC7* gene) (177,178); thiamine responsive megaloblastic anemia (associated with the *SLC19A2* gene) (179,180); and Pearson marrow pancreatic syndrome (associated with the heteroplasmic mitochondrial DNA deletions). The associated genes encode for proteins involved in the transport of iron across the mitochondrial membrane and its utilization.

Diagnosis is facilitated by the presence or absence of nonhematological manifestations, and can be confirmed by molecular testing. Treatment depends on the specific syndrome. Patients with X-linked sideroblastic anemia respond to pyridoxine and patients with thiamine responsive megaloblastic anemia respond to pharmacological doses of thiamine. In the other types of congenital sideroblastic anemia RBC transfusions are the mainstay of treatment. Hematopoietic stem cell transplantation is curative (181). In Pearson syndrome the cytopenia improves with age and hematopoietic stem cell transplantation may not be required.

Congenital Dyserythropoietic Anemia

Congenital dyserythropoietic anemias (CDA) are inherited disorders with ineffective erythropoiesis and striking morphological dyserythropoiesis. Three main types of CDA exist: CDA I, II, and III, which differ in marrow morphology, serologic findings and inheritance patterns. CDA I, II, and III disorders were linked to 15q15, 20q11.2, and 15q21-q25 chromosomal sites respectively, but only the gene for CDA I has been identified and cloned (182).

Most patients with CDA are diagnosed in late childhood or adolescence; however, some patients present in the neonatal period with variable splenomegaly, jaundice, and normocytic or macrocytic anemia. Cases of hydrops fetalis have also been described (183,184,185).

Most patients have mild anemia and do not require chronic therapy. In cases with severe anemia splenectomy, a chronic RBC transfusion program or hematopoietic stem cell transplantation should be considered. Later in life

patients can develop iron overload necessitating iron chelation as a result of ineffective erythropoiesis and multiple transfusions.

Parvovirus Infection

Parvovirus B19 is a single stranded DNA virus, which can bind directly to the P antigen on red blood cells. The expression of P antigen on erythroid and placental tissues may mediate transplacental fetal erythroid infection; however, there is accumulating evidence for the existence of a putative cellular coreceptor for efficient entry of parvovirus B19 into human cells (186).

Fetal parvovirus B19 infection may cause anemia, abortion, or stillbirth or be asymptomatic. Hydrops fetalis with lack of congenital malformations is the typical clinical presentation (187). Approximately 18% of cases of nonimmune hydrops fetalis are caused by parvovirus infection (188). Hydrops fetalis usually manifests during the second trimester of pregnancy and reflects a profound reduction of erythrocyte production in the fetal liver and marrow. This may result in severe anemia, high-output cardiac failure, and death. Myocarditis may also occur and contribute to the accumulation of fluids (189).

Bone marrow aspirates show a paucity of red blood cell precursors, with occasional giant pronormoblasts with large eosinophilic nuclear inclusion bodies, cytoplasmic vacuolization and, occasionally, "dog-ear" projections (190). Diagnosis of parvovirus infection in older immunocompetent children can be made by positive IgM serology. However, this test is unreliable in infants, in which the diagnosis should be based on detection of viral DNA in peripheral blood or bone marrow samples by dot blot hybridization or polymerase chain reaction (PCR) (191,192). Viral studies of amniotic fluid or fetal blood may also be helpful in making the diagnosis before birth (193).

Cordocentesis allows fetal blood sampling for hemoglobin measurement and PCR testing for parvovirus. During the procedure the anemia can be corrected by intravenous RBC transfusion, which can lower the mortality rate from approximately 50% to 18% (194). Postnatal monitoring of the hemoglobin level and judicious transfusions result in resolution of the condition in the majority of cases with a good long term outcome. Although rare, failure of red cell production has sometimes continued after birth (195).

Vitamin Deficiencies

Specific vitamin deficiencies may cause anemia in newborn infants because of decreased erythrocyte production, increased erythrocyte destruction, or a combination of these two mechanisms.

Nutritional anemia secondary to iron or folate deficiency is uncommon in neonates (196). Studies by Seip and Halvorsen (197) indicate that stainable iron disappears from bone marrow aspirates by 12 weeks of age in premature infants and by 20 to 24 weeks in term infants, and it is only after this period that iron deficiency manifests in infants who do not receive supplemental iron. To prevent the development of iron deficiency, premature infants should receive supplemental iron from no later than 2 months of age. Although most premature infants have low serum folate levels by 1 to 3 months of age, they rarely manifest evidence of a megaloblastic anemia. Cases of megaloblastic anemia resulting from folate deficiency typically involve infants receiving goat's milk or phenytoin therapy and infants with chronic diarrhea or infection. Folic acid and vitamin B12 deficiencies are rare disorders of later infancy and have been reviewed by Shojania (198).

P.1187

A syndrome thought to have been vitamin E deficiency anemia in newborn infants was first described by Hassan and associates (199) in 1966 and typically occurred in premature infants (birth weight <1,500 g) at 6 weeks of age. Characteristic features included anemia, reticulocytosis, thrombocytosis, decreased serum vitamin E levels (<0.5 mg/dL), increased fragility of erythrocytes in the presence of dilute solutions of hydrogen peroxide, and shortened erythrocyte survival (200). Damage to the erythrocyte membrane by lipid peroxides, formed naturally during peroxidation of polyunsaturated fatty acids (PUFA) in the erythrocyte membrane, was thought to be the mechanism of the anemia; vitamin E, a biological antioxidant, inactivates lipid peroxides and protects against erythrocyte damage. The anemia may be exaggerated by increasing the PUFA content of the diet, particularly if infants are also given supplemental iron, a catalyst in the autooxidation of PUFA to free radicals and lipid peroxides (201). After the association among the PUFA content of the diet, iron supplementation, and the vitamin E requirement of premature infants was recognized, the PUFA content of infant formulas was reduced. Vitamin E deficiency as described above has become rare in premature infants, and there is no evidence that routine vitamin E supplementation is of benefit in preventing the anemia of prematurity (202).

Evaluation of Anemia in Neonates

Anemia is characterized by an abnormally low erythrocyte mass; in clinical practice, the hemoglobin concentration is assumed to reflect the circulating erythrocyte mass, and an abnormally low hemoglobin concentration defines the anemic state. After diagnosis, causes of anemia are traditionally considered under the pathophysiologic categories of decreased erythrocyte production, increased destruction (i.e., hemolysis), and blood loss. In newborn infants, this classic approach to anemia is complicated by a hemoglobin concentration that undergoes constant physiologic change during the first few weeks of life. The site of blood sampling, quantity of blood sampled for laboratory monitoring, and the effect of rapid growth can significantly influence the hemoglobin values observed in newborn infants. Failure to consider these factors may lead to errors in diagnosis and result in unnecessary investigation and therapy.

Accuracy of Capillary Hemoglobin Levels

Blanchette and Zipursky (88) compared capillary hemoglobin values obtained by duplicate puncture of the right and left heels of 35 healthy full-term infants. The standard deviation of the difference in hemoglobin concentration of the duplicate samples was 0.8 g/dL; in an infant with a hemoglobin concentration of 17.0 g/dL, 95% of hemoglobin values obtained fall between 15.4 and 18.6 g/dL. It is evident that a difference as large as 1.5 g/dL of hemoglobin in consecutive laboratory reports may reflect the error inherent in the technique of capillary blood sampling in the newborn infant.

Effect of the Sampling Site on Hemoglobin Levels

In newborn infants, hemoglobin levels measured in capillary blood samples may be significantly higher than values obtained from simultaneously collected venous blood samples. Oettinger and Mills (203) found an average difference of 3.6 g/dL between simultaneous capillary and venous hemoglobin determinations in 24 infants studied on the first day of life. Other investigators have reported similar differences (Fig. 46-9) (88,204,205). These differences have been found in term and premature infants, and they persist through the first 6 weeks to 3 months of life (88,206). The difference in capillary and venous hemoglobin levels is most marked in the more premature infants (206). Linderkamp and colleagues (205) suggested that warming of the heel reverses the poor circulation and stasis in peripheral vessels that is largely responsible for capillary and venous differences. If the heel is prewarmed before collection of a capillary sample, the difference in capillary and venous hemoglobin values decreases significantly (204).

Correlation of Capillary Hematocrit Levels and Total Erythrocyte Mass

Erythrocyte mass is probably the best measurement of anemia. In adults, it correlates directly with hemoglobin values, which can be used as a valid means of determining anemia. In infants, the correlation between erythrocyte mass and hemoglobin values, although statistically significant, is poor (68,88). Fig. 46-10 and 46-11 show the results of measurements made using a microtechnique using ^{51}Cr to measure erythrocyte mass in premature infants in the first and sixth weeks of life (88). Extremely wide variations in erythrocyte mass occur for any given hematocrit value.

P.1188

The capillary hematocrit is often a poor reflection of the circulating erythrocyte mass in newborn infants. This is particularly true for ill infants, in whom a poor peripheral circulation may exaggerate capillary and venous hematocrit differences, and for premature infants during periods of rapid body growth, when increases in the total circulating blood volume may influence hemoglobin levels through hemodilution (205).

Figure 46-9 Simultaneous capillary (dark circles) and venous (open circles) hematocrit levels in 45 premature infants studied during the first 6 weeks of life. Each vertical line represents values for 1 infant, and the horizontal solid line represents mean capillary and venous hematocrit levels for the whole group. Data are not shown for 5 infants in whom capillary and venous hematocrit levels were identical.

Figure 46-10 Simultaneous capillary hematocrit and circulating erythrocyte mass levels in 135 premature infants who had birth weights less than 1500 g and were studied during the first week of life (r , correlation coefficient)

Of the many techniques available for measuring erythrocyte mass, the use of chromium-labeled erythrocytes (^{51}Cr) remains the gold standard (207). This technique allows a direct measurement of erythrocyte mass and does not depend on approximations involving the use of measured plasma volumes, body weights, hematocrit values, or dilution of fetal hemoglobin after transfusion. The values shown in Fig. 46-10 agree with those obtained by other researchers (90,91,92,93,94). A nonradioactive technique involving the use of biotinylated erythrocytes has been applied in neonates and yields values similar to those obtained with ^{51}Cr (208,209).

Figure 46-11 Simultaneous capillary hematocrit and circulating erythrocyte mass levels in 63 premature infants who had birth weights less than 1500 g and were studied at 6 weeks of age (r , correlation coefficient)

Work Up of a Newborn Infant with Anemia

At no other time does such a variety of disorders result in anemia as in the first week of life. The need for rapid treatment often adds to the diagnostic confusion. It is because of the multiple causes and the need for prompt therapy that the fundamentals of diagnosis should be appreciated and practiced without delay. Attempts at diagnosis begin with a history if the cause is not immediately apparent. In the family history, attention should be paid to anemia in other members of the family or to unexplained episodes of anemia, jaundice, cholelithiasis, or splenectomy. A positive family history is frequently obtained in cases of infants with hereditary spherocytosis, and a history of affected siblings may be encountered in cases of patients with enzymatic defects of the erythrocyte.

In the maternal history, information should be obtained concerning both her and her husband's ethnic origins and her medication history near term. Information about drugs known to initiate hemolysis in cases of G6PD deficiency should be sought and especially any history of recent exposure to mothballs containing naphthalene.

The obstetric history should provide information about vaginal bleeding during pregnancy, placenta previa, abruptio placentae, vasa previa, and cesarean section. Additional questions should be answered. Was the birth traumatic? Did the cord rupture? Was it a multiple birth?

The age at which anemia is first noticed is also of diagnostic value. Marked anemia at birth is usually the result of hemorrhage or severe alloimmunization. Anemia manifesting itself during the first 2 days of life is frequently caused by external or internal hemorrhages, but anemia appearing after the first 48 hours of life is most commonly hemolytic and is usually associated with jaundice.

One approach to the differential diagnosis of anemia in the newborn period is presented in Fig. 46-12. The physician should first decide whether the low hemoglobin level can be explained by blood loss from sampling. Cumulative losses, particularly in ill premature infants, may be extremely large, and correct interpretation of rapid changes in hemoglobin level can be made only if careful attention is paid to exact volumes of blood sampled and transfused. If the cause of anemia remains unknown, several laboratory tests may aid in diagnosis: reticulocyte count, a direct antiglobulin test (i.e., Coomb's test) of the infant's blood, examination of a peripheral blood smear, and examination of the maternal blood smear for fetal erythrocytes. Ultrasound examination of the head or abdomen is useful to detect occult blood loss. From these studies and the history,

P.1189

a diagnosis often can be made, or at least the list of diagnostic possibilities can be greatly shortened.

Bone marrow aspiration is rarely needed in the neonatal period for the work-up of a baby with anemia.

However, if anemia persists without evidence for hemolysis or blood loss a bone marrow should be considered to rule out conditions such as Diamond-Blackfan anemia.

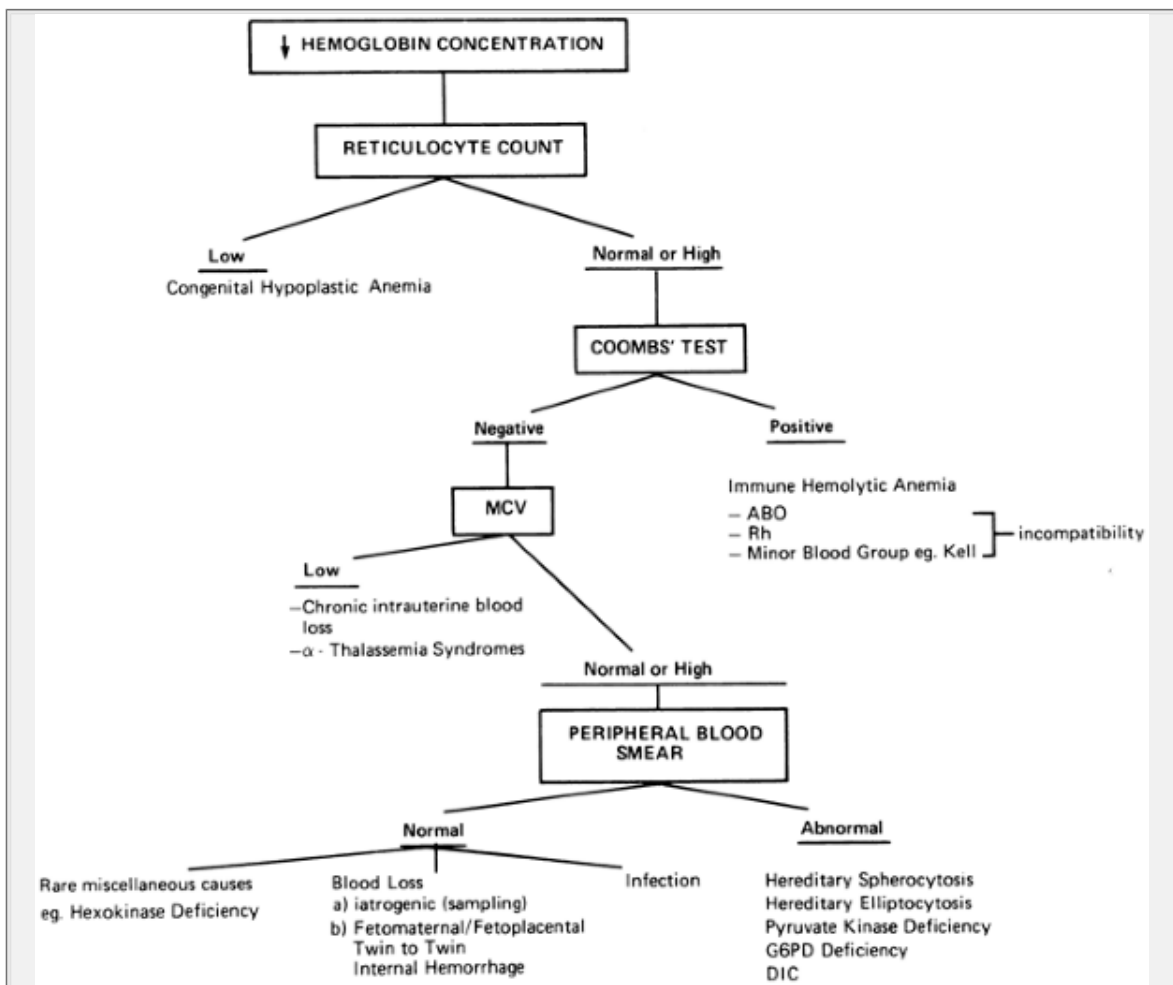

Figure 46-12 Diagnostic approach to anemia in the newborn infant.

Polycythemia

A venous hemoglobin exceeding 22.0 g/dL or a venous hematocrit more than 65% during the first week of life should be regarded as polycythemia. Although neonatal polycythemia may be the result of fetal disorders such as twin-to-twin transfusion, placental insufficiency, and certain metabolic disorders (Table 46-6), most cases occur in otherwise normal infants. Most of these infants have been full-term, appropriate for gestational age, and without asphyxia at birth. Polycythemia occurs in 1.5% to 4% of newborn infants (210,211 and 212).

The symptoms observed in the polycythemic infant appear to be primarily a consequence of hypervolemia and an increase in blood viscosity. After the central venous hematocrit reaches 60% to 65%, the increase in blood viscosity becomes much greater as a result of the exponential relationship between hematocrit and viscosity (213). Plasma and erythrocyte factors also affect the viscosity of neonatal blood (214,215,216).

Respiratory distress, thrombocytopenia, cyanosis, congestive heart failure, convulsions, priapism, jaundice, renal vein thrombosis, hypoglycemia, and hypocalcemia appear to be more common in infants with polycythemia (212). Many infants with polycythemia are asymptomatic.

TABLE 46-6 NEONATAL POLYCYTHEMIA

TABLE 46-6 NEONATAL POLYCYTHEMIA	

Possible causes by placental hypertransfusion

- Twin-to-twin transfusion
- Maternofetal transfusion
- Delayed cord clamping
 - Intentional
 - Unassisted home delivery

Possible associations

- Placental insufficiency
 - Small-for-gestational-age infants
 - Postmaturity birth
 - Toxemia of pregnancy
- Placental previa
- Endocrine and metabolic disorders
 - Congenital adrenal hyperplasia
 - Neonatal thyrotoxicosis
 - Maternal diabetes
- Miscellaneous
 - Trisomies 13, 19, and 21
 - Hyperplastic visceromegaly (i.e., Beckwith syndrome)
 - Erythroderma ichthyosiforme congenita

P.1190

In addition to supportive care, partial exchange transfusion has been used for the treatment of polycythemia. Reduction of the venous hematocrit to less than 60% may improve symptoms, but it has not been shown to improve long-term neurologic outcome (217,218 and 219).

Fetal Hemoglobin, Neonatal Erythrocytes, and 2,3-Diphosphoglycerate

Human tissue metabolism depends critically on an adequate supply of oxygen. The oxygen transport system in humans is the erythrocyte, which contains the iron-protein conjugate hemoglobin. The erythrocyte's primary function is to bring oxygen to the tissues in adequate quantities at a partial pressure sufficient to permit its rapid diffusion from the blood. The ultimate supply of oxygen to the cell is determined by a number of factors, including the content of oxygen in the inspired air, the pulmonary and alveolar ventilation, the diffusion of oxygen from the alveolar air to the capillary bed, the cardiac output, the blood volume, the hemoglobin concentration, and the passive diffusion of oxygen from the capillaries to the cells. The initial passive diffusion of oxygen from the lungs and its final release to the tissues are largely determined by the affinity of hemoglobin for oxygen.

The oxygen-hemoglobin equilibrium curve reflects the affinity of hemoglobin for oxygen (Fig. 46-13). As blood circulates in the normal lung, arterial oxygen tension rises from 40 mm Hg and reaches approximately 110 mm Hg, sufficient to ensure at least 95% saturation of the arterial blood. The shape of the curve is such that a further increase in the oxygen tension in the lung results in only a small increase in the degree of saturation of the blood. As blood travels from the lung, the oxygen tension falls as oxygen is released to the tissues from hemoglobin. In the normal adult, when the oxygen tension has fallen to approximately 27 mm Hg, at a pH of 7.4 and a temperature of 37°C, 50% of the oxygen bound to hemoglobin has been released. The P50, the whole-blood oxygen tension at 50% oxygen saturation, is 27 mm Hg. If the affinity of hemoglobin for oxygen is reduced, more oxygen is released to the tissues at a given oxygen tension. In such situations, the oxygen-hemoglobin equilibrium curve is shifted to the right of normal. It has long been recognized that increases in blood acidity, carbon dioxide content, ionic concentration, and temperature are capable of decreasing the affinity of hemoglobin for oxygen and shifting the curve to the right. If the affinity of hemoglobin for oxygen is increased, as occurs with alkalosis or a decrease in temperature, the equilibrium curve appears shifted to the left, and the tension must drop lower than normal before the hemoglobin releases an equivalent amount of oxygen.

The oxygen dissociation curve of the erythrocytes of newborn infants is shifted to the left, reflecting an increase in the affinity of the hemoglobin for oxygen, compared with the blood of adults (Fig. 46-13). This shift results

primarily from the fact that binding of 2,3-diphosphoglycerate to HbF is less than that to HbA (220). As a result, the unloading of oxygen in the tissues requires a greater fall of oxygen tension in the newborn than in adults. Conversely, the uptake of oxygen in the lung is enhanced in newborns. It is not clear whether this phenomenon is a benefit or handicap to newborns; presumably, its role in intrauterine life is to permit greater movement of oxygen from the mother to the fetus. There is no evidence that provision of blood containing HbA improves tissue oxygenation in the newborn.

Figure 46-13 The oxygen dissociation curve of normal adult blood. The oxygen tension at 50% oxygen saturation (P50) is approximately 27 torr. As the curve shifts to the right, the oxygen affinity of the hemoglobin decreases, and more oxygen is released at a given oxygen tension. With a shift to the left, the opposite effects are observed. A decrease in pH or an increase in temperature decreases the affinity of hemoglobin for oxygen.

Bleeding Disorders

The hemostatic system is not completely developed at birth, and this affects normal laboratory ranges and interpretation of bleeding disorders in neonates. There is little evidence to suggest that the immature hemostatic system places neonates at increased risk of hemorrhage. However, in the neonatal period, many hemorrhagic problems appear as a result of the diseases and disorders that occur at that time of life. The study of hemorrhagic disorders in the newborn period requires an understanding of the development of the hemostatic system, of congenital and acquired factors that can affect it, and appreciation of the role of disease in producing disturbances in the system.

Because of the incomplete development of the hemostatic system in neonates, interpretation of laboratory tests in any given infant requires knowledge of normal ranges for healthy infants of similar gestational and postnatal age, as detailed in [Tables 46-7](#) and [46-8 \(221\)](#). Ideally, each institution should develop their own normal ranges to account for variations that may be caused by the use of different reagents and coagulation analyzers ([222](#)). To minimize iatrogenic blood losses associated with multiple

P.1191

P.1192

P.1193

sampling of ill, very low birth weight infants, coagulation laboratories that service neonatal intensive care units (NICUs) should develop microtechniques for the assessment of the hemostatic system ([223](#)).

Abbreviations: PT = Prothrombin time; s = seconds; INR = international normalized ratio; APTT = activated partial thromboplastin time; TCT = thrombin clotting time; g/L = grams per litre; F = Factor; vWF = von Willebrand factor; PK = prekallikrein; HMWK = high molecular weight kininogen.

All factors except fibrinogen are expressed as units per millilitre (U/ml) where pooled plasma contains 1.0 U/ml.

All values are given as means (M) followed by the lower and upper boundary encompassing 95% of the population (B). Between 40 to 96 samples were assayed for each value for the newborn.

* Values that are indistinguishable from those of the adult.

† These measurements are skewed because of a disproportionate number of high values. The lower limit that excludes the lower 2.5% of the population has been given (B). The lower limit for factor VIII was 0.50 U/mL at all points for the infant.

† Values are different from the fullterm infant Reproduced with permission from Andrew M. The relevance of developmental hemostasis to hemorrhagic disorders of newborns. *Semin Perinatol* 1997;21:70–85.

There are several important features of the coagulation system in the newborn ([Tables 46-7](#) and [Table 46-8](#)) ([221](#)). The prothrombin time (PT) and international normalized ratio (INR) of full-term and premature infants is only slightly outside the adult range ([224,225](#)). However, the partial thromboplastin time (PTT), which is frequently used as a screening test in adults, is much longer in newborn infants, particularly premature infants ([224,225](#)). Prolongation of the PTT in newborns often results from a reduction in contact factors XI and XII and may not pose a bleeding problem. Factors XI and XII are low in premature infants (a mean of 30% and 38%, respectively), increasing to 38%

and 53%, respectively, in full-term infants ([224](#), [225](#)). Substantial prolongation of the PTT (by depression of factors XI and XII) has been observed in children with sepsis without evidence of hemorrhage, leading to the conclusion that the PTT is of limited value in the sick newborn. The two-unit thrombin time is a valuable screening test because it can detect heparin contamination and fibrinogen deficiency. Bleeding disorders in newborn infants are best separated into local bleeding problems and generalized hemorrhagic diatheses.

Local Bleeding Problems in Newborn Infants

Bleeding can occur from the cord, into the scalp, into the gastrointestinal tract, into the abdomen (e.g., liver, adrenal glands), and into the lung. There is little evidence to suggest that the physiologically low levels of coagulation factors in the newborn play any role in the genesis of these disorders.

Intraventricular hemorrhage (IVH) is a major problem of premature infants (see [Chapter 50](#)). There is little evidence to suggest that a hemorrhagic diathesis is a major initiating factor in neonates, and therapeutic trials of plasma or coagulation factor concentrates have been equivocal or unsuccessful. It appears likely that IVH occurs as a result of local phenomena related to hypoxia, hemodynamic changes and prematurity. However, it is reasonable to assume that abnormalities in hemostasis could contribute to extension of IVH once such an event has occurred, and that affected infants should receive appropriate supportive care (e.g. FFP, cryoprecipitate, platelets) designed to correct clinically significant abnormalities such as DIC and/or severe thrombocytopenia.

Hemorrhagic Disorders

Acquired Hemorrhagic Diathesis

Major causes of generalized acquired hemorrhagic diatheses as a result of blood coagulation factor deficiency in the newborn period are vitamin K deficiency, hemorrhagic disease of the newborn, DIC, and liver disease.

Vitamin K Deficiency.

It was shown many years ago that the administration of vitamin K at birth prevented hemorrhagic disease of the newborn, the classic form of which occurs in the first week of life. It has become an accepted procedure to administer 1 mg of vitamin K1 oxide intramuscularly at birth, and as a result, hemorrhagic disease in the newborn has virtually disappeared. However, there has been controversy about the question of vitamin K deficiency in newborns and the need for prophylactic treatment. Vitamin K is a cofactor necessary for the γ -carboxylation of a prothrombin precursor to active prothrombin. In the absence of vitamin K, this precursor (proteins induced by vitamin K absence [PIVKA]) may be detected in the plasma ([226](#),[227](#)). Because PIVKA was found in only one-third of term infants, it has been suggested that not all infants are vitamin K-deficient, and not all need to receive prophylactic vitamin K ([228](#)). However, evidence exists that many newborn infants are vitamin K deficient, even though elevated PIVKA levels are not found in all of them ([227](#)). Because it is not possible to select babies who are likely to bleed, it is recommended that all babies receive 1 mg of vitamin K1 at birth.

Babies born to mothers who are on anticonvulsant medication are at particularly high risk of having vitamin K deficiency (e.g., early hemorrhagic disease of the newborn), and these mothers should receive vitamin K before delivery ([229](#)). Late hemorrhagic disease of newborns (i.e., vitamin K deficiency hemorrhagic disease) manifests at 4 to 6 weeks of age. Infants with this disease characteristically have not received vitamin K prophylaxis at birth; have been maintained on breast milk, which has a low content of vitamin K; and may have suffered from diarrhea or cholestatic liver

disease (230). This disorder continues to be reported from areas in which routine prophylaxis is not given (231) or in which oral vitamin K has been used as a single dose during the first days of life (232). Oral vitamin K is effective in preventing early but not late hemorrhagic disease (233,234 and 235). These observations provide additional support for the recommendation that vitamin K should be given intramuscularly to all infants at birth to prevent hemorrhagic disease of the newborn (232). There have been concerns that intramuscular administration of vitamin K prophylactic therapy in newborns may increase the risk of malignant disease in childhood. However, recent reports on this topic do not suggest that intramuscular injection of vitamin K is linked to childhood cancer (236).

Disseminated Intravascular Coagulation (DIC).

There have been many reports of DIC in newborn infants associated with a variety of diseases. Some reports suggest that most cases of DIC in neonates are caused by cardiovascular collapse (237). This refers to those infants who have had an episode of cardiac arrest, an Apgar score of 0 to 1, or an episode of profound hypotension.

The infant is found to have a generalized hemorrhagic diathesis with bleeding from venipuncture sites, bruising, and widespread internal hemorrhage. Blood studies reveal

P.1194

prolongation of screening tests (e.g., PT or INR, PTT, thrombin time), elevated fibrin split products or D-dimers, depressed factor V levels, and hypofibrinogenemia. Platelet counts may be normal or only slightly depressed. The findings in this syndrome should be differentiated from those observed in sepsis or necrotizing enterocolitis, in which thrombocytopenia is severe, coagulation factors may be normal or slightly reduced, and bleeding is minimal (237).

Management of DIC in the newborn requires aggressive treatment of the underlying cause (e.g., cardiovascular collapse) plus supportive care with hemostatic factors if coagulation factor levels are severely depressed or bleeding is a problem. In such situations replacement therapy with cryoprecipitate (a source of fibrinogen and factor VIII), FFP (a source of all labile coagulation factors) and platelets should be given. The aim should be to maintain a fibrinogen level of 1.0 g/dL or above and a platelet count above $100 \times 10^9/L$ until the condition resolves and laboratory evidence of severe DIC has disappeared. The recommended initial dose of cryoprecipitate is 0.5 Units/kg (10 ml/kg). During the initial phases affected neonates should be monitored frequently (at approximately 4 hour intervals) with screening coagulation tests (PT/INR and PTT) plus measurement of fibrinogen levels and platelet counts. Presence of a low fibrinogen level and/or significant thrombocytopenia is evidence that DIC is ongoing.

The syndrome of DIC typically complicates a serious illness in an infant. Diagnosis and treatment of the hemorrhagic diathesis is generally relatively straightforward. Unfortunately, the underlying disease and the ischemic damage caused by DIC results in high mortality rates (237).

Localized Intravascular Coagulation (Kasabach-Merritt Syndrome).

The clinical and hematologic features of the Kasabach-Merritt syndrome include: an enlarging infantile vascular lesion, most often a hemangioendothelioma or a tufted angioma; thrombocytopenia; a consumptive coagulopathy characterized by a low fibrinogen level; and a microangiopathic hemolytic anemia. Although most affected infants have cutaneous lesions, the syndrome can be caused by visceral hemangioma. This possibility should always be considered in neonates with unexplained thrombocytopenia and coagulopathy (238). Affected infants may manifest high output cardiac failure as a result of increased blood flow through the vascular lesion(s). Management of infants with the Kasabach-Merritt syndrome is often challenging (239,240) and

includes supportive care; management of heart failure if present; judicious use of FFP, cryoprecipitate/fibrinogen concentrates and platelet transfusions to maintain hemostatic levels of platelets and fibrinogen in association with more specific therapy targeted at the vascular lesion such as corticosteroids, and/or vincristine (241); second line therapeutic interventions include use of interferon and antifibrinolytic agents; however, because of the risk of therapy associated spastic diplegia interferon should be reserved for life-threatening cases only and used for short periods with close monitoring of neurological status (239). In selected cases embolization may be of help.

Other Causes of Acquired Bleeding Disorders.

Profound liver disease can produce a hemorrhagic diathesis as a result of vitamin K deficiency or a primary failure of production of coagulation factors.

Despite the use of heparin to maintain intravenous and intraarterial catheters, a hemorrhagic diathesis from heparin therapy is unusual. The frequency of IVH has not been shown to be affected by heparinization of the infusate through arterial lines, but the confidence intervals are wide and even a major increase in the incidence of grade 3 and 4 IVH would not have been detected (242). However, it is not uncommon in studies of newborn infants for blood samples to be contaminated with heparin. All laboratories studying blood coagulation in newborns should be able to detect heparin contamination. High doses of heparin can be inadvertently administered through peritoneal dialysis.

Congenital Hemorrhagic Disorders in the Neonatal Period

Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) may present with bleeding symptoms in the newborn period (243). Because of gender-linked inheritance, male infants and only extremely rarely female infants, are affected. All cases of hemophilia A can be diagnosed at birth because the lower limit of the reference range for factor VIII (<50% or 0.5 U/mL) is similar to the adult value. Although the severe (<1%) and moderate (1%-5%) forms of hemophilia B can be confidently diagnosed in the neonatal period, boys with the mild form may require investigation in later infancy because their levels of factor IX may fall within the lower limit of the reference range for full-term and premature infants at birth (Tables 46-7 and 46-8) (221). The delay in confirming the diagnosis is usually of no consequence because children with mild deficiencies of factor IX are not at risk for spontaneous bleeding.

The bleeding manifestations of neonatal hemophilia include scalp hematomas, prolonged bleeding from venipuncture sites or from surgical procedures such as circumcision, and intracranial hemorrhage (ICH). Management of bleeding involves the infusion of factor VIII (hemophilia A cases) or IX (hemophilia B cases) to restore hemostasis; the replacement product of first choice, if available, is a recombinant factor VIII or IX concentrate (244). If recombinant products are not available a plasma derived factor VIII or IX concentrate treated during preparation to inactivate the HIV and hepatitis viruses should be used (245). In countries where these products are not available FFP (a source of factor VIII and IX), cryoprecipitate (a source of factor VIII), or even fresh whole blood may have to be used. Prothrombin complex concentrates containing factors II, VII, IX, and X should not be used in newborns other than those with known deficiencies of these factors because of the risk of inducing thrombosis.

Severe, isolated deficiencies of factors II, V, VII, X, XI, and fibrinogen are rare and are inherited in an autosomal manner (246). The homozygous forms of the disorders may present with bleeding in the newborn period. Delayed

bleeding from the umbilical stump is characteristic of homozygous factor XIII deficiency. The PT/INR, PTT, and thrombin times are normal in patients with factor XIII deficiency, and the diagnosis should

be suspected based on the finding of an increased solubility of the patient's recalcified plasma clot in urea or monochloroacetic acid and confirmed by quantitation of the factor XIII level. Treatment of these coagulation factor deficiencies involves infusion of stored plasma (except for factor V), FFP, or specific factor concentrates.

Bleeding is uncommon in newborns with von Willebrand disease (vWD) ([247](#)). With the exception of the rare form of severe (type 3) vWD, a diagnosis of vWD cannot be made with confidence in the newborn period because levels of von Willebrand factor are elevated at birth, masking the presence of the most common forms of vWD ([248](#)).

Platelet Disorders

A platelet count less than $150 \times 10^9/L$ is abnormal in term and premature infants (249). The level of platelets in the blood reflects a balance between their production and destruction. Thrombocytopenia may result from decreased production, increased destruction, sequestration, or some combination of these mechanisms. Examination of a well-stained smear of peripheral blood to assess platelet morphology and number, and of bone marrow to assess megakaryocyte morphology and number, has traditionally yielded important information concerning the mechanism of thrombocytopenia in older children. Decreased numbers of platelets and megakaryocytes indicate a production defect, and megakaryocytic hyperplasia and the presence of megathrombocytes (young large platelets) in a peripheral blood smear are characteristic of thrombocytopenic states in which there is increased peripheral destruction of platelets. In newborn infants these indices have not proved as useful as in older children because bone marrow sampling is more challenging and an adequate specimen is often not obtained. Recently, however, Sola and colleagues (250) have published a technique for bone marrow biopsies in neonates that yields small but high-quality specimens thus allowing accurate assessment of cellularity and megakaryocyte numbers.

There are many causes of thrombocytopenia in the newborn. The most common of these disorders are highlighted in Table 46-9 and have been reviewed elsewhere (249,251,252,253 and 254). Some of these disorders, selected because of their frequency or relative importance, are reviewed in detail below.

Neonatal Immune Thrombocytopenia

Immune thrombocytopenia occurs when antibody-sensitized platelets are prematurely destroyed in the reticuloendothelial system, particularly the spleen. Characteristic laboratory features include isolated thrombocytopenia and an increased number of immature megakaryocytes in a bone marrow aspirate.

TABLE 46-9 CAUSES OF NEONATAL THROMBOCYTOPENIA

Decreased production of platelets

Inherited thrombocytopenias

Thrombocytopenia-absent radius syndrome

Wiskott-Aldrich syndrome

Other X-linked, dominant or recessively transmitted thrombocytopenias

Congenital leukemias and histiocytoses

Increased destruction of platelets

Immune thrombocytopenias

Neonatal alloimmune thrombocytopenia

Neonatal autoimmune thrombocytopenia

Drug-induced thrombocytopenia

Giant hemangioma syndrome

Other states with disseminated intravascular coagulation

Both decreased production and increased destruction of platelets

Infections

Congenital, usually viral

Acquired, usually bacterial

A variety of conditions are associated with the transplacental passage of maternal antiplatelet antibodies into the fetus, resulting in immunologic destruction of platelets and fetal thrombocytopenia. The antibody may be formed against an antigen on the platelets of the infant (isoimmune or alloimmune thrombocytopenia, in which case the mother's platelet count is normal) or an antigen present on the platelets of the mother (autoimmune thrombocytopenia, in which case both the mother and child may have thrombocytopenia), as occurs in maternal immune thrombocytopenic purpura (ITP) or thrombocytopenia associated with a collagen vascular disorder such as systemic lupus erythematosus.

Neonatal Alloimmune Thrombocytopenia.

In neonatal alloimmune thrombocytopenia, the infant possesses a platelet antigen of paternal origin that is lacking in the mother. Typically, the infant's platelets cross the placenta into the maternal circulation during pregnancy or at the time of delivery and cause immunization of the mother, with the formation of antibodies against the foreign platelet antigen. Less frequently, the cause of immunization is exposure of an antigen-negative mother to antigen-positive platelets during transfusion. During pregnancy, transplacental passage of the maternal IgG antibodies leads to sensitization of fetal platelets. Sensitized platelets are rapidly destroyed in the fetal reticuloendothelial system, particularly the spleen, and the result may be thrombocytopenia in utero and in the infant at the time of delivery. This mechanism is analogous to that causing hemolytic disease of the newborn.

The platelet-specific antigen system most often involved in cases of neonatal alloimmune thrombocytopenia is HPA-1a (PIA¹) (Table 46-10) (255). Other platelet-specific antigens are involved less frequently (256,257,258,259,260,261,262,263 and 264). In the largest series of cases of suspected neonatal alloimmune

P.1196

thrombocytopenia, 91% (120 of 132) of serologically proven cases involved HPA-1a (PIA¹) alloantibodies (265). Of the remaining 12 cases, the pathologic alloantibodies were anti-HPA 5b (Br^a)-9, anti-HPA-1b (PIA²)-1, anti-HPA-3^a (Baka) with HLA antibody-1, and blood group B isoagglutinins-1. Although HLA alloantibodies often develop as a result of pregnancy, they rarely are the cause of severe neonatal thrombocytopenia.

TABLE 46-10 PLATELET-SPECIFIC ALLOANTIGENS

Nomenclature	Glycoprotein (GP)		Phenotype Frequency%		
	New	Old	Caucasian	Japanese	
HPA-1a		PIA ¹	IIIa	97.9	99.9

ND = no data

The incidence of neonatal alloimmune thrombocytopenia, based on data collected in prospective studies, is estimated to be in the order of 1 in 1800 live-born infants (255). In 85% of cases in which serological information was available, neonatal alloimmune thrombocytopenia reflected fetomaternal incompatibility for the HPA-1a (PIA¹) alloantigen. Prospective studies of HPA-1a (PIA¹) antigen negative pregnant women provide complementary information reviewed in (255). Fifty-seven of 851 HPA-1a negative women were found to have HPA-1a alloantibodies, 48 during pregnancy and 9 in the postpartum period yielding an overall incidence of HPA-1a (PIA¹) alloimmunization of approximately 1 per 650 pregnancies. Thirty infants manifested thrombocytopenia suggesting an incidence of neonatal alloimmune thrombocytopenia as a result of HPA-1a (PIA¹) alloantibodies in the order of 1 per 1200 pregnancies in a Caucasian population. Two important points emerge from these prospective screening studies: first, not all pregnancies involving an HPA-1a (PIA¹) alloimmunized mother will result in a thrombocytopenic fetus/neonate; and second, the appearance of HPA-1a (PIA¹) alloantibodies, similar to red blood cell alloantibodies in cases of hemolytic disease of the newborn, may occur for the first time in the postpartum period.

The typical infant with neonatal alloimmune thrombocytopenia is term, and thrombocytopenia is unexpected. Cutaneous manifestations of severe thrombocytopenia (e.g., bruising, a petechial rash) are often the only abnormalities found on physical examination. A complete blood count shows severe isolated thrombocytopenia with a normal hemoglobin and leukocyte count.

Affected infants are at risk of serious hemorrhage, particularly into the central nervous system (CNS). In a review by Pearson and colleagues (266), the incidence of fatal hemorrhage was 10% to 15%. In some cases, CNS hemorrhage occurs in utero before delivery (267,268,269,270 and 271). Bussell and associates (272) estimated that as many as 25% of CNS hemorrhage cases of associated with neonatal alloimmune thrombocytopenia occur antenatally.

Early diagnosis and effective therapy of infants with neonatal alloimmune thrombocytopenia is important. The disorder should be suspected in all infants with severe, isolated thrombocytopenia in whom a specific cause for the thrombocytopenic state cannot be identified (e.g., sepsis, DIC, and skeletal anomalies such as absent radii) and if the maternal platelet count is normal. These infants should receive antigen-negative, compatible platelets harvested from the mother or a phenotyped blood donor. If maternal platelets are used, supernatant plasma with pathologic antibody should be removed by centrifugation or washing, and the compatible maternal platelets infused after irradiation. In clinical practice, severely thrombocytopenic infants (i.e., platelet counts $<30 \times 10^9/L$) are often initially transfused with a unit of random donor platelets; in such cases, the platelet response is of diagnostic value (273,274). Because most individuals of European descent type positively for the HPA-1a (PIA¹) and HPA-3^a (Bak^a) antigens (98% and 88%, respectively), most random donor platelets are incompatible in cases of neonatal alloimmune thrombocytopenia involving these alloantigens in a European based population, and their infusion fails to produce a satisfactory post transfusion platelet increment, defined as a platelet count of at least 30,000/ μL . In other ethnic groups, other platelet-specific alloantigens should be considered.

P.1197

The rarity of the HPA-1a (PIA¹ negative) phenotype in individuals of African and Oriental descent explains why neonatal alloimmune thrombocytopenia as a result of HPA-1a (PIA¹) fetomaternal incompatibility, the common cause of this disorder in a Caucasian population, is extremely rare in these populations. In Japanese patients the majority of cases of neonatal alloimmune thrombocytopenia are caused by antibodies to HPA-4b (Pen^b) (275).

In situations in which alloimmune thrombocytopenia is clinically suspected, the lack of response to random donor platelets provide additional evidence for the diagnosis, and it is then most important that severely affected infants receive compatible antigen-negative platelets collected from the mother or blood donors of known antigen type. Regional blood centers serving large NICUs should be encouraged to develop a small bank of blood donors phenotyped for relevant platelet antigens who are readily available for donation. In a Caucasian based population, transfusion with HPA-1a and HPA-5b negative platelets will be effective in over 95% of cases of fetomaternal alloimmune thrombocytopenia and are the initial product of choice for this condition (276). In selected cases, it may be useful to harvest and store in the frozen state the platelets from mothers or antigen-negative donors for immediate use if an affected infant is anticipated (277).

Other therapeutic interventions for neonatal alloimmune thrombocytopenia include exchange transfusion to remove pathologic antibody and intravenous administration of large doses of immunoglobulin G (HDIVIG). This latter strategy is of proven benefit in children with ITP and has been used with variable success in infants with alloimmune thrombocytopenia (278,279,280,281,282,283). However, if compatible platelets can be quickly obtained, these additional therapeutic interventions are rarely indicated. If compatible platelets cannot be obtained, or if a significant delay can be anticipated before this ideal product will be available, the therapy of choice is a trial of HDIVIG. Current practice is to administer a total dose of 2 g/kg of body weight, given as 1g/kg over 6 to 8 hours on each of two consecutive days. Corticosteroid therapy (e.g., prednisone) is of no proven benefit if used in the traditional dose of 1 to 2 mg/kg/day.

The risk of this disorder recurring in a subsequent pregnancy of a sensitized HPA-1a (PIA¹) negative woman is high, and is dependent on the platelet genotype of the pregnant woman's partner. If the partner is homozygous (HPA-1a/1a) the rate of recurrence is essentially 100%, whereas the risk is 50% of the partner in heterozygous (HPA-1a/1b). This has led to the recommendation that in at-risk pregnancies, and especially in cases in which there is a history of a previously affected infant, fetal platelet antigen typing should be performed on fetal DNA obtained from amniocytes obtained following amniocentesis at 15 to 18 weeks gestation (reviewed in 255). If the fetus is determined to be HPA-1a (PIA¹) negative no further intervention is needed. If the fetus is HPA-1a (PIA¹) positive a cordocentesis should be planned at 20 to 24 weeks gestation to determine the fetal platelet count and to guide antenatal management (284). Options include weekly administration of intravenous immunoglobulin G to the mother with or without the addition of corticosteroids (the preferred approach in North American centers), or repeated intrauterine transfusions of compatible antigen negative platelets (the preferred approach in some European centers) (284,285).

The route of delivery is determined by the fetal platelet count obtained following cordocentesis before delivery. If the fetal platelet count is less than $50 \times 10^9/L$, delivery by cesarean section is recommended. At the time of delivery, a cord blood platelet count should be obtained, and thrombocytopenia should be verified in a peripheral blood sample obtained shortly after delivery. If the infant is severely thrombocytopenic, compatible antigen-negative platelets should be infused immediately. These high-risk pregnancies should be managed by a team of perinatologists, neonatologists, and hematologists.

Neonatal Autoimmune Thrombocytopenia.

Clinical and laboratory features of neonatal autoimmune thrombocytopenia parallel those of the alloimmune state. In both disorders, the observation of ecchymoses, a petechial rash, or both in an otherwise well infant may be the first clue to the disorder. Measurement of a maternal platelet count and examination of a peripheral blood smear obtained from the mother can help to differentiate autoimmune from alloimmune neonatal thrombocytopenia. In neonatal alloimmune

thrombocytopenia, the maternal peripheral blood smear and platelet count are normal, whereas in the autoimmune condition (e.g., mothers with autoimmune ITP), the platelet count is reduced, and the existing platelets are often large (i.e., megathrombocytes). Occasionally, the finding of unexpected thrombocytopenia in an infant may lead to the diagnosis of previously unrecognized ITP in the mother. Autoimmune thrombocytopenia may occur in infants of mothers with ITP who have normal platelet counts after splenectomy. Occasionally in mothers with ITP, increased bone marrow activity can compensate for accelerated destruction of antibody-sensitized platelets. These women may have normal platelet counts, but their infants are at risk of developing acquired thrombocytopenia.

Management of infants with autoimmune neonatal thrombocytopenia differs from that of those with the alloimmune form of the disease. Compatible platelets cannot be found because platelet autoantibodies react with all donor platelets. Therapeutic options include exchange transfusion to remove passively acquired maternal autoantibodies, corticosteroids, and HDIVIG. In infants with significant thrombocytopenia (i.e., platelet counts $<50 \times 10^9/L$) or clinical bleeding, the authors favor administration of immunoglobulin G in a dose of 1 g/kg daily for two consecutive days. A marked increment in platelet count can be anticipated within 24 to 48 hours in 75% of patients (286,287). If this response is not observed, corticosteroid therapy should be started (e.g., prednisone or an equivalent corticosteroid at a dose of 3 to 4 mg/kg/day initially, with rapid tapering once the platelet count increased above $50 \times 10^9/L$). Exchange transfusion to remove pathologic antibodies or splenectomy should not be considered in

P.1198

newborn infants unless there is a real clinical emergency with life-threatening bleeding e.g., bleeding into the CNS, and for whom front line therapies such as high-dose IVIG and corticosteroids have proved ineffective.

The same considerations apply to the route of delivery as have been outlined in the discussion of neonatal alloimmune thrombocytopenia. The maternal platelet count and levels of platelet-bound IgG and serum platelet antibody do not predict with certainty which infants will be thrombocytopenic (288,289 and 290). The management of the pregnant woman with chronic ITP (or ITP in remission after splenectomy) has been controversial. Studies indicate that the severity of the disease in the fetus is much less than previously reported and that the occurrence of ICH is rare (291,292). Reflecting these observations some experts advise that antenatal determination of the fetal platelet count is not justified in all pregnant women with ITP, and that Cesarean section should be reserved for obstetric indications only (293). If a decision is made to measure the fetal platelet count as a guide to the mode of delivery, cordocentesis is preferred over scalp vein sampling because of the poor reliability of this latter technique (293). The platelet count of affected infants should be monitored carefully in the first few days of life because values may fall to low levels requiring treatment with platelet-enhancing therapies such as IVIG and/or corticosteroids.

Decreased Production of Platelets

Decreased production of platelets in the bone marrow in the neonatal period can be as a result of various causes including perinatal infections (prenatal, natal, or postnatal), maternal drug use (e.g. azathioprine), metabolic defects (e.g. branched amino acid metabolism defects) or inherited marrow failure syndromes.

Inherited Thrombocytopenia.

Several inherited marrow failure syndromes are associated with thrombocytopenia. In some of them (e.g. thrombocytopenia absent radii syndrome) only defects in thrombopoiesis are manifest.

In others (e.g. congenital amegakaryocytic thrombocytopenia or Fanconi anemia) the first manifestation is usually thrombocytopenia but later on the complete stem cell phenotype is affected with the appearance of multilineage cytopenia.

The genes associated with some of the reported syndromes are known: *WASP* for Wiskott-Aldrich syndrome and X-linked thrombocytopenia (XLT) (294), *CBFA2* for familial thrombocytopenia with a predisposition to acute myeloid leukemia (295), *MYH9* in May-Hegglin/ Sebastian/ Fechtner/ Epstein/Alport syndromes (296), *C-MPL* in congenital amegakaryocytic thrombocytopenia (297), *GATA1* in thrombocytopenia with dyserythropoiesis (298), *FLJ14813* in autosomal dominant nonsyndromic familial thrombocytopenia (299), and *HOXA11* in thrombocytopenia associated with radioulnar synostosis (300).

Clues for the specific diagnosis of the inherited marrow failure syndrome can be provided by a family history suggestive of an inherited pattern (e.g., autosomal recessive in amegakaryocytic thrombocytopenia and autosomal dominant in familial thrombocytopenia with a predisposition to acute myelogenous leukemia); age at diagnosis (e.g., birth in thrombocytopenia absent radii syndrome and adulthood in thrombocytopenia with a predisposition to acute myelogenous leukemia); associated nonhematological manifestations (e.g., limb abnormalities in thrombocytopenia-absent radius and radio-ulnar synostosis syndromes, and renal anomalies in Alport syndrome) (301).

A battery of tests, including bone marrow aspiration and biopsy, is usually required to establish a diagnosis and early referral to a hematologist is advisable. An algorithm to assist clinicians in the diagnosis of the inherited thrombocytopenia has been reported (302). Management varies from supportive care during surgical procedures and avoidance of anti-platelet agents to hematopoietic stem cell transplantation. The efficacy of thrombopoietic growth factors in this group of patients has not yet been determined.

Thrombocytopenia in Premature Newborn Infants

The commonest example of thrombocytopenia in neonates is that seen in premature low birth-weight infants admitted to NICUs. In this patient population the frequency of thrombocytopenia, defined by a platelet count of less than $150 \times 10^9/L$, is of the order of 25% (303,304,305). In the prospective study of 807 consecutive newborn infants reported by Castle and associates (304) the incidence of thrombocytopenia was 22%; in 38% of thrombocytopenic infants the platelet count was 50 to $100 \times 10^9/L$, and in 20% the platelet count was less than $50 \times 10^9/L$.

A practical classification of thrombocytopenia in neonates has been proposed by Roberts and associates (253) and Murray (254). In this classification a distinction is made between early onset and late-onset thrombocytopenia. Early onset thrombocytopenia is present at birth or occurs within 72 hours of life. Only a minority of these cases will have immunological disorders (e.g., neonatal auto-/alloimmune thrombocytopenia) or coagulopathy (e.g., DIC) as a cause for thrombocytopenia. The vast majority of cases are preterm infants born following pregnancies complicated by placental insufficiency or fetal hypoxia e.g. maternal pregnancy-induced hypertension (PIH), fetal intrauterine growth retardation and maternal diabetes (253). Typically these infants have modest thrombocytopenia (platelet counts $100-150 \times 10^9/L$). Following birth their platelet count falls, reaching a nadir by postnatal day 4 to 5 before recovering to greater than $150 \times 10^9/L$ by 7 to 10 days of age (304). Although earlier studies suggested that, on the one hand, decreased platelet production (303), and on the other hand, increased platelet destruction (304) were the major cause of thrombocytopenia in neonates admitted to NICUs, more recent evidence suggests that early onset thrombocytopenia in low birth weight infants is primarily the result of a transient impairment of megakaryocytopoiesis (306). In contrast, late-onset neonatal thrombocytopenia defined by a platelet count of less than $150 \times 10^9/L$ occurring after the first 72

hours of life almost always results from sepsis or necrotizing enterocolitis (NEC). This late-onset thrombocytopenia has a significant natural history (254). Thrombocytopenia usually progresses rapidly with a platelet nadir that is reached within 24 to 48 hours and is frequently severe with the platelet nadir often falling below $50 \times 10^9/L$. Affected infants often require platelet transfusion support. Platelet recovery is slow, occurring over 5 to 7 days as sepsis or NEC is controlled. Neonates with this type of thrombocytopenia initially require careful monitoring of their platelet count (at least every 12 hours) to track their platelet nadir and to time appropriate intervention with platelet transfusions. In neonates with NEC a rapid fall in platelet count to a level well below $100 \times 10^9/L$ may be a useful marker of intestinal gangrene (307). Finally, in neonates with thrombocytopenia and no apparent cause, thrombosis should be considered.

Evaluation of the Neonate with Thrombocytopenia

An approach to the multiple diagnostic possibilities is outlined in Fig. 46-14. In this schema, it is as important to study the mother as it is to study the infant and to examine the placenta (for multiple hemangiomas). Points requiring specific inquiry include a history of previous bleeding in the form of purpura, bruising, or nose bleeds that might suggest a diagnosis of maternal ITP at some time in the past; ingestion of drugs that may cause thrombocytopenia in the mother and infant (e.g. quinidine, quinine); previous siblings affected with purpura, suggesting one of the immune or inherited thrombocytopenias; and skin rash or exposure to rubella in the first 8 weeks of pregnancy. Serologic evidence of congenital infections (e.g., syphilis, CMV, herpesvirus, toxoplasmosis) should be sought and recorded. An accurate maternal platelet count should be performed as soon as possible after delivery so that immune neonatal thrombocytopenia caused by maternal ITP can be differentiated from that caused by platelet alloimmunization, in which case the mother's platelet count is normal.

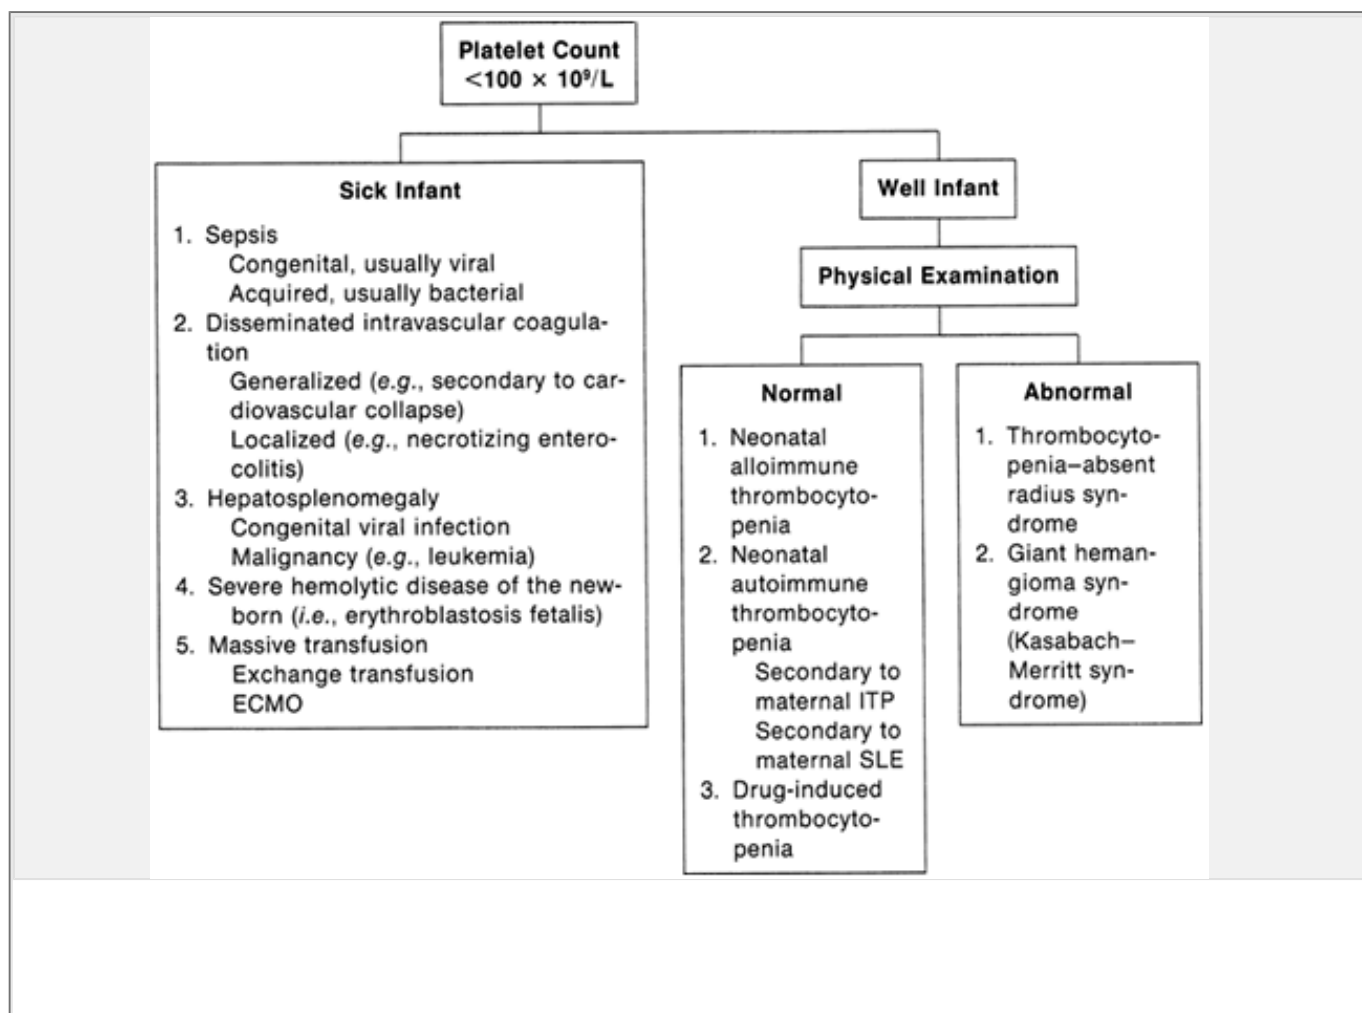

Figure 46-14 Approach to the diagnosis of the thrombocytopenic newborn (ECMO, extracorporeal membrane oxygenation; ITP, immune thrombocytopenic purpura; SLE, systemic lupus erythematosus).

Physical findings of importance in the differential diagnosis of the affected newborn include hepatosplenomegaly and congenital anomalies. Hepatosplenomegaly is often accompanied by jaundice and suggests an infectious process as the most likely cause of thrombocytopenia. In some cases, congenital leukemia may have to be considered. Among the congenital anomalies associated with neonatal thrombocytopenia, the commonest group recognizable at birth is that occurring in the rubella syndrome (congenital heart defects, cataracts, and microcephaly). Deformity and shortening of the forearms should suggest bilateral absence of the radii, with associated amegakaryocytic thrombocytopenia. A single large hemangioma or multiple smaller hemangiomas point to possible platelet trapping and should prompt a search for bruits produced by internal hemangiomas.

A complete blood count on the infant should include a hemoglobin determination, leukocyte count, platelet count, and a blood smear. Associated anemia may result from blood loss, concurrent hemolysis (e.g., infection associated with), or marrow infiltration caused by congenital leukemia. Leukocytosis of a mild degree may accompany infection or blood loss, but if this exceeds 40,000 to

P.1200

50,000/ μ L, it may point to congenital leukemia. Bone marrow examination should be considered if thrombocytopenia is persistent and a specific cause cannot be identified. Serologic tests for platelet antibodies and platelet antigen typing are generally only available in reference laboratories. If alloimmune thrombocytopenia is suspected by the finding of an otherwise normal newborn with thrombocytopenia and a healthy mother with a normal platelet count, blood should be drawn from the parents soon after delivery for serologic testing. Characteristically, the maternal serum contains an antibody reactive against paternal platelets. Platelet antigen typing should be performed on both parents, if available; in cases of neonatal alloimmune thrombocytopenia, the mother will type negative and the father positive for the pathologic platelet-specific antigen. In this situation, the infant's platelet type is assumed to be identical to that of the father because it is usually not possible to obtain sufficient blood from severely thrombocytopenic newborn infants for extensive serologic testing. Results of platelet studies may not be available for some time, and therapy should not be delayed pending their results.

Leukocytes

Neutrophil Disorders

A diverse group of leukocyte disorders is encountered in newborn infants. Different blood cells are involved (e.g., neutrophils, lymphocytes, eosinophils), and the disorders may be quantitative or qualitative in nature. This section focuses on abnormalities that are particularly relevant to newborn infants because of the frequency with which they are encountered (e.g., neutrophil changes associated with bacterial infections) or because they are unique to this age group (e.g., congenital leukemia or neonatal alloimmune neutropenia).

Normal Leukocyte Count in the Neonatal Period

The morphologic definition of a mature neutrophil is a cell in which the nucleus is distinctly segmented into two or more lobes connected by a thin filament. Cells with no lobulation and those in which the width of the narrowest segment of the nucleus is greater than one-third the width of the broadest segment are referred to as nonsegmented neutrophils or bands (Fig. 46-15). During the first two weeks of life for full-term and premature infants, a band to segmented neutrophil ratio greater than 0.3 should be considered abnormal (308). Examination of a peripheral blood smear during the first few days of life characteristically reveals an excess of polymorphonuclear neutrophils. Particularly in premature infants, some immature forms (e.g., promyelocytes, myelocytes) may be seen. Sometime between the fourth and seventh days of life, the lymphocyte becomes the predominant cell and remains so until the fourth year of life.

Figure 46-15 A band neutrophil

Counts of segmented and band (i.e., nonsegmented, young) neutrophils of full-term and very low-birth weight infants have been reported by a number of investigators (308,309,310,311,312,313 and 314). The lower limit of normal for neutrophil counts in very low-birth weight infants are significantly below those for term infants, and the data most

widely used for defining neutropenia in NICUs is that generated from the University of Texas Southwestern Medical Center at Dallas by Manroe (312) and Mouzinho (314) (Figs. 46-16, 46-17 and 46-18).

Figure 46-16 The total neutrophil count reference range in the first 60 hours of life. Subjects were 434 newborn infants (birth weight $2685 \pm 683\text{g}$; range 29-44 weeks *gestational* age) Solid circles represent single values; numbers represent the number of values at the same point. Heavy lines represent the envelope bounding these data. Reproduced with permission from Manroe BL, Weinberg AG, Rosenfeld CR, et al. The neonatal blood count in health and disease. I. Reference values for neutrophilic cells. *J Pediatr* 1979;95:89-98.

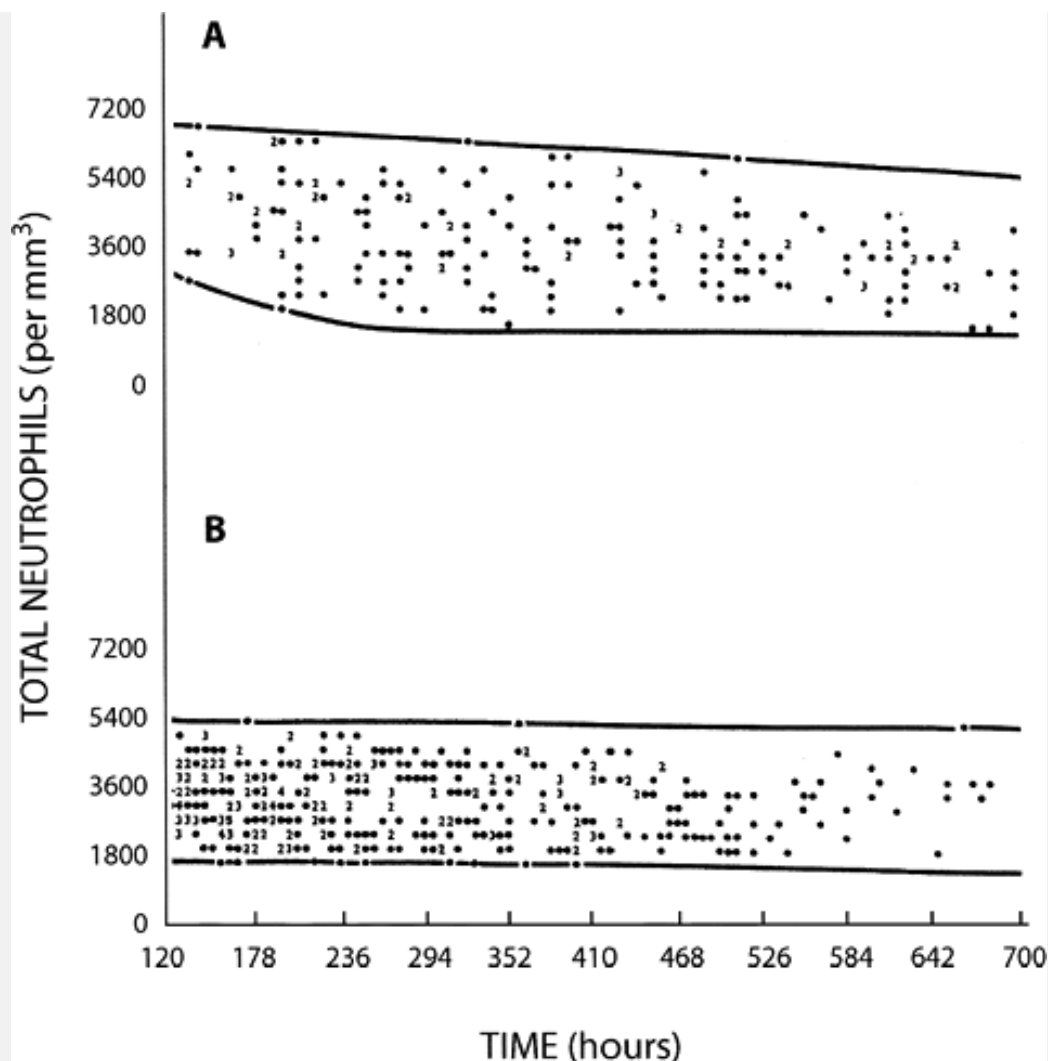

Figure 46-17 The reference range for the total neutrophil count for **(A)** infants 60 to 120 hours of life and **(B)** 120 hours to 28 days. Subjects were 434 newborn infants (birth weight $2685 \pm 683\text{g}$; range 29-44 weeks *gestational* age) Solid circles represent single values; numbers represent the number of values at the same point. Heavy lines represent the envelope bounding these data. Reproduced with permission from Manroe BL, Weinberg AG, Rosenfeld CR, et al. The neonatal blood count in health and disease. I. Reference values for neutrophilic cells. *J Pediatr* 1979;95:89-98.

Although the definition of neutropenia is essentially a statistical consideration based on data obtained from studies of healthy term and premature newborn infants, there is consensus among experts that absolute neutrophil counts above $1,000/\mu\text{L}$ are not likely to place neonates at risk of acquiring clinically significant infections (315). In our experience it is a helpful rule of thumb to consider an absolute band plus neutrophil count below $1,000/\mu\text{L}$ to be "clinically significant" in full-term and premature newborn infants.

Physiological neutrophilia is common in neonates in the first week of life. According to Thilaganathan and associates (316) total leukocyte counts in umbilical cord blood ranged between 7.25 to $48 \times 10^9/\text{L}$ with a mean of $13.8 \times 10^9/\text{L}$. After birth neutrophil counts increase to levels up to $23,000$ at 16 hours post labour and then gradually decrease to less than $9.5 \times 10^9/\text{L}$ at 5 days of age.

The mechanism for the physiological neutrophilia seems to be a surge in cytokine secretion. Barak and associates (317) found that serum and urinary colony-stimulating activity levels

were significantly increased (3-5 fold) on the first and fourth days of life, but declined to normal values by the 14th and 28th days. Ishii and associates (318) found that G-CSF and M-CSF levels were significantly higher on day 1 after birth and then gradually decreased. Granulocyte-macrophage colony-stimulating factor (GM-CSF) levels did not change significantly during the neonatal period. Interestingly, these investigators found that granulocyte colony-stimulating (G-CSF) and GM-CSF produced in the placenta (trophoblasts and decidual stromal cells) are the major cause of physiological leukocytosis in newborn infants at birth.

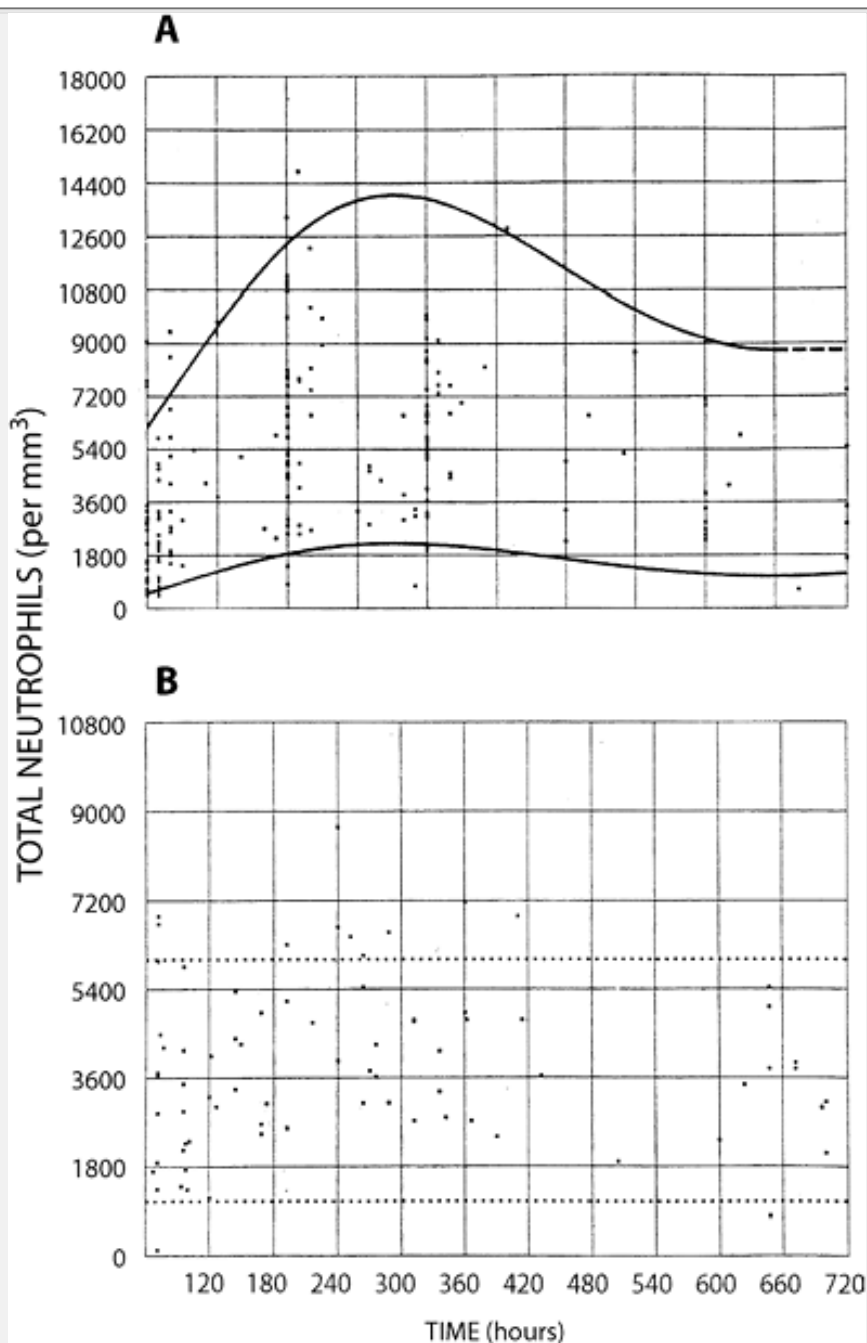

Figure 46-18 Revised reference ranges for total neutrophil values in very low birth weight infants from (A) birth to 60 hours of life and (B) 61 hours to 28 days of life. Subjects were 193 newborn infants: 50 at 1000g and 143 at 1001-1500g. Bold (A) and dotted (B) lines represent the envelopes bounding these data, respectively. Reproduced with permission from Mouzinho A, Rosenfeld CR, Sanchez PJ, et al. Revised reference ranges for circulating neutrophils in very-low-birth-weight neonates. *Pediatrics* 1994;94:76-82.

Neutropenia

Causes of neutropenia in newborn infants include decreased production of neutrophils, increased destruction, or a combination of both mechanisms (Table 46-11). Most episodes occur during the first week of life and are related to low gestational age, low birth weight, infections, pregnancy induced hypertension, severe neonatal asphyxia, drug therapy, or other perinatal events (319). Late-onset neutropenia, defined as an absolute neutrophil count of

P.1202

less than 1,500/ μ L at a postnatal age of more than 3 weeks has been reported in well, very low birth-weight infants with anemia of prematurity, and reticulocytosis (320). It is speculated that a requirement of progenitor cells for enhanced erythropoiesis associated with the physiological anemia of prematurity limits their availability for granulopoiesis leading to a decrease in neutrophil production. This condition should be considered physiological and is not generally associated with an increased risk of infection.

TABLE 46-11 CAUSES OF NEONATAL NEUTROPENIA

Decreased Production of Neutrophils

Decreased Production and Increased Destruction of Neutrophils

Infections

- Congenital, usually viral
- Acquired, usually bacterial
- Drug induced neutropenia

* Extremely rare causes of neutropenia in newborn infants.

The various causes of neutropenia in neonates are summarized in Table 46-11. The commonest causes include neutropenia associated with infection, neutropenia in premature infants, neutropenia in infants of hypertensive mothers, and allo-autoimmune neutropenia (321). Other causes for destruction or underproduction of neutrophils are rare, and include inherited marrow failure syndromes.

Changes in Blood Neutrophils During Bacterial Infection

Neutropenia frequently occurs in the setting of neonatal sepsis. It can be the cause of sepsis, but more commonly it is a consequence of infection. It is noteworthy that neutrophil function, particularly chemotaxis and phagocytosis, is reduced in newborn infants and may contribute to susceptibility to infection (322). In neonates, clinical signs of infection may be minimal, and the speed of evolution of disease may be rapid. Changes in neutrophil number and appearance are often helpful in the diagnosis of bacterial infections in this age group (310).

Changes in Neutrophil Numbers

In infants with systemic bacterial infection, the total neutrophil count is usually decreased (i.e., neutropenia), but may also be increased (i.e., neutrophilia), or normal. In a study of 24 newborn infants with proven bacterial sepsis (positive bacterial cultures from the blood, cerebrospinal fluid, bladder-tap urine, or peritoneal fluid), neutropenia was observed in five, neutrophilia in three, and normal neutrophil counts in the remaining 16 (309). Although neutrophilia is a relatively nonspecific finding and may occur in conditions other than sepsis, the finding of neutropenia is highly significant in newborn infants and may be the first clue to bacterial infection. In the study of Manroe and associates (312) neutropenia was observed in 77% of neonates with confirmed or suspected bacterial disease. Neutrophilia was absent almost as often in infected infants (42%) as it was present (58%). In a more recent study the frequency of neutropenia in newborn infants, defined by reference ranges established by Manroe (312) and Mouzinho (314), was 8.1% (135/1662 cases) (319). In 65% (41/63 cases) of neonates neutropenia was present on the day of the clinical onset of sepsis. In 13% (8/63 cases) neutropenia developed within 3 days of the onset of sepsis, and in 22% (14/63 cases) neutropenia was present before the clinical onset of sepsis. Seventy-seven % of the neutropenic episodes occurred during the first week of life; in 75% of affected neonates the duration of neutropenia ranged from 0 to 8 days, with 75% having neutropenia for less than 24 hours. In addition to neutropenia, increased numbers of immature neutrophils (band forms) and an elevated band to segmented neutrophil ratio are seen in neonates with sepsis. Although Baley and colleagues (323) did not find the immature:total neutrophil ratio to be of value in the identification of sepsis in neonates others have found the opposite and have stressed the potential clinical importance of hematologic changes in the assessment of sepsis in neonates (309,310). In a study of premature infants with proven bacterial infection 73% (11 of 15) of infants had elevated band counts and a reversed band to segmented neutrophil ratio (310).

Changes in Neutrophil Morphology

In addition to numerical changes in neutrophils, morphological changes may appear. During infection, the neutrophils of newborn infants have increased numbers of Döhle bodies (i.e., aggregates of rough endoplasmic reticulum), vacuoles, and toxic granules (310). Rodwell and colleagues (324) have proposed a hematologic scoring system for use in the early diagnosis of sepsis in neonates (Table 46-12). In their studies the combination of a neutrophil count less than or equal to $500/\text{mm}^3$ and scores more than or equal to 3 identified a poor prognostic group (325)

Neutropenia of Prematurity

The most common example of neutropenia seen in NICUs occurs in premature infants, particularly those of VLBW. The mechanisms underlying postnatal neutropenia in such

infants appears to be a combination of reduced total body neutrophil mass, together with reduced numbers of committed neutrophil precursors in the bone marrow at birth and an inability to increase granulopoiesis in response to sepsis (326). The role of recombinant hematopoietic growth factors, in particular granulocyte colony-stimulating factor (rhG-CSF) and GM-CSF remains controversial. There is now substantial data indicating that intravenous or subcutaneous administration of these growth factors at daily doses of 5 to 10 µg/kg produces significant increases in the level of circulating neutrophils (G-CSF), or both neutrophils and monocytes (GM-CSF), without significant clinical toxicity. The use of GM-CSF was found by one group to be associated with fewer episodes of postnatal neutropenia and septicemia (327), but not by another (328). Results of prospective, controlled randomized clinical trials are summarized in Table 46-13 (327,328,329,330,331 and 332). Although some studies have shown a significant decrease in nosocomial infection rates in treated newborn infants as compared to controls, most studies have failed to demonstrate a significant benefit in overall mortality for treated infants. As a result routine administration of growth factors to extremely low (<1,000 g) or very low (<1,500 g) birth-weight infants at risk for neutropenia and sepsis cannot, as yet, be considered standard of care (333,334,335). Definitive answers regarding the role of growth factors, administered either prophylactically or as part of treatment of infection in newborn infants, must await the results of future prospective, randomized controlled trials with adequate numbers of subjects to answer clinically important end-points such as morbidity, mortality, and cost.

TABLE 46-12 HEMATOLOGIC SCORING SYSTEM IN NEONATES WITH SUSPECTED SEPSIS

	Abnormality	Score
Immature: total neutrophil ratio ^a	↑	1
Total neutrophil count ^{a,b}	↑ or ↓	1
I: M ratio	≥0.3	1
Immature PMN count	↑	1
Total WBC count ^c	↑ or ↓	1
Degenerative changes in PMNs ^d	≥3 + ^e	1
Platelet count	<150,000/mm ³	1

^a normal values as defined by Manroe et al (312)
^b if no mature neutrophils are seen on the blood film, score 2 rather than 1 for total PMN count
^c ≤5,000/mm³ or ≥25,000, 30,000 and 21,000/mm³ at birth, 12-24 hours and day 2 onward, respectively
^d quantitated on 0 to 4 scale according to classification by Zipursky et al (310)
^e for vacuolization, toxic granulation, or Döhle bodies
 Abbreviations: 1 = immature; M = mature; PMN = polymorphonuclear leukocytes; WBC white blood cell

Less frequent causes of neutropenia in newborn infants as a result of either decreased production or increased destruction are summarized below.

Rare Causes of Neutropenia

Increased Destruction of Neutrophils

Neonatal Alloimmune Neutropenia.

Neonatal alloimmune neutropenia is the neutrophil counterpart of the erythrocyte disorder hemolytic disease of the newborn. Estimates of the frequency of alloimmune neutropenia vary widely, with figures ranging from one in 500 to one in 2,000 newborn infants (336,337 and 338). Alloimmune neutropenia occurs when a mother becomes sensitized to a foreign antigen present on the neutrophils of her infant and is then stimulated to form specific immunoglobulin G (IgG) antibody directed against this fetal antigen of paternal origin. Transplacental passage of IgG antibody into the fetal circulation results in accelerated destruction of neutrophils in the reticuloendothelial system with consequent neutropenia. Because neutropenia is the direct consequence of transplacentally acquired maternal IgG, the condition is self-limiting, and neutropenia persists for only a few weeks or months. The severity of neutropenia is influenced by the titer and subclass of the maternal IgG neutrophil antibody, the phagocytic activity of the infant's reticuloendothelial system, and the capacity of the infant's marrow to compensate for the shortened survival of antibody-sensitized neutrophils.

Investigation of infants with neonatal alloimmune neutropenia has contributed much to the current knowledge of neutrophil-specific antigens (Table 46-14) (339,340), and the antigen systems most often involved are NA1, NA2, and NB1. In approximately one-half of cases the responsible neutrophil-specific antigen system remains unidentified. Although human leukocyte antigen (HLA) antigens are present on granulocytes, and alloimmunization to these antigens is common in pregnancy, HLA antibodies are not thought to be a significant cause of neutropenia in newborn infants. It appears that maternal HLA antibodies are effectively absorbed by HLA antigens in placental tissue; the antibodies that reach the fetus are neutralized by soluble antigens or weakened by having to react with antigens on various cells distributed in the blood and other tissues. In contrast, neutrophil-specific antibodies cross the placenta without any obstacle and concentrate on the target antigen, which occurs only on the relatively small mass of mature neutrophils.

The clinical course of infants with alloimmune neutropenia is of interest. Neutropenia is usually severe and symptomatic infants may present with delayed separation of the umbilical cord, skin infections, otitis media, or pneumonia within the first two weeks of life. In a review of 19 affected infants reported before 1974, Lalezari and associates (341) found that 12 infants had total absence of circulating neutrophils for at least part of their course. The duration of neutropenia ranged from 2 to 17 weeks, with a mean of 7 weeks. Infections were common, and most were caused by *Staphylococcus aureus*. Two infants died, one with staphylococcal septicemia and the other with pneumonia and possible meningitis. Whilst most infections in newborn infants with neonatal alloimmune neutropenia are

P.1204

mild, affected infants with severe neutropenia are at risk for serious bacterial infections, and therapeutic intervention should be considered. In the past, in addition to intravenous antibiotic therapy for infants with suspected or proven infection, therapies included exchange transfusion to remove passively acquired maternal neutrophil antibodies, transfusion with compatible antigen-negative granulocytes harvested from the mother or known antigen-negative blood donors, corticosteroids, and high-dose intravenous immunoglobulin (HDIVIG).

TABLE 46-13 RANDOMIZED TRIALS OF RECOMBINANT GROWTH FACTORS (rhG-CSF AND rhGM-CSF) IN NEWBORN INFANTS

Study Aim	Investigator	Number of Study Subjects	Characteristics of Study Group	Study Design	Study Outcome
Treatment	Schibler 1998 (329)	20	<ul style="list-style-type: none"> • <3 days old • early onset sepsis • neutropenia 	rhG-CSF i.v. 10 µg/kg/d IV × 3 days vs placebo	<ul style="list-style-type: none"> • no difference in circulating neutrophil counts, morbidity or mortality between treatment and control groups
Prophylaxis	Cairo 1999 (328)	264	<ul style="list-style-type: none"> • birth weight 501–1000 g • age <72 h 	rhGM-CSF 8 µg/kg/d i.v. × 7 days then on alternate days × 10 doses vs placebo	<ul style="list-style-type: none"> • no difference in the incidence of nosocomial infections or morbidity/mortality between treatment and control groups
Prophylaxis	Carr 1999 (327)	75	<ul style="list-style-type: none"> • birth weight 500–1500 g • postnatal age <72h • absolute neutrophil counts ($\times 10^9/L$) 	rhGM-CSF sq 10 µg/kg/d × 5 days vs no rhGM-CSF	<ul style="list-style-type: none"> • treated infants did not develop post-natal neutropenia and had fewer episodes of septicemia (11/36 vs 18/39, NS) than did controls

Treatment	Bedford-Russel 2001 (330)	28	<ul style="list-style-type: none"> • birth weight ≥ 500-≤ 1500 g • clinical signs of sepsis • ANC $< 5 \times 10^9/L$ • postnatal age ≤ 28 d 	rhG-CSF i.v. $10 \mu\text{g}/\text{kg}/\text{d} \times 14$ days or until discontinuation of antibiotics vs placebo	<ul style="list-style-type: none"> • significantly faster increase in ANC in rhG-CSF group vs controls • significant decrease in mortality at 6 and 12 months in study group • decreased but not significantly different neutrophil counts, duration of mechanical ventilation, duration of stay in NICU, death during first 42 d

Abbreviations: GA = gestational age; g = grams; μg = micrograms; kg = kilogram; d = days; wk = week; h = hour; IV = intravenous; subcutaneous = sq; rhGM-CSF = recombinant human granulocyte macrophage colony-stimulating factor; rhG-CSF = recombinant human granulocyte colony-stimulating factor; ANC = absolute neutrophil count, NS = not significant.

There is little evidence that corticosteroids are of value in this condition. The response to intravenous IgG therapy is variable and of the order of 50% (342). The preferred treatment for neonates with severe alloimmune neutropenia is administration of the growth factor, rhG-CSF. The dose recommended is 10 µg/kg per day given by intravenous or subcutaneous injection for 3 days with titration of additional doses to keep the blood neutrophil count greater than 1000/µL (338). The response to rhG-CSF is usually rapid and evident within 24 to 48 hours; generally 2 to 3 weeks treatment is sufficient. It is important that infants be monitored for recurrence of neutropenia once rhG-CSF therapy is stopped (343). For infants who fail to respond to initial therapy with rhG-CSF, a trial of IVIG (1 g/kg/day for 2 to 5 days) alone or in combination with rhG-CSF should be considered. The use of exchange transfusion or transfusion with compatible antigen-negative neutrophils should be reserved for those rare infants who

P.1205

have failed an adequate trial of HDIVIG (1 to 2 g/kg/day for 2 to 5 days) and rhG-CSF (10 µg/kg/day or higher doses), who are clinically extremely ill and who are not responding to broad-spectrum intravenous antibiotic therapy. As the condition may recur in subsequent pregnancies we would recommend testing the next baby's neutrophil counts immediately after birth and at 1 week of age. However, asymptomatic babies may not need treatment.

TABLE 46-14 HUMAN NEUTROPHIL ANTIGENS (HNA)

Modified from Bux J. Molecular genetics of granulocyte polymorphisms. *Vox Sang* 2000;78 [Suppl 2]:125–130, with permission.

Rare cases of alloimmune neutropenia have been reported in newborn infants following transfusion of blood components or IVIG. In the case reported by Wallis and associates (344) neutropenia occurred in a newborn infant following a RBC transfusion; pathologic antibodies to the neutrophil specific antigen, HNA1b, were subsequently detected in the donor plasma of the transfused unit. A similar mechanism was speculated in the cause of neutropenia in newborn infants following infusion of IVIG for neonatal thrombocytopenia (345).

Neonatal Autoimmune Neutropenia.

Transient neutropenia in the neonatal period may reflect transfer of IgG neutrophil antibodies from mother to fetus during pregnancy (346). In these cases, the maternal serum contains the pathologic neutrophil antibodies, and the mother may be neutropenic and may have a history of an autoimmune disorder, such as systemic lupus erythematosus (347,348). Most children are asymptomatic and the neutropenia resolves spontaneously by the 3rd to 4th months of life.

Autoimmune Neutropenia of Infancy.

Autoimmune neutropenia of infancy typically occurs in children between the ages of 3 to 30 months (348,349). The mechanism involves production of autoreactive antibodies usually against antigens of the NA1 or NA2 antigens on the Fc γ receptor IIIb (350). Rarely it can be seen in the neonatal period (351). In such cases an underlying immunodeficiency should be ruled out. The disorder is self-limiting, and only 5 to 10% of the children require treatment with G-CSF or IVIG (342).

Decreased Production of Neutrophils.

Infants of Hypertensive Women.

Neutropenia can be seen in infants born to mothers with PIH. The mechanism is reduced production as a result of an inhibitor interfering with normal granulopoiesis (352). Neutropenia resolves spontaneously in 3 to 5 days.

Kostmann Syndrome.

Congenital neutropenia is severe in patients with Kostmann syndrome; cases are reported in which there was striking neutropenia (usually $<0.2 \times 10^9/L$) from the first day of life (353). Bone marrow smears typically reveal normal cellularity, with a maturation arrest at the promyelocyte-myelocyte level. Inheritance is autosomal dominant, and is associated with activating mutations in one copy of the *ELA2* gene (354), causing abnormally activated neutrophil elastase with exclusive membrane localization (355) and increased apoptosis of myeloid precursors (356). Cases associated with mutation in either the *ELA-2* repressor gene *GF11* (357) or the *WASP* gene (358) were also described. Severe bacterial infections occur early in life, in 50% of patients within the first month of life, and the disorder is usually fatal. Treatment with G-CSF increases neutrophil counts and prevents infection in 90% of cases (359). In patients non responsive to G-CSF alone addition of low dose prednisone to the G-CSF regimen (360), or hematopoietic stem cell transplantation (361) may be successful.

Cyclic Neutropenia.

Cyclic neutropenia is a sporadic or familial disorder characterized by a regular, repetitive decrease in peripheral blood neutrophils at approximately 21-day intervals (362,363). It is caused by *ELA2* gene mutations at the active site of neutrophil elastase causing defective membrane localization of the enzyme (355) and a cycling increase in apoptosis of myeloid precursors (356). Patients may develop severe infection and mouth sores during the neutrophil nadir leading to chronic gingivitis. Diagnosis requires the demonstration of regular neutrophil cycles and thus is usually made after the neonatal period. Treatment with G-CSF improves symptoms in most patients.

Glycogen Storage Disease Type Ib.

Patients with this autosomal recessive disorder have classical features of glycogen storage disease type Ia, which includes hepatomegaly and metabolic crisis with hypoglycemia and lactic acidosis. Additionally, they have neutropenia and impaired neutrophil chemotaxis and respiratory burst. Granulocytes are reduced and dysfunctional probably because they are apoptotic with translocation and activation of the Bax proapoptotic protein (364). The genetic defect is different from glycogen storage disease type Ia, and resides in the gene encoded for the glucose 6-phosphate translocase enzyme. Neutropenia may be severe and cause serious infection and inflammatory bowel disease. Most patients require G-CSF, which successfully increases the neutrophil counts, improves function, and prevents infection (365).

Barth Syndrome.

Barth syndrome is an X linked-recessive disorder with dilated cardiomyopathy, skeletal myopathy,

P.1206

3-methylglutaconic aciduria, and neutropenia (366). The disorder is associated with the *TAZ* gene mutation, which encodes 10 different proteins called "taffazins" of still unknown function (367). Neutropenia varies from mild to very severe. The mechanism for the neutropenia is unclear. Marrow specimens are of normal cellularity but with maturation arrest at the myeloid stage. Most patients do not require treatment for their neutropenia. However, in our experience, in cases with severe bacterial infections, G-CSF can be given with a very good response.

Neutropenia Associated with Immunodeficiency Syndromes.

Neutropenia may occur in association with immunodeficiency syndromes.

Therefore, it is imperative to assess lymphopoiesis in patients with neutropenia, particularly as some of these disorders need urgent change in management. Immune abnormalities, typical features and inheritance patterns that help identify the cause of the neutropenia and the molecular defects are summarized in Table 46-15.

Agammaglobulinemia.

Approximately one-third of patients with agammaglobulinemia develop neutropenia in the first year of life during periods of infection. Typically patients with agammaglobulinemia have low or absent IgG production; however, the passage of IgG from the mother to the fetus may result in detectable IgG in the first months of life. In contrast, detection of IgM, which does not cross the placenta, is a reliable indicator of B cell function even at an early age. In most cases the disorder is caused by a defect in the expression or function of the Bruton tyrosine kinase (*BTK*) gene in B cells. In recent years, mutations in other genes responsible for B cell development have been identified as a cause of a similar phenotype (368). These genes are important for B lymphocyte development, however because B cells normally constitute only 5% to 20% of total lymphocytes, lymphopenia is usually not evident.

TABLE 46-15 NEUTROPENIA ASSOCIATED WITH IMMUNODEFICIENCIES

Disorder	Typical Immune Abnormalities	Associated Features	Inheritance Pattern	Genetic Defect
Agammaglobulinemia	Low/Absent IgG	None	X-linked; autosomal recessive	<i>BTK</i>
Common Variable Immunodeficiency	Low IgG	None	Variable	Unknown
IgA deficiency	Low IgA	None	Autosomal recessive/dominant	Unknown
Hyper IgM syndrome	High IgM. Low/normal IgG	Liver disease, ectodermal dysplasia	X-linked; autosomal recessive	<i>CD40 ligand, AID, CD40, NEMO-IKK</i>
Wiskott-Aldrich syndrome	Variable T/B cell counts	Eczema, small platelets thrombocytopenia	X-linked	<i>WASP</i>
Cartilage-hair hypoplasia	Variable T/B cell counts	Dwarfism, fine hair	Autosomal recessive	<i>RMRP</i>
Shwachman-Diamond syndrome	Variable T/B cell counts	Pancreatic insufficiency	Autosomal recessive	<i>SBDS</i>
Griscelli disease	T cell	Albinism; HLH	Autosomal recessive	<i>RAB27a</i>
Autoimmune lymphoproliferative syndrome (ALPS)	Variable T/B cell count	Hepatosplenomegaly, lymphadenopathy	Autosomal dominant	<i>CD95, CD95 ligand, caspase 8, caspase 10</i>

Chediak-Higashi syndrome	NK cells	Bleeding, albinism, cytoplasmic granules	Autosomal recessive	<i>LYST</i>
HLH	T cells	Hepatosplenomegaly, lymphadenopathy, fever	Variable	<i>Perforin, IL- 2R gamma, PNP, RAB27a</i>
WHIM syndrome	Low IgG	Warts, myelokathexis	Autosomal dominant	<i>CXCR4</i>
Dyskeratosis congenita	Variable T/B cell count	Skin pigmentation, nail dystrophy, dental abnormalities, pancytopenia	X-linked; autosomal dominant/ recessive	<i>DKCI, TERC</i>
Reticular dysgenesis	SCID	None	Autosomal recessive	Unknown

Abbreviations: HLH = hemophagocytic lymphohistocytosis; NK = natural killer cells; SCID = severe combined immunodeficiency

Hyper IgM Syndrome.

Neutropenia is often observed in patients with the hyper IgM (HIGM) syndrome in which defects in the immunoglobulin class switch recombination and somatic mutation prevent generation of an appropriate antibody repertoire. Typically IgM levels are high with low or near normal IgG and IgA levels. Recently, mutations in several genes have been identified as causing the hyper IgM syndrome. HIGM type 1 is inherited as an X linked recessive trait as a result of abnormal T cell expression of the CD40 ligand. Affected males suffer from recurrent bacterial and

P.1207

opportunistic infections (e.g., pneumocystis carinii pneumonia and watery diarrhea as a result of cryptosporidium infection) from a young age. Severe liver disease is also a feature of the disorder. Patients with the autosomal recessive HIGM type 2 disorder present with enlarged tonsils and lymph nodes, sinopulmonary infections but without opportunistic infections. HIGM type 2 is caused by mutations in the activation-induced cytosine deaminase gene. Patients with defects in the B cell receptor CD40 have been recently described and are designated HIGM type 3; their clinical condition is similar to type 1 cases. A fourth form of HIGM affects males and is characterized by the association of hypogammaglobulinemia with hypohidrotic ectodermal dysplasia. These conditions are caused by mutations of the gene in *NEMO/IKK* (γ), which is the same gene responsible for incontinentia pigmenta in heterozygous females (369).

Wiskott-Aldrich Syndrome.

Up to one-quarter of males with Wiskott-Aldrich syndrome manifest neutropenia (370). Characteristic features of the disorder include eczema and thrombocytopenia with small (pin-point) platelets on a peripheral blood smear (371). The identification of the gene responsible for the Wiskott-Aldrich Syndrome (*WASP*) facilitates the diagnosis especially in cases without typical features, and has revealed that in some instances neutropenia may be the only symptom (372).

Cartilage Hair Hypoplasia.

Severe and persistent neutropenia can occur in cartilage hair-hypoplasia (CHH). The disorder is characterized fine hair, short limbed dwarfism, metaphyseal dysplasia (not often evident in the first year of life) and T cell abnormalities. This autosomal recessive condition is caused by mutations in the *RMRP* gene (373). Although common in the Finish and Amish, the disorder has been reported in other populations (374). In those patients with severe immunodeficiency, hematopoietic stem cell transplantation can correct the immune dysfunction.

Another familial disease involving bone formation, neutropenia and

immunodeficiency was recently described (375). In affected subjects severe congenital neutropenia and hypogammaglobulinemia were associated with infantile osteoporosis with multiple bone fractures.

Chediak-Higashi Syndrome.

Chediak-Higashi syndrome is an autosomal recessive disorder caused by mutations in the lysosomal trafficking regulator gene. It is characterized by variable degrees of oculocutaneous albinism, easy bruising and bleeding as a result of platelet dysfunction. Patients suffer from recurrent infections as a result of neutropenia, impaired chemotaxis and bactericidal activity and abnormal natural killer (NK) cell function. The hallmark of the disease is the presence of large cytoplasmic granules in circulating granulocytes (376).

Griscelli Disease.

Patients with Griscelli disease have some features similar to those with the Chediak-Higashi syndrome including partial albinism, frequent episodes of fever and pyogenic infections, neutropenia and thrombocytopenia (377). Their immune abnormalities may lead to uncontrolled T lymphocyte and macrophage activation syndrome. However, affected patients lack abnormal cytoplasmic granules. The disorder is caused by mutations in the *RAB27A* gene (378).

Hemophagocytic Lymphohistiocytosis.

Hemophagocytic lymphohistiocytosis (HLH) is characterized by pancytopenia, fever, hepatosplenomegaly, neurologic findings, liver and coagulation abnormalities and elevated triglyceride and ferritin levels. Mutation in several genes important for immune function have been found among patients with familial HLH (379).

Autoimmune Lymphoproliferative Syndrome.

Neutropenia is a frequent finding in patients with autoimmune lymphoproliferative syndrome (ALPS). In this disorder, neutropenia is often associated with other autoimmune disorders. In some patients defects in genes associated with lymphocyte apoptosis have been identified (380).

WHIM Syndrome.

Patients with autosomal dominant WHIM (Warts, Hypogammaglobulinemia, Infections, and Myelokathexis) syndrome may present in the first months of life. The neutropenia results from a defective release of marrow cells into the peripheral blood. Fever, stress and possibly G-CSF administration may temporarily

overcome the confinement of neutrophils to the marrow (381). Recently, mutations in the chemokine receptor gene *CXCR4* were identified as the cause of the WHIM syndrome (382).

Reticular Dysgenesis.

Reticular dysgenesis, the cause of which is still unknown, is one of the rarest and most extreme forms of neutropenia associated with severe combined immunodeficiency (SCID). It is characterized by congenital agranulocytosis, lymphopenia and lymphoid and thymic hypoplasia (383). Neutrophil counts usually do not improve with administration of G-CSF and the patients often die within the first weeks of life unless they receive hematopoietic stem cell transplantation (384).

Congenital Leukemia in Infants

Leukemia in infants is a rare disorder (385,386). Infants show a larger proportion of the predominant form of congenital acute myeloid leukemia, commonly either monoblastic or myelomonocytic leukemia; whereas leukemia in older children is typically lymphoblastic. The clinical presentation is defined by a high white blood cell count, hepatosplenomegaly and in many cases central nervous system involvement. Skin involvement is common in myeloid but not in lymphoid leukemia.

In 60% to 70% of cases of infants with acute lymphoblastic leukemia (ALL) the leukemic blasts harbor a chromosomal translocation, internal duplication or deletion involving the mixed lineage leukemia (*MLL*) gene (also called *ALL1* or *HRX*) encoded at chromosome band

P.1208

11q23 (387). Among the numerous translocations involving *MLL*, t(4;11) is most frequent in infant ALL (388). Despite the high intensity of multiagent chemotherapy protocols developed for infant ALL, the prognosis remains unfavorable and long-term survival is achieved in only 25% to 50% of cases (386). Particularly poor outcomes are associated with an age of less than 6 months at diagnosis or the presence of *MLL* gene rearrangement. Hematopoietic stem cell transplantation has not been shown to improve the dismal outcome of infants with ALL and t(4;11) (388). In contrast to ALL, young age and the presence of 11q23/*MLL* abnormalities have no clear adverse prognostic value in infant AML (386). A megakaryoblastic phenotype of the blasts and the t(1;22) (389,390,391,392) are thought to be associated with a less favorable prognosis (393). Treatment outcomes in infants with AML do not appear to be different from older children, in whom event-free survival rates between 40% and 50% can be achieved (211).

The study of newborns has significantly advanced our understanding of leukemia. The prenatal origin of leukemia became evident from studies showing that ALL may arise in monozygotic twins from a prenatally shared population of leukemic blasts after a variable latency period (394). Back tracking experiments demonstrate that specific translocations present in the leukemic blasts of childhood ALL such as the t(12;21), which results in the expression of the TEL-AML1 fusion protein, are in fact already detectable at birth in neonatal blood spots of approximately 75% of cases (395).

Transient leukemia (transient myeloproliferative disorder) in infants with Down syndrome

Children with Down syndrome (constitutional trisomy 21) have a 10- to 20-fold increased overall risk of developing ALL or acute myeloid leukemia (AML) (396). Acute megakaryoblastic leukemia, a form of AML, is estimated to occur with a 500 fold increased frequency (397,398). Contrary to previously held opinions chemotherapy of AML in children with Down syndrome results in superior outcomes with the probability of event-free survival exceeding 70% when compared to the general pediatric population (399,400). This favorable response has at least in part been attributed to the greater sensitivity of leukemic blasts derived from individuals with Down syndrome to chemotherapeutic agents such as cytosine arabinoside (401). Children with Down syndrome and ALL have outcomes comparable to their general pediatric population when they are treated appropriately despite their propensity for complications such as mucositis and pulmonary infections (402).

Unique to individuals with Down syndrome, a transient myeloproliferative syndrome (TMD), also transient leukemia (TL), is observed in at least 10% of newborns (reviewed in 403). Classically these infants are well and show in their peripheral blood circulating blasts that are indistinguishable from those of acute megakaryoblastic leukemia. The number of blasts may exceed 100,000/mm³ or may be barely detectable. Some infants have hepatosplenomegaly or skin infiltrates. Remarkably, the blasts of TL/TMD in Down syndrome disappear spontaneously in the majority of cases in the first 3 to 4 months of life. After this spontaneous resolution of the TMD/TL, however, approximately 20% of these children go on to develop acute megakaryoblastic leukemia later in life (403). Of note, TL/TMD may also develop in phenotypically normal appearing newborn infants with mosaicism for trisomy 21. At present therapeutic intervention is reserved for the approximately 15% to 20% of cases of TMD/TL who develop life-threatening complications such as hyperleukocytosis, pericardial or pleural effusions, and acute liver failure (404). Progressive liver failure as a result of blast infiltration or fibrosis is frequently fatal (405) despite therapeutic reduction of the circulating and infiltrating blasts.

Inactivating mutations within the gene encoding the hematopoietic transcription factor GATA1 were recently shown to be specific for the blasts of acute megakaryoblastic leukemia in Down syndrome (406). These mutations are also present in the blasts of TL/TMD of Down syndrome (407,408,409,410,411) supporting a pathogenic concept in which prenatal mutations of GATA1 give rise to TL/TMD (412,413). Second, as yet undetermined, events eventually result in the transformation of a clone of TMD/TL blasts to acute megakaryoblastic leukemia (408,414).

Management of newborns with Down syndrome should include a complete blood count with a careful review of the blood smear. Immunophenotyping and cytogenetic evaluation of any blast population is recommended. Although observation is sufficient for the majority of newborns with Down syndrome and TL/TMD, neonatologists need to be aware of the potential complications and the availability of chemotherapeutic intervention (415).

Juvenile Myelomonocytic Leukemia

Juvenile myelomonocytic leukemia (JMML), previously referred to as juvenile chronic myelogenous leukemia (JCML) or chronic myelomonocytic leukemia (CMML) is a rare myeloproliferative disorder in the neonatal period and early infancy (416). Suggestive clinical features include hepatosplenomegaly, lymphadenopathy, pallor, fever and skin rash (417,418). The peripheral blood shows leukocytosis with immature myeloid cells and monocytosis. Fetal hemoglobin may be elevated. Clonal chromosomal abnormalities, for example monosomy 7, support the diagnosis. The Philadelphia chromosome and BCR-ABL fusion transcript, which are typical of adult chronic myelogenous leukemia are absent in JMML. *In vitro* bone marrow cultures show growth factor-independent growth (419) and hypersensitivity to granulocyte macrophage-colony stimulating factor (420). JMML is associated with neurofibromatosis (417) and Noonan syndrome (421) as a result of germ line mutations of the *NF1* and *PTPN11* genes respectively. Somatic mutations of *NF1* (422) and *PTPN11* (421) have also been found in nonsyndromic cases of JMML. Clinical responses can be introduced with 13-cis-retinoic

P.1209

acid and novel agents such as farnesyltransferase inhibitors are being evaluated (423). However, at present hematopoietic stem cell transplantation is the only curative therapy for JMML.

Neutrophilia and Neonatal Leukemoid Reactions

The incidence of leukemoid reactions with leukocyte counts more than $50 \times 10^9/L$ among neonates in the NICU varies between 1.3 to 15% (424,425,426 and 427). It is most commonly seen in the first week of life. The most common causes

include administration of betamethasone antenatally, infection, and transient leukemoid reactions of Down syndrome. However, Rastogi and associates (425) did not find concurrent pathology in nine cases with leukemoid reaction in a retrospective study of 60 preterm infants. The mechanism involves accelerated neutrophil production. Serum cytokine measurement did not show a consistent increase in G-CSF or GM-CSF, thus, marrow paracrine secretion or other mechanisms are possible. The leukemoid reaction resolves within several days to weeks, and the main clinical significance is the possibility of an underlying pathology. Rastogi and associates (425) noted that the neonates who had been able to mount a leukemoid response had a better chance of survival than those who did not. Recently, an association has been reported between leukemoid reaction with leukocyte counts more than $50 \times 10^9/L$ and the development of bronchopulmonary dysplasia and chronic lung disease (427). Congenital infections such as CMV disease, toxoplasmosis, and syphilis may manifest as hepatosplenomegaly with a pronounced leukemoid response in the peripheral blood. Severe bacterial infections also may be associated with a leukemoid blood picture.

Evaluation of the Infant with Neutropenia

The unexpected finding of neutropenia in a newborn infant should prompt consideration of bacterial infection. A peripheral blood smear should be carefully examined for Döhle bodies, vacuolization, and toxic granulation, and the band to segmented neutrophil ratio should be determined. In infants with some combination of neutropenia, an increased band to segmented neutrophil ratio, and morphology suggestive of bacterial infection, empirical broad-spectrum antibiotic therapy should be started until the results of cultures are known. If there is no clinical or laboratory evidence of infection, other causes of neutropenia must be considered; however, it is still prudent to utilize broad-spectrum antibiotic coverage until it is clear from cultures and the infant's clinical course that sepsis is not the etiology of the neutropenia. As noted, preeclampsia and/or hypertension in the mother is a common cause of neutropenia and should be considered in the differential diagnosis. A maternal history, including a drug history, and a maternal neutrophil count should be obtained to exclude maternal illness (e.g., systemic lupus erythematosus) as a cause of neutropenia. The physician should obtain a careful family history asking specifically about family members with documented neutropenia or a history of severe or unusual infections or early neonatal deaths. Early neonatal deaths may be caused by overwhelming infection secondary to neutropenia before any diagnosis is made. This information may provide an important clue to the possibility of an inherited neutropenic syndrome (e.g. Kostmann syndrome). Physical examination of affected infants suggests or excludes hypersplenism and congenital viral infections as the likely cause of neutropenia. In well infants with no apparent cause for the neutropenic state, neonatal alloimmune neutropenia should be considered. In such cases, a search

should be made for neutrophil antibodies in a sample of maternal and/or baby's serum and neutrophil-specific antigen typing of the biologic parents of the affected neonate should be requested. These tests are best performed in neutrophil reference laboratories and require inclusion of the granulocyte agglutination test, the granulocyte immunofluorescence test, and the monoclonal antibody immobilization of granulocyte antigens assay for optimal detection of known antibodies (338,341). Ideally samples are obtained from the affected neonate (or biologic father acting as a surrogate) and the mother. It is important to stress that treatment of the infant should not be delayed whilst confirmatory serologic studies are in progress. Finally, a bone marrow aspirate and biopsy should be considered if neutropenia is severe ($<500/\mu\text{L}$), unresponsive to medical therapy, and persists for longer than one week.

Lymphopenia

Lymphocytes account for approximately 30% of the circulating white blood cells in newborn infants. Lymphopenia should always be considered when the total lymphocyte count is below the lower 5th percentile for age and particularly if the absolute lymphocyte count is less than $1,500/\mu\text{L}$ (428). Lymphopenia may occur in a number of immunodeficiency diseases, during infections or as part of an autoimmune process. Disorders in which lymphopenia is often diagnosed with neutropenia are detailed in the section neutropenia associated with immunodeficiency although those in which isolated lymphopenia is the hallmark of the disease are reviewed below. Of importance in the investigation of these disorders is the assessment of lymphocyte subsets and function. The values must be compared to age adjusted normal ranges (429). Usually in the newborn, 35% to 64% of lymphocytes express CD4 and are designated as "helper" T lymphocytes and 12% to 18% of lymphocytes express CD8 which is a marker for "suppressor/cytotoxic" T-lymphocytes. CD19 (a B cell marker) is found on 6% to 32% of lymphocytes and CD16/56 which designate natural killer cells is detected on 4% to 18% of cells. Typical laboratory features that may help to clarify the etiology of lymphopenia in newborn infants and the molecular defects are summarized in Table 46-16.

TABLE 46-16 LYMPHOPENIA IN THE NEONATAL PERIOD

Disorder	Typical Immune Abnormalities	Associated Features	Inheritance	Genetic Defect
SCID, gamma, Common chain deficiency type	SCID (T-, NK-, B+)	None	X-linked recessive	IL-2R <i>gamma</i>
SCID, Jak-3 deficiency type	SCID (T-, NK-, B+)	None	Autosomal recessive	<i>JAK-3</i>
SCID, IL-7 R alpha deficiency type	SCID (T-, NK+, B +/-)	None	Autosomal recessive	IL-7R <i>alpha</i>
SCID, CD3 TCR deficiency type	SCID (T-, NK+, B +)	None	Autosomal recessive	CD3 <i>epsilon/gamma/delta</i>
SCID, CD45 deficiency type	SCID (T-, NK+, B +)	None	Autosomal recessive	<i>CD45</i>
SCID, ZAP-70 deficiency type	SCID (CD8-, NK+, B+)	None	Autosomal recessive	<i>ZAP-70</i>
Di-George syndrome	Variable (T+/-, NK +, B+)	Hypocalcemia, cardiac abnormalities	Autosomal dominant, Autosomal recessive	22q11.2 chromosome deletion
SCID, Omenn's type	SCID (T+/-, NK+, B-)	Erythroderma, splenomegaly, lymphadenopathy	Autosomal recessive	<i>RAG1, RAG2, Artemis</i>
SCID, ADA deficiency type	SCID (T-, NK-, B-)	Bone dysplasia	Autosomal recessive	<i>ADA</i>
AT	Variable T/B cells	Ataxia, increased AFP, telangiectasia	Autosomal recessive	<i>ATM</i>
Nijmegen syndrome	Variable T/B cells	Microcephaly	Autosomal recessive	<i>nibrin</i>
Hyper-IgM syndrome	High IgM, low/normal IgG	Liver disease, ectodermal dysplasia	X-linked recessive, Autosomal recessive	<i>CD40 ligand, AID, CD40, NEMO-IKK</i>
Wiskott-Aldrich syndrome	Variable T/B cells	Eczema, thrombocytopenia, small platelets	X-linked recessive	<i>WAS</i>

Abbreviations: SCID = Severe combined immunodeficiency syndrome; AT = Ataxia telangiectasia; ADA = Adenosine deaminase deficiency; AFP = Alpha fetoprotein; NK = natural killer

Severe Combined Immunodeficiency Syndrome

One disorder, severe combined immunodeficiency (SCID) deserves special mention. This rare but serious disorder carries a grave prognosis unless recognized early in life and treated promptly. The most frequently identified cause of SCID is abnormal expression or function of the gamma (also known as common) chain of the interleukin (IL)-2 receptor. Because the gene is located on the X chromosome only males are affected and they often present in the first months of life with life-threatening infections and lymphopenia. T and NK cell numbers and/or function are significantly decreased (430). B cell numbers and immunoglobulin levels can be reduced, normal, or elevated. The thymus is often undetected by chest radiograph or ultrasound, and lymphatic tissue such as lymph nodes or tonsils are absent. The only definitive treatment is bone marrow transplantation. Recently replacing the abnormal protein by viral mediated gene therapy has been achieved. If newborn infants with SCID require blood transfusions they should be given only irradiated blood products so that graft versus host disease does not develop.

Mutations in *Jak-3*, which is a signaling molecule downstream of the IL-2 receptor, may cause a similar phenotype both in males and females (431). Defects in another lymphocyte receptor, the alpha chain of the IL-7 receptor, can also result in SCID with low T cell numbers, variable B cell numbers, but normal NK activity (432). Mutations in several components of the *CD3* complex expressed on T cells result in abnormal T cell development with normal B and NK cell function (433). Similarly, mutations in the transmembrane protein tyrosine phosphase (*CD45*) result in diminished T cell number and function and normal B cell number; however, patients also have decreased serum immunoglobulin levels (434). Mutations in another T cell signaling molecule, *ZAP-70* affect primarily CD8 development (435).

Abnormal adenosine deaminase (ADA) enzyme activity has been observed in approximately 15% of patients with SCID. Infants with ADA deficiency have a more profound lymphopenia than do children with other types of SCID, because the accumulation of ADA substrates or their metabolites is toxic to T, B, and NK cells. Patients with ADA deficiency may have chondroosseous dysplasia, which is evidenced by the presence of multiple skeletal abnormalities on radiographic examination, including flaring of the costochondral junctions. Enzyme replacement therapy with polyethylene glycol-modified bovine ADA or bone marrow transplantation has resulted in some clinical and immunologic improvement, and recently, successful correction of the defect by therapy has been reported (436).

P.1211

Other Disorders

In a few of the immunodeficiency disorders associated with lymphopenia, there are clinical features that may aid in the diagnosis. Di-George syndrome, also referred to as velo-cardio-facial syndrome, is often caused by microdeletion in the 22q11.2 region. It occurs with an estimated frequency of 1 in 4,000 and is accompanied by reduced T cell numbers in more than 50% of affected patients. In the minority of subjects, complete absence of T cells was reported and bone marrow or thymus transplantation were attempted (437). The commonly associated hypocalcemia, cardiac defects and typical facial dysmorphism assist in the diagnosis.

Omenn's syndrome, which is often caused by mutations in the recombinant activating genes (*RAG*), may present with erythroderma, hepatosplenomegaly, lymphadenopathy and eosinophilia. Although some *RAG* mutations result in severely reduced B and T cell numbers, several missense mutations in the gene allow limited T cell development. Recently, abnormal function of another gene involved in recombination, *Artemis*, was identified as leading to an early arrest of both B and T cell maturation (438,439).

Patients with ataxia-telangiectasia (AT) often present in the 3rd to 4th year of life with cerebella ataxia followed by the appearance of cutaneous telangiectasia, and variable, humoral and cellular immunodeficiencies. A minority of patients may present in the first year of life with increased susceptibility to infection and lymphopenia (440). Elevated serum α fetoprotein is characteristic and assists in the diagnosis that should be made as early as possible to minimize any exposure to radiation. Ataxia-telangiectasia is caused by defects in the *ATM* gene. Patients with Nijmegen breakage syndrome caused by defects in the *NBS1* gene also have an increased sensitivity to ionizing radiation. Similar to patients with ataxia-telangiectasia, they too may present very early in life with lymphopenia. However, those with Nijmegen breakage syndrome often have microcephaly and normal serum α fetoprotein levels which allows a distinction between to two diseases (441).

Other immunodeficiencies, such as hyper-IgM syndrome, Wiskott-Aldrich syndrome, cartilage hair hypoplasia, Schwachman-Diamond syndrome, dyskeratosis congenita and reticular dysgenesis which may cause lymphopenia and neutropenia are reviewed elsewhere in this chapter.

Eosinophilia

An elevated eosinophil count is common in premature infants. Normal values for a group of healthy premature infants studied by us are illustrated in Fig. 46-19. The upper limit of normal (95th percentile) for absolute eosinophil counts in a group of 167 full-term infants was 1,016/ μ L, 1,323/ μ L, and 1,372/ μ L at 0, 1, and 5 days, respectively. The corresponding mean values were 475/ μ L, 496/ μ L, and 540/ μ L. In a prospective study of 45 premature infants, Bhat et al (442) found the incidence of eosinophilia to be 75.5%. Similar results have been reported by other investigators (443,444,445). In Bhat's study, an absolute eosinophil count of more than 700/ μ L was considered to be abnormal. The frequency and severity of eosinophilia were greatest in the subgroup of infants younger than 30 weeks gestational age. There was a significant association between the development of eosinophilia and number of blood transfusions administered, use of parenteral nutrition, and duration of intubation. The causative nature of these associations is uncertain because these features are common in ill, premature infants. Prolonged processing of antigens at the cellular level is required for the development of eosinophilia, and the investigators suggested that eosinophilia in the premature infant may be a physiological process needed to handle foreign antigens. The fact that eosinophilia is more frequent in premature infants than in term infants may reflect immaturity of barrier mechanisms in the gastrointestinal tract, respiratory tract, or both.

Figure 46-19 Eosinophil counts in 142 healthy, premature infants. Data at the first point, day 0 are cord blood values. Subsequent points represent data from capillary blood samples on 1, 5, 7, 14, 28, 35, and 42 days of life. The heavy line represents the mean of each point. The shaded area includes 95% of the infants studied, excluding the top and bottom 2.5% of the group.

Pancytopenia

Shwachman-Diamond Syndrome

Shwachman-Diamond syndrome is a multisystemic autosomal recessive disease characterized by varying degrees of bone marrow failure and cytopenia, most commonly neutropenia (446). Exocrine pancreatic dysfunction, metaphyseal dysplasia, neutropenia and various B, T and natural killer (NK) cell abnormalities characterize Shwachman Diamond Syndrome (447). Patients may present in the neonatal period with failure to thrive, a small chest with thoracic dystrophy or infection as a result of neutropenia. The bone marrow may show hypocellularity with maturation arrest of myeloid elements, but from our experience it may also appear completely normal in the first several years of life. The cytopenia may progress to pancytopenia and severe aplasia as a result of increased apoptosis through the Fas pathway (448) and abnormal marrow stromal function. The syndrome is associated with the *SBDS* gene mutation (449). Patients with SDS are susceptible to recurrent viral, bacterial and fungal infections. Overwhelming sepsis is a well recognized fatal complication

P.1212

of the disorder particularly early in life (447). Transfusions or cytokine therapy may be required to treat the cytopenia in addition to pancreatic replacement enzymes; however, the only curative treatment is allogeneic hematopoietic stem cell transplantation.

Fanconi Anemia

Fanconi's anemia is an inherited marrow failure syndrome with a defect in DNA repair and accelerated apoptosis. At least 11 different genes are associated with the disease (*FANCA, B, C, D1 [BRCA2], D2, E, F, G, I, J, L*); nine of them were identified as of June 2004 (450). Some children present with only hematological abnormalities, although others have multiple congenital anomalies including thumbs, kidneys, cardiac and skin defects. Patients may have characteristic facies. Diagnosis is usually made at the age of 4 to 8 years, when children develop cytopenia, macrocytosis, and a high fetal hemoglobin. However, early diagnosis is possible if the characteristic nonhematological manifestations are evident at birth. Further, approximately 4% of the children have cytopenia in the neonatal period (451) and some develop congenital tumors (452). The chromosomal fragility test is positive in almost all patients. Treatment of the cytopenia includes transfusion, cytokines and androgens, but only allogeneic hematopoietic stem cell transplantation is curative.

Dyskeratosis Congenita

Typically patients have cytopenia, macrocytosis, high fetal hemoglobin, mucous membrane leukoplakia, dystrophic nails, reticulated skin pigmentation and increased lacrimation as a result of atresia of the lacrimal ducts which appear in early or late childhood (453). From our experience and others (453) severe cases can present in the neonatal period with thrombocytopenia, immunodeficiency and varying CNS malformations. In some of these patients T cell abnormalities and opportunistic infection have been reported (454,455). At least 3 genes are associated with the

diseases: *DKC1* (X-linked recessive), *hTR* (autosomal dominant) (456) and an unknown autosomal recessive gene. The gene products are involved in telomere maintenance (456). Treatment of the hematological complications include transfusions and cytokines, but only allogeneic hematopoietic stem cell transplantation is curative (453,457).

Congenital Amegakaryocytic Thrombocytopenia

Children with this disorder present with thrombocytopenia at birth, which gradually progresses to pancytopenia. Initially the bone marrow shows a paucity of megakaryocytes, but later on varying degrees of decreased cellularity develops. Nonhematological manifestations can occur, but are not frequent. This disorder is associated with mutations in the gene (*C-mpl*) encoding for the thrombopoietin receptor (458,459). The only curative treatment is allogeneic hematopoietic stem cell transplantation from a sibling (460) or an unrelated donor (461).

Cytopenia Related to Metabolic Disorders

Neutropenia can be seen in inherited defects in the metabolism of branched amino acids such as propionic aciduria and methylmalonic aciduria. The neutropenia is probably related to a toxic effect of specific metabolites whose serum levels are increased causing underproduction (462).

Deterioration in the cytopenia can occur with episodes of metabolic crisis. Pearson disease is caused by deletional mutations in mitochondrial DNA (463), and is associated with variable degrees of pancreatic dysfunction, pancytopenia, and metabolic acidosis (464). Marrow aspirates show ring sideroblasts and vacuoles in myeloid and erythroid precursors. The cytopenia tends to improve with age (465,466).

Transfusion of Blood and Blood Products

Transfusions of blood products to newborn infants are essential in many clinical situations, and guidelines for transfusion practice in this patient population have been published and updated (467,468). However, guidelines simply provide a list of acceptable clinical situations in which transfusions may be given, and they should not serve as absolute indications for transfusion therapy. In all cases, the responsible physician should take into account the general condition of the infant. The decision to transfuse blood products should reflect careful consideration of the risk-benefit ratio for the individual patient. Physicians should clearly document, in writing, the indication for each transfusion administered and perform an assessment of the efficacy of the transfusion (e.g. relief of symptoms of anemia, cessation of bleeding). Informed consent from a parent or guardian (if appropriate), a process that includes discussion of risks, benefits and alternatives to transfusion, should be obtained in accordance with all applicable local, state and national regulatory requirements (468).

Erythrocyte Transfusions

Transfusion of erythrocytes in newborn infants, particularly in premature newborns, is a common practice. The indications are those that hold for any other time of life; hypovolemia and anemia. Transfusion for anemia has created much controversy. Anemia is defined as a hemoglobin concentration lower than that which is normal for the given patient. This concept of normality is difficult to apply to the premature infant, who as part of his/her normal course may require respiratory assistance, may have apneic spells, and may have much blood sampled for laboratory tests. There is significant controversy about whether a low hemoglobin concentration is harmful to infants or whether transfusions to maintain an arbitrary hemoglobin concentration improve their clinical condition. Guidelines for administering a RBC transfusion are presented in Table 46-17 and, although lacking definitive proof, are provided as an aid with the recognition that

P.1213

practice is variable and that criteria should be developed and updated as required by an appropriate process at each local institution.

TABLE 46-17 GUIDELINES FOR TRANSFUSION OF RED BLOOD CELLS IN PATIENTS LESS THAN FOUR MONTHS OF AGE

1. **Hct <20% with low reticulocyte count and symptoms of anaemia***

2. **Hct <30% with an infant:**

- on <35% hood O₂
- on O₂ by nasal cannula
- on continuous positive air way pressure and/or intermittent mandatory ventilation with mechanical ventilation with mean air way pressure <6 cm H₂O
- with significant apnea or bradycardia†
- with significant tachycardia or tachypnea‡
- with low weight gain [black up-pointing triangle]

3. **Hct <35% with an infant:**

- on >35% hood O₂
- on continuous positive air way pressure/intermittent mandatory ventilation with mean airway pressure ≥6–8 cm H₂O

4. **Hct <45% with an infant:**

- on ECMO
- with congenital cyanotic heart disease

* Tachycardia, tachypnea, poor feeding.

† More than six episodes in 12 hr or two episodes in 24 hr requiring bag and mask ventilation while receiving therapeutic doses of methylxanthines.

‡ Heart rate > 180 beats/min for 24 hr; respiratory rate > 80 breaths/min for 24 hr. [black up-pointing triangle] Weight gain of <10 g/day observed over 4 days while receiving ≥100 kcal/kg/day

In newborn infants almost all RBC transfusions are packed RBCs as compared to whole blood or reconstituted whole blood which should be considered a special request and indicated only in specific clinical situations (Table 46-18).

Small volume (10-15 ml/kg) transfusions of packed RBCs are frequently required in extremely low birth weight (<1000 g) or very low birth weight (<1500 g) newborn infants. There are two phases of RBC transfusion need following preterm delivery: (a) early, in infants requiring major surgery or intensive care; and (b) later, during the period of the physiologic anemia of prematurity. Factors that influence the need for RBC transfusion in premature infants include (a) the initial endowment of the infant with blood at birth reflected by the initial red cell mass; (b) the magnitude of iatrogenic blood losses, related to the degree and duration of intensive care; and (c) failure of erythropoiesis (469). As a result of the impact of placental transfusion at birth (a source of autologous blood) (470,471), more restrictive practices for RBC transfusion in LBW infants (472,473), and the elimination of a fixed iatrogenic blood loss as a "trigger" for RBC transfusion, significantly fewer small volume RBC transfusions are given to low birth-weight

infants (473,474 and 475). As an example in the study reported by Widness and colleagues (475) the percentage of infants with a birth weight of 1.0 to 1.5 kg who were given RBC transfusions was 83% in 1982, 67% in 1989 and 34% in 1993; the average number of RBC transfusions (15 ml/kg) given per patient was 7.0 in 1982, 5.0 in 1987, and 2.3 in 1993. In a more recent study of extremely low birth weight infants (birth weight <1000 g) reported by Maier and colleagues (473) the median number of RBC transfusions decreased from 7 in the period 1989 to 1991 to 2 in the period 1995 to 1997 with a corresponding reduction in the median number of blood donors per infant from 5 to 1; impressively, the percent of extremely low birth weight (ELBW) infants not transfused with packed RBC in the same periods increased from 3% (1989-1991) to 25% (1995-1997). These changes in transfusion practices need to be taken into consideration when evaluating the results of erythropoietin (EPO) trials in newborn infants, and there is general consensus among experts that, based on available data, the more liberal transfusion practices of the 1980s and early 1990s can be replaced by a more restrictive transfusion policy in small preterm infants without any significant adverse short-term effects; future trials of RBC transfusion and EPO administration in low birth weight infant should focus on long-term outcomes such as neurological development (472). Efforts to reduce iatrogenic blood loss by restricting phlebotomy, miniaturized analyses in the laboratory and transcutaneous blood gas monitoring in ill, small preterm infants need to be stressed (473).

TABLE 46-18 GUIDELINES FOR TRANSFUSION OF WHOLE BLOOD OR RECONSTITUTED WHOLE BLOOD

1. **Exchange Transfusion for:**
 - hemolytic disease of the newborn
 - hyperbilirubinemia with risk of kernicterus
2. **After cardiopulmonary bypass**
3. **Extracorporeal membrane oxygenation (ECMO)**
4. **Massive transfusion***

* Defined as transfusion of >1 blood volume in 24 hr

The type of RBC product for use in small volume (15 + 5 ml/kg) transfusions has been reviewed in detail by Strauss and colleagues (476). Based on a critical review of available literature, it is apparent that a dedicated single-donor system, in which RBCs are collected into AS-1 or AS-3 anticoagulant from either unrelated donors or biologic parents, and stored for up to 42 days, is able to supply all small

volume RBC transfusions needed by individual patients without adverse effects (476). Their protocol at the University of Iowa Hospital and Clinics is of interest in this regard; depending on the anticipated RBC needs of individual preterm infants up to 50% of a fresh RBC unit is reserved for use by each infant throughout the 42 days of RBC storage. With this dedicated single-donor system, 88%

P.1214

of transfused preterm infants received RBCs from only one donor, with the remaining 12% being exposed to only two donors. The ideal goal of only one donor per infant was almost achieved without compromising safety (476), and with acceptable cost-effectiveness (477). In addition to recommending use of RBCs stored in extended-storage anticoagulant or preservative solutions to limit donor exposures (as compared to relatively fresh RBCs), Strauss and colleagues (476) recommended the use of CMV safe (CMV seronegative or leukocyte-reduced RBCs) to minimize and potentially eliminate transfusion-transmitted CMV, and γ -irradiation to prevent transfusion-associated graft versus host disease (TA GVHD).

One area of interest is the choice of blood products in newborn infants with activation of the Thomsen-Friedenreich neoantigen (T antigen), a condition often reported in association with NEC. The condition may be associated with hemolysis and is thought to reflect exposure of the Thomsen-Friedenreich cryptantigen (T antigen) by removal of *N*-acetylneuraminidase acid (also known as sialidase). Neuraminidase is produced by a large number microbial agents including bacteria, viruses and protozoa. *In vivo* T activation has been reported in association with anaerobic, particularly clostridial sepsis, and other infections. In one recent study 48 of 375 (12.8%) neonates admitted to a tertiary referral center were found to have T or t-variant activated RBCs (478). Thirteen of the 48 infants (27%) developed at least one episode of sepsis and 9 (19%) NEC during their hospital stay; however, T-activation was not always temporally associated with NEC or sepsis. Twenty-three of the 48 (48%) of infants with T-activated RBCs received standard blood products without evidence of transfusion-associated hemolysis. Based on these observations the investigators concluded that, in the neonatal population, routine screening for T-activation of infants with sepsis or NEC is not justified and that the routine provision of low-titer anti-T blood components, washed RBCs or platelet suspended in additive is not warranted and should be considered only in the very small percentage of infants with true T-activation (as compared to T-variant activation) and clinically significant transfusion-associated hemolysis (478). These findings and recommendations are at slight variance to those of Williams and colleagues who reported an incidence of 11% of T-antigen activation in 72 infants with NEC, four of whom experienced hemolysis (one severe) associated with the transfusion of standard blood products (479). The investigators proposed a transfusion protocol that included the use of washed RBCs/platelets or blood components with low anti-T reactivity. Although it is clear that prudence should be exercised in selecting blood components for neonates with RBC T-activation, it is important that such infants, many of whom are small

and ill, not be denied the benefits of essential hemostatic components (e.g. plasma, cryoprecipitate, platelets) because of a perceived potential risk of hemolysis from standard donor products that are likely to contain anti-T antibodies (480).

Preparation of Blood for Transfusion and Crossmatching

There are several principles of blood transfusion and crossmatching that should be understood by those caring for neonates. First, omission of the crossmatch for initial and subsequent transfusions of neonates is recommended if the initial antibody screen does not demonstrate unexpected antibodies and the erythrocytes transfused are of an ABO and Rh type that is compatible with the baby and mother. This recommendation reflects the fact that newborn infants appear unable to form alloantibodies to erythrocyte antigens (481,482). Repeated blood sampling for pretransfusion testing only contributes to phlebotomy losses for small newborn infants. Second, the practice of using FFP to adjust erythrocyte preparations to a predetermined hematocrit value for small-volume transfusions (i.e., not exchange transfusion) may lead to exposure of newborn infants to two different donors pre transfusion. This practice should be discouraged (483). If necessary, isotonic saline should be used to adjust hematocrit.

Exchange Transfusions

The authors recommend that blood for exchange transfusion be as fresh as possible and less than 5 days old. Because extracellular potassium increases rapidly during storage of erythrocyte concentrates at 4°C, it is recommended that erythrocyte units for exchange transfusion of ill premature infants be saline washed before reconstitution with FFP. Manual and automated saline wash processes are effective (484). This maneuver effectively eliminates any chance of iatrogenic hyperkalemia, a complication reported in ill premature infants after exchange transfusion (485).

Platelet Transfusions

A platelet count less than $150 \times 10^9/L$ in a newborn infant is abnormal and requires investigation. In older children and adults, the risk of serious internal hemorrhage, particularly ICH, increases significantly when the platelet count falls below 20,000/ μL . Donor platelets are usually infused prophylactically when this degree of thrombocytopenia occurs. The situation in newborn infants is less clear. Particularly in ill premature infants, in whom the risk of hemorrhage into the CNS is high, factors other than the absolute platelet count may play a role. Many of these infants are on medications, such as antibiotics, that may impair platelet

function. Immaturity of blood vessels in the periventricular area and changes in cerebral blood flow and pressure associated with fluid and ventilation therapy may play a role. Alternatively, IVH may be the final result of cerebral infarction, perhaps related to asphyxia, with hemorrhage into the infarcted area. The clinical impact of significant neonatal thrombocytopenia (i.e., platelet counts $<100 \times 10^9/L$) in infants weighting less than 1,500 g at birth has been studied prospectively by Andrew and associates (486). The incidence of IVH in 97 thrombocytopenic infants was 78%, compared with 48% in nonthrombocytopenic control infants. The more severe grades

P.1215

of IVH (i.e., grades III and IV) were more frequent in the thrombocytopenic infants. Despite this, a trial of platelet transfusion for platelet counts less than $150 \times 10^9/L$ during the first 7 days of life failed to decrease the incidence of developing or extending IVH in sick premature infants (487).

TABLE 46-19 GUIDELINES FOR TRANSFUSION OF PLATELET CONCENTRATES IN NEONATES^a

Premature infants (gestational age <37 weeks)
Blood platelets $<30 \times 10^9/L$ in a stable infant
Blood platelets $<50 \times 10^9/L$ in a sick infant
All other infants
Blood platelet count $<20 \times 10^9/L$
Blood platelet count $<50 \times 10^9/L$ with active bleeding or the need for an invasive procedure
Blood platelet count $<100 \times 10^9/L$ with active bleeding plus DIC or <i>other coagulation abnormalities</i> ^b
Bleeding with <i>qualitative platelet defect</i> and <i>marked prolongation</i> of bleeding time, regardless of the platelet count
Cardiovascular bypass surgery with unexplained <i>excessive bleeding</i> , regardless of the platelet count

^b Statements in *italics* require additional definition by a local transfusion committee.

Guidelines for transfusion of platelet concentrates are outlined in Table 46-19. The standard platelet product available from blood banks is harvested from a single whole-blood donation of approximately 450 mL. After centrifugation of this whole-blood unit, platelet-rich plasma (PRP) is separated from the erythrocyte fraction, and the PRP is further centrifuged to yield 1 unit of FFP and 1 unit of random

donor platelets. Each platelet concentrate contains approximately 0.7×10^{11} platelets in a volume of 50 mL; this product can be stored for as long as 5 days at 22°C. The objective of most platelet transfusions is to increase the infant's platelet count to more than $100 \times 10^9/L$. This can be achieved by the infusion of 10 mL of a standard platelet concentrate per kilogram of body weight. Generally, this volume is not excessive, providing intake of other fluids is monitored and adjusted as needed. Although methods exist to reduce the volume of platelet concentrates, additional processing should be performed with care because of possible platelet loss, clumping, and dysfunction caused by the additional handling (488). Platelets should be administered through a standard 170- μm blood filter as rapidly as the infant's overall condition permits and certainly within 2 hours. A microaggregate filter should not be used because it will trap a large number of platelets.

Granulocyte Transfusions

Although granulocyte transfusions have been beneficial in some forms of neutropenia (489), they are now rarely used in neonatal units. The reasons for this are the difficulty in obtaining fresh granulocytes and the apparent efficacy of G-CSF in rapidly elevating neutrophil counts in neutropenic infants with sepsis (490), alloimmune neutropenia (338), or other causes of neutropenia (491)

TABLE 46-20 ESTIMATED RISK OF TRANSFUSION

Risk Factor	Estimated Risk per Unit Transfused
Viral Infection	
Hepatitis B	1/220,000
Hepatitis C	1/800,000–1.6 million
HIV	<1/1.4–2.4 million
Bacterial Contamination	
Red cells	1/500,000
Platelets	1/2,000
Immune	
Acute hemolytic reaction	1/250,000–1 million
Delayed hemolytic reaction	1/1,000
Transfusion-related acute lung injury	1/8,000
Transfusion associated graft-versus-host disease	1/500,000–1 million

Adapted from Goodnough LT. Risks of blood transfusion. *Crit Care Med* 2003;31:S678–S686, with permission.

Risks

Potential complications of blood transfusion have been reviewed by Mollison (492). For newborn infants, posttransfusion hepatitis, CMV infection, HIV infection, and graft-versus-host disease are of particular concern. Because of these potential complications (Table 46-20), it is important that physicians order blood or blood product support for newborns only in situations in which the infant will clearly benefit from such therapy.

Hepatitis.

Transfusion-associated hepatitis may be caused by the hepatitis A or B viruses or more commonly by the hepatitis C virus (HCV) (493,494). Cases of HCV were previously classified as non-A, non-B hepatitis. Available information indicates that neonates given blood before anti-HCV screening (introduced in the early 1990s) were at substantial risk for posttransfusion hepatitis C and may constitute a sizable proportion of those with chronic HCV infection who were infected during childhood (495). Infection in neonates seems to be clinically silent and biochemical abnormalities may be minimal or absent. However, although it appears that chronic hepatitis C is clinically milder in children than adults, the long-term outcome of individuals infected with hepatitis C in the newborn period is unknown (495). Of note, parents/guardians of children and particularly neonates transfused immediately or shortly after birth and not requiring ongoing transfusion support may be unaware of their child's previous transfusion history and risk status for hepatitis C (496). Some have

P.1216

therefore urged that neonatologists become partners in lookback programs by reviewing their files to identify at-risk patients transfused as neonates so that they (or their parents) can be contacted to offer hepatitis C testing (495). Children identified to have continuing HCV infection through such programs will require ongoing follow-up for their condition and encouragement to maintain a lifestyle that minimizes the risk of progression of their infection. In particular, excessive alcohol use and needle sharing should be avoided. It is very important that they be vaccinated to prevent co-infection with the hepatitis A and B viruses (497), because severe and even life-threatening fulminant hepatitis has been described in individuals with chronic hepatitis C who became superinfected with acute hepatitis A (498)

Cytomegalovirus Infection.

Transfusion-acquired CMV infection can occur when at-risk CMV antibody-negative infants are infused with CMV antibody-positive blood products. In the study by Yeager and colleagues (499), 13.5% (10 of 74) of seronegative infants who received CMV antibody-positive erythrocytes developed CMV infection. Infection did not occur in 90 seronegative infants who received only CMV antibody-negative

blood. Two of the ten infected infants in this series died, and three others developed serious symptoms including pneumonia, hepatitis, hemolytic anemia, and thrombocytopenia. All of the fatal or other serious infections occurred in infants with a birth weight less than 1,200 g; infection was more common in infants who received 50 mL or more of blood. Similar data have been reported by Adler and colleagues (500), and other reports have stressed the morbidity and mortality that may be associated with transfusion-acquired CMV infection in neonates (501,502).

Based on these studies, it has been recommended that CMV antibody-negative blood products be made available to preterm infants of birth weight 1,250 g or less who are CMV antibody-negative. A study by Preiksaitis and associates (503) challenges this recommendation for all neonates. In this prospective study of 120 seronegative infants, only one case of acquired CMV infection was observed. Because no mortality and little morbidity could be attributed to transfusion-acquired CMV, the investigators did not recommend that all neonatal units provide specialized blood components for the prevention of CMV infection (503). The indications for use of CMV-seronegative blood products in newborn infants currently include: low birth weight neonates (birth weight <1,500 g) born to seronegative mothers in centers that have documented a high incidence of transfusion-acquired CMV infection in neonates; low birth weight neonates born to seronegative or seropositive mothers and who require granulocyte transfusions; and neonates receiving extracorporeal membrane oxygenation (ECMO).

The importance of breast milk as a source of CMV infection in newborn infants has also been stressed (504,505). In future studies of transfusion-acquired CMV infection in newborn infants, it will be important to control for this variable, particularly in nurseries in which pooled breast milk is used. If a decision to transfuse CMV low-risk blood products to selected low birth weight infants is made, and CMV-seronegative erythrocytes are not available, products that are associated with a low risk transmitting CMV infection include frozen, deglycerolized erythrocytes; washed erythrocytes; and filtered erythrocytes (506,507 and 508).

It is now recommended that to avoid transfusion-induced CMV infection newborns should receive either blood products from CMV-negative donors or filtered blood, which in recent studies appears to be highly effective in preventing CMV infection even in immunosuppressed patients (509). Furthermore, transfusion of prestorage leukocyte-reduced packed RBCs was associated with improvement in several clinical outcomes in premature infants (510).

Acquired Immunodeficiency Syndrome.

Since the first report of AIDS in 1981, much has been learned about the disorder (511). The causative agent of the syndrome is now known to be the HIV-1 virus.

The virus can be grown in culture, and antibody to the virus can be detected with immunologic techniques, such as an enzyme-linked immunosorbent assay. Blood donations are routinely screened for evidence of antibodies to the HIV-1 virus, and the risk of HIV-1 transmission by blood products is extremely small. However, HIV-1 transmission has occurred in newborn infants, and this potentially fatal complication demands that blood or blood component therapy be restricted to situations in which therapy is clinically indicated and is likely to be of benefit to the newborn infant (512,513 and 514). The potential complication of HIV infection is a major reason to limit the number of blood donors to whom a given newborn infant is exposed.

Graft-Versus-Host Disease.

Graft-versus-host disease has been reported in congenitally immunodeficient infants, after blood transfusion in premature infants, after ECMO, and in apparently normal infants with Rh isoimmunization who have received intrauterine transfusions followed by exchange transfusion (515,516,517,518 and 519). Features of transfusion-associated graft-versus-host disease (TAGVHD), usually a fatal disorder, include fever, generalized rash, diarrhea, hepatitis and pancytopenia. Irradiation of blood products to prevent graft-versus-host disease is recommended for the following groups:

- Neonates with known or suspected cellular immune deficiencies
- Neonates requiring intrauterine transfusions
- Neonates who receive intrauterine transfusions and who require transfusion postnatally
- Recipients of cellular blood products from first-degree blood relatives
- Premature infants weighting less than 1,200 g at birth

Data supporting the last recommendation are not available. However, very-low-birth-weight infants (<1,200 g) may have an associated immunodeficiency, and it is reasonable to offer protection to this group of infants (468). White

P.1217

blood cell reduction has not been shown to prevent TAGVHD. The only known method of preventing TAGVHD is irradiation at 2500 cGy using a device approved

for blood irradiation of the FDA (468). The shelf life of irradiated RBCs is reduced to 28 days after irradiation as a result of acceleration of the storage lesion (468).

Plasma Derivatives

Albumin

Albumin is available in 5% and 25% solutions. Although albumin infusion has been recommended as a means of drawing more bilirubin into the intravascular space before exchange transfusion, convincing data in support of such a practice is lacking.

Fresh-Frozen Plasma

Centrifugation of a single donor unit of whole blood within 6 hours of collection yields a concentrate of erythrocytes and 1 unit of FFP. If stored at -30°C, the plasma product has a shelf life of 12 months and contains all coagulation factors.

Cryoprecipitate

Cryoprecipitate is prepared from FFP derived from multiple donors by slow thawing at 2°C to 4°C. Each unit of cryoprecipitate contains approximately 80 units of factor VIII and 250 mg of fibrinogen in 5 to 10 mL of plasma. If stored at -30°C, the product has a shelf life of 12 months. Cryoprecipitate also contains various amounts of factor XIII.

Factor VIII and IX Concentrates

Concentrates of factors VIII and IX are commercially manufactured from large pools (2,000-20,000 donors) of plasma. Each concentrate lot is assayed for coagulation factor activity, and this value is stated in units on each vial. Traditionally, concentrates of factors VIII and IX have not been used in newborn infants or young children because of the increased risk of hepatitis associated with infusion of factor VIII and IX concentrates, and of DIC and thrombotic complications associated with infusion of factor IX concentrates because of thrombogenic materials in such concentrates and low antithrombin III levels in newborns. Disseminated intravascular coagulation is particularly likely if liver dysfunction occurs. The introduction of very high-purity, virus-inactivated, plasma derived and recombinant factor concentrates appears to have eliminated the risk of HIV-1 infection and to have significantly reduced the incidence of hepatitis, altering the previous general recommendations. However, factor IX concentrates are not recommended for use in newborns other than those with proven congenital factor IX deficiency (hemophilia B). Most North American hemophilia

centers now recommend that infants with newly diagnosed severe hemophilia immediately receive hepatitis B immunization, and that they receive very high purity, virus inactivated plasma derived or recombinant factor concentrates, as clinically indicated for prevention or control of bleeding (245).

Hyperimmune Serum Globulin

Prevention of Hepatitis B Virus Infection.

Infants of mothers who are positive for hepatitis B surface antigen (HBsAg) are frequently infected with hepatitis B virus. Infection is most likely to occur if mothers are also positive for hepatitis Be antigen. Approximately 90% of infants whose mothers are positive for both markers will become infected, and most of these infants will be permanent carriers of the hepatitis B virus. It is estimated that one in four infants who are chronic carriers after perinatal infection will later develop cirrhosis or hepatocellular carcinoma (520).

Infants receive greatest protection from a combination of active immunization with three doses of hepatitis B vaccine, together with passive immunization using hepatitis B immune globulin (HBIG). The following schedule is recommended: at birth, 0.5 mL of HBIG and 10 µg of hepatitis B vaccine (520). Both the vaccine and the immunoglobulin are given intramuscularly and can be administered at the same time if separate sites are used. At 1 and 6 months, 10 µg of hepatitis B vaccine is given. Infants should be tested for presence of anti-HBsAg at 9 months. If they are found to be negative (<10% of all cases), a repeat dose of the vaccine should be given.

Prevention of Cytomegalovirus Infection.

The administration of CMV hyperimmune globulin to CMV antibody-negative patients who undergo bone marrow transplantation decreases the incidence of transfusion-acquired CMV infection. Whether a similar approach may be beneficial for the CMV antibody-negative premature infant exposed to multiple blood products is unknown.

Thrombosis and Embolism

Thromboembolism (TE) is uncommon in the neonatal period. However, TE can cause significant morbidity and mortality. Neonatal TE represents approximately 50% of the TE in the pediatric population (521). The reported incidence of symptomatic TE in newborn infants is approximately one case per 400 admissions to a NICU (522), or one case per 20,000 births (523).

Risk Factors and Pathogenesis

Three major factors contribute to the formation of thrombi (Virchow's triad): abnormalities of the vessel wall, disturbances of blood flow, and changes in blood coagulation.

Abnormalities of the Vessel Wall

Intravascular Catheters

Although the vessel walls of aorta and inferior vena cava are shown to have antithrombotic properties in the young compared to adults (524,525), these vessels can often be damaged by intravascular catheters in sick newborns. Indeed, intravascular catheters have become the single most important risk factor for neonatal thrombotic disease (522). The

P.1218

placement of such catheters carries a potential risk of thrombosis, regardless of which vessel is used; possibly because of their widespread use, umbilical catheters have received the most attention to date. In a retrospective review of 4,000 infants who underwent umbilical artery catheterization in the 1970s, severe symptomatic vessel obstruction was observed in approximately 1% of patients (526). Clinically silent thromboses have been detected more often at autopsy or during contrast angiography in asymptomatic infants with an umbilical artery catheter in place. Between 3% and 59% of cases have had postmortem evidence of catheter-related thrombosis (527,528,529,530,531,532,533). In six prospective angiographic studies, thrombosis was demonstrated in 10% to 95% of patients (534,535,536,537,538,539). Very recently, thrombi associated with a correctly placed umbilical venous catheter were documented venographically at the time of elective catheter removal in 30% (14/47) of asymptomatic infants (540). In the same study, it was found that real-time and Doppler flow ultrasonography was not sufficiently accurate to diagnose such thrombi. Before this report, neonatal thrombosis, which was associated with central venous catheters, had been

estimated to occur in approximately 14% of asymptomatic infants, based on serial echocardiography (541,542).

Abnormal chorionic vessels are present in a range of maternal disorders such as PIH or placental infection. These abnormal blood vessels predispose to the development of chorionic thrombi, which can embolize into the fetal circulation, particularly into the pulmonary arteries and portal veins (543). Paradoxical emboli have also been reported as the cause of neonatal cerebral infarction (544,545).

Abnormal Blood Flow

Blood flow is a critical determinant of thrombus formation. Increased blood viscosity (as a consequence of polycythemia or dehydration) has been implicated in cases of neonatal thrombotic disease (522,523). Hyperviscosity caused by polycythemia is also thought to contribute to the alleged thrombotic tendency in infants with diabetic mothers (546). Shock is another example of a severe disturbance of blood flow, predisposing to thrombosis (547). The presence of a catheter within the lumen of blood vessels attenuates blood flow and is the commonest predisposition of a thrombus in neonate (522).

Abnormal Blood Coagulation

Epidemiologic studies in adults have confirmed several hereditary disorders and coexistent genetic defects as risk factors for thromboembolism (548,549). Much less is known about hereditary thrombophilia in newborn infants. The occurrences of homozygous protein C and S deficiencies have been strongly linked with severe neonatal thrombotic disease (550,551). Heterozygous deficiencies of antithrombin, factor V Leiden (resistance to activated protein C), prothrombin G20210A mutations and, elevated lipoprotein (a), polymorphisms (677CST) of methylenetetrahydrofolate reductase (MTHFR) have also been associated with neonatal thrombosis and purpura fulminans in isolated case reports and series (552,553,554). Whether a congenital prothrombotic state contributes to the development of thrombosis in the presence of a strong stimulus such as venous catheters remained controversial (555).

Clinical Features

Neonatal TE can occur in either the venous or arterial system. In the Canadian Registry, thrombosis was venous, arterial, and mixed in 62, 34, and 4 %, respectively (522). The vessels affected are numerous; they include renal, adrenal, portal, hepatic, and cerebral veins; peripheral, cerebral, pulmonary, coronary, renal, and mesenteric arteries; and the aorta, vena cava, and right atrium (546). The clinical presentation of thrombosis is variable. Signs and symptoms may be fairly specific, such as a cool, pale, and pulseless limb in the

case of peripheral arterial obstruction. Often, however, the clinical presentation is very nonspecific: examples include respiratory insufficiency and profound hypoxemia caused by pulmonary emboli (556) and seizures caused by arterial stroke or cerebral venous thrombosis (557,558,559,560,561). Occasionally, thrombosis is suspected only retrospectively when sequelae of vessel occlusion become apparent (e.g., portal hypertension as a consequence of portal vein thrombosis). Table 46-21 summarizes the major sites of thrombotic vessel obstruction and their clinical symptoms and signs in the newborn infant.

The most common predisposing factor for thrombosis is the presence of a catheter (522,523). In thrombosis unrelated to a catheter, renal vein thrombosis is the most common (523). Thrombocytopenia often accompanies thrombosis in newborns. Patients should be evaluated for a thromboembolic disorder if thrombocytopenia cannot be explained by other conditions.

Purpura fulminans is characterized by ecchymotic lesions that increase in a radial fashion and become purplish black with bullae, and then necrotic and gangrenous. In the presence of purpura fulminans, protein C or protein S deficiencies should be considered.

Management

The literature on neonatal thrombotic disease consists almost entirely of case reports and case series (562). Such anecdotal observations are poor guides to management, as they are uncontrolled and fraught with bias (562). Extrapolation of findings in adult patients to newborn infants may be inappropriate because the etiology, the localization of thrombi, the coagulation system and its response to antithrombotic and fibrinolytic agents differ markedly between the two age-groups. Current approaches to the management of neonatal thrombosis remain to be validated in future clinical trials. Updated information on the use of antithrombotic agents are published regularly by American College of Chest Physicians (563).

Diagnosis

Whenever thrombotic disease is suspected in the newborn, every effort should be made to confirm or refute the

P.1219

diagnosis. Contrast angiography with the use of nonionic contrast media is the "gold standard" imaging technique for the confirmation of thrombosis before embarking on thrombolytic or surgical therapy. Other, less invasive tests such as real-time ultrasonography or Doppler flow studies may be helpful adjunctive measures, but their precision and accuracy in neonatal thrombotic disease are still uncertain (564). The advantages of this technique are that it is noninvasive, does

not require exposure to ionizing radiation, and can be performed at the bedside.

TABLE 46-21 CLINICAL PRESENTATION OF THROMBOEMBOLIC DISEASE IN NEWBORN INFANTS

Site of Vessel Obstruction	Clinical Signs and Symptoms
Venous	
Vena cava inferior	May be associated with renal venous thrombosis; edema and cyanosis of legs
Vena cava superior	Soft-tissue edema of head, neck, and chest; chylothorax
Cerebral	Seizures
Renal	Enlarged kidney(s); hematuria
Adrenal	Often associated with adrenal hemorrhagic necrosis
Portal and hepatic	Mainly clinically silent during acute phase
Arterial	
Aorta	Congestive heart failure; systolic gradient between upper and lower limbs; decreased femoral pulses; renal failure
Peripheral	Pulselessness; fall in skin temperature; discoloration
Cerebral	Prolonged apnea; seizures
Pulmonary	Respiratory distress; pulmonary hypertension
Coronary	Congestive heart failure; cardiac shock
Renal	Systemic hypertension (usually self-limiting if microemboli in end arterioles); congestive heart failure
Mesenteric	Signs of "necrotizing enterocolitis"

The accuracy of ultrasound may be reduced by the presence of a catheter because reduced compressibility of the vessel lumen by the ultrasound probe (a sign of thrombosis) is difficult to assess (565). Low pulse pressure in preterm and sick newborns may also limit the interpretation of Doppler flow study. In one series of 47 infants with umbilical venous catheters, the accuracy of Doppler echocardiography was poor compared to contrast venography in detecting asymptomatic thrombus (540). Thrombi were detected by venogram in 14 patients (30%). The sensitivity and specificity of echocardiographic diagnosis for the three cardiologists who interpreted both studies ranged from 21 to 43% and 76 to 94%, respectively. However, the relative accuracy of these techniques to detect symptomatic thrombosis is not known.

For diagnosis of cerebral venous thrombosis, angiogram remains the gold standard. However, magnetic resonance imaging (MRI) with venography or

Doppler flow ultrasound through the anterior fontanelle may also be used. For the diagnosis of arterial ischemic stroke, MRI is more sensitive to small or early infarcts that are frequently missed by computed tomography (CT) scan (565,566).

For neonates that are diagnosed to have a thrombus, whether a prothrombotic workup needs to be done is controversial (567). In most circumstances, the diagnosis of a prothrombotic state does not alter the management of the patient, except for protein C, protein S or antithrombin deficiencies. For patients with purpura fulminans, spontaneous thrombotic events or extensive thrombosis, prothrombotic workup including protein C, protein S and antithrombin level should be done. Parents should be counseled before testing is done. The clinical utility of testing for other prothrombotic state such as factor V Leiden, prothrombin G20210A mutations, elevated lipoprotein (a), point mutation (677→T) of MTHFR, and elevated homocysteine need to be assessed on an individual basis and ideally in a study context.

Treatment

Organ or limb dysfunction as a result of thrombosis is the most compelling indication for active intervention. The lack of strong evidence for the benefits and safety of antithrombotic therapy in this population does not usually justify aggressive therapy for asymptomatic thrombosis. In the absence of well-designed studies to address the efficacy and safety of intervention, supportive care alone may be appropriate for asymptomatic thrombosis. Catheters should be removed in catheter related thrombosis. Objective monitoring of the thrombus should be undertaken if supportive care only is chosen.

Intracranial hemorrhage or hemorrhagic infarction should be ruled out by suitable imaging techniques before anticoagulant or fibrinolytic drugs are prescribed. In all infants who receive antithrombotic therapy, the platelet count should be maintained above $50 \times 10^9/L$, and the fibrinogen concentration greater than 1 g/L (564).

P.1220

Anticoagulation Therapy

Anticoagulation therapy in neonate usually involves the use of unfractionated heparin (UFH) or low molecular weight heparin (LMWH).

Unfractionated Heparin

Unfractionated heparin is a glycosaminoglycan (GAG) composed of a heterogeneous mixture of polysaccharide chains of varying lengths (3,000-30,000 Daltons). Un-fractionated heparin catalyzes the inactivation of various clotting

factors, such as factor Xa and thrombin, by antithrombin. The binding of antithrombin to heparin is mediated by a unique pentasaccharide sequence that is randomly distributed along the heparin chains (568). The inactivation of thrombin, but not factor Xa, requires the formation of a ternary complex in which heparin binds to both antithrombin and thrombin (569). This ternary complex (containing heparin, antithrombin, and thrombin) forms only on pentasaccharide-containing chains with at least 18 saccharide units. The inactivation of factor Xa by heparin only requires the presence of pentasaccharide with no minimum requirement of the chain length on the heparin molecule.

Unfractionated heparin (UFH) offers the advantages of rapid reversibility and low cost. Unpredictable pharmacokinetic response and resultant requirement for frequent monitoring are the disadvantages of UFH.

The use of a dedicated intravenous catheter for UFH infusion avoids interruption of anticoagulation therapy and minimizes the risk of inadvertent flushing of the catheter that may lead to excessive anticoagulation.

Dose.

The dose of heparin therapy in newborns is based on a prospective cohort study of UFH treatment in 65 children with thrombosis, of whom 29 were less than one year of age, including 13 newborns (570). Heparin is administered intravenously with a loading dose of 75 U/kg and an initial maintenance dose of 28 U/kg per hour. Dosing is adjusted to maintain an aPTT of 60 to 85 sec, which corresponds to an antifactor Xa activity of 0.35 to 0.7 U/mL (563). The dose can be adjusted according to a published nomogram (571). The therapeutic range is an extrapolation from adult data. The therapeutic range for UFH in neonates may be different from adults because the plasma concentrations of prothrombin and antithrombin in neonates are decreased compared to adults (572).

The duration of therapy is uncertain. One approach is to monitor the thrombus with ultrasound and continue therapy until the thrombus has resolved for a maximum of three months of therapy. Low molecular weight heparin can be used for prolonged therapy.

Adverse Effects

The major side effects of UFH are bleeding, heparin-induced thrombocytopenia (HIT), and osteoporosis (573). The risk of bleeding in newborns is uncertain. In one pediatric prospective study of which 13 were newborns, none had significant bleeding (95% CI, 0%-25%) (570). As in adults, bleeding likely relates to the concentration of heparin and presence of underlying disorders that predispose to bleeding (574). If bleeding occurs, UFH should be discontinued. For heparin reversal, 1 mg of protamine sulfate can inactivate 100 U heparin. The dose of

protamine depends on the amount of heparin being given, and is calculated by assuming the half-life of heparin to be 1 hour.

Heparin-induced thrombocytopenia is a well-recognized complication of heparin therapy in adults (575,576,577 and 578). Two major mechanisms cause this thrombocytopenia. One mechanism appears to be a direct effect of heparin on platelet activation. In most of these cases, the fall in platelet count occurs within the first two days after heparin initiation, often returns to normal with continued heparin administration, and is of no clinical consequence, at least in adults. The incidence of this type is estimated at 10% to 20% of adults receiving UFH. The second type is mediated by antibodies to a heparin-platelet factor 4 complex, which results in platelet activation and aggregation and enhanced generation of thrombin (579,580). This occurs in 3% or less of adults receiving UFH for more than 4 days (576,578,581).

Heparin-induced thrombocytopenia has been described in newborns (582). However, it is difficult to evaluate the incidence because critically ill newborns have many reasons to have thrombocytopenia and/or thrombosis. One report described 34 newborns (mean gestational age 29 weeks) who developed thrombocytopenia (platelet count $<70,000/\mu\text{L}$, $n = 23$), a precipitous fall of 30 to 50% in the platelet count ($n = 5$) or thromboses ($n = 6$) while receiving heparin (583). Heparin-associated antiplatelet antibodies were found in 14 patients; these patients had clinical characteristics comparable to the 20 infants without antibodies, including the presence of an umbilical artery catheter in all but one patient in each group. Among those who had abdominal ultrasonography, aortic thrombosis occurred in 11 of 13 (84%) infants with and 5 of 20 (25%) without antibodies. Bleeding was not observed. However, the sensitivity of ultrasound to detect an asymptomatic thrombus in newborns is poor (540). Thus, the relationship between antibody formation and thrombosis in this population remains uncertain. In a more recent randomized controlled trial with 138 newborns who received prophylactic doses of UFH, none of the patients developed HIT (97.5% CI, 0%-2.6%) (584). Heparin-induced thrombocytopenia should be considered in a newborn receiving UFH with thrombocytopenia of no apparent cause, although the condition is uncommon and thrombocytopenia from other causes occurs frequently in ill LBW infants.

Osteoporosis has been reported in adult patients receiving UFH for more than 6 months (585). Bone loss is thought to occur because of decreased bone formation, increased bone resorption, or both. However, there is no information on this complication in newborns (565).

Low Molecular Weight Heparin

Low molecular weight heparin is prepared from UFH by chemical or enzymatic degradation. Like UFH, LMWH

potentiates the inactivation of factor Xa by AT. However, the effect of LMWH on the AT inhibition of thrombin is decreased compared to UFH because most of the molecules in LMWH do not contain enough saccharide units to form the ternary complex in which thrombin and AT are bound simultaneously (573). As a result, LMWH in the usual therapeutic dose does not prolong the aPTT. The aPTT can be prolonged by higher doses of LMWH, but not to the same extent as UFH.

Limited information is available on the efficacy and safety of LMWH in newborns (586,587,588). One prospective cohort study included 173 children who were treated with the LMWH preparation enoxaparin because they had or were at high risk for thromboembolic events (587). Patients ranged in age from one day to 18 years; 21 (14.5%) were less than 36 weeks gestational age and 48 (33.5%) were less than 3 months postnatal age when treatment was initiated. Thrombi resolved clinically in 94% of patients who received therapeutic doses. In those receiving prophylaxis, 96% had no symptoms of new or recurrent TEs. Major bleeding occurred in seven (4%) of patients, of whom four were newborns. In a more recent report, the incidence of bleeding in neonates treated with enoxaparin is estimated to be 6% (588).

Over the last few years, LMWH has been used more frequently than UFH in neonates. The advantages of using LMWH are more predictable pharmacokinetics, ease of administration, at least equal efficacy and safety compared to UFH and probably decreased risk of HIT and osteoporosis. Low molecular weight heparin can be administered subcutaneously and requires minimal laboratory monitoring and dose adjustment; these are important for newborns with poor venous access (589).

Dose.

There are several LMWH preparations and they should not be used interchangeably (590). In the United States, four preparations (enoxaparin, dalteparin, ardeparin, and tinzaparin) are currently approved by the FDA for different clinical indications. Dosing in pediatric patients has been reported for enoxaparin (586), dalteparin (591), clivarin (592), and tinzaparin (593). For neonates, the most experience lies in the use of enoxaparin.

For treatment of thrombosis, enoxaparin can be initiated in a dose of 1.5 mg/kg per dose subcutaneously twice each day (588,594). Dalteparin is initiated in a dose of 150 IU/kg per dose once each day (590). Doses are adjusted to maintain an antifactor Xa concentration (measured four hours after the dose) of 0.5 to 1 U/mL, the therapeutic range established in adults (595).

For prophylaxis, enoxaparin is initiated at 0.75 mg/kg per dose twice each day. Dalteparin is initiated at 100 IU/kg per dose once each day. The target

concentration of antifactor Xa (0.1-0.3 U/mL) is lower for prophylaxis than for treatment (594).

The duration of therapy is uncertain. Our approach is to monitor the thrombus with ultrasound and continue therapy until the thrombus has resolved or, if still present, for up to 3 months.

If bleeding occurs, LMWH should be discontinued. The dose of protamine sulfate for reversal of heparin effect depends on the dose of LMWH and the time since LMWH was last administered. If LMWH was given within four hours, the maximum dose of protamine is 1 mg per 100 U LMWH, given by slow intravenous push. If LMWH was given more than four hours previously, a lower dose of protamine should be used. However, protamine only partially neutralizes the effects of LMWH (596).

Adverse Effects.

The major adverse effect of LMWH is bleeding. The largest reported cohort of neonates that had been treated with enoxaparin showed a bleeding risk of 6% (95% CI 1.8%- 15.7%). The premature neonates are probably at increased risk compared to term neonates (588). The incidence of HIT related to the use of LMWH in neonates is unknown but is likely to be less than 1%.

Warfarin

Warfarin is not recommended in the neonatal period because of the potential risk of bleeding (565). The effect of warfarin is mediated through reduction of the functional plasma concentration of the vitamin K-dependent coagulation factors (factors II, VII, IX, and X). However, the concentration of these factors is physiologically reduced in newborns and is often similar to those of adults receiving warfarin therapy. Breast-fed newborns are especially sensitive to the effect of warfarin because human milk has low concentrations of vitamin K. On the other hand, formula-fed babies are relatively warfarin resistant because of vitamin K supplement in infants formula.

Warfarin is only available in tablet form. Splitting or crushing the tablet into powder may cause variability in the dose. Additionally, treatment with warfarin requires frequent monitoring of the INR.

Thrombolytic Agents

There is limited experience in using fibrinolytic agents in newborn infants (597,598). Over the years, a gradual shift seems to have occurred from streptokinase to urokinase and, more recently, to tissue plasminogen activator (tPA) (597). A wide range of doses, both with or without boluses, have been used

with variable successes and failures (522, 523,597,598). In the absence of any controlled data in this population on the superiority of one thrombolytic agent over the others, the choice of drug should be determined by familiarity and cost.

Any clinician who is contemplating thrombolytic therapy in sick neonates must weigh the risk of prolonged vessel occlusion and the uncertain drug benefits against the infant's risk of suffering from serious bleeding complications. Contraindications should be seriously considered before the initiation of the thrombolytic therapy (599).

Dose.

The dose of tPA in newborns is extrapolated from doses in older children and adults. For systemic therapy, tPA can be given as a continuous infusion at a rate of 0.1 to 0.5 mg/kg per hour for six hours, without a loading dose

P.1222

(563). The drug can be given through a central or peripheral venous catheter.

Transfusion of FFP before initiation of thrombolytic therapy may decrease the risk of bleeding. Furthermore, FFP provides plasminogen, which may enhance the effect of the tPA. Fresh frozen plasma and/or cryoprecipitate can be given if the fibrinogen concentration is <1 g/L or if there is bleeding (563).

Aside from resolution of the thrombus, there is no easy way to measure the effectiveness of the tPA infusion. The presence of d-dimers or fibrin/fibrinogen degradation products only indicates a fibrinolytic state.

Treatment of bleeding following use of tPA includes use of cryoprecipitate to increase the fibrinogen concentration, stopping the tPA infusion if possible, and administration of platelets if needed.

Adverse Effects.

Bleeding is the most concerning side effect of fibrinolytic therapy. However, as a result of the variety of dosing regimens and whether contraindications for the use of fibrinolytic therapy are followed, the bleeding risk associated with the use of fibrinolytic therapy remains unclear but certainly may be major.

Surgery.

The main objectives of surgical intervention in neonatal large vessel thrombosis have been, first, to remove the occluding clot and, second, to resect a nonviable product of the vessel obstruction (amputation for limb gangrene; resection of necrotic bowel). Thrombectomy may be used in selected cases, particularly if the thrombus obstructs a major artery.

Because of the devastating functional loss with all ensuing problems, amputation in peripheral arterial occlusion should be postponed as long as possible. The main aim is to prevent superimposed secondary infection. Ideally, surgical intervention should be delayed until the necrotic parts are well demarcated. In some cases, surgery is not necessary at all because autoamputation occurs, which results in the least possible loss of tissue.

Prognosis.

The vast majority of infants with thrombotic disease survive; mortality rates are highest among infants with aortic thrombosis or with central venous catheter-associated TEs affecting the right atrium or the superior vena cava (522). In the Canadian Registry, for example, the mortality rates for both aortic and right atrial or superior vena cava thrombosis were 33%. In the Netherlands Registry, the mortality rate was 15% but none of the deaths were directly related to the TEs (523). Data on long-term follow-up of neonatal TEs are very limited. The outcome of the following conditions is relatively better studied.

Renal Vein Thrombosis

A total of 58 neonates with renal venous thrombosis have been followed for 0.1 to 17 years by four different investigator teams (600). Persistent hypertension was found in 28% of all children, and 21% had residual renal tubular defects (600). In another study, 26 out of 39 affected kidneys were atrophic (601).

Aortic Thrombosis

The available follow-up data on survivors of aortic thrombosis suggests that blood pressure and renal function are likely to normalize during early childhood, but persistent hypertension, leg-growth discrepancies, and abnormalities in renal size and function have been described (602,603,604,605).

Cerebral Venous Thrombosis

The best available data on the outcome showed 77% of the newborns surviving sinovenous thrombosis are neurologically normal (606).

Arterial Ischemic Stroke

One third of the neonates with arterial ischemic stroke are normal with the rest having neurological deficits. Lesions that involve the motor cortex, internal capsule, and basal ganglia together are associated with increased disability as compared to lesions limited to the cortex or basal ganglia alone (565).

Prothrombotic states such as Factor V Leiden were associated with a worse

neurological outcome in perinatal arterial infarction (607).

Prophylaxis

To reduce the risk of TE disease in the newborn, intravascular catheters should be used judiciously, and blood flow should be optimized at all times.

Arterial Catheters

In a systematic review of five clinical trials, heparinization decreased the risk of catheter occlusion (relative risk 0.20, 95% CI, 0.11-0.35) (242). However, the risk of aortic thrombosis, IVH, death, or clinical ischemic events did not appear to be affected. Therefore, fluid infused through an umbilical arterial catheter should contain UFH in a concentration of 0.5 to 1.0 units/mL.

Although data are limited in newborns, use of UFH prolongs the patency of peripheral arterial catheters (608,609,610). Fluid infused through a peripheral arterial catheter should also be heparinized, using a similar concentration.

Central Venous Catheters

Fluid infused through a central venous catheter should contain heparin in a concentration of 0.5 units/mL to prevent thrombosis and catheter occlusion. However, heparinization of central venous catheters (umbilical or peripherally placed percutaneous) has not been studied in well designed trials (611). At the present time, there is no data to support systemic anticoagulant prophylaxis to prevent catheter related thrombosis and thus this approach cannot be recommended.

Acknowledgments

The authors are grateful to Dr. Hans Hitzler (Division of Hematology/Oncology, The Hospital for Sick Children,

P.1223

Toronto, Canada); Dr. Eyal Grunebaum (Division of Immunology, The Hospital for Sick Children, Toronto, Canada); Dr. Greg Denomme (Canadian Blood Services, Toronto, Canada) for their useful contributions to the chapter and to Dr Alvin Zipursky for his critical review and comments during the preparation of this manuscript. This chapter was prepared with the editorial assistance of Lu Ann Brooker.

Chapter 47

Bacterial and Fungal Infections

Robert L. Schelonka

Bishara J. Freij

George H. McCracken Jr.

Infections cause significant mortality and long-term morbidity in neonates, especially for premature infants of very low birth weight (1,2,3,4,5,6). Temporal and geographic differences in the relative frequencies of various neonatal pathogens are well recognized (7,8,9,10,11). In North America in the 1930s and 1940s, gram-positive cocci such as group A β -hemolytic streptococci and *Staphylococcus aureus* were the most common bacterial isolates from neonates with sepsis, with *Escherichia coli* accounting for most of the remaining cases. *S. aureus* and *E. coli* became the major pathogens in the 1950s, but since the late 1960s, group B β -hemolytic streptococci and *E. coli* have predominated. Coagulase-negative staphylococci emerged in the 1980s and have surpassed *S. aureus* and gram-negative enteric bacilli as the bacteria most frequently associated with nosocomial infections in many neonatal intensive care units (NICUs), and several *Candida* species have increased in frequency to become major neonatal pathogens in the 1990s. This has largely been a consequence of the survival of very-low-birth-weight (VLBW) infants who require lengthy hospitalizations and considerable mechanical and nutritional support (12,13). Since the 1990s there has been an emerging problem of multiple-drug-resistant gram-positive and gram-negative enteric bacilli in NICUs (14,15,16,17).

The outcome of neonatal infections may be improved if illness is recognized early and appropriate antimicrobial agents are administered promptly. This chapter presents pertinent epidemiologic and pathogenetic concepts of specific infections, clinical manifestations, and diagnostic evaluations of patients with these diseases, with a rational approach to therapy of neonatal infections.

EPIDEMIOLOGY

The two principal sources of newborn infection are the mother and the nursery environment. Infection is acquired from the mother transplacentally, at the time of delivery, or in the postnatal period. The infant may acquire infection postnatally from environmental sources, such as nursery personnel, respiratory equipment, sinks, contaminated total parenteral nutrition solutions or medication vials, and incubators. Infections manifesting within the first week of life are usually the result of exposure to microorganisms of maternal origin, but infections presenting

later can have a maternal or environmental source.

Myriad aerobic and anaerobic bacteria, mycoplasmas, chlamydiae, fungi, viruses, and protozoa can be found in the maternal genital tract. Some of these organisms pose little threat to the newborn infant (e.g., *Lactobacillus*, α -hemolytic streptococci, *Veillonella*), and others are infrequent causes of neonatal disease (e.g., *Streptococcus pneumoniae*, *Neisseria meningitidis*) (18,19,20). More commonly, organisms such as groups A and B γ -hemolytic streptococci, *E. coli*, *Listeria monocytogenes*, *Haemophilus influenzae*, *Neisseria gonorrhoeae*, cytomegalovirus, and herpes simplex virus are responsible for serious neonatal infections (3,4).

Within a few days after birth, α -hemolytic streptococci, *S. epidermidis*, and gram-negative enteric bacilli colonize the throat, nose, umbilicus, and stool (21,22,23). The gastrointestinal (GI) tract of newborns becomes heavily colonized by lactobacilli. Infants in NICUs tend to have delayed colonization, which probably is related to early antimicrobial therapy for possible sepsis, and are more likely to acquire nosocomial strains of gram-negative bacilli such as *Klebsiella*, *Enterobacter*, *Citrobacter*, and *E. coli* (24,25,26). Colonization of the scalp, axilla, and groin by coagulase-negative staphylococci is universal by 48 hours of age (12). In a prospective study of 18 premature infants admitted to a NICU, *S. epidermidis* as the only coagulase-negative staphylococcal species isolated from the axilla, ear, nasopharynx, and rectum was found in about 11% of infants during their first postnatal day; this increased to 100% by 4 weeks of age. None of these infants had a

P.1236

predominant *S. epidermidis* biotype on the first day compared with 89% by 4 weeks of age. The prevalence of slime production and multi-drug resistance among isolates rose from 68% to 95% and from 32% to 82%, respectively, during the 4-week study period (27).

Postnatal fungal colonization is more likely to occur in low-birth-weight (LBW) infants. An estimated 10% of term infants have GI *Candida* colonization within the first 5 days of life; infants weighing less than 1,500 g have colonization rates of about 60% (28). Early colonization (less than 2 weeks of age) is more common, involves the GI and respiratory tracts, and is with *Candida albicans* or *C. tropicalis*, unlike late colonization (≥ 2 weeks of age), which usually involves the skin and is more likely to be with *C. parapsilosis* (29). *C. albicans* colonization of infants is usually of maternal origin, whereas *C. parapsilosis* colonization is acquired from exogenous sources such as the hands of nursery personnel (30). Cutaneous colonization with *Malassezia (Pityrosporum) furfur*, a lipophilic yeast best known as the cause of tinea versicolor, is common and is found in as many as two-thirds of all critically ill newborns; fewer than 3% of healthy newborns and young infants have skin colonization by this fungus (31,32,33). The use of water-in-oil emollient creams (e.g., Eucerin Creme) as a moisturizer for premature

infants does not appear to alter colonization patterns by bacteria or fungi (34), but in a randomized controlled trial of topical emollient cream there was an 5% absolute increased risk (25.8% vs. 20.4%; RR: 1.26; 95% CI: 1.02,1.54) of acquiring nosocomial bacterial sepsis. This increase in infection rates due mostly to an increase in the number of coagulase-negative staphylococci infection (35). The vagina or cervix of asymptomatic, sexually active women is colonized by *Ureaplasma urealyticum* in 40% to 80% and by *Mycoplasma hominis* in 21% to 53%. Vertical transmission rates from 45% to 66% for preterm and term neonates have been reported for *U. urealyticum* (36). By 3 months of age, about 33% to 68% of these infants continue to have detectable pharyngeal, ocular, or vaginal colonization (37). Vertical transmission rates for infants born to women with cervical *Chlamydia trachomatis* infections have been estimated at 40% to 70%; about 35% of untreated infants continue to be infected at one or more sites (e.g., conjunctiva, nasopharynx, oropharynx, rectum, vagina) at 12 months of age (38,39,40).

In the United States, bacterial sepsis affects up to 32,000 infants annually, and the incidence of neonatal sepsis is from 1 to 8 cases per 1,000 live births (41,42,43). The average national incidence rate for nursery-acquired infections is about 1.4%, but figures reported for NICUs are considerably higher and range from 5% to 30% (3,44,45,46,47). The most important risk factors for acquiring a nosocomial infection are low birth weight and gestational age; others include prolonged hospitalization, invasive procedures, placement of indwelling devices such as central venous catheters or ventriculoperitoneal shunts, bacterial or fungal colonization, and overcrowded nurseries.

PHARMACOLOGIC BASIS OF ANTIMICROBIAL THERAPY

Selection of antimicrobial therapy for neonatal infections must be based on pharmacokinetic properties of antibiotics in newborn infants of different gestational and postnatal ages, antimicrobial susceptibilities of commonly encountered pathogens within each nursery, and the natural history of the infectious disease being treated (48).

Combining two or more antibiotics is the usual clinical practice when initiating therapy for presumed systemic bacterial disease (e.g., ampicillin and an aminoglycoside are combined to treat suspected early onset septicemia or meningitis before identification of the pathogen). After a bacterium has been identified and its susceptibility to various antimicrobial agents is determined, a single appropriate antibiotic usually is satisfactory for treating most infections.

Although antibiotics are used commonly to prevent infection, they are effective prophylactically only if directed against a single pathogen. For example, a single dose of penicillin G given intramuscularly at birth reduces the colonization rate

and incidence of early-onset group B streptococcal (GBS) disease, except in infants who acquire the infection *in utero* (49). However, if antibiotics are used as broad-spectrum coverage against many potential pathogens, they rarely are effective. This umbrella method of chemoprophylaxis encourages the emergence of resistant strains among previously susceptible bacteria and alters the normal flora of the GI and respiratory tracts with overgrowth of potentially virulent organisms. Broad-coverage prophylaxis may partially suppress a bacterium, masking the development of clinical disease and causing neglect of important surgical measures or serious delay in administering more effective therapy.

SEPSIS NEONATORUM

The term sepsis neonatorum describes a disease of infants who are younger than 1 month of age, are clinically ill, and have positive blood cultures. The presence of clinical manifestations differentiates this condition from the transient bacteremia observed in some healthy neonates.

The bacteria responsible for neonatal sepsis vary geographically. GBS and *E. coli* predominate in the United States, whereas *S. aureus* and gram-negative bacilli are much more common in developing countries (8). The bacterial etiology of sepsis also varies by the postnatal age of the infant. In a study of a cohort of 6,956 VLBW infants (401 to 1,500 g) admitted to 15 medical centers in the United States during a 32-month period between 1998 and 2000, the incidence of early-onset sepsis (occurring during the first 72 hours of life) was 1.5% and that of late-onset sepsis (occurring after 3 days of age) was 25%. The nature of the pathogens associated with the early-onset and late-onset infections differed markedly, with *E. coli* predominating (44% of cases) in the former and coagulase-negative staphylococci (48% of cases) in the latter (Table 47-1) (3,4).

TABLE 47-1 DISTRIBUTION OF PATHOGENS IN A COHORT OF 5,447 (EARLY-ONSET) AND 6,956 (LATE-ONSET) VERY-LOW-BIRTH-WEIGHT INFANTS (401-1,500 G) IN THE UNITED STATES FROM SEPTEMBER 1, 1998 TO AUGUST 1, 2000.

Pathogenesis

Maternal, environmental, and host factors determine which infants exposed to a potentially pathogenic organism will develop sepsis, meningitis, or other serious invasive infections.

Many prepartum and intrapartum obstetric complications have been associated with increased risk of infection in the newborn, the most significant of which are premature onset of labor, prolonged rupture of fetal membranes, chorioamnionitis, and maternal fever. In one study of 963 pregnancies complicated by premature rupture of membranes, the incidence of clinical sepsis increased from 2% among infants born within 23 hours of membrane rupture to 7% and 11% among those delivered 24 to 47 hours and 48 to 71 hours after rupture, respectively. The risk was highest for the premature, LBW infants (50). The incidence of infection has been estimated at 8.7% for infants born to mothers with prolonged rupture of membranes (≥ 24 hours) and clinical chorioamnionitis (51). Intraamniotic infection is associated with a higher incidence of sepsis among infants weighing less than 2,500 g at birth compared with those weighing 2,500 g or more (16% and 4%, respectively). Death from sepsis is greater in the LBW group (11% and 0%, respectively) (52). Isolation of bacteria from the chorioamnion has been associated with an increased risk of neonatal death among preterm infants (53). Maternal urinary tract infections, low parity, and the use of internal monitoring devices are risk factors for chorioamnionitis (54). Concurrent maternal and neonatal bacteremia has been documented for many microorganisms (55,56,57).

With improved supportive care of the sick neonate has come increased

opportunity for microorganisms of relatively low virulence to cause systemic disease. The use of arterial and venous umbilical catheters, central venous catheters, indwelling urinary catheters, and endotracheal tubes provides access to the debilitated infant for organisms in the respiratory, GI, or genitourinary tract, on the skin, or in respiratory support equipment.

Bacterial colonization of the skin and mucosal surfaces precedes invasive disease in most infants with sepsis. Type III strains of GBS, the ones most commonly associated with early-onset septicemia and with meningitis at any age in early infancy, adhere better to vaginal and neonatal buccal epithelial cells *in vitro* than do other GBS strains (58,59). Bloodstream invasion generally follows local multiplication of the organism at sites of colonization. Aspiration of infected amniotic fluid is another proposed route for fetal infection among infants born to mothers with chorioamnionitis.

Animals have been used to define the host-bacteria interactions that determine pathogenesis of disease. Bloodstream infection in infant rats or mice caused by *E. coli* K1 or any of the GBS serotypes can be prevented by pretreatment with type-specific capsular polysaccharide antibody (60,61). The orogastric route for *E. coli* K1 in the infant rat and the intratracheal installation of GBS in the

P.1238

rhesus monkey or rat produce illnesses that closely parallel the human syndromes (62,63,64).

Several investigations of the host-parasite association of humans with GBS have focused on measurement of specific antibody in the serum of infected and colonized persons. Protective concentrations of antibody to GBS serotype III were found in 73% of women whose newborn infants were well but in only 17% of women whose neonates developed sepsis or meningitis caused by this organism (65). The amount of antibody to GBS serotype III was considerably lower in ill infants than in healthy neonates born to mothers with vaginal colonization (65). Levels of GBS serotype III antibodies correlate with *in vitro* opsonic activity and *in vivo* protection of animals experimentally infected with these strains (66,67). The administration of standard intravenous immunoglobulin preparations with activities against GBS, of human GBS monoclonal antibodies, or of GBS hyperimmune polyclonal antibodies provides significant protection to animals experimentally infected with this pathogen (68,69). Asymptomatic colonization also is associated with antibody formation (70,71). Although less extensively studied, similar observations have been made for other GBS serotypes (69,72,73,74,75).

Evidence suggests that antibodies to the K1 *E. coli* antigen are protective against infection by this organism, but this is not firmly established (76). Neonatal serum has been shown to be inefficient in killing *E. coli* because of a deficiency of nonimmunoglobulin G serum components, such as complement factor 9 (77,78).

Physiologic deficiencies of the classic and alternative pathways of complement activation in neonates contribute to inefficient bacterial opsonization (79,80). Organisms such as GBS and *E. coli* that have high capsular sialic acid content tend to be poor activators of the alternative complement pathway (81).

Fibronectin is a multifunctional glycoprotein found in the plasma and on the surface of certain epithelial cells, basement membranes, and connective tissues. In plasma, fibronectin acts as a nonspecific opsonin that enhances clearance of invading bacteria (82). Fibronectin is deficient in neonatal plasma, and its concentration varies inversely with gestational age (82,83). Septic infants have been shown to have significantly lower plasma concentrations of this glycoprotein than healthy, age-matched controls (84). The soluble form of fibronectin binds poorly to GBS (85). Fibronectin enhances phagocyte function *in vitro* and *in vivo* (82).

Quantitative and qualitative deficiencies in neonatal neutrophils contribute to the immaturity of the immune system of newborns. The abnormalities become most pronounced at times of stress or during infections and include impaired chemotaxis, decreased deformability, reduced C3bi receptor expression, depressed bacterial killing by phagocytes, and oxidative metabolic abnormalities. The neutrophil storage pool of neonates is markedly depleted compared with that of adults (86). Stem cell proliferative rates are at near maximal capacity and cannot increase appreciably in response to infection (87).

Clinical Manifestations

Most infants with septicemia present with nonspecific signs that are usually observed first by the nurse or mother rather than by the physician. The most common of these vague signs are temperature instability, lethargy, apnea, and poor feeding (88). Although hypothermia is more common, a temperature elevation above 37.8°C is significant in the neonate and frequently associated with bacterial infections, especially with temperatures higher than 39°C (89). The clinical signs in some infants may suggest respiratory or GI disease (e.g., tachypnea and cyanosis or vomiting, diarrhea, and abdominal distention). Septicemia must always be included in the differential diagnosis when evaluating an infant with these findings (88).

Clinical manifestations of sepsis in very-low-birth weight infants (501-1,500 g) include increasing apnea (55%), feeding intolerance, abdominal distension, or heme-positive stools (43%), increased respiratory support (29%), and lethargy and hypotonia (23%). Abnormal white blood cell count, unexplained metabolic acidosis, and hyperglycemia are noted in 46%, 11%, and 10%, respectively (47).

Although it is tempting to recommend an evaluation for septicemia in all infants with nonspecific clinical manifestations, this is impractical and unnecessary in many cases. A complete history and physical examination, coupled with clinical

experience, are the best guides to determine the extent of the evaluation. If septicemia cannot be reasonably excluded on clinical grounds, a blood culture should be obtained and empiric antibiotics administered. Hepatosplenomegaly, jaundice, and petechiae are classic signs of neonatal infection but represent late manifestations.

Streptococcal Disease

In the 1970s, Group B γ -hemolytic streptococci infections emerged a leading infectious cause of morbidity and mortality in the United States (90,91). By the 1980s, GBS were the most common gram-positive bacteria isolated from blood of infants with septicemia in North America (92). Although control measures such as intrapartum antibiotic therapy which were in widespread practice in the 1990s have reduced the incidence of early onset Group B streptococcal (GBS) disease, GBS remains an important cause of neonatal sepsis. GBS accounts for 10% to 40% of sepsis cases occurring in the first week of life (3,93,94).

In the mid 1980s, clinical trials demonstrated that administering intrapartum intravenous antibiotics could prevent early onset neonatal GBS sepsis (95). In response to these findings, the American Academy of Pediatrics in 1992 provided guidelines recommending intrapartum antibiotic prophylaxis (IAP) of selected GBS carriers (96). In 1996, with additional data and the collaborative efforts of clinicians, researchers, professional organizations and the public health community, the Centers for Disease Control and Prevention (CDC) issued consensus guidelines recommending IAP to prevent GBS maternal-infant transmission

P.1239

(97,98). The 1996 national guidelines recommended that women colonized with GBS at 35 weeks or more of gestation or women with intrapartum risk factors (delivery <37 weeks gestation, intrapartum temperature $\geq 100.4^{\circ}\text{F}$ or rupture of membranes ≥ 18 h) should be offered intrapartum chemoprophylaxis. Additionally, women having a previous infant with invasive GBS disease or women with GBS bacteriuria during pregnancy should also be offered intrapartum chemoprophylaxis. Because of the routine implementation of IAP, the incidence of early onset neonatal infections decreased by 65 percent, from 1.7 per 1000 live births in 1993 to 0.6 per 1000 in 1998 (99). With the decline in early onset GBS disease, there has been a concomitant rise in *E. coli* and ampicillin-resistant *E. coli* sepsis in very low birth weight and preterm infants (4). The CDC and the American College of Obstetricians and Gynecologists have recommended universal screening at 35 or more weeks of gestation and IAP for GBS-colonized women (100,101).

The epidemiology, pathogenesis, and clinical features of GBS disease have been defined (102). The organism is a common inhabitant of the female genital tract

and can be isolated from vaginal and anorectal cultures of as many as 35% of asymptomatic pregnant women (102,103,104,105). Risk factors for maternal GBS colonization include lower parity, higher frequency of intercourse, multiple sexual partners, and concurrent colonization with *Candida* spp (104). Peripartum GBS colonization of the lower urogenital tract has been associated with several maternal complications including preterm labor, premature rupture of membranes, endometritis, chorioamnionitis, urinary tract infection, intrapartum or postpartum fever, late abortions, and invasive infections, such as bacteremia or meningitis (57,106). The identical serotype can be isolated frequently from urethral cultures of the sexual partners of these culture-positive women (107). Although most infected pregnant women have normal, healthy infants, 1% to 2% of pregnancies involving maternal infection result in stillbirths or infants with neonatal disease. Vertical transmission of group B Streptococci occurs in approximately 50% to 70% of mother-infant pairs, resulting in neonatal colonization rates of from 8% to 25%. Transmission is most likely to occur among infants born to heavily colonized mothers (108). The early-onset GBS syndrome occurs within the first 72 hours of life (mean age of onset 20 hours), and 65% of reported cases involve premature infants. There is often a history of other maternal obstetric complications (Table 47-2) (106). Onset is sudden and follows a fulminant course, with the primary focus of inflammation in the lungs, although meningitis can develop. Respiratory distress is the most common initial sign among infants with early onset meningitis (109). Apnea, hypotension, and disseminated intravascular coagulation cause rapid deterioration and often lead to the patient's demise within 24 hours. It is difficult to identify the infant with respiratory distress caused by GBS infection, because in 60% of infected patients, the chest radiograph shows a reticulogranular pattern with air bronchograms indistinguishable from that seen with uncomplicated hyaline membrane disease. The mortality rate is approximately 6% and is inversely correlated with birth weight (110,111). All five GBS serotypes have been incriminated in early-onset disease in roughly similar proportions. A similar syndrome has been associated with groups D and G streptococci (112,113).

TABLE 47-2 Risk factors for early-onset group B streptococcal disease

Premature Delivery
Low Birth Weight
Increased interval between membrane rupture and delivery
Rupture of membranes before labor onset
Amnionitis and intrapartum fever
Maternal group B streptococcal rectovaginal colonization (especially heavy colonization)
African American race
Young (<20 yr) maternal age
Group B streptococcal bacteriuria during current pregnancy

Low level of capsular polysaccharide type-specific antibodies

Previous stillbirth or spontaneous abortion

Multiple gestation

Previous delivery of infant with group B streptococcal disease

Prolonged duration of intrauterine monitoring

Adapted from Schuchat A. Epidemiology of group B Streptococcal disease in the United States: Shifting paradigms. Clin Microbial Rev 1998; 11:497.

A late-onset syndrome caused by GBS or *L. monocytogenes* occurs most frequently at 2 to 4 weeks of age, but it may be seen as late as 16 weeks. The onset is insidious; poor feeding and fever are the most frequent presenting signs. A fulminant illness with rapid onset and progressive deterioration occasionally is encountered (114). Meningitis is seen in approximately 60% of infants with the late-onset syndrome, and GBS serotype III accounts for about 95% of these cases (102). Rarely, infants with late-onset meningitis caused by GBS present with hydrocephalus. These infants may appear to have uncomplicated hydrocephalus with normal lumbar cerebrospinal fluid (CSF). Examination of ventricular fluid reveals pleocytosis, and the organism is recovered on culture. Spinal fluid cultures of infants with meningitis caused by gram-positive organisms usually are sterile within 24 to 36 hours of therapy, and the mortality rate is 10% to 15%.

Approximately 20% of neonatal infections caused by GBS do not fit into the early- or late-onset syndromes and extend over a broad clinical spectrum involving many different organ systems. Several manifestations have been observed (102,115,116):

- Cellulitis
- Scalp abscess
- Impetigo
- Fasciitis
- Breast abscess
- Adenitis
- Supraglottitis

Conjunctivitis

- Orbital cellulitis

P.1240

- Ethmoiditis
- Otitis media
- Pneumonia complicated by empyema
- Myocarditis
- Endocarditis
- Hepatitis
- Septic arthritis
- Osteomyelitis
- Bursitis
- Urinary tract infection
- Omphalitis
- Peritonitis
- Asymptomatic transient bacteremia.

The transient bacteremia is remarkable because these infants appear clinically well and are cultured because of a history of maternal obstetric complications. A repeat blood culture before the institution of antibiotic therapy frequently is sterile. Both relapses and reinfections can occur after invasive GBS infections (102).

Reasons for relapse may include an inadequate penicillin dose, a short duration of therapy of the initial episode, or unrecognized foci of infection (e.g., endocarditis, brain abscess). Reinfection can occur because of maternal GBS mastitis (117). Rifampin (20 mg/kg/d for 4-7 days) has been used to eradicate GBS carriage in infants with recurrent disease and is given after completion of systemic penicillin therapy (117).

Coagulase-Positive Staphylococcal Disease

The phage group I *S. aureus*, which was common in the late 1950s, still exists in some nurseries and occasionally causes serious systemic neonatal disease. The pathogenicity of this organism is based on its ability to invade the skin and musculoskeletal system, producing furuncles, breast abscesses, adenitis, and osteomyelitis. Septicemia usually is secondary to local invasion. After *S. aureus* is recovered from blood cultures of neonates, a careful search should be made for a primary focus. Some group I *S. aureus* strains produce toxic shock syndrome toxin-1, formerly known as enterotoxin F or pyrogenic toxin C, and have caused toxic shock syndrome in older neonates (118,119). Clinical characteristics of this disease include the sudden onset of fever, diarrhea, shock, mucous membrane hyperemia, and a diffuse erythematous macular rash with subsequent desquamation of the hands and feet, commencing on about the fifth or sixth day of illness.

In the early 1970s, phage group II coagulase-positive staphylococci emerged as a common cause of neonatal infection. Although this organism may be invasive, pathogenicity depends principally on production of exotoxins (e.g., exfoliative or epidermolytic toxins A and B). Common areas of primary infection include the umbilical stump, conjunctiva, and throat; infection of a surgical wound has been described (120). The exfoliative toxins act on the zona granulosa of the epidermis and cause epidermal splitting through activity of the toxins on the desmosomes (121). Clinical disease may take one of several forms, including bullous impetigo, toxic epidermal necrolysis (Ritter disease), and nonstreptococcal scarlatina. Collectively, these diseases have been referred to as the expanded scalded skin syndrome (Fig. 47-1) (122).

Figure 47-1 A 10-day-old Caucasian boy with staphylococcal scalded skin syndrome. He was treated with fluids, oral dicloxacillin, and wound care. His skin healed completely and without scarring within 2 weeks of this photograph being taken.

The initial finding in Ritter disease is generalized erythema associated with edema and tenderness on palpation, usually noticed between days 3 and 16 of life (123). After several days, a distinctive desquamation of large sheets of epidermis occurs, which is different from the fine desquamation observed in the second and third weeks of streptococcal scarlet fever. Large flaccid bullae commonly observed in Ritter disease will, on rupture, leave a tender, weeping erythematous base. Some infants may appear quite toxic with the generalized form of disease. A rare, congenital form of staphylococcal scalded skin syndrome has been described (124). Spread within a nursery can occur, and its recognition warrants the prompt institution of infection control measures to limit the spread of the toxigenic strain of *S. aureus* (125).

Umbilical venous or arterial catheters and central venous lines are well-recognized risk factors for staphylococcal bacteremia. *S. aureus* is second only to coagulase-negative staphylococci as a cause of catheter-related infections (126).

The mortality rate for neonates with *S. aureus* bacteremia is about 20%. LBW infants are at highest risk of death from this infection (127).

Coagulase-Negative Staphylococcal Disease

can be significant, and these bacteria should not be dismissed as contaminants. Of the at least 30 recognized coagulase-negative staphylococcal species, *S. epidermidis* is clinically the most significant for neonates (128,129,130). Experience indicates that these bacteria are responsible for about 10% to 27% of all cases of sepsis in NICUs, but can account for as many as 48% of late-onset sepsis cases in VLBW infants (3,92) Coagulase-negative staphylococcal infections are nosocomial in origin and result in substantially longer hospitalizations for affected infants (131,132). Risk of infection with these organisms increases with decreasing gestational age and birth weight (133,134,135,136).

Clinical manifestations of coagulase-negative staphylococcal infections are similar to those caused by other pathogens and include apnea, bradycardia, temperature instability (e.g., hypothermia, hyperthermia), respiratory distress (e.g., tachypnea, retractions, cyanosis), GI manifestations (e.g., poor feeding, abdominal distention, bloody stools), lethargy, and metabolic acidosis (12,129). Clinical illnesses include septicemia, meningitis with or without CSF abnormalities, necrotizing enterocolitis, pneumonia, omphalitis, soft tissue abscesses associated with persistent bacteremia, endocarditis, and scalp abscesses and osteomyelitis at insertion sites of fetal monitoring electrodes (133,134,135,136,137,138,139,140,141,142,143,144).

Risk factors for coagulase-negative staphylococcal infections include the presence of foreign bodies, such as central venous lines, ventriculoperitoneal shunts, or peritoneal dialysis catheters, prior antibiotic therapy, and intravenous infusion of lipid emulsions for nutritional support (129, 145,146). The organisms travel along catheter tracks from colonization sites. They eventually adhere to, and proliferate on, certain biosynthetic materials and later cause local or systemic reactions. The mechanism by which adherence occurs appears initially to involve hydrophobic and electrostatic interactions between the bacteria and the biopolymers (129). Once attached, a viscous exopolysaccharide referred to as slime is formed. Slime covers the bacteria to form a surface biofilm that protects them from such environmental factors as antibiotics and host defenses although allowing continued access to nutrition (129). The density of the biofilm may be increased if the organisms are exposed to subinhibitory concentrations of antibiotics to which they are susceptible (e.g., vancomycin) (147). Slime appears to inhibit neutrophil chemotaxis and phagocytosis and the lymphoproliferative responses of mononuclear cells to mitogens (148,149). Slime-producing strains account for most coagulase-negative staphylococci isolated from infants with invasive infections (135). Ineffective opsonophagocytosis as a result of intrinsic deficiencies in neonatal host defenses contributes to the increased susceptibility of LBW infants to infection with these organisms (150,151).

Coagulase-negative staphylococci produce a variety of toxins that may serve as virulence factors, including hemolysins, proteases, urease, and fibrinolysin (12). Most fecal isolates produce a hemolysin that functionally and immunologically is identical to the delta toxin produced by *S. aureus* (152). This toxin causes severe mucosal necrosis and hemorrhage when injected into ligated infant rat bowel loops and may play a role in the pathogenesis of neonatal necrotizing enterocolitis (153,154).

Listeria monocytogenes Disease

The incidence of perinatal listeriosis decreased by about 51% between 1989 and 1993, from 17.4 to 8.6 per 100,000 persons younger than 1 year of age (155,156). This reduction was related temporally with industry, regulatory, and educational efforts to aggressively enforce food monitoring policies.

The pathogenesis of clinical diseases caused by *L. monocytogenes* is similar to those caused by GBS. A fulminant, disseminated disease (granulomatosis infantiseptica) may occur during the first several days of life. The pathogen is acquired transplacentally or by aspiration at the time of vaginal delivery, and multiple organ systems (e.g., liver, spleen, kidneys, lungs, brain, and skin) are involved; 35% to 55% of infants die of their infection (157,158). The infant frequently presents with hypothermia, lethargy, and poor feeding. Early passage of meconium in a premature infant suggests *Listeria* infection (159). A characteristic rash consisting of small, salmon-colored papules scattered primarily on the trunk can be observed in some infants. The chest roentgenogram shows parenchymal infiltrates suggestive of aspiration pneumonitis in most infants. A miliary-type of bronchopneumonia can be seen in some cases. *Listeria* serotypes Ia, Ib, and IVb produce the early onset disease, whereas serotype IVb is the predominant type in late-onset meningitic disease (160).

A delayed form of neonatal listeriosis occurs during the second through fifth weeks of life and primarily involves the meninges (160,161). The infected infant usually is the full-term product of an uncomplicated labor and delivery. Onset of symptoms and signs is relatively insidious and indistinguishable from those observed with meningitis caused by other pathogens. The source of the organism in late-onset disease is unclear. Although acquisition of *Listeria* may occur during passage through an infected birth canal, it appears that most cases result from postpartum horizontal spread. In favor of the latter route of infection are several reported clusters of neonatal listeriosis and the demonstration of cross-infections between newborns using enzyme electrophoretic typing and DNA fingerprinting (157,162,163,164).

The peripheral leukocyte count usually shows a brisk leukocytosis, with a predominance of polymorphonuclear leukocytes in the differential count (165). A significant elevation in the number of monocytes, to 7% to 21% of the total

leukocyte count, has been documented on admission laboratory evaluation of infected infants. A monocytosis of this magnitude can be demonstrated in most remaining infants on repetitive testing of the peripheral leukocyte count, but monocytes typically are not found in the spinal fluid of infants infected with *L. monocytogenes*. Polymorphonuclear leukocytes predominate in about 75% of cases, with a relative lymphocytosis in the

P.1242

remaining 25%. In contrast, adults with *Listeria* meningoencephalitis may have CSF monocytosis of 80% to 90% (158). As with other pyogenic meningitides, hypoglycorrhachia and elevated protein concentrations are frequent findings. Examination of the stained smear of spinal fluid has not been rewarding in more than 50% of cases. This is a reflection of the relatively low concentrations of organisms in the fluid. The bacteriology laboratory should be forewarned of the clinical suspicion of *Listeria* meningitis, because these microorganisms occasionally are discarded as contaminants because of their tinctorial and morphologic similarities with diphtheroids. Overnight refrigeration of spinal fluid specimens frequently enhances growth of this organism.

Enterococcal Infection

Group D streptococci were formerly divided into enterococcal and nonenterococcal types. The enterococci are now included in the new genus *Enterococcus*; most neonatal infections are caused by *Enterococcus faecalis* and, to a lesser extent, by *E. faecium* (166,167,168).

Early onset enterococcal disease (less than 7 days of age) is relatively mild and presents clinically with respiratory distress or diarrhea. No associations with underlying conditions, invasive procedures, or maternal obstetric complications have been observed (169). Late-onset disease (≥ 7 days of age) most commonly afflicts low-birth weight infants with complicated clinical problems that often require surgical procedures (e.g., bowel resection), central venous catheters, or prior treatment with antimicrobials. Clinical manifestations of late-onset disease include apnea, bradycardia, circulatory failure, meningitis, pneumonia, scalp abscesses, catheter-related bacteremia, and necrotizing enterocolitis-associated septicemia (169). About 20% of enterococcal blood isolates represent skin contamination; clinical correlation is needed to differentiate contamination from true infection (167).

Enterococci can spread rapidly within a nursery (170). Nosocomial outbreaks of enterococcal septicemia in NICUs are well documented (168,171). The mortality rate is estimated at 6% to 11%, but it can be as high as 17% in infants with necrotizing enterocolitis-associated septicemia (167,169).

The importance of identifying *Enterococcus* as the etiologic agent in septicemia primarily relates to selection of proper antimicrobial agents. The enterococci are

moderately resistant to penicillin alone, as a result of certain properties of their penicillin-binding proteins (167,172). Some enterococcal strains have acquired new mechanisms of antibiotic resistance that include γ -lactamase production and high-level aminoglycoside resistance (minimal inhibitory concentrations [MIC] $\geq 2,000 \mu\text{g/mL}$) (170,173,174). Strains resistant to the glycopeptides vancomycin and teicoplanin (glycopeptide-resistant enterococci) were first described in 1987 and since have emerged as major nosocomial pathogens (175,176,177,178,179). Nonenterococcal group D streptococci continue to be susceptible to penicillin (167).

Gram-Negative Bacterial Infection

In North America, *E. coli* is the most common gram-negative organism causing septicemia during the neonatal period. *Klebsiella* and *Enterobacter* strains are second (3,92). In contradistinction to illness caused by GBS and *L. monocytogenes*, *E. coli* infections do not fit into distinct clinical syndromes of early- and late-onset disease. Approximately 40% of *E. coli* strains causing septicemia possess K1 capsular antigen, and strains identical with those isolated from blood cultures usually can be identified in the patient's nasopharynx or rectal cultures. The clinical features of *E. coli* sepsis generally are similar to those observed in infants with disease caused by other pathogens. Respiratory distress is noted in about 73% with *E. coli* sepsis occurring during the first week of life (180). Localized *E. coli* infections have included breast abscess, cellulitis, pneumonia, lung abscess, empyema, osteomyelitis, septic arthritis, urinary tract infection, ascending cholangitis, and otitis media.

An increase in the proportion of neonatal *E. coli* sepsis cases caused by ampicillin-resistant strains has been noted by several investigators (3,180,181) This shift occurred as maternal intrapartum prophylaxis for the prevention of early onset GBS sepsis was being implemented more widely by obstetricians at these medical centers. Most deaths were seen in neonates infected with ampicillin-resistant *E. coli* strains.

Pseudomonas septicemia may present with a characteristic violaceous papular lesion or lesions that, after several days, develop central necrosis. Although these skin lesions most commonly are seen in *Pseudomonas* infection, they may be associated with other organisms (182). *Pseudomonas* typically is encountered in late-onset sepsis, although occasional newborns with an early-onset form of this infection have been reported.

Neonatal infections caused by *H. influenzae* biotype IV have increased in frequency in the last 20 years and currently account for about 8% of early-onset sepsis in very LBW infants (401-1,500 g) (3,183). These strains are nontypeable, have a distinct multilocus enzyme genotype revealed by clonal analysis, express peritrichous fimbriae and a variant P6 outer membrane protein, and have a characteristic outer membrane electrophoretic profile. Genetic analysis suggests

that these strains represent a cryptic genospecies only distantly related to *H. influenzae* or *Haemophilus haemolyticus* (183,184).

Anaerobic Infections

Anaerobes account for up to 25% of all bacteria isolated from blood cultures of neonates with suspected septicemia in various studies (185,186,187,188). A recent retrospective review of neonatal bacterial infections suggests that the incidence of anaerobic isolates is about 1% (189). *Bacteroides* spp, primarily *Bacteroides fragilis*, and clostridia are most commonly recovered (187).

Peptostreptococcus spp, *Veillonella* spp, *Propionibacterium acnes*, *Eubacterium* spp, and *Fusobacterium* spp occur relatively infrequently. Anaerobes are found

P.1243

mixed in cultures with aerobic bacteria in about one-third of cases. Clinical illnesses include transient bacteremia, fulminant septicemia, postoperative infections, and intrauterine death associated with septic abortion (185). Localized diseases such as omphalitis, cellulitis, and necrotizing fasciitis are seen commonly with clostridia (190). Conditions predisposing to anaerobic septicemia include prolonged rupture of membranes, chorioamnionitis, prematurity, and GI disease.

Anaerobes isolated from blood within the first 2 days of life are usually gram-positive and penicillin G-susceptible, but those isolated from older newborns tend to be gram-negative and penicillin G-resistant (186). Gram-positive anaerobes are more likely to be recovered from blood of infants with sepsis associated with chorioamnionitis, whereas gram-negative anaerobes predominate in necrotizing enterocolitis-associated bacteremia (186). The mortality rates for reported cases of anaerobic septicemia are about 35% for illnesses caused by *Bacteroides* spp and 12% for other anaerobes (187).

Genital Mycoplasmas

M. hominis and *U. urealyticum* occasionally are isolated from the blood of neonates with sepsis. Cassell and colleagues (36) observed concomitant bacteremia in 40% and 26% of preterm infants with positive endotracheal cultures for *M. hominis* and *U. urealyticum*, respectively. Other investigators were unable to recover genital mycoplasmas from the blood or CSF of neonates with suspected sepsis (191- 192). An association between persistent pulmonary hypertension and *U. urealyticum* sepsis and pneumonia has been observed (193).

Fungal Infections

Fungal sepsis occurs in as many as 12% of LBW infants (3). Most cases are as a result of *Candida* spp, particularly *C. albicans* (194,195,196). *C. tropicalis*, *C. parapsilosis*, *C. lusitanae*, and *C. glabrata* also cause systemic candidiasis (196).

Congenital candidiasis is uncommon and results from ascending infection through intact membranes. It usually manifests with early skin lesions (e.g., maculopapular rash, pustules, vesicles, desquamation, skin abscesses), but disseminated and life-threatening infections can occur (197,198).

The incidence of candidemia in NICUs is increasing steadily. In one such unit in Norfolk, Virginia, the rate of candidemia increased over 11-fold in the 15-year period between 1981 and 1995. Additionally, *C. parapsilosis* was responsible for 60% of all candidemias during the last 5 years of the study period (199).

Risk factors for late-onset systemic candidiasis include prematurity, low birth weight, use of broad-spectrum antimicrobial agents, H2 blocker therapy, steroid therapy, central vascular catheters, parenteral hyperalimentation, intralipid infusions, prolonged endotracheal intubation, necrotizing enterocolitis, and immunologic immaturity (200,201,202). The most important of these factors appears to be the number of prior antibiotics and the duration of therapy (203,204). LBW infants in whom mucocutaneous candidiasis develops are at considerable risk of subsequent invasive disease (203,204,205). Infants with invasive candidiasis caused by *C. albicans* are more likely to have antecedent candidal thrush or perineal dermatitis and to die of their infection than neonates with severe *C. parapsilosis* infections (199,206). Clinical manifestations vary and are indistinguishable from those caused by other pathogens. A fungal cause for sepsis should be considered strongly in an infant weighing less than 1,500 g who has been hospitalized for a prolonged period, is receiving parenteral hyperalimentation through a central vascular catheter, and previously has been treated with multiple antibiotics; a history of GI disease or surgery adds to the clinical suspicion. Diseases caused by *Candida* spp include, but are not limited to, pneumonia, endocarditis, endophthalmitis, meningitis, cerebral abscesses, pyelonephritis, renal mycetoma (fungal balls), peritonitis, hepatosplenic abscesses, arthritis, and osteomyelitis (194,207,208,209,210,211,212,213,214,215).

Malassezia furfur causes invasive neonatal fungal disease. Most infections involve chronically ill premature infants who are receiving lipid emulsions through a central venous catheter (216). The most commonly reported presenting signs include fever (50%) and respiratory distress (50%). Pathologic analysis reveals mycotic thrombi around catheter tips, endocardial vegetations, and lung lesions that include mycotic emboli with occlusion of pulmonary arteries, septic thrombi, pulmonary vasculitis, and alveolitis (216). Involvement of other organs is uncommon. *Malassezia pachydermatis* is a recently recognized human pathogen that has been incriminated in NICU outbreaks of bloodstream, urinary tract, and central nervous system infections. In one reported outbreak, the source of *M. pachydermatis* was the contaminated hands of health care workers who were colonized from their pet dogs at home (217). Systemic infections as a result of other fungi such as *Torulopsis glabrata*, *Hansenula anomala*, *Aspergillus* spp,

Cryptococcus neoformans, *Coccidioides immitis*, *Blastomyces* spp, and *Trichosporon beigeli* are rare (218,219,220,221).

Laboratory Tests and Findings

Since the early 1970s, several screening tests and scoring systems have been described that are purported to aid the physician in making the diagnosis of neonatal infection. Although a few are helpful in identifying the infant at high risk of developing infection, the diagnosis of septicemia can be made only by recovery of the organism from blood cultures or other normally sterile body fluids (221,222). It is imperative that these cultures be obtained by strict aseptic technique. Blood should be obtained from a peripheral vein rather than from the umbilical vessels, the outer several millimeters of which are contaminated frequently with bacteria. Femoral vein aspiration may result in cultures contaminated with coliform organisms from the perineum. Heelstick samples have low sensitivities. The skin

P.1244

overlying the vein to be punctured should be cleansed with an antiseptic solution, such as an iodophor, and allowed to dry for maximal antiseptic effect. The amount of blood drawn is critical; 1 to 2 mL of blood is required for optimal results (223). The sensitivity of a single blood culture in identifying septicemia is only 80% (222). Obtaining blood cultures from multiple sites may enhance the yield and aid in identifying false-positive results (224). Quantitative blood cultures, if available, are helpful in differentiating true pathogens from culture contaminants (225,226). Routine blood culture methods are sufficient for the detection of *Candida* septicemia (227); however, if *M. furfur* is a suspected pathogen, the microbiology laboratory should be alerted so that blood can be inoculated onto special media that provide for the organism's absolute nutritional requirement for medium-chain fatty acids (196).

It frequently is helpful to obtain cultures of other sites before initiating antimicrobial therapy. For example, percutaneous bladder aspiration of urine for culture can be helpful in identifying the urinary tract as the focus of infection. This is particularly true for illness occurring after the third postnatal day.

Nasopharyngeal, skin, umbilical cord, gastric, and rectal cultures frequently are positive in the early septicemic form of listeriosis and GBS disease. However, these colonization sites are not predictive of the cause of bloodstream infection and should not be used to guide antimicrobial therapy (228). All clinically stable infants with suspected septicemia should have CSF obtained for examination and culture before therapy. This practice has been challenged for infants younger than 7 days of age because of its low yield; the yield from a lumbar puncture is much higher when performed on infants older than 1 week of age (229,230,231,232,233,234,235). Practitioners opting to forego performing a lumbar puncture for infants with suspected early onset sepsis should anticipate

that, on occasion, the diagnosis of meningitis will be delayed or missed because not all newborns with bacterial meningitis have positive blood culture results (234,236).

The peripheral leukocyte count is the most frequently used indirect indicator of bacterial infection. After correction for the nucleated erythrocyte count, the total absolute neutrophil count and the ratio of immature to total neutrophilic forms are compared with normal standard values for age. In the absence of maternal hypertension, severe asphyxia, periventricular hemorrhage, maternal fever, or hemolytic disease, absolute total neutropenia and an elevated ratio of immature to total neutrophilic forms suggest bacterial infection (237,238). Infants born in high-altitude areas have higher total and immature neutrophil counts (239). Wide interreader differences in band neutrophil identification have been observed, thereby limiting the utility of the immature to total neutrophil ratio in actual clinical practice (240). Repeating complete blood counts within 24 hours of birth may enhance the value of the test as a screen for sepsis high-risk infants (239). In the absence of clinical signs of sepsis, leukocyte values are unlikely to rule out infection. In a prospective, observational study of 856 near-term or term neonates without clinical signs of sepsis who were exposed to maternal chorioamnionitis, 99% had at least 1 abnormal neutrophil value based on published reference values (237,238,239,240,241,242). Single or serial neutrophil values did not assist in the diagnosis of early onset infection or determination of duration of antibiotic therapy in the at risk but culture-negative infants (243).

Gastric aspirate stains and culture, erythrocyte sedimentation rate, C-reactive protein (CRP), and the nitroblue tetrazolium test have not proved useful as indicators of bacterial infection, although in combination these tests may offer some guidance (244). CRP values appear not to be influenced by perinatal asphyxia, hyperbilirubinemia, periventricular hemorrhage, or respiratory distress syndrome (245). Serial CRP measurements may be helpful in identifying infants not likely to be infected and in whom antibiotics can be safely stopped (246). The detection of interleukin-6 (IL-6) in serum, especially in conjunction with an elevated CRP or procalcitonin measurement, may be useful in the early diagnosis of neonatal infection (243,244,245,246,247,248,249,250,251,252). The levels of granulocyte colony-stimulating factor, neutrophil CD11b expression, circulating intracellular adhesion molecule-1, interleukin-1 receptor antagonist (IL-1ra), serum procalcitonin, and interleukin-8 are all elevated in newborns with sepsis, but how these laboratory findings can best be utilized for the diagnosis of neonatal sepsis is yet to be defined (247,249,250,253,254). In one study, IL-1ra and IL-6 levels were found to be elevated (a 15-fold median maximal increase) 2 days before a diagnosis of sepsis was made (250).

Detection of the soluble antigens of *E. coli* KI, GBS, *H. influenzae* type b, *N. meningitidis*, and *S. pneumoniae* by latex particle agglutination (LPA) is useful for identifying the infant infected with these pathogens. The absence of antigen does

not rule out infection by these organisms. Substantial sensitivity differences have been found among the commercially available LPA assays for GBS antigen (255). False-positive LPA test results for GBS in urine specimens can result from contamination of bag specimens with these bacteria from perineal and rectal colonization, cross-reacting antigens, or absorption of antigen from the GI tract (256,257). Similar false-positive test results may be obtained for the other bacteria. Rapid diagnosis of invasive *Candida* infection by detection of its circulating cell wall (e.g., mannan), cytoplasmic (e.g., enolase), or heat-labile antigens is possible, although the reliability of these tests is yet to be proved (258).

Therapy

After septicemia is suspected, suitable cultures should be obtained and therapy with ampicillin and an aminoglycoside started immediately. If meningitis has been excluded, ampicillin is administered intravenously or intramuscularly in individual doses of 50 mg/kg given every 12 hours, or 8 hours for infants weighing <2,000 g or ≥2,000 g, respectively. The frequency is increased 3 or 4 times daily for infants 1 to 4 weeks of age, depending on their birth weight. The selection of the aminoglycoside

P.1245

antibiotic should be based on antimicrobial susceptibilities of enteric organisms isolated from infants in each nursery. Gentamicin is the drug of choice for treatment of infections caused by susceptible gram-negative organisms and is administered intravenously or intramuscularly in a dosage of 4 to 5 mg/kg at 24 to 48 hour intervals depending on the infant's postmenstrual and postnatal age (259).

Aminoglycoside-resistant *E. coli* have been encountered in some nurseries in North America. In these nurseries or in an infant from whom an isolate is shown to be resistant to kanamycin or gentamicin, amikacin or cefotaxime should be used. Studies have demonstrated no significant ototoxicity in infants and children who were treated in the neonatal period with kanamycin or gentamicin (48). However, in premature infants and in those receiving these drugs for prolonged periods, brainstem evoked response audiometry should be performed whenever possible. Serum concentrations of the aminoglycosides should be monitored in LBW premature infants because of erratic absorption and elimination of the drugs in these infants. Although cefotaxime should not be used routinely for initial empiric therapy of neonatal sepsis, it is an effective agent when used alone or combined with an aminoglycoside for infections caused by coliform bacilli.

When the type of skin lesions or historic experience suggests the possibility of *Pseudomonas* infection, ceftazidime, piperacillin or ticarcillin with or without an aminoglycoside is the therapy of choice. Although not approved for use in neonates by the Food and Drug Administration, we have successfully used

ticarcillin-clavulanate and piperacillin-tazobactam for treatment of sepsis caused by multiresistant gram-negative enteric bacilli, *Pseudomonas*, and anaerobic bacteria.

If *S. aureus* sepsis is suspected but not proved, parenteral methicillin or nafcillin should be substituted for penicillin or ampicillin, because approximately 80% of these staphylococci will be penicillin-resistant. Although gentamicin and kanamycin possess activity against most staphylococci, these agents cannot be recommended because there are no studies of their efficacy in neonatal staphylococcal disease. For disease caused by coagulase negative staphylococci or multiresistant *S. aureus* strains, vancomycin is the preferred therapy. Peak and trough serum vancomycin concentrations should be monitored because of the drug's narrow therapeutic index.

After the pathogen is identified and its antimicrobial susceptibilities are known, the most appropriate drug or drugs should be selected. As a general rule, gentamicin alone or in combination with ampicillin, or cefotaxime alone or in combination with an aminoglycoside, should be used for susceptible *E. coli*, *Klebsiella* spp, and *Enterobacter* spp; amikacin alone or in combination with cefotaxime for gentamicin-resistant coliform bacteria; ceftazidime, piperacillin, ticarcillin, piperacillin-tazobactam, or ticarcillin-clavulanate, with or without an aminoglycoside, for *Pseudomonas*; ampicillin alone or in combination with an aminoglycoside for *P. mirabilis*, enterococci, and *L. monocytogenes*; and penicillin for other gram-positive organisms, except for penicillin-resistant *S. aureus*, for which methicillin or nafcillin is the drug of choice. Vancomycin is used for coagulase-negative staphylococci and MRSA. Rarely, coagulase-negative staphylococcal strains that are resistant to vancomycin can emerge during treatment with this agent (260). *S. aureus* strains with reduced susceptibility to vancomycin (glycopeptide-intermediate *S. aureus* [GISA]) have been isolated from a few patients with a variety of infections. The first such clinical isolate was described in a 4-month-old Japanese infant with a nosocomial surgical site infection (261,262). No GISA strains have been identified in newborns to date. Treatment of GISA-related infections generally requires the use of drugs such as linezolid. The MIC and minimal bactericidal concentration (MBC) of penicillin and ampicillin should be determined for GBS because a small percentage of these organisms are tolerant (i.e., have an MBC to MIC ratio greater than 32) to these antibiotics (263). These strains are best treated with a penicillin-aminoglycoside combination. Penicillin resistant and vancomycin-tolerant pneumococci have been reported in newborn infants in France but not yet in North America (264). The therapeutic options for vancomycin-resistant enterococcal infections in neonates are seriously limited. Some strains may be susceptible to a combination of penicillin or ampicillin and an aminoglycoside. Chloramphenicol or tetracyclines may be effective against some strains, but these drugs have serious toxicities for neonates. Nitrofurantoin is active against many vancomycin-resistant enterococcal strains and has been used to treat enterococcal urinary tract infections in adults.

Dalfopristin-quinupristin is approved for use in adults, but there are no data on its use in infants. Several investigational ketolides, oxazolidinones, glycylicyclines, and even newer semisynthetic glycopeptides with in vitro activities against vancomycin-resistant enterococci are being evaluated (265). *U urealyticum* infections are treated with erythromycin (266).

Three classes of antifungals are commonly used in the treatment of systemic fungal infections in neonates: the polyene macrolides (amphotericin B [deoxycholate and lipid preparations]); the azoles (fluconazole); and the fluorinated pyrimidines (flucytosine). The drug of choice for systemic fungal infections is amphotericin B, with or without flucytosine (194,267). The half-life and serum concentrations of amphotericin B are highly variable during the neonatal period (268). The drug appears to be better tolerated by infants than older children and adults, but renal and hepatic functions should be monitored carefully (194,269). The optimal daily dosage of amphotericin B is not universally agreed on. The most commonly used dosage regimen is to begin with 0.5 mg/kg of the drug on the first day and, if tolerated, to increase the daily dosage to 1.0 mg/kg by the second or third day of treatment. The cumulative dosage of amphotericin B needed for the adequate treatment of systemic *Candida* infection is not well defined, but it is estimated to be 20 to 30 mg/kg (194). Resistance to amphotericin B among *Candida* species is not a major clinical problem (270). Amphotericin B frequently is combined with flucytosine for the treatment of central nervous system fungal infection because of flucytosine's

P.1246

excellent CSF penetration and the *in vitro* synergy of this drug combination against *Candida*. GI intolerance, myelosuppression, and hepatotoxicity are common side effects of flucytosine (194).

Experience with the use of liposomal amphotericin B preparations in newborns is growing (271,272,273,274,275,276). Linder and colleagues (275) compared the effectiveness and tolerability of three antifungal preparations, amphotericin B, liposomal amphotericin B (LamB) and amphotericin B colloidal dispersion (ABCD), for the treatment of 52 neonates with *Candida* bloodstream infection. Sterilization of the blood was achieved with amphotericin B in 68% of patients, LamB in 83% and ABCD in 57%, when used as monotherapy; with the addition of a second antifungal agent, success rates were 100%, 83.3%, and 92.8%, respectively. There were no differences between the groups in the time to resolution of fungemia. No patients had immediate local or systemic adverse events and none showed deterioration in renal function. Juster-Reicher and colleagues (276) evaluated high-dose (5-7 mg/kg/day) liposomal amphotericin B in 37 very low birth weight infants with systemic candidiasis. Candidiasis was as a result of *C. parapsilosis* in 17 cases, and *C. albicans* in 15 cases. Fungal eradication was achieved in (95%) episodes; median duration of therapy until fungal eradication was 8.76 4.5 days. The authors concluded that high-dose liposomal amphotericin

B was effective and safe in the treatment of neonatal candidiasis. Additionally, fungal eradication was more rapid in patients treated early with high doses and in patients who received high-dose liposomal amphotericin B as first-line therapy. At present, lipid formulations of amphotericin B do not appear to be more efficacious than conventional amphotericin B deoxycholate, and their use should be limited to patients who are either refractory to, or intolerant of, the regular amphotericin B preparation (277).

The use of fluconazole for the treatment of neonatal candidiasis is increasing slowly, but the cumulative published experience is meager (278,279,280). Wenzl and colleagues (280) successfully treated three premature infants (gestational ages 24 to 29 weeks) with *C. albicans* sepsis using oral fluconazole at doses of 4.5 to 6 mg/kg once daily for 4 to 6 weeks. Huttova and associates (279) from the Slovak Republic treated 40 newborns with fluconazole, 28 of whom weighed less than 1,500 g at birth. All infants had fungemia with *C. albicans*. Fluconazole was administered as a single daily intravenous dose of 6 mg/kg for a total of 6 to 48 days. A cure rate of 80% was achieved; 10% died as a direct consequence of their infection. Mild elevations of liver enzyme concentrations were noted in 5% of neonates. The same group has subsequently reported their experience in 40 neonates with breakthrough fungemias as a result of *C. albicans* and *C. parapsilosis* appearing although receiving fluconazole therapy even though initial antifungal susceptibility testing demonstrated that the isolates were susceptible to fluconazole (281). At present, there is little evidence to support the use of fluconazole as mono-therapy in neonatal fungal sepsis.

Guidelines for determining duration of therapy in the neonatal period often are lacking, because objective evidence of illness may be minimal. Culture of the blood should be repeated 24 to 48 hours after initiation of therapy; if positive, alteration of therapy may be necessary. In the absence of deep tissue involvement or abscess formation, treatment usually is continued 5 to 7 days after clinical improvement. If multiple organs are involved or clinical response is slow, treatment may need to be continued for 2 to 3 weeks.

Suspected central venous catheter-related bacterial sepsis can be managed initially with the intraluminal infusion of vancomycin combined with ceftazidime or an aminoglycoside. After infection is confirmed and the pathogen identified, single-drug therapy usually is sufficient. Reported cure rates with antibiotics alone without catheter removal have ranged from 50% to more than 90% for pediatric patients. Persistently positive blood cultures after 2 to 4 days of appropriate antimicrobial therapy warrants catheter removal. A continuous infusion of a low dose of urokinase for 24 hours may help in clearing catheter-related infections in some infants who fail conventional antibiotic therapy but this product is no longer available (282). Patients responding to antibiotic therapy should be treated for 2 to 3 weeks or at least for 10 days from the time of the first negative blood culture. Catheter-related fungal infections are rarely cured without catheter removal (283).

Immunotherapy of neonatal sepsis is discussed in Chapter 46. Extracorporeal membrane oxygenation for newborns with persistent pulmonary hypertension as a result of overwhelming early onset GBS sepsis may improve their survival (284).

Prevention

The identification of high-risk GBS-carrier mothers and the subsequent interruption of vertical transmission by intrapartum maternal chemotherapy can prevent many cases of early-onset neonatal GBS disease (43,49,99,110). Many approaches have been suggested and some have been tested. They range from giving penicillin prophylaxis to all newborns or ceftriaxone prophylaxis to all women in labor, to screening all pregnant women for GBS carriage at one or more points in pregnancy and treating antepartum or intrapartum with penicillin or ampicillin, to only offering intrapartum antibiotics to women who meet certain criteria that place them at high risk of delivering an infant with early onset GBS disease. Currently, the CDC and the American College of Obstetricians and Gynecologists recommend universal screening to detect maternal GBS colonization and treatment of those gravidas who are positive with intrapartum antibiotics (Table 47-3).

Intrapartum antibiotic prophylaxis-related adverse effects include the small but real risk of death from anaphylaxis for women (estimated risk of 0.001%) and an increase in the proportion of infants with sepsis caused by ampicillin-resistant bacteria (4). A recent study examined the susceptibility profile of 119 colonizing and 8 invasive GBS strains

P.1247

collected from two hospitals in Birmingham, Alabama, between January 1996 and September 1997 from predominantly vaginally delivered term newborns and found that the GBS isolates almost universally were penicillin susceptible, with only a small minority of the strains showing moderate penicillin or ampicillin susceptibility (285). However, between 16% to 21% of GBS isolates are erythromycin resistant and 4% to 15% are clindamycin resistant, which raises concerns about the possible inadequacy of currently recommended alternatives for penicillin- allergic women (285,286).

<p>TABLE 47-3 SUMMARY OF CENTERS FOR DISEASE CONTROL AND PREVENTION RECOMMENDATIONS FOR THE PREVENTION OF NEONATAL EARLY-ONSET GROUP B STREPTOCOCCAL SEPSIS</p>
--

- All pregnant women should be screened at 35–37 weeks gestation for vaginal and rectal GBS colonization. At the time of labor or rupture of membranes, intrapartum chemoprophylaxis should be given to all pregnant women identified as GBS carriers.
- Women with GBS isolated from the urine in any concentration during their current pregnancy should receive intrapartum chemoprophylaxis.
- Women who have previously given birth to an infant with invasive GBS disease should receive intrapartum chemoprophylaxis.
- If the result of GBS culture is not known at the onset of labor, intrapartum chemoprophylaxis should be administered to women with any of the following risk factors: gestation <37 weeks, duration of membrane rupture ≥ 18 hours, or a temperature of $\geq 100.4^{\circ}\text{F}$ ($\geq 38.0^{\circ}\text{C}$).
- Women with threatened preterm (<37 weeks' gestation) delivery should be assessed for need for intrapartum prophylaxis to prevent perinatal GBS disease.
- GBS-colonized women who have a planned cesarean delivery performed before rupture of membranes should not routinely receive intrapartum chemoprophylaxis for perinatal GBS disease prevention.
- For intrapartum chemoprophylaxis, the following regimen is recommended for women without penicillin allergy: penicillin G, 5 million units intravenously initial dose, then 2.5 million units intravenously every 4 hours until delivery. An alternative regimen is ampicillin, 2 g intravenously initial dose, then 1 g intravenously every 4 hours until delivery.
- Intrapartum chemoprophylaxis for penicillin-allergic women but not at high risk for anaphylaxis should be given cefazolin, 2 g intravenously initial dose, then 1 g intravenously every 8 hours until delivery. Women at high risk for anaphylaxis should be given either clindamycin, 900 mg intravenously every 8 hours until delivery, OR erythromycin, 500 mg intravenously every 6 hours until delivery.
- Routine use of antimicrobial prophylaxis for newborns whose mothers received intrapartum chemoprophylaxis for GBS infection is not recommended.

Adapted from Schrag S, Gorwitz R, Fultz-Butts K, et al. Prevention of perinatal group B streptococcal disease. Revised guidelines from CDC. *MMWR Recomm Rep* 2002;51:1, with permission.

The rectovaginal swabs for GBS cultures should be placed in a transport medium that will maintain GBS viability, unless direct inoculation into a selective broth medium is possible. One study suggests that rectovaginal swabs placed in standard transport media can be used as long as the specimens subsequently are transferred to selective growth media within 2 hours of collection (287).

The management of infants born to women given intrapartum antimicrobial prophylaxis depends on their clinical status. If signs or symptoms suggestive of

sepsis are present, then a full diagnostic evaluation is performed and empiric antibiotic therapy is started. If the neonate has no clinical signs of sepsis at birth but is less than 35 weeks of gestation, or if the infant is more than or equal to 35 weeks of gestation but intrapartum antibiotic prophylaxis was given 4 hours or less before delivery, then a complete blood count and differential and a blood culture should be obtained and the infant should be observed for at least 48 hours. If sepsis subsequently is suspected based on clinical signs, then a full diagnostic workup and empiric therapy are initiated. No evaluation or therapy is needed for neonates without signs of sepsis born at more than or equal 35 weeks of gestation and whose mothers had received intrapartum antibiotic prophylaxis more than 4 hours before delivery. These infants should be observed for at least 48 hours for signs suggestive of sepsis (99). The timing of intrapartum penicillin or ampicillin administration is important. In one study from Spain, the rate of GBS colonization of neonates born to carrier mothers was 46%, 29%, 2.9%, and 1.2% when ampicillin was given less than 1 hour, 1 to 2 hours, 2 to 4 hours, and more than 4 hours before delivery, respectively (288).

Immunologic approaches to prevention include passive or active immunization of mothers, with transplacental passage of protective antibodies to the fetus. A number of vaccines are currently being development against Group B streptococcal capsular polysaccharide antigens of serotypes Ia, Ib, II, III and V (289,290,291,292). Although these tetanus toxoid conjugate vaccines appear to be safe and immunogenic, they have not been evaluated extensively during pregnancy, and are not currently available outside of clinical trials.

SYPHILIS

T. pallidum subsp *pallidum*, the causative agent of syphilis, is a motile, nonculturable, gram-negative, microaerophilic spirochete that is too slender to be observed by light microscopy. The laboratory differentiation of *T. pallidum* from the other pathogenic treponemes that cause yaws (*T. pallidum* subsp *pertenue*), endemic syphilis (*T. pallidum* subsp *endemicum*), or pinta (*T. carateum*) is difficult.

P.1248

Ultrastructurally, *T. pallidum* has an outer cell membrane (i.e., envelope), periplasmic flagella that arise at each end of the cell, cell wall, and a multilayer cytoplasmic membrane; a capsulelike amorphous layer coats the organism (293). Several outer membrane-associated proteins have been identified, and these are present in 100-fold lower amounts than typically is found in gram-negative bacteria. This property has been related to the chronicity of syphilitic infection (294).

Person-to-person transmission of *T. pallidum* occurs primarily through contact with infectious lesions during sexual activity. The organism enters the body

through sites of minor trauma that disrupt mucosal or epithelial barriers (295). Fibronectin receptors appear to mediate the attachment of *T. pallidum* to epithelial or mucosal cells (296). Parenteral transmission of this spirochete through transfusions is rare because of routine serologic screening of blood or blood products, but intravenous drug users occasionally acquire syphilis by sharing needles contaminated with *T. pallidum*-infected blood (297). Intrauterine transmission from an infected mother to her developing fetus accounts for most congenitally infected infants; rarely, infection is acquired at birth through contact with a genital lesion (298). *In utero* transmission can occur as early as 9 to 10 weeks of gestation. The most important determinant for the risk of fetal infection is the maternal stage of syphilis. Mothers with primary, secondary, early latent, or late latent stages of syphilis have at least a 50%, 50%, 40%, or 10% risk, respectively, of delivering an infant with congenital syphilis (CS) (298). The risk of fetal infection also may be higher in more advanced stages of pregnancy (299). Concomitant maternal infection with *T. pallidum* and HIV-1 may enhance the transplacental spread of either pathogen to the fetus (298).

Natural and experimental *T. pallidum* infections elicit complex cellular and humoral immune responses. Most antitreponemal antibodies produced during the course of a syphilitic infection cross-react with antigens from nonpathogenic treponemes (i. e., culturable treponemes that are part of the normal oral, intestinal, or genital flora) and are not pathogen specific (300-301). Antibodies directed against integral membrane lipoproteins with molecular masses of 47, 44.5, 17, and 15.5 kilodaltons appear to be *T. pallidum* specific; their detection on Western immunoblot assays indicates syphilitic infection (302,303,304). A variety of other host immunologic defenses are activated after *T. pallidum* infection, including infiltration of inoculation sites with polymorphonuclear leukocytes that contain treponemicidal peptides (defensins), T-lymphocyte activation and proliferation with interferon production, cytokine secretion, macrophage-mediated phagocytosis and intracellular killing of opsonized *T. pallidum*, and complement activation (305,306,307,308). Autoantibodies to blood cells, serum components, fibronectin, and collagen also are generated (309). Some treponemes manage to evade these clearance mechanisms during the acute phase of untreated infection, which allows them to disseminate and establish a chronic infection (307,310).

Congenital Syphilis

Epidemiology

The number of cases of CS reported to the CDC increased steadily between 1980 and 1991, reflecting a true increase in the number of primary and secondary maternal syphilis cases and a change since 1989 in the surveillance case definition for CS (311). The new surveillance case definition was implemented to provide guidelines for reporting but not for making a clinical diagnosis of CS (312). In

essence, the change involved considering stillbirths and infants born to women with untreated syphilis as presumptively infected, regardless of symptoms or results of subsequent follow-up evaluations. Because vertical transmission of *T. pallidum* does not occur in all instances, the new definition leads to the inclusion of a number of uninfected infants in the "presumptive case" category (312). The older surveillance case definition led to underestimates of the true incidence of CS. Many infants in whom the diagnosis could not be made at birth were treated presumptively but not reported because the diagnosis could not be confirmed; others were reported inconsistently or lost to follow-up. The new case definition improved sensitivity at the expense of specificity (313,314). Compared with traditional criteria for diagnosis, the new definition results in about a five-fold increase in the reported number of CS cases (298,315).

The CDC analyzed national surveillance data for CS. During 2000 to 2002, the rate of CS decreased 21.1%, from 14.2 to 11.2 cases per 100,000 live births with an absolute reduction of CS cases from 578 cases in 2000 to 451 cases in 2002. During 2000 to 2002, the rate of CS declined in all racial/ethnic minority populations in the United States. The rate of CS declined 50.6% among American Indian/Alaska Native infants, 22.4% among Hispanic infants, 21.4% among Asian/Pacific Islander infants, and 19.8% among non-Hispanic black infants; the rate remained unchanged among non-Hispanic white infants. Additionally, rates of CS declined in all regions of the United States except the Northeast. The rate of CS declined 29.5% in the South, 22.9% in the West, and 12.5% in the Midwest; the rate increased 0.9% in the Northeast. Among the 451 cases of CS reported in 2002, a total of 333 (73.8%) occurred because the mother had no documented treatment or received inadequate treatment for syphilis before or during pregnancy. In 63 (14.0%) cases, the mother was treated adequately but did not have an adequate serologic response to therapy, and the infant was evaluated inadequately for CS. In 39 (8.6%) cases, the mother was treated adequately but did not have an adequate serologic response to therapy, and the infant's evaluation revealed laboratory or clinical signs of CS. A total of 16 (3.6%) cases were reported for other reasons (316).

Clinical Manifestations

The pathologic and morphologic alterations of CS are as a result of host immune and inflammatory responses to

P.1249

spirochetal fetal invasion (317,318,319). The most prominent histopathologic abnormalities are vasculitis with resultant necrosis and fibrosis (320). Syphilitic stillbirths usually are macerated with *T. pallidum*-rich vesiculobullous cutaneous lesions, hepatosplenomegaly, and protuberant abdomen.

Most infants with CS do not show signs of disease at birth. Infants who develop

clinical manifestations during the first 2 years of life are considered to have early CS, whereas features that appear later, usually near puberty, comprise late CS (320).

The placenta may be larger and paler than normal. The main histopathologic abnormalities are a focal, proliferative villitis with necrosis and focal mononuclear cell infiltration; endovascular and perivascular proliferation in villous vessels, leading to vascular obliteration; and focal or diffuse villous immaturity. *T pallidum* is demonstrable in the placenta using immunohistochemical stains; silver staining methods are difficult to perform and easy to misinterpret (321). Polymerase chain reaction (PCR) of placental tissue may confirm the diagnosis of CS, even in some cases that do not have the histopathologic features (322). The focal placental villitis and obliterative arteritis are associated with increased resistance to placental perfusion. Antenatal measurements of uterine and umbilical systolic-to-diastolic ratios using Doppler velocity waveform analysis reveal higher mean ratios in pregnancies complicated by syphilis compared with noninfected controls (323). Necrotizing funisitis, a deep inflammatory process involving the matrix of the umbilical cord and accompanied by phlebitis and thrombosis, is common in syphilitic stillbirths and infants symptomatic at birth (324-325).

Clinical signs of CS appear in approximately two-thirds of affected infants during the third to eighth week of life and in most by 3 months of age (320). Symptoms may be generalized and nonspecific (e.g., fever, lymphadenopathy, irritability, failure to thrive). Alternatively, the highly suggestive triad of snuffles, palmar and plantar bullae, and splenomegaly may be apparent (320). The severity of the clinical illness can vary from mild to fulminant, life-threatening disease (326,327,328,329). Premature infants are more likely to have hepatomegaly, respiratory distress, and skin lesions than similarly infected term neonates (330).

Congenitally infected infants may be small for their gestational ages (320). However, a carefully conducted study by Naeye (331) of 36 stillborn and newborn infants with CS revealed that fetal growth was almost normal despite widespread evidence of tissue destruction. The observed growth retardation in some reports may be related to confounding factors such as maternal intravenous drug use or coinfection with other pathogens.

Hepatosplenomegaly occurs in 50% to 90% of infants with early CS (298,320). The enlargement is caused mainly by abundant extramedullary hematopoiesis and by subacute hepatic and splenic inflammation. Jaundice, with direct and indirect hyperbilirubinemia, occurs in about one-third of infants and may be contributed to by hepatitis or hemolysis (298). Syphilitic hepatitis is common and may worsen with penicillin therapy (327,332,333,334). Alkaline phosphatase elevation is a frequent biochemical abnormality (327). Transaminase and *g*-glutamyl transferase concentrations may be high at presentation and increase with antimicrobial therapy to levels approaching 150 times normal (332). Fulminant syphilitic hepatitis can manifest with hypoglycemia, lactic acidosis, encephalopathy,

disseminated intravascular coagulation, and shock, mimicking metabolic or other infectious causes of acute liver failure (328,335). Hepatic and splenic abnormalities may persist for as long as 1 year after treatment (320). Liver cirrhosis is uncommon (298).

Generalized lymphadenopathy is found in 20% to 50% of infants with CS (320). The enlarged nodes are firm and nontender.

The mucocutaneous lesions of CS are varied and occur in 30% to 60% of infants (320). The most characteristic are vesiculobullous eruptions that are most pronounced on the palms and soles. The blister fluid abounds with active spirochetes and is highly infectious (320). When a blister ruptures, it leaves behind a macerated red surface that rapidly dries and crusts. The most commonly encountered rash consists of oval, red, maculopapular lesions that are most prominent on the buttocks, back, thighs, and soles; they later change to a copper-brown color with superficial desquamation. Other lesions may be annular, circinate, petechial, or purpuric, or have a blueberry-muffin appearance (320). Mucous patches involving the nares, palate, tongue, lips, and anus can occur; these lesions become deeply fissured and hemorrhagic and subsequently result in rhagades (Parrot radial scars of late CS) (320). Condyloma lata usually are encountered later in infancy in untreated patients. These raised, flat, moist, and wartlike lesions most commonly affect perioral (nares, angles of mouth) and perianal areas (298).

Rhinitis (snuffles) is encountered in 10% to 50% of infected infants and usually precedes the appearance of cutaneous eruptions by 1 to 2 weeks (320,327,336). The extremely contagious discharge initially is watery, but it later becomes thicker, purulent, and even hemorrhagic (320). Without treatment, the nasal cartilage ulcerates with ensuing chondritis, necrosis, and septal perforation leading to the saddle-nose deformity of late CS (298). Throat involvement can produce hoarseness or aphonia (320).

Roentgenographic abnormalities are detected in 20% to more than 95% of infants with early CS (336,337,338,339,340,341). The lower rates usually are seen in asymptomatic infants (339). Multiple, symmetric bony lesions are common. The metaphyses and diaphyses of long bones, particularly those of the lower extremities, are most commonly affected. Radiologic changes include osteochondritis, periostitis, and osteitis (298). The earliest changes occur in the metaphysis and consist of transverse, serrated radiopaque bands (i.e., Wegner sign) alternating with zones of radiolucent osteoporotic bone (320,338). Osteochondritis becomes evident radiographically 5 weeks after fetal infection (320). The

metaphysis may become fragmented. Focal erosions involving the proximal medial tibia are referred to as Wimberger's sign. Periosteal reactions may consist of a

single layer of new bone formation, multiple layers (i.e., "onion peel periosteum"), or a severe lamellar form (i.e., periostitis of Pehu) (338). Periostitis is radiologically apparent after at least 16 weeks of fetal infection (320). Osteitis can give rise to a celery-stick appearance of longitudinal translucent lines that extend into the diaphysis or lead to a diffuse moth-eaten rarefaction of the shaft. Dactylitis, absence of lower extremity ossification centers, cranial nodules, and pathologic fractures or joint involvement leading to immobility of the affected limb (i.e., pseudoparalysis of Parrot) occasionally are seen (320,338, 342,343).

Hematologic abnormalities are common and include anemia, leukocytosis, leukopenia, and thrombocytopenia (336). Anemia may be as a result of Coombs-negative hemolysis, replacement of bone marrow by syphilitic granulation tissue, or maturation arrest in the erythroblastoid cell line (298). Thrombocytopenia is as a result of shortened peripheral platelet survival.

Clinically silent CNS involvement occurs in as many as 60% of infants with CS (298). Acute syphilitic meningitis may present with neck stiffness, vomiting, bulging anterior fontanelle, and a positive Kernig's sign. CSF examination reveals a normal glucose concentration, modestly elevated protein content, and mononuclear pleocytosis (usually less than 200 cells/ μ L), a pattern consistent with aseptic meningitis. Chronic meningovascular syphilis develops in untreated infants and manifests in late infancy with progressive, communicating hydrocephalus, cranial nerve palsies, optic atrophy, and cerebral infarctions leading to hemiplegia or seizure disorders (320, 344).

Other less common pathologic changes of early CS involve the eyes (e.g., salt and pepper chorioretinitis, glaucoma, chancres of eyelids, uveitis), lungs (e.g., pneumonia alba, interstitial scarring, extramedullary hematopoiesis), and kidneys (e.g., nephrotic syndrome, glomerulonephritis) (320,345,346). Nonimmune hydrops is found in one-sixth of live born infants with CS (347). Myocarditis, hypopituitarism, pancreatitis, diarrhea, and malabsorption also occur (320,348).

The clinical manifestations of late CS represent residual scars after therapy of early congenital infection or persistent inflammation in untreated persons. Abnormalities of dentition are secondary to early damage incurred by developing tooth buds and can be prevented by penicillin treatment during the neonatal period or in early infancy. Unilateral or bilateral interstitial keratitis occurs in about 10% of patients and usually is diagnosed between 5 and 20 years of age. Saddle-nose deformity, high-arched palate, and poor maxillary growth are late consequences of syphilitic rhinitis. Eighth-nerve deafness occurs infrequently (3% of patients) and is as a result of osteochondritis of the otic capsule and resulting cochlear degeneration. Rhagades are linear scars that radiate from sites of earlier mucocutaneous lesions of the mouth, nares, and anus. Skeletal manifestations are caused by persistent or recurrent periostitis and its associated bone thickening (320, 349,350).

Diagnosis

Antenatal sonography may reveal placental thickening or fetal abnormalities such as hydrops, hepatomegaly, ascites, or dilated small bowel loops (351,352,353,354,355). Musculoskeletal abnormalities may be visualized on rare occasions with antenatal ultrasonography (356). Spirochetes can be visualized in amniotic fluid samples using darkfield microscopy or indirect immunofluorescent staining (351,353,357). The presence of *T pallidum* or its deoxyribonucleic acid (DNA) in amniotic fluid can be demonstrated by rabbit infectivity tests or PCR techniques, respectively (358,359). With the availability of umbilical blood sampling, intrauterine infection has been confirmed as early as 24 weeks of gestation by detecting the spirochete or its DNA in fetal blood and by measuring specific IgM antibodies directed against the 47-kilodalton antigen of *T. pallidum* in fetal serum (351,354,358). By testing amniotic fluid using the rabbit infectivity test and PCR analysis, some investigators have been able to confirm intrauterine *T. pallidum* infection antenatally as early as 17 weeks of gestation (359).

At birth, the diagnosis of CS is best established by demonstrating the spirochete or its DNA in tissues or body fluids as previously alluded to. Serologic data obtained from cord blood or neonatal sera are helpful if interpreted with their limitations in mind.

Rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL) measurements on cord blood samples yield false-positive and false-negative results in 10% and 5% of cases, respectively (360). Serum from the infant, rather than from the umbilical cord, should be used because of lower false-positive and false-negative reactions (361). If an infant's RPR or VDRL titer is at least four-fold higher than a concomitantly obtained maternal titer, the diagnosis of CS is likely. The RPR may be negative in infants whose mothers had acquired syphilis shortly before delivery (327). The FTA-ABS-IgM test yields false-positive and false negative results in 35% and 10% of cases, respectively (298). This is as a result of interference with test performance by rheumatoid factor (fetal IgM antibodies directed against maternal immunoglobulin G [IgG]). This problem can be overcome by separating the IgG and IgM fractions of the serum and then testing the IgG-depleted fraction for FTA-ABS-IgM. This assay is known as FTA-ABS-19S-IgM, and it is still investigational (304). The detection of IgM antibodies against specific *T. pallidum* antigens, especially the 47-kilodalton outer membrane protein antigen, by Western immunoblot assays is diagnostically helpful (298,362,363).

In addition to serologic tests for syphilis, the complete diagnostic evaluation of an infant with CS should include bone radiography, CSF examination, complete blood count, platelet count, liver enzyme concentrations, and HIV-1 antibody determination. However, Moyer and colleagues (341)

demonstrated that the results of long-bone radiographs in newborns do not

differentiate between active and past infection, and that the results do not alter the management of infants being evaluated for CS.

The diagnosis of congenital neurosyphilis is difficult to ascertain. CSF abnormalities such as mononuclear pleocytosis (≥ 25 cells/ μL), elevated protein concentration (greater than 170 mg/dL), and reactive CSF VDRL are widely used criteria (298). However, the CSF VDRL can be positive in the absence of neurosyphilis because of passive diffusion of nontreponemal IgG antibodies from serum to CSF and in infants with traumatic lumbar punctures (298). The yield of lumbar punctures in asymptomatic newborns with CS is poor (364). A specific IgM response to the *T. pallidum* 47-kilodalton antigen has been detected in the CSF of some infants with congenital syphilis, and this may prove helpful for the diagnosis of neurosyphilis. CSF IgM reactivity can be present in infants with negative CSF VDRL test results (365). The presence of *T. pallidum* in the CSF of some infants with normal CSF cell counts, protein concentrations, and VDRL test results has been demonstrated using sensitive rabbit infectivity tests or PCR methods (298,366).

Treatment

Infants should be treated at birth if they are symptomatic, if maternal therapy was inadequate or unknown, or if follow-up cannot be ensured. Adequate maternal therapy is defined as penicillin treatment at a dose appropriate for the stage of syphilis and started at least 30 days before delivery (367).

One of two dosage regimens can be used for confirmed or presumptive CS:

- Aqueous crystalline penicillin G at a dose of 100,000 to 150,000 U/kg/d administered intravenously as 50,000 U/kg/dose every 12 hours during the first 7 days of life, and every 8 hours thereafter for a total of 10 days.
- Procaine penicillin G at a dose of 50,000 U/kg/dose given intramuscularly once daily for 10 days.

If more than 1 day of therapy is missed, the entire course should be restarted (368). Benzathine penicillin G given as a single intramuscular dose of 50,000 U/kg is recommended only for infants whose evaluation (complete blood count and platelets, CSF examination, long bone radiographs) is normal and follow-up is certain. The Jarisch-Herxheimer reaction occurs in some infants within hours of initiation of penicillin therapy.

The VDRL titers should be monitored every 2 to 3 months until they become nonreactive or the titer declines by at least fourfold. Untreated infants should

have FTA-ABS tests. Passively acquired maternal antibodies usually disappear by 6 to 12 months of age in uninfected infants (369). If the VDRL titers are stable or rising or if the FTA-ABS test result remains positive beyond 15 months of age, the infant should be thoroughly reexamined and treated. The VDRL titers of adequately treated infants with CS gradually decline, but FTA-ABS reactivities persist. Infants with CSF abnormalities should be retested at 6 months of age. If the CSF VDRL is positive at that time, a second course of penicillin is indicated. Follow-up examinations should emphasize developmental assessment and a careful search for stigmata of CS.

BACTERIAL MENINGITIS

The incidence of bacterial meningitis is 0.4 per 1,000 live births, but rates as high as 1 per 1,000 live births have been reported in a few nurseries (88). The disease is seen more commonly in premature infants (234), male infants, and infants born to mothers with complicated pregnancies or deliveries. In a recent study of 9641 very low birth weight infants, meningitis was diagnosed in 1.4% infants (234).

Etiology

The bacteria causing neonatal meningitis are similar to those causing sepsis neonatorum. Group B γ -hemolytic streptococci and *E. coli* presently account for approximately 75% of all cases. The next most common etiologic agent is *L. monocytogenes* (370).

Pathology

The pathologic findings in cases of neonatal meningitis are similar, regardless of the bacterial agent. The most consistent finding at necropsy is a purulent exudate coating the meninges and ependymal surfaces of the ventricles (371).

Perivascular inflammation is observed. The inflammatory response of neonates is similar to that in adults with meningitis, with the exception that babies show a relative sparsity of plasma cells and lymphocytes during the subacute stage of meningeal reactions. Hydrocephalus and a noninfectious encephalopathy can be demonstrated in approximately 50% of infants dying of meningitis. Subdural effusions occur rarely in neonates. Various degrees of phlebitis and arteritis of intracranial vessels can be found in all infants. Thrombophlebitis with occlusions of veins may occur in the subependymal zone. Ventriculitis can be demonstrated in virtually all infants dying of meningitis and in approximately 75% of infants at the time of diagnosis.

Clinical Manifestations

The signs and symptoms of central nervous system infection frequently are

indistinguishable from those associated with neonatal septicemia. Lethargy, feeding problems, and altered temperature are the most frequent presenting complaints, and respiratory distress, vomiting, diarrhea, and abdominal distention are common findings. Seizures are observed frequently and may be caused by direct central nervous system inflammation or may be associated with hypoglycemia or hypocalcemia. Signs suggesting meningeal

P.1252

involvement, such as a bulging anterior fontanelle, neck stiffness, or opisthotonus, are infrequent.

Pathogenesis

Most cases of meningitis result from bacteremia; spread from a contiguous infected focus is rare. Although there are more than 100 K types of *E. coli*, the K1 type accounts for more than 70% of *E. coli* meningitis cases (60). Most pathogenic *E. coli* carry both the capsular antigen K1 and S fimbria adhesins; the latter promote adherence of *E. coli* to epithelial cells in the choroid plexus and brain ventricles, and to vascular endothelial cells (372). The extracellular polysaccharide capsule allows the organism to avoid host clearance mechanisms. The outer membrane lipopolysaccharide (i.e., endotoxin) is released from dying bacteria and initiates an intense inflammatory reaction. Endotoxin stimulates the production of tumor necrosis factor, interleukin-1 γ (IL-1 γ), and other mediators by monocyte-macrophage cells. Tumor necrosis factor and IL-1 γ induce phospholipase A2 activity, production of other mediators, and receptor-ligand interactions between leukocytes and endothelia. Phospholipase A2 then acts on membrane phospholipids to produce a variety of lipid proinflammatory substances such as platelet-activating factor, leukotrienes, prostaglandins, and thromboxanes. The inflammatory changes result in vascular injury and alterations in the permeability of the blood-brain barrier, with resultant vasogenic edema. The cytokines activate adhesion-promoting receptors on cerebral vascular endothelial cells, which leads to recruitment of leukocytes to sites of stimulation. These polymorphonuclear leukocytes subsequently enter the subarachnoid space, release toxic substances, and cause cytotoxic edema (373). The net pathophysiologic effect is the development of increased intracranial pressure and severe brain edema. Cerebral edema, increased intracranial pressure, systemic hypotension, decreased cerebral perfusion pressure, and a variety of vascular changes result in global or regional reductions of cerebral blood flow and can lead to brain ischemia (374). The pathophysiologic aberrations ultimately cause focal or diffuse neuronal injury, which may be irreversible.

Among the five GBS serotypes, the BIII organisms account for more than 80% of cases of neonatal GBS meningitis. The presence of type-specific antibodies enhances opsonization of the organism in the presence of complement. Cell wall components of the organism can stimulate the inflammatory cascade in a manner

similar to that described for endotoxins.

Laboratory Findings

Interpretation of CSF values in newborn infants may be difficult (Table 47-4). The upper limits of "normal" for infants with birth weights of 1,500 g or less are even higher than those for term newborns (375,376,377).

It is important to examine carefully a stained smear of the CSF of every infant with suspected meningitis. In babies with meningitis caused by GBS or coliform bacteria, each oil-immersion field usually contains several to many bacteria. This is because there are 10^4 to 10^8 colony-forming units (CFU) per 1 mL of spinal fluid (average 10^7 CFU/mL) present at the time of diagnosis. *Listeria* organisms often are difficult to identify on stained smears because the bacterial counts frequently are on the order of 10^3 CFU/mL. Bacterial antigens can be detected by LPA for GBS, *E. coli* K1, *H. influenzae* type b, *S. pneumoniae*, and non-type B meningococci. Polymerase chain reaction assays for the detection of bacterial DNA in CSF specimens are being developed (378,379,380). Nonculture methods of diagnosis are most useful for newborns who receive antibiotics before a lumbar puncture is performed.

TABLE 47-4 CEREBROSPINAL FLUID VALUES OF NONINFECTED TERM NEWBORNS

CSF Parameter	Age (d)	Mean	SD	Median	Range
WBC count/mm ³	0-7	15.3	30.0	6	1-130
	8-14	5.4	4.4	6	0-18
	15-21	7.7	12.1	4	0-62
	22-30	4.8	3.4	4	0-18
ANC/mm ³	0-7	4.4	15.2	0	0-65
	8-14	0.1	0.3	0	0-1
	15-21	0.2	0.5	0	0-2
	22-30	0.1	0.2	0	0-1
Protein (mg/dL)	0-7	80.8	30.8	NA	NA
	8-14	69	22.6	NA	NA
	15-21	59.8	23.4	NA	NA

Adapted from Ahmed A, Hickey SM, Ehrett S, et al. Cerebrospinal fluid values in the term neonate. *Pediatr Infect Dis J* 1996;15:298, with permission.

Blood and urine cultures should be obtained from every infant suspected of meningitis. As many as 33% of infants with positive CSF cultures have sterile blood cultures (229,236).

Treatment

Considerable data have been gathered on the pharmacokinetic properties of antibiotics in neonates with meningitis (381,382). After an intramuscular dose of 2.5 mg/kg of gentamicin, peak levels in lumbar CSF and ventricular fluid are approximately 1 to 2 µg/mL. If lumbar intrathecal gentamicin is added to this regimen, values of 20 to 40 µg/mL or greater several hours after instillation may be observed in the lumbar area. Intraventricular administration of 2.5 mg results in ventricular fluid levels of 20 to 80 µg/mL and in lumbar spinal fluid values of 10 to 50 µg/mL 1 to 4 hours later. With kanamycin, peak CSF values of 6 to 10 µg/mL

P.1253

are observed 4 to 6 hours after an intramuscular dose of 7.5 mg/kg. Peak values of 10 to 30 µg/mL are demonstrated in CSF approximately 2 to 4 hours after a 50 to 70 mg/kg dose of ampicillin.

For the aminoglycosides, the MIC values for the common pathogens frequently are greater than the antibiotic levels achieved in CSF. For example, an *E. coli* with a gentamicin MIC value of 2.5 or 5 µg/mL is considered susceptible when bloodstream infection is being treated but may be considered resistant when therapy is for meningitis. This is because peak cerebrospinal and ventricular fluid gentamicin levels after parenteral therapy usually are lower than this MIC value. Alternative therapeutic regimens must be considered, such as adding a second antibiotic, selecting a different antibiotic class, or changing the route of administration. In experimental models of *E. coli* meningitis, the administration of the total daily gentamicin dose undivided results in CSF concentrations of the drug that are three-fold higher than those achieved in animals receiving conventional dosing, and the rate of bacterial killing is greater early on in animals receiving once-daily gentamicin (383).

Ampicillin and gentamicin or ampicillin and cefotaxime are recommended for initial empiric therapy of neonatal meningitis. The dosage of ampicillin or cefotaxime is 200 to 300 mg/kg/d in three divided doses during the first week of life and 200 mg/kg/d in three or four divided doses thereafter. The gentamicin dosage is the

same as that used for septicemia. All infants should have repeat spinal fluid examinations and cultures at 48 hours after initiation of therapy. If organisms are seen on a Gram stain of the fluid, the patient should be reevaluated completely regarding making alterations in antimicrobial therapy and to obtaining computed tomography of the head. The radiologic procedures may demonstrate the presence of a subdural empyema, brain abscess, or ventriculitis that requires neurosurgical intervention.

Cefotaxime, with or without an aminoglycoside, can be used for therapy of neonatal meningitis as a result of susceptible gram-negative enteric organisms (384). Although there are no large controlled trials of cefotaxime in neonates, accumulated experience from open studies indicates that this cephalosporin is effective for therapy of neonatal sepsis and meningitis.

The Neonatal Meningitis Cooperative Study group reported that there is no beneficial effect of lumbar intrathecal or intraventricular instillation of gentamicin in the therapy of meningitis caused by gram-negative organism (382). The mortality rate in infants given intraventricular gentamicin was threefold greater than that in infants treated with systemic therapy only. The mean and peak ventricular CSF concentrations of endotoxin and IL-1 γ were significantly higher for infants treated with intraventricular gentamicin than those receiving intravenous antibiotics alone (385). This difference may have resulted from the enhanced bacterial killing achieved through higher ventricular CSF gentamicin concentrations, with the consequent increased release of damaging inflammatory mediators, which resulted in greater periventricular inflammation.

Therapy for meningitis is continued for a minimum of 2 weeks after sterilization of CSF cultures. This equates to 14 days of therapy for meningitis caused by gram-positive organisms and a minimum of 21 days of therapy for meningitis caused by gram-negative pathogens.

Treatment for *Candida* meningitis is with amphotericin B and flucytosine for a period of 3 to 6 weeks (196). Fluconazole has been used to treat neonatal candidal meningitis, but the optimal dose is not known and the published experience is very limited (279). In an experimental model of *C. albicans* meningitis, amphotericin B was more effective than fluconazole in clearing the infection at the dosage levels that were used (386).

Attention to general supportive therapy is essential in caring for infants with meningitis and is the single most important factor that accounts for the improved outcome during recent years. Disturbances of fluid and electrolyte balance are common, particularly in the first several days of illness when inappropriate antidiuretic hormone secretion may lead to fluid retention and hyponatremia. Hypoglycemia, hypocalcemia, and hyperbilirubinemia are frequent complications. Ventilatory assistance frequently is necessary, and blood pressure should be monitored carefully. During the course of illness, hemoglobin and hematocrit

values should be checked frequently because infection may exaggerate and prolong the anemias of infancy, particularly in premature infants. Because of the frequent occurrence of bleeding diathesis, platelet counts, prothrombin time, and partial thromboplastin time should be followed. Neurosurgical evaluation is needed for neonates with a brain abscess to determine the need for abscess decompression.

Prognosis

The mortality from neonatal meningitis is considerable. The overall mortality rate is approximately 10% to 30%, but this varies with etiologic agent, infant population, and the nursery or intensive care unit.

Short- and long-term sequelae of neonatal meningitis are frequent. The acute complications include communicating or noncommunicating hydrocephalus, subdural effusions, ventriculitis, and blindness (387). In 70% of infants with *Citrobacter koseri* (formerly *diversus*) meningitis, there is associated brain abscess (Fig. 47-2) (381,382,388,389). Jan and colleagues recently reported a study of diffusion weighted imaging in neonates with acute meningitis. In 12 of the 13 infants studied, there was evidence of cortical or deep white-matter infarcts. Magnetic resonance angiography detected vasculitis in 2/5 infants studied. This imaging modality also appears to be sensitive in detecting extra-axial fluid collections representing empyemas (390). Many infants appear relatively normal at the time of discharge. It is only after prolonged and careful follow-up that perceptual difficulties, reading problems, or minimal brain damage is apparent. It is estimated that 30% to 50% of survivors have some evidence of neurologic damage (109,391,392,393,394,395). Recurrence of gram-negative bacillary meningitis may occur in as many as 10% of patients (387).

Figure 47-2 Contrast-enhanced computed tomographic scan of the head of a 25-day-old African-American girl with *Citrobacter koseri* infection of the central nervous system. Note the cavitating enhancing lesion abutting the lateral ventricle on the left, with surrounding vasogenic edema.

P.1254

OSTEOMYELITIS AND SEPTIC ARTHRITIS

Because of the unique nature of the vascular supply of the neonatal skeletal system, osteomyelitis and septic arthritis frequently occur concomitantly. During the first 12 months of life, capillaries perforate the epiphyseal plate of long bones and provide a communication between the metaphysis and the joint space (396). Infections originating in one anatomic location easily spread to the other. This is not true after approximately 1 year of age, when the perforating capillaries disappear.

The capsules of the hip and shoulder attach below the metaphysis of the femur and humerus, respectively. Infection of the epiphyseal cartilage may rupture through the periosteum and enter the joint space, producing purulent arthritis. Because of the capsular articulation of the hip and shoulder, osteomyelitis and septic arthritis may coexist, making the origin of infection difficult to determine.

Infections of the musculoskeletal system are uncommon in the neonate, but incidence figures are not available.

Etiology and Pathogenesis

The infecting organisms in osteomyelitis and septic arthritis vary, but the predominant ones are GBS, *S. aureus*, and gram-negative enteric organisms such as *Klebsiella* spp, *Proteus* spp, and *E. coli*. Although gonococcal arthritis and tenosynovitis were encountered commonly in previous decades, they are seen only occasionally today. Other etiologic agents associated with newborn bone and joint infection are *Salmonella* spp, *Pseudomonas* spp, *H. influenzae*, *S. pneumoniae*, coagulase-negative staphylococci and *C. albicans* (397,398,399,400,401,402). Hospital-acquired methicillin-resistant *S. aureus* (MRSA) osteomyelitis and septic arthritis can develop in sick premature infants after catheter-associated septicemia (401).

Osteomyelitis and arthritis have been reported after several invasive procedures in newborns, including heel puncture, femoral venipuncture, exchange transfusions, fetal monitoring electrode placement, and umbilical artery catheterization (143,397). Osteomyelitis of cranial bones has complicated infected cephalhematomas. In most cases, the origin is unknown and is presumed to be hematogenous.

Clinical Presentation

Nonspecific symptoms of infection, such as lethargy, irritability and poor feeding, may be the initial manifestations of neonatal musculoskeletal infection. Diminished movement of the affected limb, unrelated temporally to birth trauma, is a common clinical sign (403). Warmth, erythema, and swelling are late manifestations. The long bones are affected most commonly. Occasionally, the diagnosis is made unsuspectingly when purulent material is obtained on attempted aspiration of the femoral vein and the needle enters the swollen hip capsule. GBS osteomyelitis is indolent and usually involves a single bone, most commonly the proximal humerus, but can involve the vertebral spine as well (396,404).

Although blood cultures frequently are positive, the infants usually are not clinically toxic. The exception is group A γ -hemolytic streptococcal infection, in which the infant may appear gravely ill.

Laboratory Tests and Findings

Blood cultures should be obtained from all infants with suspected infection of the musculoskeletal system. A diagnostic aspiration of the joint or subperiosteal space should be attempted in all patients, and the material obtained should be treated with Gram stain and cultured. Identification of the organism is particularly important, because it may be necessary to treat with more than one potentially nephrotoxic drug until the causative bacterium has been isolated.

The peripheral leukocyte count frequently is elevated, and juvenile forms may be

seen. There is little information regarding the erythrocyte sedimentation rate during the neonatal period. In older infants and children, the sedimentation rate is accelerated in osteomyelitis; its return toward normal is a rough indicator of therapeutic success.

Radiographs of the affected bone or joint taken early in illness may be normal or show widening of the articular space. Later in the course of disease, subluxation and destruction of the joint are common. If osteomyelitis is

P.1255

present, the normal fat markings on roentgenograms of the deep tissues may be obliterated, indicating inflammation. Lifting of the periosteum from the bone may be observed, but cortical destruction is unusual before the second week of illness. A complete skeletal survey should be performed because of frequent involvement of multiple sites (403,405). Resolution of bone changes is considerably slower than clinical improvement. Although radioisotope scans (e.g., technetium, gallium) of bone are useful in early diagnosis of osteomyelitis in older infants and children, they may be normal in newborns with proven infection (397). Nevertheless, bone scintigraphy remains more sensitive than plain radiography for the early diagnosis of osteomyelitis (406).

Therapy

Selection of initial antimicrobial therapy should be based on results of the Gram stain of aspirated purulent material and associated clinical findings, such as furuncles or cellulitis. If gram-positive cocci are observed on stained smears, methicillin or nafcillin should be started. Vancomycin may be preferable in nurseries with multiresistant *S. aureus* strains. Cefotaxime or gentamicin is indicated if gram-negative organisms are observed. If no organisms are identified on stained smears, a combination of an antistaphylococcal drug and an aminoglycoside is used. After the organism has been identified and susceptibility studies are available, the most appropriate antibiotic or combination of antibiotics should be used. Direct instillation of an antimicrobial agent into the joint space is unnecessary because most antibiotics penetrate the inflamed synovium, and adequate concentrations are achieved in purulent material (407). This also applies to treatment of osteomyelitis; direct instillation of antibiotics into infected bone is unwarranted.

As a general rule, infection of the joint space and bone should be drained by repeated aspiration or by surgery. Suppurative arthritis of the hip and shoulder is best treated with incision and drainage to prevent vascular compromise or extension of infection into the metaphysis. Orthopedic consultation must be obtained for all patients.

Antimicrobial therapy of neonatal musculoskeletal infections caused by *S. aureus* or coliform organisms should be continued for approximately 3 weeks and, in

some patients, for a longer period. For gonococcal or streptococcal infections, 10 days of therapy generally are sufficient with adequate surgical drainage. The duration of therapy must be individualized. In general, systemic symptoms disappear within several days of initiation of therapy and drainage, but local signs such as heat, erythema and swelling may persist for 4 to 7 days. Full range of motion of the involved limb may not return for several months, and physical therapy should be instituted early to prevent contractures. Complete resolution of roentgenographic changes may take several months. The use of large oral dosages of antibiotics for outpatient therapy of neonatal musculoskeletal infections has not been studied systematically and should be undertaken with caution (408).

Prognosis

Death from these diseases is unusual. However, morbidity may be considerable, particularly if weight-bearing joints such as the hip are involved. Bone deformations or shortening, contractures, or muscle damage can be permanent (397,408,409,410,411).

CUTANEOUS INFECTIONS

Most infections of the skin and subcutaneous tissues in neonates are caused by *S. aureus*. There are three major presentations of superficial staphylococcal disease. The first and most common are pustules and furuncles, which may be solitary or appear in clusters during the neonatal period. Pustules are frequently in the periumbilical and diaper areas, and they may coalesce gradually and spread to other areas of the body. Bloodstream or organ invasion is unusual unless the cutaneous infection involves extensive areas. Omphalitis usually is caused by staphylococci or streptococci, and infected circumcisions are usually caused by *S. aureus*.

The occurrence of staphylococcal skin infections in several infants from the same nursery should alert the physician to the possibility of nosocomial infection caused by a single, virulent strain of *S. aureus*. If infections are caused by the same strain of *Staphylococcus*, prompt measures should be instituted so that the source of infection can be determined and further colonization and disease can be prevented.

Therapy of cutaneous staphylococcal disease depends on the extent of the lesions and the general condition of the infant. Small, isolated pustules can be managed by local care with a mild cleansing agent or an antiseptic agent such as hexachlorophene or povidone-iodine. Infants with more extensive cutaneous involvement, systemic signs and symptoms of infection, or both should be treated with parenteral antimicrobial agents. The selection of the proper penicillin is based on historic experience and antimicrobial susceptibility studies of staphylococci

isolated from the nursery unit.

The second form of neonatal staphylococcal disease has been described as the expanded scalded skin syndrome (122). This group of illnesses includes bullous impetigo, toxic epidermal necrolysis (Ritter disease), and nonstreptococcal scarlatina, usually caused by phage group II staphylococci. The pathogenesis of these entities appears to be related to release of exotoxins (e.g., epidermolytic toxins A and B) that act primarily on the stratum granulosum of the epidermis, causing a generalized erythema, edema, and tenderness, frequently progressing to desquamation and formation of flaccid bullae. The usual sites of staphylococcal infection are conjunctivae, throat, and umbilicus. Infants usually are afebrile. Cultures of blood, nasopharynx, eyes, and other areas should be obtained before therapy. Because phage group II staphylococci frequently are resistant to penicillin, methicillin is the initial drug

P.1256

of choice. Vancomycin should be used for multiresistant strains. *Pseudomonas putida* sepsis presenting as scalded skin syndrome has been described in a 9-day-old newborn (412).

The third form of staphylococcal disease is necrotizing fasciitis, which also can be caused by streptococci, *E. coli*, *Klebsiella*, and anaerobes (413,414,415,416,417,418,419). Necrotizing fasciitis, an unusual disease of newborns, is associated with surgical procedures, circumcision, birth trauma, or cutaneous infections. In this condition, subcutaneous tissues, including muscle layers, are invaded, and the organism spreads along the fascial planes. Overlying skin may appear violaceous, and the borders of the lesion usually are indistinct. Extensive surgery to resect the destroyed tissue is imperative in treating necrotizing fasciitis. Blood and tissue cultures should be obtained, and the patient started on methicillin or nafcillin and an aminoglycoside until culture results are available. If necrotizing fasciitis involves the abdomen or perineum, then either clindamycin or metronidazole should be added (418). The necrotic fatty tissue may combine with calcium, resulting in tetany and convulsions. Vigorous fluid resuscitation and correction of electrolyte imbalances are critical.

Breast abscesses most commonly are caused by *S. aureus*, but gram-negative enteric organisms can be causative (420). Anaerobes can be recovered from as many as 40% of samples, one-half of which are in mixed cultures with aerobic bacteria (421). Bacteremia is rare. The physician should attempt to establish an etiologic diagnosis by expressing fluid from the nipple after thorough cleaning or by needle aspiration of the abscess. Treatment is with methicillin, with or without an aminoglycoside, depending on the results of the Gram stain and culture, and it should be continued for 5 to 7 days. For mild infections, antibiotic therapy is adequate; with more severe inflammation, incision and drainage of the abscess are required. Long-term follow-up studies suggest that some girls will have diminished tissue in the affected breast.

Scalp abscesses occur most commonly as a complication of fetal monitoring in which scalp electrodes are used and may occur as localized manifestations of systemic disease (e.g., enterococcal sepsis) (169,422). Etiologic agents include staphylococci, enterococci, gram-negative enteric bacteria, and gonococci (169,422,423). Polymicrobial flora, including anaerobes, are commonly isolated. Treatment consists of incision and drainage. If there is an associated cellulitis, antibiotics are given and continued for 5 to 7 days.

Fungal infections of the neonatal skin can range from localized or widespread candidal dermatitis (424), to localized, discrete follicular pustules, plaques, or nodules caused by *Trichophyton tonsurans*, to rapidly progressive ulceration and necrosis requiring surgical debridement seen with mucormycosis (425,426,427). The characteristic pathology of mucormycosis is invasion of blood vessels by fungal hyphae resulting in ischemia and infarction of areas supplied by these vessels. Predisposing factors for serious cutaneous fungal disease includes prematurity, disruption of the barrier function of newborn skin associated with adhesive removal, multiple antibiotic treatment courses, and postnatal steroid therapy (425,428). In one study, wooden tongue depressors used to make splints were identified as the source of *Rhizopus microsporus* invasive infection in premature infants (425). The choice of antifungal agent for therapy depends on the specific infection being treated: griseofulvin for superficial dermatophyte infections, topical nystatin for mild-to-moderate candidal dermatitis, fluconazole or amphotericin B for extensive candidal dermatitis, and amphotericin B for mucormycosis.

URINARY TRACT INFECTION

Improved methods for obtaining sterile specimens have made it possible for investigators to define more accurately the incidence of neonatal urinary tract infection. Bacteriuria may be demonstrated in 0.5% to 1.0% of full-term infants and as many as 3% of premature infants in studies using the bladder aspiration technique (429). Urinary tract infections are more common in babies born to bacteriuric mothers and in male neonates, in contrast to the predominance of female infants beyond this period of life.

Etiology

E. coli is the most common etiologic agent of urinary tract infection, as found in older patients. Approximately 50% of causative *E. coli* strains belong to one of eight common O antigen groups. Several polysaccharide capsular antigens (e.g., K1i, K2, K12, K13) are found more often in infants with upper tract disease. This particularly pertains to the K1 antigen (430). Fimbriated *E. coli* can attach to specific receptors on uroepithelial cells. Glycolipids of the P blood group constitute a specific receptor that is believed to be associated with pyelonephritis in patients

who do not have reflux. *Klebsiella* and *Pseudomonas* species are encountered less frequently. Gram-positive bacteria, with the exception of enterococci, are rare causes of urinary tract infections. Fungal cystitis and pyelonephritis are encountered in chronically ill premature infants previously treated with multiple broad-spectrum antibiotics and are associated with mucocutaneous candidiasis or invasive disease (194,215,431).

Clinical Manifestations

Many infants with significant bacteriuria are asymptomatic (432). If clinical signs are present, they usually are nonspecific and consist of poor weight gain, altered temperature, cyanosis or gray skin color, abdominal distention, malodorous urine, and poor feeding. In a few patients, jaundice and hepatomegaly may be the presenting features of urinary tract infection (433,434). Thrombocytopenic purpura is found in some of these infants. Localizing signs suggesting urinary tract involvement are unusual; they usually consist of a weak urinary stream or an abdominal

P.1257

tumor from bladder distention or hydronephrosis (434). Gross hematuria has been described as the only presenting symptom, but this is rare (435). The most important predisposing factor is vesicoureteral reflux, which allows easy access for bacteria to ascend to the kidneys and leads to residual urine in the bladder (434,435,436). Circumcised infants have a lower risk of acquiring a urinary tract infection compared with those who are uncircumcised (437).

Diagnosis

The diagnosis of urinary tract infection is confirmed by examination and culture of urine. The result of these tests depends largely on the method of urine collection. Most pediatricians obtain urine with a sterile, plastic receptacle applied to the cleansed perineum. However, urine obtained by this method may have an elevated cell count because of recent circumcision, vaginal reflux of urine, or contamination from the perineum. Neonatal asphyxia may increase the urinary cell count. Leukocytes must be differentiated from round epithelial cells that appear in the urine in appreciable numbers during the early days of life. Although pyuria commonly accompanies significant bacteriuria, cells can be few or absent in the presence of bacteriuria in as many as one-half of the patients (438). Direct microscopic examination of uncentrifuged, fresh urine is useful. If bacteria are seen readily in each oil-immersion field, there are generally more than 10^5 CFU/mL. Glitter cells are believed by many to be diagnostic of urinary tract infections.

Quantitative urine cultures from infants with documented disease contain more than 50,000 CFU/mL (usually $\geq 100,000$ CFU/mL), but a smaller number of organisms can be found in as many as 20% of patients (439). Any number of

bacteria in a urine specimen obtained by percutaneous needle puncture of the bladder should be considered significant. This latter procedure is the single best source of urine for culture and is safe in most newborn infants. Its primary complication is transient gross hematuria lasting less than 24 hours in 0.6% of patients (434,440). Very rare complications of suprapubic bladder aspirations include bowel perforation, peritonitis, hema-toma, abdominal wall abscess, and bacteremia (440).

Treatment

There are several approaches to the treatment of neonatal urinary tract infections. Antimicrobial agents initially should be administered parenterally, because septicemia is found in 15% to 30% of infants, and absorption after oral administration may be erratic in neonates (441). The physician should assume that there is infection of renal parenchyma resulting from hematogenous spread.

Antibiotic selection should be based on results of antimicrobial susceptibility studies. Gentamicin is effective against the commonly encountered coliform bacteria. Because urinary concentrations of these drugs are considerably higher than those seen in serum, the usual dosages may be halved. For gentamicin, 2 to 3 mg/kg/d is satisfactory, provided the initial blood cultures are sterile. Ampicillin and gentamicin should be administered to symptomatic infants with pyuria before results of culture and susceptibility tests. Renal candidiasis should be treated systemically with amphotericin B. Bladder irrigation with amphotericin B for infants with uncomplicated *Candida* cystitis has not been properly evaluated, and its use cannot be recommended (442).

A repeat urine culture should be sterile 36 to 48 hours after initiation of appropriate therapy. Infants with persistent bacteriuria must be evaluated for possible abscess formation, with or without urinary obstruction. In the uncomplicated patient, therapy usually is continued for a period of approximately 10 days. Blood urea nitrogen and serum creatinine levels should be determined at the initiation of therapy. If there is evidence of renal compromise, dosage and frequency of administration of the drugs, particularly the aminoglycosides, may need to be reduced. Approximately 1 week after therapy is discontinued, a repeat urine culture is obtained. If the culture is positive, therapy is reinstated and a thorough investigation of the urinary tract is made to rule out obstruction or abscess formation.

All infants with documented urinary tract infections should have radiologic evaluation of the urinary tract. A renal scan or ultrasound examination is obtained some time during therapy so that the possibility of gross congenital abnormalities of the urinary system can be excluded. Technetium 99m dimercaptosuccinic acid cortical scintigraphy is more sensitive than ultrasound examinations and is abnormal in as many as 73% of infants with pyelonephritis (Fig. 47-3) (443). If

obstruction is demonstrated, urologic procedures to ensure proper drainage are mandatory if therapy is to be successful. A voiding cystourethrogram usually is obtained several weeks after therapy has been completed. Radiologic abnormalities, such as vesicoureteral reflux, obstructive uropathy, and renal scars, are found in approximately 45% of infants, especially in girls (434,441,444).

Prognosis

It is the physician's responsibility to be certain that neonates with documented urinary tract infections do not have congenital abnormalities of the urinary system. In such patients, recurrent urinary tract infections are common, and physical growth may be retarded until definitive surgery for stage IV or V vesicoureteral reflux has been performed (445). Renal growth retardation is common after neonatal urinary tract infections, even in patients without reflux (445). Patients with recurrent urinary tract infections may be at increased risk of hypertension or renal insufficiency, but the magnitude of this threat is poorly defined (447). Every patient must have careful long-term follow-up studies to detect recurrent infections, many of which are asymptomatic. Prophylactic antibiotics such as trimethoprim-sulfamethoxazole or nitrofurantoin should be provided for infants with clinically significant reflux to avoid

P.1258

new scar formation and to ensure normal renal growth. Siblings of infants with urinary tract infection and vesicoureteral reflux should be screened with a voiding cystourethrogram because their risk of having vesicoureteral reflux is 27% to 45% (448).

Figure 47-3 Technetium 99m dimercaptosuccinic acid (DMSA) cortical scintigraphy study done on an 11-day-old Caucasian boy with ampicillin-resistant *Escherichia coli* pyelonephritis. This posterior image of the renal beds shows that the left kidney is larger than the right and has a large cold defect involving its superior half.

NEONATAL OPHTHALMIA

Infections of the eye of the newborn may be caused by a variety of microorganisms, including *N. gonorrhoeae*, *C. trachomatis*, *S. aureus*, and *P. aeruginosa*. From a review of 302 cases of eye infections diagnosed in newborns at Grady Memorial Hospital in Atlanta, Georgia, between 1967 and 1973 it was determined that 29% were caused by chlamydiae, 14% by gonococci, 10% by staphylococci, 2% by chemical reactions, and 1% by mixed gonococcal and chlamydial infections (449). The causes of the remaining 44% were uncertain. This frequency distribution of etiologic agents was typical of the experience at large urban general hospitals.

The incidence of ophthalmia neonatorum has not paralleled the significant increase in gonococcal disease rates among adolescents and young adults (450). This almost certainly is a result of universal neonatal gonococcal prophylaxis. The invasive, destructive ophthalmitis described so vividly in old literature is rarely seen today. Several agents have been effective prophylactically against gonococci: 1% silver nitrate, erythromycin or tetracycline ophthalmic ointments, one dose of ceftriaxone administered intramuscularly, and 2.5% solution of povidone-iodine (451,452,453).

Clinical Manifestations

Gonococcal ophthalmia usually becomes apparent within the first 5 days of life and initially is characterized by a clear, watery discharge. Conjunctival hyperemia and chemosis are associated with a copious discharge of thick, white, purulent material. Both eyes usually are involved but not necessarily to the same degree. Untreated gonococcal ophthalmia may extend to involve the cornea (i.e., keratitis) and the anterior chamber of the eye. Corneal perforation and blindness may occur. Before the introduction of adequate prophylactic measures, ophthalmia neonatorum was the most frequent cause of acquired blindness in the United States.

Differential Diagnosis

Any infant presenting with a conjunctival discharge should be evaluated carefully to determine the cause. Three tests should be performed:

- Gram stain of the exudate
- Culture of the exudate
- Direct immunofluorescent chlamydial stain of scrapings made from the lower palpebral conjunctiva after exudate has been wiped away (454).

Appropriate therapy should be instituted on the basis of the results of the stained smears.

Conjunctivitis occurring in the first days of life can be chemical or bacterial. Chemical irritants, such as silver nitrate, cause transient conjunctival hyperemia and a watery discharge that rarely turns purulent.

If gram-negative rods are seen in the stained exudate, the greatest concern is *P. aeruginosa* because of the virulent, necrotizing endophthalmitis that can result. In this condition, a relatively mild conjunctivitis can progress to infection of the entire globe within 12 to 24 hours. Systemic complications such as bacteremia, meningitis, and brain abscess can occur without evidence of invasive eye disease, especially in VLBW infants (455). Prompt diagnosis and immediate institution of appropriate antimicrobial therapy are mandatory (456). A blood culture should be obtained before antibiotics are started (455).

Conjunctivitis during the second or third week of life may be caused by viral, bacterial, or chlamydial agents. Viral conjunctivitis frequently is associated with other symptoms of respiratory tract disease, such as rhinorrhea, cough, and rash. Several persons in the family or nursery simultaneously may have the disease. The discharge in viral conjunctivitis is watery or mucopurulent but rarely purulent. Preauricular adenopathy is common. Staphylococci, streptococci, *H. influenzae*, *Branhamella (Morexalla) catarrhalis*, and occasionally gonococci cause conjunctivitis in this age group. A smear of purulent material offers some help in differentiating between these bacterial agents. However, the presence of bacteria on a gram-stained smear of exudate is not necessarily related etiologically to the conjunctivitis. Normal inhabitants of the skin and mucous membranes, such as *Staphylococcus*, diphtheroids, and *Neisseria* species may be observed.

P.1259

Chlamydial eye infection may begin in the first days of life, but it usually does not come to the attention of the physician until the second or third week (457). Clinical manifestations of chlamydial infection vary from mild conjunctivitis to intense inflammation and swelling of the lids, associated with copious purulent discharge. Pseudomembrane formation and a diffuse injection of the tarsal

conjunctiva are common. The cornea rarely is affected, and preauricular adenopathy is unusual. In the early stages of disease, one eye may appear more swollen and inflamed than the other, but both eyes usually are involved. The physician establishes the diagnosis by scraping the tarsal conjunctiva and looking for typical cytoplasmic inclusions within epithelial cells or by direct immunofluorescent staining for chlamydial antigens. The scrapings also can be cultured or tested for chlamydial antigens by enzyme immunoassays. Polymerase chain reaction and ligase chain reaction assays for the detection of *C. trachomatis* in ocular and nasopharyngeal specimens appear to be equally specific and more sensitive than culture methods, but the tests are not yet widely used for diagnosis of chlamydial conjunctivitis (458,459,460).

Therapy

Initial therapy is based on the results of stained smears of exudate and epithelial cells. If gonococci are seen, a single dose of ceftriaxone (25 to 50 mg/kg, maximum 125 mg) is given intramuscularly or intravenously (461). If staphylococci are seen, methicillin or another penicillinase-resistant penicillin analog is used. Topical antibiotics are unnecessary, because ample antibiotic to inhibit bacteria exists in the eye secretions (461).

Pseudomonas eye infection should always be treated with parenteral therapy consisting of ceftazidime piperacillin, or ticarcillin and gentamicin. Gentamicin ophthalmic drops are used for simple *Pseudomonas* conjunctivitis, and subconjunctival or sub-Tenon space injections of gentamicin may be needed for endophthalmitis (462).

Ophthalmic solutions containing 1% tetracycline, erythromycin, or sulfacetamide are inferior to oral erythromycin in the treatment of chlamydial conjunctivitis. Topical therapy suppresses chlamydial growth, whereas oral erythromycin eradicates the organism from the eyes and nasopharynx in most infants (463). Erythromycin is used at a dose of 50 mg/kg/d orally divided into four doses for 10 to 14 days. Erythromycin therapy is associated with a 20% to 30% failure rate, which may require second and third courses of therapy. Erythromycin therapy of infants younger than 6 weeks of age has been associated with an increased risk of infantile hypertrophic pyloric stenosis. A shorter course of the azalide antibiotic, azithromycin, may be effective in the treatment of neonatal conjunctivitis, but the optimal dosage and duration of therapy have yet to be determined (464).

Patients with gonococcal ophthalmia should be segregated, and strict hand-washing techniques should be used because of the highly contagious nature of the exudate. The eyes should be irrigated with saline to remove the purulent material. Follow-up examination of infants treated for gonococcal ophthalmia is important to treat subsequent *C. trachomatis* ophthalmia, which can manifest after completion of therapy for gonococcal infection.

DIARRHEAL DISEASE

Although diarrhea disease during the neonatal period usually is brief and self-limited, it can cause significant morbidity in some infants and represents a potential danger to other infants in the nursery unit.

Etiology and Pathogenesis

The most common cause of diarrhea in young infants is alteration of diet and feeding practices, rather than specific bacterial or viral pathogens. Of the infectious causes of diarrhea, rotaviruses are important agents. Both sporadic infections and nursery epidemics have been described. Rotavirus is stable on environmental surfaces and is difficult to eradicate using the usual disinfectants. As a result, it can remain endemic in a nursery for as long as 2 years once established (465). One study from France indicated that 32% of neonates shed rotavirus in their stools; however, of the neonates shedding the virus, 71% had no associated diarrhea (466). Reasons for the asymptomatic nature of most neonatal rotavirus infections are not clear but may include passive protection from transplacentally acquired maternal rotavirus antibodies, the presence of rotavirus antibodies and trypsin inhibitors in breast milk, immaturity of the pancreatic enzymes which may not allow the VP4 protein of the virus to be cleaved (an important step that allows the virus to infect intestinal epithelial cells), and the possibility that rotaviruses that circulate in nurseries may represent attenuated strains of the virus (465). However, neonatal rotavirus diarrhea can be severe and associated with dehydration, hypocalcemia, seizures, and increased frequencies of apnea and bradycardia episodes. It also has been associated with the development of necrotizing enterocolitis (465,468). The finding of rotavirus in the stools of a neonate with diarrhea may be coincidental and not represent the true etiologic agent.

Diarrhea caused by *E. coli* can be mediated through several mechanisms. Some strains are enterotoxigenic (elaborate heat-labile and/or heat-stable toxins), whereas others are enteropathogenic (cause effacement of microvilli and show intimate adherence between the bacterium and the epithelial cell membrane in localized areas), enterohemorrhagic (produce Shiga-like toxin), enteroaggregative (adhere diffusely to intestinal epithelial cells), or enteroinvasive (invade the colonic epithelium and cause ulceration). Enteropathogenic *E. coli* serotypes once were considered the most common bacterial agents responsible for diarrhea in young infants (469). Enterotoxigenic strains of *E. coli* have been identified in nursery outbreaks of diarrheal disease (470). These organisms inhabit the small bowel, in which they attach to, but do not invade, the intestinal

mucosa. The enterotoxin produced by these organisms stimulates cyclic adenosine

monophosphate, which inhibits sodium and chloride transport across the intestinal wall. These salts are lost into the lumen of the upper bowel, followed passively by water, causing a net loss of stools high in electrolyte content. *Vibrio cholerae*, *V. parahaemolyticus*, *Aeromonas*, and some strains of *Campylobacter* and *Yersinia* are examples of other bacteria that cause diarrhea by this mechanism.

Toxigenic and nontoxigenic *Clostridium difficile* strains commonly are recovered from stool cultures of newborn infants (471). Their significance, however, is unknown because most culture-positive or toxin-positive infants are asymptomatic.

Shigella causes diarrhea through invasion of the intestinal mucosa. Colonic invasion, with subsequent destruction of the mucosa, causes an outpouring of polymorphonuclear cells and mucus. The resultant diarrhea usually is bloody and contains mucus and pus (472). Other organisms causing bloody diarrhea are *Campylobacter*, *Yersinia*, and *Aeromonas* species (473,474,475,476). *Salmonella* species also invade the intestinal mucosa, but extensive destruction does not occur. The epithelial lining is left intact and the organisms reach the lamina propria, in which an inflammatory response is elicited.

Epidemiologic Control

Serotyping of *E. coli* for identification of the traditional enteropathogenic strains no longer is practiced in most hospitals. After an index case of enteropathogenic *E. coli* diarrhea is recognized in a nursery, secondary cases are likely to ensue. This applies to the other etiologic agents of diarrhea in neonates. Any nursery infant with diarrhea should be suspected of having a potentially communicable disease. Ill and healthy colonized infants should be segregated. Infants with diarrhea caused by noninvasive strains of *E. coli* can be treated with nonabsorbable drugs such as oral neomycin (100 mg/kg/d in four divided doses) or colistin sulfate (15 mg/kg/d in three divided doses) for 5 days. Neomycin causes rapid disappearance of the organism and abbreviates the period of diarrhea, but approximately 20% of infants revert to the asymptomatic carrier state after treatment (477). Repeated surveillance of infants is necessary until the pathogenic strain has been eliminated from the nursery.

Clinical Manifestations

The cause of diarrhea cannot be differentiated on clinical grounds in newborn infants. Diarrhea caused by enteropathogenic strains of *E. coli* is insidious in onset, is associated with seven to ten green, watery stools daily, and usually is without blood or mucus. The infants do not appear acutely ill. Complications are rare and are related primarily to dehydration and electrolyte disturbances.

Shigella infection is uncommon, usually episodic in neonates, and does not spread within nurseries. Shigellosis in the newborn may present as a diarrheic or

dysenteric syndrome or may be evidenced only by a septic or toxic infant (472). Suppurative complications are rare, but dehydration and electrolyte disturbances are common and need immediate and constant attention. *Campylobacter* species can cause bloody diarrhea in otherwise asymptomatic infants (478). Enteritis is the most common manifestation of neonatal *Campylobacter* infection, but more serious disease such as sepsis or meningitis can occur, albeit infrequently (479,480).

Rotavirus infection may be asymptomatic or associated with vomiting and diarrhea. The infants usually are afebrile, but temperature elevation as high as 39° C can occur. Most patients vomit, and the diarrhea is characterized by watery stools containing mucus and no blood. Moderate or severe dehydration may occur, which results in significant electrolyte disturbance in some infants. Fatal disease has been described in a small number of infants. In one report, an outbreak of necrotizing enterocolitis was associated with rotavirus infection (481).

Other viruses can cause neonatal diarrhea. These include enteric adenoviruses, enteroviruses, small round viruses, and coronavirus. The clinical symptoms associated with enteroviruses can vary from a self-limited GI illness to more severe systemic manifestations such as fever, rash, aseptic meningitis, apnea, or myocarditis (480).

Therapy

The most important aspect of therapy for diarrheal disease of newborn infants is maintenance of hydration and electrolyte balance. Parenteral solutions containing appropriate electrolytes should be administered during the time of active diarrhea, and the infant should be examined and weighed frequently so that proper rehydration and prevention of complications are ensured. Estimation of fluid loss from diarrhea and vomiting should be recorded carefully and used as a basis for replacement therapy.

Selection of appropriate antimicrobial therapy depends, in part, on the mechanism of diarrhea. An absorbable antibiotic, such as ampicillin or trimethoprim-sulfamethoxazole, is indicated for disease caused by invasive bacteria (e.g., shigellosis), but orally administered nonabsorbable drugs, such as neomycin or colistin sulfate, are used for noninvasive organisms that produce enterotoxin (e.g., strains of *E. coli*).

Antimicrobial therapy for *Salmonella* gastroenteritis is controversial. Antibiotics do not alter the course of illness and usually prolong intestinal carriage of the organism. Clinical relapse is more common in antibiotic-treated infants. We do not recommend antibiotic therapy for uncomplicated *Salmonella* gastroenteritis if it occurs in older infants and children. Therapy probably is indicated for those with prolonged illness or evidence of colitis, for all neonates, and for infants with systemic symptoms suggesting bloodstream invasion. Ampicillin or amoxicillin

usually is satisfactory, as are trimethoprim-sulfamethoxazole, cefotaxime, or ceftriaxone.

Ampicillin was formerly the antibiotic of choice for shigellosis, but significant resistance to this agent has been

P.1261

observed in many areas of the country in recent years. Most strains are susceptible in vitro to trimethoprim-sulfamethoxazole, and infants respond clinically and bacteriologically to a regimen of 10 mg of trimethoprim with 50 mg/kg/d sulfamethoxazole in two divided doses given for 5 days. However, we have limited experience with this agent in newborn infants, and the drug should not be used in those with jaundice. For multiresistant *Shigella* strains, ceftriaxone or cefotaxime may be effective. Erythromycin is the preferred drug for the treatment of symptomatic *Campylobacter* infections.

Any infant with diarrhea must be isolated from other babies in the nursery. Surveillance of all infants in contact with the index case and adoption of strict infection control measures are mandatory.

LOWER RESPIRATORY TRACT INFECTION

Lower respiratory tract infection is an important cause of morbidity in the neonate and is demonstrable on postmortem examination in approximately 20% of neonatal deaths.

Pneumonias can be divided into three categories on the basis of route of acquisition and age at presentation. The first is transplacental pneumonitis, which is acquired *in utero* and presents clinically in the early hours of life. Pneumonia may be part of a generalized congenital infection caused by cytomegalovirus, herpesvirus, rubella virus, *T. gondii*, or *L. monocytogenes*. *T. pallidum* produces a severe, usually fatal pneumonitis (i.e., pneumonia alba), and genital mycoplasmas can cause congenital pneumonia. These infants usually have many organ systems involved, and the pneumonitis may be obscured. Clinical findings may include hepatosplenomegaly, cutaneous manifestations such as rash or petechiae, neurologic abnormalities, and teratogenic effects.

The second category, aspiration pneumonia, is acquired in the immediate perinatal period, and onset of illness occurs within the first hours to days of life. Pathogenesis is by aspiration of amniotic fluid or material from the maternal cervix during the period immediately before or during delivery. Most infants with roentgenographic evidence of aspiration have not swallowed infected material and do not require antimicrobial therapy. This is also true of meconium aspiration, in which the pneumonitis is chemical. The bacterial pathogens most commonly encountered are the group B γ -hemolytic streptococci and coliform organisms. Infants with these infections may present in the first 12 hours of life with acute

respiratory distress, with or without shock. Mortality is considerable in this condition, even if appropriate antimicrobial therapy is instituted early.

The third category consists of pneumonias acquired during delivery or in the postpartum period, usually beyond the first week of life. Acquired pneumonitis may be caused by viral, chlamydial, or bacterial agents and most frequently is bronchopneumonic or interstitial. Respiratory syncytial virus (RSV) is the most important pathogen causing lower respiratory tract disease in young infants (482). The parainfluenza viruses, enteroviruses, rhinoviruses, and adenoviruses cause bronchiolitis and pneumonia during early infancy. Herpes simplex virus infection can be acquired at the time of delivery and present in the first week of life. Bronchiolitis, pneumonia, or both usually occur in epidemics among premature and full-term nursery infants or in the community.

Documented nursery outbreaks of lower respiratory tract disease have been associated with RSV, adenovirus, echovirus type 22, influenza A and B viruses, and parainfluenza virus infections. During these outbreaks, many infants are colonized with the epidemic virus strains, but only a few manifest clinical disease.

S. aureus and coliform organisms are the most common bacterial pathogens causing postnatally acquired pneumonia. Disease caused by *S. aureus* and *K. pneumoniae* may occur sporadically or in epidemic fashion during the neonatal period. Pyogenic complications, such as septicemia, osteomyelitis, and meningitis, frequently are associated with the epidemic form of these infections.

Acquisition of *C. trachomatis* in the intrapartum period may result in conjunctivitis (i.e., inclusion blennorrhoea) or in pneumonia that usually presents between the fourth and twelfth weeks of life. The pneumonia is associated with a staccato cough, often terminating in vomiting or cyanosis, and with tachypnea; the infants usually are afebrile (483). Rales are heard, and there may be a history of the infant having conjunctivitis in the newborn period. Eosinophilia is seen in approximately half the patients. Chlamydial pneumonia occasionally can occur in the early neonatal period (first 2 weeks of life) (484,485). *C. trachomatis* can cause severe and chronic pneumonia in LBW infants (486,487). *C. trachomatis* pneumonia in otherwise healthy infants has been associated with long-term pulmonary function abnormalities (488).

A considerable body of data indicates that *U. urealyticum* colonization of LBW infants is associated with the subsequent development of chronic lung disease (489,490,491,492,493,494,495). *Ureaplasma*-positive infants have much higher ratios of IL-1 γ to IL-6 and tumor necrosis factor to IL-6 in their tracheal aspirates than do *Ureaplasma*-negative infants (496). Thus, in the preterm lung, *U. urealyticum* may contribute to early injury by inducing the release of inflammatory cytokines. However, treatment of *U. urealyticum* colonization with erythromycin has not been shown to reduce the incidence of chronic lung disease in premature infants (497,498). *Pneumocystis jiroveci* is an uncommon cause of pneumonia in

the neonatal period; susceptible infants include malnourished premature newborns living in endemic geographic areas, infants with congenital immunodeficiencies (e.g., severe combined immunodeficiency), and neonates infected with the human immuno-deficiency virus type 1 (499,500,501).

Legionella pneumonia is uncommon but has been described in newborns, most of whom had underlying problems such as prematurity,

P.1262

chronic lung disease, congenital heart disease, steroid treatment, or hypoxic ischemic encephalopathy. *Legionella* can cause a range of respiratory symptoms from a mild influenza-like illness to severe cavitary pneumonia and death (502,503). *Bordetella pertussis* infection continues to occur and should be suspected in newborns with paroxysmal cough and a parent or sibling with a persistent cough.

Clinical Manifestations

The early signs of lower respiratory tract disease in the neonate and young infant frequently are nonspecific and include change in feeding status, listlessness or irritability, and poor color. More specific findings that may not be present at the onset of illness are tachypnea, dyspnea, cyanosis, hypothermia, cough, and grunting. Accentuation of the normal irregularity of breathing is a common finding in neonates.

The physical findings of pneumonia vary. Flaring of the alae nasi, rapid respirations, and sternal and subcostal retractions frequently are observed. A cough is indicative of lower respiratory tract involvement; a brassy cough frequently is found in viral disease. Percussion dullness is difficult to demonstrate, but it is indicative of consolidation, effusion, or both. Auscultation may reveal diminished breath sounds over the affected area. Rales, wheezes, or both usually can be heard on deep inspiration or when the baby is crying, but may be absent early in the illness. The clinician frequently is surprised by the meager clinical signs in the face of clearly demonstrable and sometimes extensive roentgenographic findings of pneumonia.

Infants with pertussis usually become ill between weeks 2 and 6 of life. The characteristic whoop seen in older infants and children usually is absent. Paroxysmal cough, excessive mucous, and apneic spells are common in these infants. Complications of pertussis are many and include secondary bacterial pneumonia, atelectasis, and asphyxia.

Diagnosis

The leukocyte count may assist in the differentiation of viral from bacterial pneumonia. Infants with early-onset bacterial pneumonia with sepsis may have

leukopenia with an increased number of immature neutrophils. Chorioamnionitis has been demonstrated in the mothers of some infants with congenital pneumonia.

Cultures of blood and material from the trachea frequently help to define the etiologic agent of neonatal pneumonia. However, results of cultures from the ear canal, throat, and other external sites are not helpful and may be misleading in newborn and young infants. Thoracentesis or lung puncture should be considered in infants with pleural effusion or consolidated pneumonia, respectively, if the cause is unknown or the infant fails to respond to conventional antimicrobial therapy. Material obtained at puncture should be Gram stained for direct visualization of bacteria and cultured. Chlamydial pneumonia is best diagnosed by culture of nasopharyngeal secretions or by the polymerase chain reaction (504). Under certain circumstances, the tracheal aspirates or fluid obtained after bronchoalveolar lavage can be examined for *P. jiroveci* cysts, cultured for viruses, fungi, mycoplasmas, *B. pertussis*, acid-fast bacteria, and *Legionella*, and examined by polymerase chain reaction assays for a variety of infectious agents including *U. urealyticum*, *B. pertussis*, and viruses such as herpes simplex virus and cytomegalovirus (501,503,505,506).

A chest radiograph may reveal roentgenographic evidence of pneumonia despite the absence of physical findings. Although it usually is not possible to determine the cause of neonatal pneumonia from chest radiographs, certain roentgenographic patterns may be associated with specific diseases. A consolidating bronchopneumonia with pneumatoceles, with or without empyema, suggests staphylococcal disease. This is particularly true when the radiologic findings advance markedly in a few hours. If a lobar infiltrate is associated with bulging fissures on the radiograph, *K. pneumoniae* infection should be considered. A miliary-type of bronchopneumonia in a septic neonate is characteristic of listeriosis. GBS pneumonia frequently is indistinguishable radiographically from hyaline membrane disease. A bronchopneumonic infiltrate noted on chest roentgenogram during the first postnatal month of life may be caused by aspiration of sterile or infected amniotic fluid or by viral, chlamydial, or bacterial pathogens, or it can represent patchy atelectasis (507).

Staphylococcal pneumonia is found most commonly in young infants; 30% of patients are younger than 3 months of age, and 70% are younger than 1 year of age. Epidemics of staphylococcal disease caused by phage group I organisms are encountered infrequently.

Staphylococci cause a confluent bronchopneumonia characterized by extensive areas of hemorrhagic necrosis and irregular areas of cavitation. The pleural surface is usually covered by a thick layer of fibrinopurulent exudate. Multiple small abscesses are scattered throughout the lungs. Rupture of a small subpleural abscess may result in a pyopneumothorax, which may erode into a bronchus, producing a bronchopleural fistula.

The onset of illness in staphylococcal pneumonia is abrupt, with fever, cough, and respiratory distress as the major manifestations. Tachypnea, grunting respirations, retractions, cyanosis, and anxiety usually are observed. Severe dyspnea and a shock-like state may occur. Rapid progression of symptoms is characteristic. Moist, scattered rales, diminished breath sounds, and rhonchi may be heard early in the illness. With the development of pleural effusion, dullness on percussion is associated with diminished breath sounds.

Most patients with staphylococcal pneumonia have roentgenographic evidence of bronchopneumonia early in the illness. The infiltrate may be patchy and limited in extent or be dense and homogeneous, involving an entire lobe or hemithorax. Pleural effusions or empyema are found in most infants (508). Pneumatoceles of various sizes are common. Although no radiographic change can

P.1263

be considered diagnostic, progression over a few hours from bronchopneumonia to effusion or pyopneumothorax with or without pneumatoceles is highly suggestive of staphylococcal pneumonia.

Treatment

All diagnostic procedures and cultures should be obtained before initiation of therapy. Methicillin is the initial drug of choice for staphylococcal pneumonia and should be administered parenterally in a dosage of 75 mg/kg/d divided in two or three doses for infants younger than 1 week of age and in a dosage of 100 mg/kg/d divided in four doses for older infants.

If infection extends to the pleural surfaces, surgical intervention usually becomes necessary. With small amounts of effusion, repeated pleural taps may be successful in removing fluid, but empyema is best treated by closed drainage with a chest tube of the largest possible caliber.

Vancomycin is preferred for disease as a result of MRSA. For pneumonia caused by *K. pneumoniae* or other coliforms, kanamycin or gentamicin should be used in a total dosage of 15 mg/kg/d or 5 to 7.5 mg/kg/d, respectively. Alternatively, a third-generation cephalosporin, such as cefotaxime, can be used. Treatment for *Listeria* pneumonia is parenteral ampicillin in a dosage of 50 to 100 mg/kg/d divided in two doses for infants younger than 1 week of age and 100 to 150 mg/kg/d divided in three doses for older neonates. Infants with GBS septicemia and pneumonia should be given penicillin as outlined earlier for sepsis neonatorum. Larger doses are required for meningitis. Ampicillin or cefotaxime may be used in place of penicillin.

Pertussis and chlamydial and ureaplasma pneumonias probably are treated best with orally or intravenously administered erythromycin, depending on the infant's clinical status. This agent has been shown to shorten the course of illness and to eradicate shedding of the organisms from the nasopharynx. *Legionella* pneumonia

also is treated with erythromycin; rifampin sometimes is added (503). Trimethoprim-sulfamethoxazole is the initial drug of choice for *P. jiroveci* pneumonia; pentamidine and trimetrexate are reserved for treatment failures.

Pneumonia may be one manifestation of generalized congenital viral infections. It is important to differentiate these infections from CS and bacterial pneumonias resulting from aspiration. Ganciclovir can be used for cytomegalovirus pneumonia, but infants may worsen again on discontinuation of the drug. Vidarabine or acyclovir is effective if given early in disease caused by herpes simplex virus.

Most infants with aspiration pneumonia do not require antimicrobial therapy. It frequently is difficult to differentiate infants with aspiration of sterile amniotic fluid from those aspirating infected materials. If doubt exists, therapy with penicillin and an aminoglycoside should be initiated and continued until results of cultures are available.

OTITIS MEDIA

Otitis media is a frequent finding in premature infants receiving intensive care and an almost universal finding in autopsy studies of infants who died after a period of intensive care (509,510,511,512). A principal predisposing factor for otitis media in the newborn is nasotracheal intubation that results in ipsilateral obstruction of the eustachian tube, establishing the conditions eventuating in middle-ear infection. The diagnosis is missed frequently because pneumatic otoscopy is not performed routinely in neonates.

The exact incidence of this condition is unknown. In one prospective study of 70 term infants followed from birth, 34% developed their first episode of otitis media before 2 months of age (513). Symptoms are nonspecific and include irritability, lethargy, fever, cough, diarrhea, vomiting, tachypnea, and anorexia (514). An associated conjunctivitis, pneumonia, or meningitis may be found in as many as half the patients. The diagnosis usually is made by pneumatic otoscopy. Tympanometry is unreliable in neonates.

Pathogenic organisms include *S. pneumoniae*, *H. influenzae*, *S. aureus*, *β. catarrhalis*, *P. aeruginosa*, and coliforms. The predominant isolates vary in different study populations (509,510,511,512,513,514,515,516,517).

Tympanocentesis should be performed on all newborns with otitis media who develop illness while in the nursery or intensive care unit (518). This may yield an etiologic agent when cultures of other sites are sterile. Some infants have positive blood cultures (517). The choice of antibiotic therapy can be based on the results of the Gram stain and culture of the aspirated middle ear effusion. If no organisms are seen on the smear, treatment should be with methicillin and an aminoglycoside until additional information is available. Infants with otitis media

who are seen in the clinic or office usually do not require tympanocentesis for etiologic diagnosis if the illness is mild and can be managed at home. In these infants, amoxicillin is preferred for therapy, and the patients should be reexamined 2 or 3 days after initiation of therapy to ascertain improvement. Infants with onset of otitis media before 2 months of age may need as long as 3 months to clear the effusion, and 33% of them develop chronic otitis media (513).

PERITONITIS

Spontaneous bacterial (i.e., primary) peritonitis without an evident intraabdominal source is rare during the neonatal period (519). It is postulated that bacteria can reach the peritoneal cavity by means of hematogenous, lymphatic, genital, or transmural (i.e., across the gut wall) routes of spread (520). A concurrent omphalitis is common (521). Gram-positive bacteria (e.g., *S. pneumoniae*, groups A and B streptococci) are the predominant pathogens, but gram-negative bacilli such as *Pseudomonas* or *Klebsiella* are responsible for some cases.

Most infants develop peritonitis after perforation of an abdominal viscus, usually as a complication of necrotizing

P.1264

enterocolitis. Other predisposing conditions include spontaneous focal GI perforations, wound infections after abdominal surgery, traumatic perforations (e.g., feeding tube, rectal thermometer), ruptured omphalocele, and meconium peritonitis with subsequent bacterial contamination. Organisms isolated from peritoneal fluid cultures generally mirror the infant's gut flora and include *E. coli*, *Klebsiella* spp, *Enterobacter* spp, *Pseudomonas*, coagulase-positive and coagulase-negative staphylococci, streptococci, enterococci, anaerobic bacteria (e.g., clostridia, *Bacteroides* spp), and *Candida* (522,523,524).

Clinical signs of peritonitis include vomiting, abdominal distention, abdominal wall edema or discoloration, constipation, diarrhea, grunting, temperature instability (usually hypothermia), shock, and scrotal or vulvar swelling. Abdominal radiographs may reveal free air in the peritoneal cavity, indicating intestinal perforation, or patterns suggesting necrotizing enterocolitis (e.g., pneumatosis intestinalis) or intestinal obstruction. Abdominal ultrasound is helpful in visualizing peritoneal fluid. An abdominal paracentesis may yield pus or reveal a different cause for the illness (e.g., hemoperitoneum, bile peritonitis). Aerobic and anaerobic cultures of the peritoneal fluid and of the blood should be obtained in all cases.

The management of peritonitis consists of supportive measures aimed at reversing hypovolemia, shock, and electrolyte imbalances; surgical correction of underlying conditions; and administration of broad-spectrum antimicrobial agents. Acceptable initial antibiotic regimens include ampicillin, gentamicin and clindamycin, ticarcillin-clavulanate or piperacillin-tazobactam and an

aminoglycoside, or vancomycin, ceftazidime, and metronidazole. The broadest antibacterial coverage is attained by the vancomycin, ceftazidime, and metronidazole combination. Treatment can be simplified after the blood and peritoneal fluid culture results become available. Antibiotics are usually administered for a minimum of 10 days. The prognosis depends on several factors, including birth weight and precipitating conditions, and fatality rates range from 10% to 50% (519).

Chapter 48

VIRAL AND PROTOZOAL INFECTIONS

Introduction

Microorganisms can reach and infect a fetus or newborn via a number of routes. Vertical spread of a pathogen from an infected mother can occur *in utero*, during delivery, or postnatally (e.g., ingestion of infected breast milk). Horizontal spread of infectious agents to newborns by means of contaminated hands, stethoscopes, blood products, total parenteral nutrition fluid, or respiratory therapy equipment is well documented and can lead to outbreaks of disease in neonatal intensive care units.

Iatrogenic fetal infections occasionally occur after invasive procedures such as fetal scalp monitoring or intrauterine transfusions (1). Infection control in the NICU is discussed in detail in [Chapter 49](#).

Maternal infections acquired shortly before conception or during gestation can adversely affect pregnancy outcome indirectly through nonspecific effects of severe maternal illness (e.g., increased rates of spontaneous abortions, stillbirths, or premature births associated with measles infection during pregnancy) or directly through microbial invasion of the fetus or neonate (2). Pathogens can be transmitted from mothers to their infants through hematogenous spread across the placenta (e.g., cytomegalovirus [CMV], *Toxoplasma gondii*), ascension from an infected cervix (e.g., herpes simplex virus [HSV]), or intimate contact between a fetus and infected genital secretions during vaginal delivery (e.g., HSV, hepatitis B virus [HBV], human immunodeficiency virus type 1 [HIV-1], papillomaviruses) (3,4,5). Maternal coinfection by other microorganisms may enhance the risk of fetal infection by either or both pathogens (6).

The outcome of a fetal or neonatal infection depends on the stage of pregnancy during which infection occurs, virulence of the pathogen, preexisting maternal immunity to the infecting agent, and efficacy of drug therapy for maternal or neonatal disease. Intrauterine infections may lead to resorption of the embryo, fetal demise resulting in a spontaneous abortion or stillbirth, or delivery of an infected neonate. Infected infants who are asymptomatic at birth may develop chronic problems in late infancy or early childhood (e.g., HIV-1, CMV, hepatitis C virus [HCV]) or during adulthood (e.g., rubella, HBV) (7,8,9,10). Others suffer from severe acute neonatal disease such as pneumonia or hepatitis (e.g., HSV, syphilis), congenital malformations (e.g., CMV, rubella), intrauterine

growth retardation, or prematurity ([8,10,11](#)). The number of infants born each year with these conditions is substantial ([Table 48-1](#)), and the lifetime expenditures for their medical and educational needs are considerable ([12,13,14,15,16,17,18,19,20,21,22,23](#)).

The acronym TORCH (*T. gondii*, "other," rubella virus, CMV, HSV) has long been used as a reminder that a number of pathogens can cause clinically indistinguishable illnesses in the neonate. These agents originally were grouped together because of shared clinical features (e.g., microcephaly, hepatosplenomegaly, petechiae, ocular abnormalities), their ability to cause asymptomatic infections in the mother and newborn, and their propensity for causing long-term sequelae that may be inapparent at birth ([24](#)). Because many other agents (e.g., HIV-1, *Treponema pallidum*, varicella-zoster virus [VZV], coxsackievirus, human parvovirus B19, *Mycobacterium tuberculosis*) are capable of causing similar illnesses, the diagnostic workup of infants suspected of having a TORCH infection should not be restricted to the original four agents, as is common in medical practice ([25](#)). The clinical utility of this mnemonic is limited, and its use should be minimized or abandoned altogether ([26,27](#)).

The epidemiology, clinical manifestations, diagnosis, and treatment of maternal and fetal infections caused by rubella virus, HSV, CMV, VZV, human parvovirus B19, hepatitis B, hepatitis C, HIV-1, and *T. gondii* is discussed in this chapter. Strategies for the prevention of maternal infection by these organisms or their vertical spread to the fetus or newborn infant are emphasized. Infections caused by other pathogens are addressed in less detail. Respiratory and gastrointestinal viruses that spread horizontally in nursery settings are covered in [Chapter 49](#).

TABLE 48-1 ESTIMATED NUMBER OF INFANTS WITH SELECTED CHRONIC CONGENITAL OR PERINATAL INFECTIONS BORN ANNUALLY IN THE UNITED STATES

Infection	Number of Infants	Year of Estimate
Congenital cytomegalovirus (12)	40,000	1992
Hepatitis B virus (9)>	20,000	1999
Exposed	5,500	1999
Chronic carriers ^a		
Hepatitis C virus (13 , 14) ^b	1,000–3,000	2002
Congenital toxoplasmosis (15) ^c	4,100	2001
Congenital syphilis (16)	451	2002
Perinatal human immunodeficiency virus type 1 (17) ^d	390	2001
Neonatal herpes (18)	1,500	2002
Congenital rubella syndrome (19) ^e	1	2002

^a If not given hepatitis B immune globulin and hepatitis B recombinant vaccine at birth

^b Some infants will spontaneously clear the virus by two years of age

^c Rates as low as 1:12,000 live births have been reported from Massachusetts, suggesting a significantly lower estimate for the annual number of infants born with congenital toxoplasmosis in the United States ([20](#))

^d An additional 140 infected children had no reported or identifiable risk factors for their HIV-1 infection

^e Due to the passive nature of the reporting system and to missed diagnoses of less severe cases, this figure probably represents an underestimate of the actual cases ([21,22](#)).

Rubella

Rubella (i.e., German measles, third disease) typically is a subclinical or mild exanthematous infection of children and adults. Gestational rubella can have deleterious effects on the fetus. The infant may have physical and mental abnormalities, such as cataracts, congenital heart disease, deafness, microcephaly, or psychomotor retardation, or present with severe neonatal disease that may include thrombocytopenia, bleeding, hepatosplenomegaly, pneumonia, and myocarditis. Some manifestations of congenital rubella infection may not appear until years or decades later, even among patients asymptomatic at birth (8).

The rubella virus is an enveloped, single positive-stranded ribonucleic acid (RNA) virus that is spherical and has spike-like projections containing hemagglutinin. Only one antigenic type of the virus is known, but there are differences between rubella virus strains in their properties (e.g., hemagglutination, cell tropism), virulence, and teratogenicity. Man is the only natural host for rubella virus, but some animals such as primates, rabbits, and ferrets can be infected under experimental conditions. Rubella virus has three structural polypeptides; two are envelope acylated glycoproteins (E1 and E2) observed as spikes in the form of E1-E2 heterodimers on the virion surface, and one is a nonglycosylated RNA-associated capsid protein (C). E1 contains the domains responsible for binding to host cell receptors and for hemagglutination. The function of E2 is not well defined, but it may carry strain-specific antigens, partial hemagglutination epitopes, and a weak neutralizing domain associated with virus infectivity. The C protein may be involved in the transfer of viral RNA into host cell cytoplasm (28). Rubella virus also possesses a nonstructural polyprotein (p200); this polyprotein and its cleavage products (p150, p90) have enzymatic activities (e.g., helicase, replicase, protease) and are involved in viral RNA replication (29,30). Molecular techniques such as the polymerase chain reaction (PCR) and nucleotide sequencing allow the differentiation between rubella virus strains. This is useful in the analysis of the molecular epidemiology of the virus and in differentiating between wild-type virus and the RA 27/3 vaccine strain when rubella virus is isolated from individuals with possible vaccine-related adverse effects (31,32).

Person-to-person transmission usually occurs by airborne spread of infected respiratory secretions, and direct contact with virus-containing urine or feces is a less likely route of infection. Although rubella virus can be recovered from the genital tract of infected women, vertical transmission during pregnancy is believed to occur almost exclusively through the placenta (33,34).

On entry into the body in cases of postnatal infection, the rubella virus multiplies in nasopharyngeal epithelial cells and in local lymph nodes. This is followed by a

period of viremia and shedding from the throat. It is during this maternal viremic phase that placental and fetal infection occurs. The frequency and nature of fetal involvement depends on the mother's immune status against the virus and the timing during gestation of maternal rubella (8).

The mechanisms by which the virus ravages the fetus are not clearly understood. Necrotic placental vascular endothelial cells can serve as a source of virus-infected emboli. Damage to endothelial cells can lead to thrombosis of small blood vessels, resulting in hypoxic tissue damage (35,36). Rubella-infected cells have diminished mitotic activity as a result of chromosomal breaks. They produce a growth-inhibiting protein and show ultrastructural mitochondrial

P.1276

changes that may interfere with cell metabolism. The virus damages the cytoskeletal microtubular system by altering the arrangement of actin filaments (37). Rubella virus generally establishes a chronic nonlytic infection in the fetus and can potentially infect any organ (29). As with other viruses, it can induce apoptosis of infected cells, but a role for this in its teratogenicity has not been demonstrated. Focal lysis of infected cells can be seen in some organs, but inflammation is not a salient feature of congenital rubella (35). Noninflammatory necrosis in the structures of the heart, eyes, brain, and ears have been seen in aborted rubella-infected fetuses (29). Growth-retarded infants have reduced cell numbers on histopathologic examination (38). Moreover, the virus can modify cell receptors for specific growth factors (39). Late-onset manifestations of congenital rubella may be as a result of viral persistence with ongoing cell destruction or to organ damage by means of a number of immune mechanisms such as circulating rubella-specific immune complexes, defective cytotoxic effector cell function, or the development of autoimmunity (28,40-44). The rubella virus E1 and E2 proteins, but not the C nucleoprotein, appear to be responsible for autoantibody induction (45).

Long-lasting immunity normally develops after recovery from postnatal rubella. Reinfections can occur in persons with low antibody titers, but these are usually asymptomatic. Persons with low antibody levels after rubella vaccination are more prone to reinfections than persons with similarly low titers after natural infection (34).

Circulating antibodies and cell-mediated immune responses are generated after rubella infection. Rubella-specific immunoglobulin M (IgM), immunoglobulin G (IgG), immunoglobulin A (IgA), immunoglobulin D (IgD), and immunoglobulin E (IgE) antibodies are induced in response to postnatal infection (46). IgM antibodies appear early and are short lived. They usually disappear 5 to 8 weeks after onset of illness, although rubella-specific IgM antibodies rarely can persist for months or years (47). The IgM re-sponse after rubella vaccination or natural reinfection generally is weak and of brief duration (48,49,50). Moreover, rubella-specific IgM antibodies can be detected in acute infections caused by viruses such as

parvovirus B19 and Epstein-Barr virus (51). Specific IgD and IgE antibodies appear early and then decline more slowly than specific IgM antibodies (46). Specific IgA antibodies generally emerge within the first 10 days of illness, and they may continue to be measurable for periods ranging from 3 weeks to several years (46,52). Rubella-specific IgG antibodies increase rapidly and persist throughout life; rubella-specific IgG1 has been shown to be the principal IgG subclass (34,53). The most vigorous antibody and lymphocyte proliferative responses in postnatal rubella are directed against glycoprotein E1 (54,55). The avidity of specific IgG to rubella antigens increases with time after primary infection; a low avidity index (less than 40%) can be seen up to 6 weeks after onset of the rubella rash, whereas a high avidity index (greater than 60%) is not seen until after 13 weeks (51). Measurement of rubella IgG avidity can be useful in women with positive rubella-specific IgM reactions, as it can help distinguish primary infections from unusually prolonged IgM persistence or from reinfection. Rubella-specific IgG also can be detected in the urine, and the results correlate well with serum IgG measurements (56). Men and women appear to differ in the nature and magnitude of their antibody responses to rubella virus structural proteins (57). Men never produce anti-E2 IgA and generate significantly lower levels of IgG antibodies directed against E2 than women. Anti-E1 IgM and IgG antibodies appear earlier in male patients, but female patients have higher levels of rubella-specific IgG antibodies after recovery from the illness. The observed gender differences in antibody responses to viral proteins may be under genetic or hormonal influences and may be related to the increased susceptibility of women to the joint complications of rubella (57).

Immune responses in congenitally infected infants differ from those observed in adults with rubella. Fetal IgM production usually begins after 16 weeks of gestation. Rubella-specific IgM antibodies are detectable until 6 to 12 months of age. Specific IgG antibody levels decrease over time; as many as 20% of affected children have no measurable antibody titers by 5 years of age (34). Circulating antirubella antibodies in infants with intrauterine infection have lower affinities to rubella antigen than antibodies from adults with natural infection (58,59). Serum antibodies to the E2 glycoprotein are quantitatively more abundant than those directed against E1 in some patients with congenital rubella, particularly among older infants. Antibody reactivities against the C protein are poor (54,60). Infants with congenital rubella have diminished cell-mediated immune responses on exposure to rubella antigens compared with children or adults with postnatal infection, and the responses are weakest for infants infected earlier during gestation. The reduction in response is mainly seen with the E1 protein (53,61).

Maternal Rubella

Epidemiology

Major epidemics of rubella formerly occurred at 6- to 9-year intervals in the United States. The last major pandemic took place between 1964 and 1965, at which time 20,000 cases of congenital rubella occurred. Rubella did not become a notifiable disease in the United States until 1966. Since licensure of the rubella vaccine in 1969, the number of postnatal rubella and congenital rubella syndrome (CRS) cases declined by 99% and 97%, respectively. The incidence of reported postnatal rubella cases declined from 0.45 per 100,000 in 1990 to less than 0.02 per 100,000 in 2002. The annual number of reported cases during that same period ranged from a high of 1,412 in 1991 to a low of 18 in 2002, with a median of 192 (19,62).

A significant change in the characteristics of postnatal rubella cases has been noted between 1990 and 2000. Between 1990 and 1992, 50% to 70% of all cases were in

P.1277

children 14 years of age or younger. By 2002, 72% of all cases occurred in individuals 15 to 39 years of age. Only 23% of the 18 postnatal rubella cases in 2002 were in females. Between 1995 and 2000, Hispanics comprised from 56% to 78% of all patients with this infection, most of whom were born outside the United States. Between 1996 and 1999, rubella was reported in 281 women of childbearing age, 26% of whom were pregnant at the time of rash onset (19,62). For the time period from 1990 to 1999, there were 65 outbreaks of rubella (each with five or more epidemiologically linked cases). Common settings for these outbreaks included religious communities, correctional facilities, worksites, and higher education institutions (62). Most affected individuals were either unimmunized or had unknown vaccination status (21,62-64).

Medical students and other health professionals can also serve as vectors for rubella infection, placing susceptible pregnant women to whom they are exposed in a medical setting at significant risk (65). In a study of one hospital system in St. Louis, Missouri, 5.3% of about 6,000 new employees were found to be seronegative for rubella (66).

Approximately 10% to 20% of women of childbearing age in the United States are susceptible to rubella, and the rates are comparable for Hispanics, non-Hispanic whites, and African Americans. Hispanics aged 20 to 29 years are more likely to be seropositive for rubella if born outside the United States (67). Between 1990 and 1999, women delivering infants with CRS tended to be young (median age, 23 years), Hispanic, and foreign-born (62). Rubella susceptibility rates for women of child-bearing age in European countries generally are comparable to those found in the United States, but lower seropositivity rates are encountered among island populations such as those in Hawaii and Jamaica and in certain tropical African countries (34,68-72). Significant regional differences have been found in large countries, such as India and China (73,74).

Clinical Manifestations

Twenty percent to 50% of postnatal rubella infections are subclinical (75). Illness occurs 12 to 23 days (mean 18) after exposure. A prodrome consisting of malaise, low-grade fever that rarely lasts beyond the first day of the exanthem, headache, and conjunctivitis precedes the rash by 1 to 5 days. The exanthem consists of discrete macules or papules that initially appear on the face and behind the ears, spread downward over 1 to 2 days, and usually disappear over 3 to 5 days; rubella virus can be isolated from these skin lesions (76). Postauricular, suboccipital, and posterior cervical lymphadenopathy is common and may persist for several weeks. Complications of rubella develop more frequently in adults. Transient arthralgias may occur in as many as one-third of infected women, but arthritis is uncommon (8). Other complications are rare and include thrombocytopenic purpura, hemolytic anemia, hepatitis, Guillain-Barré syndrome, encephalitis, progressive panencephalitis, myelitis, peripheral neuritis, myocarditis, and pericarditis (8,77-80).

Pregnancy has no effect on the natural course of rubella infection. However, rubella is associated with an increased risk of miscarriages, spontaneous abortions, and stillbirths (8).

Laboratory Diagnosis

The diagnosis of rubella on clinical grounds alone is unreliable, because enteroviruses, measles virus, or parvovirus B19 may produce similar illnesses. Laboratory confirmation by virus isolation or serologic testing thus is essential in pregnant women, for whom an accurate diagnosis of gestational rubella is critical. Shirley and colleagues (81) investigated 627 patients clinically suspected of having rubella, but they could confirm this diagnosis in only 229 (37%). Human parvovirus B19 infection accounted for 7%, measles for 1%, and other infectious agents for 1%; the causes for the remaining 54% could not be determined.

Rubella virus is shed from the nasopharynx for 1 week before and 1 week after onset of the rash. However, the cultures become negative in 50% of patients by the fourth day of the rash. The virus is present in blood and urine during the week preceding the exanthem. Shortly after the rash appears, rubella virus is no longer detectable in the serum but can be found in circulating mononuclear cells for about a week. Rubella virus isolation is impractical for diagnostic purposes because it is expensive, labor intensive, and frequently unavailable to the clinician. The cell line recommended for isolation of rubella virus from clinical specimens is primary African green monkey kidney, but Vero or RK-13 can be used also. Isolation of the virus can take longer than 10 days, especially if present in low titers (82).

Serologic techniques are the most useful methods for diagnosing rubella infection.

Available tests include hemagglutination inhibition, enzyme-linked immunosorbent assay (ELISA), immunofluorescence, radioimmunoassay, hemolysis in gel, complement fixation, passive hemagglutination, and latex agglutination tests (50,82). Serum specimens obtained as soon as feasible after the appearance of the exanthem and again 2 weeks later can prove the diagnosis if seroconversion or a fourfold or greater rise in rubella-specific antibody titers can be documented. Paired sera are best tested in unison because of the variability in results of assays done on separate days or by different personnel. If measured by ELISA, hemagglutination inhibition, or radioimmunoassay, rubella-specific IgG antibodies can be found as early as 1 to 2 days before the emergence of the rash; if assayed by the less readily available passive hemagglutination method, these antibodies are not detected until 15 to 50 days after onset of the exanthem and peak approximately 6 to 7 months later. The detection of rubella-specific IgM antibodies within 28 days of the appearance of the rash usually is diagnostic, the caveats being that IgM responses sometimes can persist for a year or more after a primary infection and that they also can be detected in some patients with rubella reinfection (83). Only 50% of postnatal rubella patients have detectable IgM

P.1278

on the day of symptom onset, but more than 90% become IgM positive by the fifth day after the rash appears (82). Newer tests that can be used for the diagnosis of acute postnatal rubella include avidity ELISA in which acutely infected persons have low IgG avidity compared with persons previously immune to rubella who exhibit greater IgG avidity (51). IgG produced in response to rubella vaccination shows low avidity to rubella antigens during the first 2 months after immunization, but this increases significantly over the ensuing months and remains at high levels thereafter (84). Immunoblot techniques have been developed for the sensitive detection of rubella-specific IgG, IgM, and IgA antibodies (85).

Rubella reinfections are confirmed by a fourfold or greater rise in the titer of preexisting rubella-specific IgG antibodies. The specific IgM response is absent or weak, but it is sometimes high enough to be within the range deemed sufficient for the diagnosis of primary rubella (50).

False-positive IgM reactions can occur in sera containing rheumatoid factor, although the IgM capture assay appears to be unaffected by its presence (50). Cross-reactions between rubella and human parvovirus B19, Epstein-Barr virus, or CMV infections in specific IgM tests necessitate caution in interpreting low or equivocal levels of rubella-specific IgM antibodies (75).

Rubella virus RNA can be detected in clinical specimens using a reverse transcription nested PCR assay. This molecular technique has been used on pharyngeal swabs, chorionic villi, amniotic fluid, fetal blood, and lens aspirates (86,87,88).

Treatment

There is no specific therapy for postnatal rubella. Patients with rubella shed the virus from the nasopharynx for 1 week after appearance of the rash; therefore, these patients should avoid contact with susceptible persons until the exanthem has vanished.

Prevention

The principal goal of rubella immunization programs is the elimination of CRS. The vaccine used in the United States is the RA 27/3 attenuated live rubella virus vaccine. It is available in a monovalent form (i.e., rubella only) and in combination with measles and mumps (i.e., measles-mumps-rubella). The vaccine induces antirubella antibodies in more than 95% of recipients 12 months of age or older, and its protective efficacy is greater than 90% for at least 15 years (89).

Immunizing children whose pregnant mothers are susceptible to rubella does not pose a threat to the mother or her fetus. The vaccine is recommended for all susceptible persons 12 months of age or older and usually is given at 15 months of age; a second booster dose is given to children at the time of school entry.

A clinical diagnosis of rubella is considered unreliable and cannot be considered proof of immunity. Persons are deemed protected if they have serologic evidence of immunity or previously had been vaccinated on or after their first birthday. Birth before 1957 is not acceptable evidence of rubella immunity for women who could become pregnant (90).

Pregnant women whose rubella-immune status is not known should be tested for the presence of antirubella antibodies during their first prenatal visit. If a previously unimmunized pregnant woman with unknown antibody status is exposed to rubella, a blood sample should be immediately obtained for rubella antibody testing. If antibody to rubella is found, the woman is considered immune (91). The risk of rubella reinfection after natural disease or vaccination is small, but it is more likely to occur in women with low specific IgG titers (92). Rubella reinfections do not seem to be related to a lack of neutralizing antibodies or to an impaired rubella-specific lymphocyte transformation response (93). Significant fetal pathology after reinfection occurs infrequently, despite rubella virus transmission to the fetus, and is typically not seen if this occurs after the twelfth week of gestation (94,95,96,97,98,99,100,101,102,103).

Susceptible women exposed to rubella should be informed of the risks to the fetus if maternal infection occurs. If the woman develops fever, lymphadenopathy, or a rash within the expected incubation period, serum for rubella-specific IgM measurement should be obtained. If a clinical illness does not occur, serum should be obtained 6 to 8 weeks after exposure to exclude a subclinical infection. For women who seroconvert or become positive for rubella-specific IgM, the rate of

fetal infection is 81% after maternal rubella during the first 12 weeks of gestation, 54% at 13 to 16 weeks, 36% at 17 to 22 weeks, 30% at 23 to 30 weeks, 60% at 31 to 36 weeks, and 100% at more than 36 weeks of pregnancy. Infants infected before 11 weeks of gestation usually develop congenital defects, most often cardiac anomalies and deafness, but only 35% of infants infected at 13 to 16 weeks of gestation have abnormalities at birth, usually deafness (104). In a study of 106 infants with confirmed CRS in whom the timing of maternal infection was known with reasonable accuracy, Munro and colleagues (105) found deafness in 58% of patients, and it was the sole abnormality in 40% of all infants; infants with congenital cardiac, ocular, or CNS defects almost always were deaf as well. The risk of deafness is small if maternal infection occurs at 17 weeks of gestation or later (104,105). Other investigators have confirmed that rubella virus can be transmitted to the fetus at any stage of pregnancy, and that the earlier the maternal infection during pregnancy, the greater is the severity of congenital defects (106,107,108).

If maternal rubella occurs during the first 5 months of pregnancy, the option of therapeutic pregnancy termination can be considered. Infections occurring after this time do not produce congenital defects. If available, an attempt at prenatal diagnosis can be made, because fetal involvement after maternal rubella is not universal. The virus has been isolated from amniotic fluid by culture or directly visualized using electron microscopy in a few cases

P.1279

(109,110). The low sensitivities of these methods limit their usefulness. Amniotic fluid cells in rubella-infected patients are abnormal when examined with a transmission and scanning electron microscope (lack of chromatin, disappearance of electron-dense cytoplasmic layer, membrane damage expressed by a decrease in the size and number of microvilli) (111). Daffos and colleagues studied 18 pregnancies complicated by maternal rubella; fetal blood was obtained at 20 to 26 weeks of gestation, and rubella-specific IgM was detected in 12 fetuses. Contamination of fetal blood specimens by maternal blood was excluded. Of the six fetuses without detectable rubella-specific IgM antibodies, one was found to be infected at birth (112). In another study, investigators were able to detect rubella-specific IgM and IgA as early as 22 weeks of pregnancy (52). Hwa and colleagues performed fetal blood sampling at 22 to 30 weeks gestation (at least 2 weeks after appearance of the rash) on 93 rubella-specific IgM positive pregnant women. Of six infants infected *in utero*, five had rubella-specific IgM in cord blood (113). The drawbacks of this method are that the fetus does not synthesize IgM until the fifth month of gestation, and the quantity produced initially may be meager and below the limits of detection of the assay. Despite these disadvantages, the technique still is helpful in the management of pregnancies complicated by maternal rubella (114).

Terry and associates detected rubella antigens and ribonucleic acid (RNA)

sequences in a chorionic villus biopsy specimen obtained at 11 weeks of gestation from a woman with rubella in early pregnancy, and this led to pregnancy termination at week 13 of gestation. Infection was verified in the aborted fetus and placenta by virus isolation, immunoblotting, and hybridization methods (115). However, the detection of rubella virus in chorionic villus samples may not always predict fetal infection (87). PCR has been used successfully to detect rubella virus RNA in fetal and placental tissues, amniotic fluid, chorionic villus samples, and fetal blood (110,116-119). Positive results can be obtained within 24 to 48 hours with PCR, several days to a few weeks earlier than is possible with virus culture methods (87,88,118). In some infected fetuses, rubella virus RNA can be detected in fetal blood but not in concurrently-collected amniotic fluid samples (119). It is generally suggested that the interval between maternal rubella infection and sampling of fetal blood and amniotic fluid should be six to eight weeks to minimize the chance for a false-negative PCR assay result for rubella virus RNA (119).

The administration of immunoglobulin to susceptible pregnant women who are exposed to rubella does not prevent maternal or fetal infection. Its use is confined to women who would not contemplate pregnancy termination under any circumstances (89).

Pregnant women who do not have rubella antibody should be immunized in the immediate postpartum period. However, reports by a group of investigators from Canada have suggested that acute arthritis can occur in as many as 8% of women receiving the rubella RA 27/3 vaccine in the postpartum period, and that some subsequently develop chronic arthropathy, neurologic abnormalities such as the carpal tunnel syndrome or paresthesias, and chronic rubella viremia. These women tend to transmit rubella virus to some of their infants through breast-feeding, and a few infected infants go on to develop chronic rubella viremia (120,121). The same research group conducted a prospective, placebo-controlled, double-blind trial of postpartum rubella immunization (using the RA 27/3 vaccine) in 543 seronegative women and showed a higher incidence of acute joint problems, but only a marginally increased risk of chronic or recurrent arthralgias, in vaccine recipients (122). Data from the United States and elsewhere indicate that such complications are rare with the RA 27/3 live rubella vaccine (89,123,124). The mechanisms of rubella vaccine-induced joint disease are poorly understood, but they may include infection of the synovial membrane by vaccine virus or the deposition of rubella antigen-containing immune complexes in the synovium (125,126,127). Certain human leukocyte antigen class II (HLA-DR) phenotypes may be associated with an increased risk of postpartum arthropathy following rubella vaccination. The relative risk of arthropathy is eightfold higher for persons with both DR1 and DR4 and sevenfold higher for those with both DR4 and DR6 (128). It is advised that all susceptible pregnant women be vaccinated against rubella before hospital discharge (89). About 40% to 55% of CRS cases could be prevented with implementation of postpartum rubella immunization of susceptible women. Although rubella vaccine virus can be shed in breast milk,

breast-feeding is not a contraindication to maternal immunization (89,129).

The rubella vaccine should not be knowingly administered during pregnancy because of its small risk of teratogenicity. Data from the Centers for Disease Control and Prevention (CDC) for the period 1979 to 1988 indicate that none of 562 infants born to 683 women inadvertently immunized with the RA 27/3 vaccine within 3 months of conception in the United States had malformations compatible with CRS (130). Between January 1971 and April 1989, 321 known rubella-susceptible women who had been immunized against rubella within 3 months before or after their estimated date of conception with the RA 27/3 or earlier vaccines (Cendehill, HPV-77) were followed by the CDC; none of the 324 infants born to these women had defects consistent with the CRS (89). Combined data from the United States, United Kingdom, Sweden, and Germany on 680 live births to susceptible women who received one of the three rubella vaccines (RA 27/3, Cendehill, HPV-77) 3 months before or during pregnancy showed that none of the infants was born with CRS (131). The RA 27/3 rubella vaccine virus, however, does cross the placenta and produces a subclinical infection in about 3% of infants; the rate of fetal infection was considerably higher (20%) for the earlier rubella vaccines (130). Infection of the fetus by the RA 27/3 rubella vaccine strain can be persistent with virus shedding lasting for several months after birth, even in an otherwise normal infant (132). The possible risk of serious congenital defects after

P.1280

accidental rubella vaccination has been calculated by the CDC to be 0.5%; the observed risk has been zero (131). This risk is considerably lower than the 20% or greater risk of CRS after maternal gestational infection, and it is comparable to the 2% to 3% rate of major birth defects observed in the absence of rubella vaccine exposure (130). Because of the very low, if any, risk of CRS after inadvertent rubella vaccination in pregnancy, the Advisory Committee on Immunization Practices has shortened the interval to avoid pregnancy after receiving a rubella-containing vaccine from three months to 28 days (131).

Congenital Rubella

Epidemiology

The incidence of congenital rubella has shown a consistent decline since the introduction of rubella vaccination programs in the United States. For the period 1990 through 1999, the CDC received reports of 110 confirmed cases of CRS and 7 others that were probable CRS (62). Their mothers were young (median age, 23 years), white (82%), and of Hispanic ethnicity (50%). Hispanic mothers, most of whom were born outside the United States, accounted for 83% of infants with CRS born between 1997 and 1999. Most of the maternal exposures to rubella

virus occurred within the United States (62). An additional 13 cases of CRS were reported between 2000 and 2002, but there are no published details about them (19). Because of the passive nature of the CRS reporting system, it is estimated that the reported number of infants with CRS represents only 20% to 30% of actual cases (22).

CRS continues to be a problem in other parts of the world (68). In 1999, the World Health Organization reported that 52% of its member countries offered routine rubella vaccination programs (75). Nevertheless, rubella immunization programs have been successful in reducing the occurrence of CRS wherever implemented (133,134). As an example, the incidence of CRS declined from 3.5 per 100,000 live births in 1980 to 0.41 per 100,000 live births in 1986 in 19 European birth defects registries (133).

Clinical Manifestations

More than one-half of all newborns with congenital rubella are asymptomatic at birth, but most later manifest with one or more signs and symptoms of disease. The most common abnormalities encountered in CRS listed in order of decreasing frequency are sensorineural hearing loss, mental retardation, cardiac malformations, and ocular defects (8). Table 48-2 is a summary of the clinical abnormalities encountered in congenital rubella (37,38,41,42,77,105, 135-174).

If the findings of mental retardation and infection of neurosensory organs such as the eyes or ears are combined, then central nervous system (CNS) involvement occurs in more than 80% of CRS patients (77). Vascular abnormalities, prominent pathologic characteristic of congenital rubella, contribute to the neuropathology by causing ischemic necrosis of adjacent tissues. Microcephaly may be as a result of the generalized organ hypocellularity seen with rubella infection (38).

The development of late-onset CRS manifestations that were inapparent in early infancy may be related to persistence or reactivation of rubella virus infection, the body's immune responses to the infection, or vascular damage. Insulin-dependent diabetes mellitus occurs in about 20% of patients by 35 years of age (174). Rubella virus can infect human fetal pancreatic islet cells and can reduce secretion of insulin (175). About 20% of CRS patients and 50% to 80% of those with glucose intolerance have circulating pancreatic islet cell cytotoxic or surface antibodies (176). These autoantibodies are triggered by rubella virus and cause destruction of pancreatic cells, unmasking the person with a genetic susceptibility to diabetes mellitus (177,178). Thyroid abnormalities develop in about 5%; thyroid microsomal or thyroglobulin antibodies are found more frequently in deaf CRS patients than in those who are hearing impaired from other causes (42). In contrast, none of 25 young adults with CRS from Finland and Poland had detectable islet cell antibodies or insulin autoantibodies, and only 16% had antibodies to thyroid peroxidase (179). Rare cases of growth hormone deficiency

of hypothalamic origin have been described (180). About 10% of CRS patients incur additional forms of late-appearing ocular insults, such as glaucoma, keratoconus, corneal hydrops, and spontaneous lens absorption. Permanent damage to the vascular endothelium can induce the formation of obstructive lesions of major vessels such as the pulmonary and renal arteries. Choroidal neovascularization with significant visual loss can complicate CRS retinopathy. Autism and behavioral problems usually are delayed in appearance and can be progressive. Progressive rubella panencephalitis is a rare but ultimately fatal CNS manifestation of CRS that appears late, usually in the second decade of life (174).

Diagnosis

The CDC has established clinical and laboratory criteria for the classification of CRS cases to allow better CRS surveillance (Table 48-3) (181).

The diagnosis of CRS usually is suspected on the basis of the maternal history and the clinical findings. A definitive diagnosis can be achieved by isolating the virus from pharyngeal washings or, less commonly, from urine, cerebrospinal fluid (CSF), conjunctivae, blood, or available organs such as the lens at surgery or autopsy. Although nasopharyngeal shedding of rubella virus may continue for 6 to 12 months, the frequency of its isolation declines from about 85% during the first month of life to approximately 10% at 9 to 12 months of age (182). In children with congenital rubella encephalitis, the virus can be isolated from the CSF for months or even years (151). However, viral isolation seldom is used in clinical practice because of its difficulty, expense, and limited availability. Rubella virus RNA can be detected in clinical specimens using PCR, and the results become available sooner than with traditional culture methods; these assays are not widely available (75,82,86).

P.1281

P.1282

TABLE 48-2 CLINICAL ABNORMALITIES IN INFANTS WITH SYMPTOMATIC CONGENITAL RUBELLA

Clinical Abnormality	Remarks
General	
Intrauterine growth retardation	Common (50%-85%); usually have other manifestations of congenital infection; may be due to reduced number of body cells (38)
Postnatal growth retardation	Retarded growth is most severe in infants with multiple congenital defects; long-term follow-up studies indicate that most will have subnormal growth (136, 137)
Cardiovascular system	
Patent ductus arteriosus	Most frequently encountered structural defect (30%); may occur with other heart lesions, especially pulmonary valvular or artery stenosis (105)
Pulmonary artery stenosis	Second most common heart defect; results from intimal proliferation (138)
Miscellaneous defects	Individually uncommon; include coarctation of the aorta, atrial and ventricular septal defects, myocarditis, tetralogy of Fallot, ventricular aneurysm, and aneurysms of the arteries of the limbs and viscera (135, 138, 139)
Hearing loss	The most common congenital defect; almost always present in infants with other malformations; uncommon if maternal rubella occurs at ≥ 17 weeks of gestation; usually bilateral; may be present at birth or develop later; can be progressive (8, 140)
Ocular abnormalities	

Cataract	Found in about 35% of infants; can be unilateral or bilateral; noted at birth or early infancy; virus can be isolated from lens; spontaneous reabsorption of cataracts has been described in rare cases (141, 142, 143, 144)
Retinopathy	Common (35%-60%); may be present at birth or appear later in life; often unilateral; salt-and-pepper appearance; does not affect visual acuity (145, 146, 147, 148)
Cloudy cornea	Rare; usually present at birth; may coexist with glaucoma; resolves spontaneously; rarely persists (149)
Glaucoma	Occurs in $\leq 10\%$; may be bilateral; can be found at birth or appear later in life; leads to blindness if not treated (8, 135, 148)
Microphthalmia	Common in infants with cataract; concomitant glaucoma common (8, 148)
Miscellaneous abnormalities	Uncommon; includes iris hypoplasia, strabismus, and iridocyclitis
Interstitial pneumonia	Occurs in about 5%; probably immunologically mediated; may be acute, subacute, or chronic (41, 150)
Central nervous system	

Meningoencephalitis

Occurs in as many as 20%; manifests with bulging anterior fontanelle, hypotonia, irritability, and seizures; cerebrospinal fluid findings include elevated protein concentration, mononuclear pleocytosis, and rubella virus isolation in 30%; transient; most infants have neurodevelopmental deficits; progressive rubella panencephalitis is a delayed manifestation of chronic infection that begins 10 years after the primary infection and characterized by fibrinoid necrosis, severe neuronal loss and demyelination, and old microinfarcts (37, 77, 135, 151, 152)

Microcephaly

Uncommon in earlier reports, but more frequently described in recent case series; may be associated with normal intelligence (135)

Intracranial calcifications

May be present in early infancy (103, 153, 154)

Electroencephalographic abnormalities

Occurs in 36%; usually resolves by 1 year of age (77)

Mental retardation

Occurs in 10%-20%; associated with other stigmata of congenital rubella (135)

Speech defects

Uncommon in absence of hearing impairment

Behavioral disorders

Common; occurs primarily in deaf patients (151, 155)

Miscellaneous problems

Autism; central language disorders; spastic quadriplegia; hydrocephalus; cerebral arterial stenosis

Skin

Blueberry-muffin spots

Transient; infrequent (5%); represents dermal erythropoiesis (156)

Chronic rashes

Generalized; persists for weeks; appears in infancy; virus can be isolated from skin (157, 158)

Dermatoglyphic abnormalities

May serve as marker for viral teratogenicity (159)

Miscellaneous abnormalities

Skin dimples; seborrhea; cutis marmorata; patchy pigmentation; circumscribed scleroderma (158, 160)

Genitourinary system

Cryptorchidism; testicular agenesis; scrotal calcifications; polycystic kidneys; renal agenesis; renal artery stenosis with hypertension; hypospadias; hydroureter; hydronephrosis; ureteral duplication ([161](#), 162, 163, 164, 165)

Skeletal system

Metaphyseal radiolucencies

Occurs in 10%-20%; most common in distal femur and proximal tibia; usually normalizes by 3 months of age; due to a direct inhibitory effect of rubella virus on bone and cartilage cells (135,166, 167, 168, 169, 170)

Large anterior fontanelle

Found in the most severely affected infants (166)

Miscellaneous problems

Micrognathia; pathologic fractures; myositis

Gastrointestinal system

Hepatosplenomegaly

Common (>50%); transient

Hepatitis

Occurs in 5%-10%; may not be associated with jaundice

Obstructive jaundice

Infrequent (5%)

Miscellaneous problems	Esophageal, jejunal, or rectal atresia; pancreatitis; chronic diarrhea; intraabdominal calcifications (165)
Blood	
Thrombocytopenic purpura	Occurs in 5%-10%; associated with severe disease; transient (166, 171)
Anemia	Transient (171)
Miscellaneous abnormalities	Hemolytic anemia; altered blood group expression (172)
Immune system	
Hypo- or dysgammaglobulinemia	Rare; transient (160, 173)
Thymic hypoplasia	Rare; fatal
Endocrine glands	Diabetes mellitus; hypothyroidism; hyperthyroidism; thyroiditis; growth hormone deficiency; precocious puberty (8, 42, 174)

TABLE 48-3 OUTLINE OF THE CENTERS FOR DISEASE CONTROL AND PREVENTION CRITERIA FOR THE CLASSIFICATION OF CONGENITAL RUBELLA SYNDROME CASES

I. Congenital rubella syndrome confirmed

Defects present and at least one of the following:

Isolation of rubella virus

Detection of rubella-specific IgM antibodies

Persistence of rubella-specific HI titer beyond the period expected from that of passively transferred maternal antibodies

II. Congenital rubella syndrome compatible

Incomplete laboratory data for confirmation of diagnosis and any two complications from A or one from A and one from B:

A. Cataracts or congenital glaucoma, congenital heart disease, hearing loss, pigmentary retinopathy

B. Purpura, splenomegaly, jaundice, bone radiolucencies, meningoencephalitis, microcephaly, mental retardation

III. Congenital rubella syndrome possible

Some compatible clinical findings but insufficient criteria for the confirmed or compatible categories

IV. Congenital rubella infection only

No defects, but laboratory evidence of infection is found

V. Stillbirths

Stillbirths believed to be a consequence of maternal rubella infection

VI. **Congenital rubella syndrome excluded**

At least one of the following inconsistent laboratory findings in a child without evidence of an immunodeficiency disease:

Absence of rubella-specific HI titer in a child ≤ 24 months of age

Absence of rubella-specific HI titer in the mother

Decrease of rubella-specific HI titer in an infant in a manner consistent with that expected from passively transferred maternal antibodies (i.e., a twofold dilution drop per month)

HI, hemagglutination inhibition.

Adapted from Centers for Disease Control and Prevention. Rubella and congenital rubella syndrome—New York City. *MMWR* 1986;35:770, with permission.

Rubella-specific IgM usually is present in congenitally infected infants and may persist for 6 to 12 months. It can be used to make a definitive diagnosis of congenital rubella infection; false-positive results may be encountered in sera containing rheumatoid factor. Delays in obtaining serum for IgM measurements can introduce interpretation difficulties because of the possibility that the infant may have acquired rubella infection postnatally. About 20% of infected infants may test negative for rubella-specific IgM at birth but develop detectable titers by a month of age (75,82). Thus, infants suspected of having CRS who test negative for rubella-specific IgM at birth should be re-tested at one month of age. Persistence of rubella-specific IgG antibodies at 6 to 12 months of age, especially in high titers, provides presumptive evidence of congenital or early postnatal infection.

Other techniques for establishing the diagnosis of congenital rubella include negative virus-specific lymphocyte transformation responses in seropositive children younger than 3 years of age, detection of rubella-specific IgM in CSF or saliva, demonstration of low-avidity rubella-specific IgG in seropositive infants, or immunoblotting (58,59,183,184,185 and 186).

Treatment

There is no specific therapy for CRS. A few patients have been treated with amantadine or interferon- α with minimal or no clinical improvement (43,187,188 and 189). Intravenous immunoglobulins can be used in infants with hypogammaglobulinemia (160,173). Susceptible pregnant women should avoid contact with CRS patients during their first year of life. The appearance of delayed manifestations of CRS that were not present early in life underscores the importance of close follow-up. CRS patients often require surgical correction of heart or genitourinary defects, removal of dense cataracts, hearing aids, and

special schooling. The visual outcome after cataract surgery for infants or children with CRS is generally poor because of the myriad associated

P.1283

ocular abnormalities such as glaucoma, amblyopia, or optic atrophy. In one study, visual acuity after cataract surgery was less than 3/60 in 55% of children with CRS, and 6/24 or better in only 15% (190).

Herpes Simplex Virus Infections

Infections caused by herpes simplex virus (HSV) are common in the United States. Conservative estimates had placed the number of people each year that have their first episode of genital herpes at about 500,000, but recent studies suggest that the actual number is closer to 750,000 to 1,600,000 (191,192,193). At least 50 million people are living with genital herpes in the United States (194). About 2% of women seroconvert to HSV-2 during pregnancy (195). Neonatal HSV infection occurs in at least 1,500 newborns each year, but other estimates place the minimum number at 2,500 (18,196). It is also estimated that 720,000 cesarean sections are performed annually for the purpose of preventing neonatal herpetic infection (197). The optimal management of women with active or suspected genital HSV infections during pregnancy or at labor continues to generate controversy.

HSV is an enveloped double-stranded deoxyribonucleic acid (DNA) virus that can infect a broad range of hosts. The virus enters the body through mucosal surfaces or abraded skin, and it multiplies in cells of the epidermis or dermis. A number of cellular receptors for HSV have been identified, the most important of which appears to be herpesvirus entry mediator C. Sensory or autonomic nerve endings in the vicinity become infected, and the virus travels intraaxonally in a retrograde fashion to the ganglia. HSV then can continue its multiplication in the ganglia and later spread to other skin and mucous membrane areas through anterograde travel along peripheral sensory nerves, or it can enter a phase of latency in the ganglia. In latently infected ganglia, viral DNA persists as an episome (198). The virus intermittently reactivates and travels to the body surface, in which it can produce clinical disease. Exposure to ultraviolet light, trauma to skin, or immunosuppression can provoke HSV reactivation. Antibody- and cell-mediated immune reactions are generated in response to HSV, both of which are important for control of the infection (191).

The various HSV strains found in the general population can be grouped into two serologic subtypes, HSV-1 and HSV-2. The two subtypes have a high degree of homology but can be differentiated on the basis of their cell culture range, restriction endonuclease analysis, monoclonal antibody-based serologic assays, or polymerase chain reaction (PCR) (198,199).

At least 11 HSV surface glycoproteins (g) have been described (gB, gC, gD, gE, gG, gH, gI, gJ, gK, gL, gM). They mediate attachment and penetration of HSV into cells, play a role in its pathogenesis and spread, and generate host immune responses to the virus (191). Antibodies to the two HSV subtypes cross-react extensively, but two of the glycoproteins (gG and gC) have type-specific antigens and have been found to be helpful in differentiating HSV-1 from HSV-2 antibody responses (200).

Maternal Infection

Epidemiology

Serologic surveys conducted in the United States reveal that the prevalence of antibodies to HSV increases with age, and that it is higher in persons from lower socioeconomic strata and in groups with greater levels of sexual activity. Antibodies to HSV-1 may be present in 90% or more of adults from lower socioeconomic groups but in only about 30% of college students. Antibodies to HSV-2 are present in approximately 21.9% of the United States population 12 years of age or older, and in 27.2% of persons 30 to 49 years of age. African Americans are more likely to have antibodies against HSV-2 than Caucasians or Mexican-Americans (45.9%, 17.6%, and 22.3%, respectively). Among African Americans, women are more likely than men to be seropositive for this virus (55.1% vs. 34.7%, respectively). However, only 2.6% of adults report ever having genital herpes. The seroprevalence of HSV-2 has increased by about 30% during the period from 1988 to 1994 as compared with the years 1976 to 1980 (201). HSV-2 seropositivity is significantly correlated with being female, African American or Hispanic, having a low educational level, income below the poverty line, having ever used cocaine, and the number of lifetime sexual partners (201,202). A 2002 survey of 36 randomly chosen, relatively affluent primary care physician offices surrounding six major United States cities revealed an HSV-2 seroprevalence of 25%; only 12% of seropositive individuals reported a history of genital herpes (203).

Two percent or more of susceptible pregnant women become seropositive for HSV during pregnancy, but only one-third of them will have symptoms consistent with a herpes infection. The risk of transmission from an HSV-seropositive male to a seronegative female is approximately 20% annually. Seroconversion that was completed

by the time of onset of labor was not associated with increased neonatal morbidity or cases of congenital herpes infection in one study; however, infants born to mothers who acquired HSV infection shortly before delivery had an almost 50% chance of developing neonatal herpes (195). A study of 35,940 pregnant women in Norway found no association between HSV-2 infection during pregnancy and fetal death (204).

By measuring type-specific antibodies against HSV-2 gG in a group of 190 pregnant women and their husbands, Kulhanjian and colleagues found that 73% of the couples were concordant with respect to their HSV-2 serologies (i.e., both partners were seronegative or seropositive). However, about 9.5% of the pregnant women were seronegative but had seropositive spouses, and therefore they were at risk of gestational primary HSV-2 infection; 56% of these husbands had no history of previous genital

P.1284

HSV infection. Approximately 5% of pregnant women in this particular study were susceptible to HSV-2 infection but were unaware of their risk of acquiring the virus from their seropositive spouses, who gave no history of prior genital herpes (205).

Asymptomatic shedding of HSV occurs in 0.2% to 7.4% of pregnant women and in 0.2% to 4% of those at or near term. Most HSV infections during pregnancy represent recurrent disease. The frequency of asymptomatic shedding increases as pregnancy advances (10).

Clinical Manifestations

Many primary HSV infections are subclinical. Symptomatic primary HSV disease can include gingivostomatitis, genital herpes, herpetic whitlow, keratitis, chorioretinitis, encephalitis, esophagitis, pneumonia, and hepatitis (10,206).

The most common manifestations of primary HSV-1 infections are gingivostomatitis and pharyngitis, but these occur rarely during pregnancy (207,208,209). HSV-1 causes from 10% to over 50% of primary genital herpes infections in various populations (192,210). Recurrent episodes of herpes labialis are common, and HSV-1 may be recovered from the pharynx of 1% to 5% of asymptomatic healthy persons (191). One study suggested that the incidence of herpes labialis recurrences was lower during early pregnancy, but that women who did have clinical reactivation had them at higher frequencies than before they became pregnant (211).

The most common clinical illness caused by HSV-2 is genital herpes. Sixty-five percent to 90% of initial HSV-2 infections are subclinical or mild (192). Symptomatic patients can have extensive, painful, vesicular or ulcerative genital lesions with or without associated systemic manifestations (191). Over 75% of patients with symptomatic primary HSV-2 infection will have lesions of the skin and mucous membranes of the genital tract, but another 13% present with cystitis, meningitis, urethritis, or cervicitis (192). Serious complications of HSV infections include pneumonia, hepatitis, disseminated intravascular coagulation, shock, acute retinal necrosis, and encephalitis (191, 212-217). Recent data show that some individuals with no prior history of orolabial or genital herpes and who are seronegative for both HSV-1 and HSV-2 can have T cell responses to HSV suggesting that they may have either undetected infection or acquired immunity to the virus without actual infection (218).

Women with recurrent disease typically have mild or subclinical infections. The likelihood of reactivation of HSV infection is greater for genital than oral-labial disease and for HSV-2 than for HSV-1 (219,220). One-fifth of all patients with primary genital herpes subsequently will have nongenital recurrences; this is most likely to occur on the hands and face for HSV-1 and on the buttocks and legs for HSV-2. Buttock recurrences occur less frequently but last longer than genital lesions (221). Asymptomatic HSV-2 shedding occurs more often during the first 3 months after the primary genital HSV-2 infection than during subsequent periods (220). The overall rate for of cervical or external genital shedding during the first year after primary infection is 1.2% of days for HSV-1 and 4.3% of days for HSV-2 (210). For patients with a documented first episode of genital HSV-2 infection, 90% will have at least one recurrence within a year of diagnosis, 38% will have at least six recurrences, and 20% will have 10 or more recurrences (222). Among women with recurrent genital herpes, 55% of those with HSV-2 and 29% of those with HSV-1 had recurrences during a median follow-up of 105 days in one study (223). HSV-2 shedding (detected by culture) occurred on 2% of all days and usually lasted for 36 hours per recurrence; however, 5.5% of women shed HSV-2 for 4 days or longer. Subclinical shedding is more common in women with frequent symptomatic recurrences (223). When 42 women with no past history of genital herpes, but who were seropositive for HSV-2, were prospectively evaluated with daily swab specimens from their cervicovaginal, vulvar, and perianal areas for about three months, 69% were found to have subclinical shedding of the virus by culture methods at some point; the rate was 80% when a PCR assay was added. Viral shedding was documented on 3% of all days without lesions. For 46 women in the same study who

did have a history of genital herpes, the frequency of viral shedding during the follow-up period (symptomatic and asymptomatic) was 91% and they shed the virus on 3.6% of all days with no apparent lesions (224).

Genital herpes infections are categorized according to HSV subtype, serologic evidence of past HSV-1 or HSV-2 infection, and the presence or absence of symptoms. This classification scheme is useful when examining the impact of gestational HSV infection on pregnancy outcome according to the type of maternal genital infection. First episode, primary HSV-1 or HSV-2 infection is considered present if the virus is isolated from the genital tract of a symptomatic or asymptomatic woman who has no serologic evidence of prior infection with HSV-1 or HSV-2 in the acute phase serum, but she subsequently has antibodies to the same HSV subtype when convalescent serum is tested. If the acute-phase serum contains antibodies to the other HSV subtype (e.g., HSV-1 antibodies in a woman with an HSV-2 genital isolate), first episode, nonprimary genital infection is considered present. Recurrent HSV-1 or HSV-2 infection is diagnosed if the patient has antibodies to the same HSV subtype isolated from the genital tract in the acute- and convalescent-phase sera (225). The value of this classification scheme is apparent from a study by Hensleigh and colleagues who evaluated 23 women whose clinical illnesses were consistent with the diagnosis of primary genital herpes. The diagnosis was verified serologically in only one woman with primary HSV-1 infection, whereas three others had nonprimary HSV-2 infection; the remaining 19 women proved to have recurrent disease (226). Wald and her co-investigators found that 62% of HSV-2 seropositive persons with no past history of genital herpes subsequently identified typical herpetic lesions once educated about the infection and its clinical manifestations (224).

P.1285

Diagnosis

The diagnosis can be made by isolating the virus from tissue cultures of ocular, mucocutaneous, or genital lesions. The best specimen is usually vesicle fluid obtained within 3 days of its appearance. Positive culture results may be obtained within 16 hours to 7 days, depending on the viral load in the clinical specimen. Shell vial cultures may become positive within 16 to 48 hours (227). The enzyme-linked virus-inducible systems (ELVIS tests) have sensitivities comparable to those of standard and shell vial cultures. They are done using genetically-altered cell lines that have a reporter gene β -galactosidase that is driven by the promoter from a specific HSV gene. Once infected by HSV, the cell lines express the reporter gene resulting in a color change (199).

Direct or indirect fluorescent antibody staining, with or without cytopinning, can detect HSV antigens in exfoliated cells within less than two hours. The sensitivity of the direct fluorescent antibody (DFA) stain is higher for specimens from vesicular lesions as compared to healing lesions (199). The Tzanck smear is a rapid and inexpensive method, but it is only 60% sensitive for HSV infections. It involves scraping the base of a fresh vesicle with a scalpel and spreading the cells and debris on a glass slide. The adherent cells are stained with Giemsa, Sedi, or Wright stain. The slide is examined for the presence of virus-induced cytopathic abnormalities, such as multinucleated giant cells, atypical keratinocytes with large nuclei, and ground-glass cytoplasm. A positive Tzanck smear cannot differentiate between VZV and HSV lesions (228).

Serologic methods can be used for the diagnosis of acute HSV infections. Earlier assays did not accurately distinguish HSV-1 from HSV-2 antibodies. Beginning in 1999, type-specific ELISA and immunoblot antibody assays based on gG became available in the United States. The ELISA assay has a sensitivity of 91% to 96% and a specificity of 92% to 95% for HSV-1. For HSV-2, the ELISA assay has a sensitivity of 80% to 98% and a specificity of 96% or higher. The immunoblot assays have higher sensitivities and specificities for HSV-1 and HSV-2 antibodies when compared to ELISA tests. False-negative results can be encountered if testing is done early in the course of an infection. Demonstrating seroconversion is diagnostic of an acute HSV infection. These tests are also useful in distinguishing primary from recurrent infection in pregnant women with their first clinical episodes of genital herpes (194, 199,200). IgM tests based on gG are not commercially available. Western blot assays for HSV antibodies are helpful in patients in which the antibody profiles are not clear for either HSV-1 or HSV-2, but these tests are time-consuming, expensive, and not readily available (199,200).

Molecular biological techniques have been applied for the diagnosis of HSV infection through the detection of viral DNA in clinical specimens (199,228-233). The PCR continues to detect HSV DNA in clinical specimens for several days after the culture becomes negative. The test is relatively rapid and can be completed within a few hours. The yield of PCR in detecting asymptomatic genital shedding is greater when specimens are collected using cervicovaginal lavage instead of a swab (234). The clinical relevance in obstetrical practice of culture-negative, PCR-positive results from genital specimens remains to be elucidated. PCR detection of HSV DNA in CSF specimens helps in the diagnosis of herpes encephalitis (235). Because the PCR technique is sensitive to

even minuscule amounts of HSV, contamination from external sources, such as laboratory personnel, physicians, or nurses who may be shedding the virus, can yield false-positive results. The possibility of laboratory contamination is decreased with the use of real-time PCR detection systems (199). Extreme care should be taken while handling the CSF specimen to avoid making an erroneous diagnosis of herpes encephalitis and possibly missing the true culprit (236). False-negative PCR results can occur as a result of problems with the reaction, the presence of inhibitors in the clinical specimens, or because of timing issues such as obtaining the samples too early or too late during the course of the infection (199).

Treatment

Three oral drugs are currently available for the treatment of primary and symptomatic recurrent genital HSV infection: acyclovir, valacyclovir, and famciclovir. The experience with acyclovir is the most extensive, particularly regarding its use in pregnant women.

Acyclovir inhibits the replication of HSV-1, HSV-2, and VZV. Acyclovir is converted in the body to its active triphosphate form, initially through the action of viral thymidine kinase to the monophosphate form and later by cellular enzymes to the diphosphate and triphosphate forms. Acyclovir triphosphate concentrations are 40 to 100 times higher in HSV-infected cells than in uninfected cells. The active form of the drug competes with deoxyguanosine triphosphate as a substrate for viral DNA polymerase and, once incorporated into viral DNA, leads to termination of HSV DNA synthesis (237).

The use of acyclovir during pregnancy is not approved by the Food and Drug Administration and generally is reserved for life-threatening or severe HSV infections such as pneumonia. However, it can be given orally to pregnant women with first episode genital herpes or severe recurrent herpes (194). Maternal antiviral therapy may fail to prevent fetal infection with HSV (238). Acyclovir is teratogenic in rats (239). It crosses the placenta, concentrates in amniotic fluid, and can accumulate in human breast milk (240,241).

A registry of acyclovir use in pregnancy was established on June 1, 1984. As of June 30, 1993, 601 acyclovir-exposed pregnancies from 18 countries had been reported and followed. Of 425 exposures that took place during the first trimester, outcomes included 47 spontaneous fetal losses, 67 legal induced abortions, 298 live births without congenital malformations, and 13 with congenital anomalies. Among 176 second- and third-trimester exposures, three infants were born with anomalies. The reported birth defects were heterogeneous and without a specific pattern.

P.1286

These findings were not different from what was expected for the general population of pregnant women. The size of the cohort in the registry was adequate to detect a teratogenic risk that is twofold higher than expected, but was not large enough to detect smaller increases in risk of birth defects should they exist (242). Similarly, a case-control study performed in Denmark found no association between the use of either systemic or topical acyclovir during pregnancy and adverse outcomes such as congenital malformations, low birth weight, preterm birth, stillbirth, or spontaneous abortion (243).

TABLE 48-4 RECOMMENDED ORAL TREATMENT REGIMENS FOR ADULTS WITH GENITAL HERPES

	Acyclovir	Valacyclovir	Famciclovir
First clinical episode ^a	400 mg three times daily for 7–10 d OR 200 mg orally five times daily for 7–10 d	1 g orally twice a day for 7–10 d	250 mg orally three times a day for 7–10 d
Recurrent infection (HIV-negative)	200 mg orally five times a day for 5 d OR 800 mg orally twice a day for 5 d	1 g orally once a day for 5 d OR 500 mg orally twice a day for 3–5 d	125 mg orally twice a day for 5 d
Recurrent infection (HIV-positive)	200 mg orally five times a day for 5–10 d OR 400 mg orally three times a day for 5–10 d	1 g orally twice a day for 5–10 d	500 mg orally twice a day for 5–10 d

Suppressive therapy (HIV- negative)	400 mg orally twice a day	500 mg orally once a day ^b OR 1 g orally once a day	250 mg orally twice a day
Suppressive therapy (HIV- positive)	400–800 mg orally twice or three times a day	500 mg orally twice a day	500 mg orally twice a day

Abbreviations: d, day; HIV, human immunodeficiency virus.

^a Treatment can be extended if there is incomplete healing by the tenth day of therapy.

^b This regimen may be less effective than others for women with 10 or more recurrences per year.

Adapted from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines 2002. *MMWR* 2002;51(RR-6):1, with permission.

Acyclovir-resistant HSV strains are uncommon, except in patients with AIDS. The prevailing mechanism of resistance appears to be a mutation that renders the virus deficient in thymidine kinase (237). Infections caused by these acyclovir-resistant HSV strains can be treated with foscarnet, cidofovir, or vidarabine; none is approved by the Food and Drug Administration for use during pregnancy (198,244,245). Foscarnet is an organic analogue of inorganic pyrophosphate and does not require activation by kinases, including thymidine kinase. It has to be administered intravenously and the drug is associated with serious adverse effects such as nephrotoxicity, anemia, and seizures. Foscarnet-resistant HSV strains have been reported (198). Cidofovir is a nucleotide analogue whose main use has been in the treatment of cytomegalovirus retinitis. This drug is active against HSV, including thymidine-kinase deficient strains, but is also nephrotoxic.

Valacyclovir and famciclovir are active against HSV and have been approved for the management of genital herpes in nonpregnant adults. Valacyclovir is the L-valyl ester of acyclovir; it is rapidly absorbed and hydrolyzed in the body to acyclovir and results in much greater bioavailability of the active drug (198,246,247). Famciclovir is a guanosine analogue of the antiviral drug penciclovir (248). Penciclovir, like acyclovir, is phosphorylated to its active metabolite penciclovir triphosphate (198). Acyclovir-resistant HSV mutants usually are resistant to these two drugs as well, although penciclovir may be active against some of these strains (244). Both drugs are classified by the Food and Drug Administration as being in pregnancy category B.

The recommended dosage regimens for the management of genital herpes are summarized in Table 48-4. For severe genital herpes or its extragenital complications (e.g., pneumonia, encephalitis), intravenous acyclovir at a dose of 5 to 10 mg/kg of body weight should be infused every eight hours for 2 to 7 days or until clinical improvement is evident, followed by oral therapy for a total of at least 10 days of antiviral chemotherapy (194). About 70% to 80% of patients with recurrent genital herpes using acyclovir, valacyclovir, or famciclovir for suppressive therapy are recurrence-free after four months. There is also an 80% to 90% reduction in the number of days with subclinical HSV shedding (222). A recent study using different dosage regimens of famciclovir found that the drug reduced both symptomatic and asymptomatic anogenital HSV shedding, and it also delayed the onset of asymptomatic viral shedding in women with frequently recurring genital herpes (249).

Fetal and Neonatal Infection

Epidemiology

Most neonatal HSV infections are acquired during passage through an infected birth canal. Transplacental spread occurs occasionally, with major deleterious fetal effects. About 40% of newborns with herpes are delivered before week 36 of pregnancy (10).

P.1287

Intrapartum transmission is more likely to occur with primary maternal HSV genital infection. Other risk factors for HSV acquisition by the infant are cervical HSV infection, multiple genital lesions, prematurity, prolonged rupture of maternal membranes, intrauterine instrumentation (e.g., scalp electrodes), and absent or low titers of transplacentally acquired neutralizing HSV antibodies. The risk of vertical transmission is about 33% to 50% for mothers with late term primary herpes and about 1% to 3% for those with recurrent infections (10,18). Postpartum HSV spread to newborns occurs infrequently (191).

The perception at medical centers caring for infants with neonatal HSV infection is that the incidence of the disease is increasing. Data from Seattle had shown a 10-fold increase in the incidence of neonatal HSV infection between 1966 and 1982 (18). However, data for the State of California showed no change in the number of

infants (1 to 42 days of age) per 100,000 live births that were discharged from the hospital with a diagnosis of neonatal HSV infection between 1985 and 1995 (250).

Clinical Manifestations

Asymptomatic HSV infections are rare in the newborn. Disease manifestations may be localized or widely disseminated. About 70% to 85% of infants with HSV infections are born to women who are asymptomatic at the time of delivery and who have no history of genital herpes (18). Infants born to asymptomatic women shedding HSV in early labor are ten times more likely to develop neonatal HSV infection if the mother had recently experienced a first episode genital herpes than neonates born to women whose HSV shedding is secondary to reactivated infection (251).

Intrauterine HSV infection is uncommon and accounts for about 5% of all neonatal herpes cases (252,253,254). Its hallmarks are a vesicular rash that is present at birth or appears shortly thereafter. Associated abnormalities include microcephaly (60%), chorioretinitis (40%-50%), and microphthalmia (25%). The rash is more likely to be generalized than localized. Other skin lesions include bullae and cutaneous scars in 10% to 15% of patients. The intracranial calcifications seen in 15% may be present at birth or evolve later in infancy. Lesions indicative of brain damage, such as hydranencephaly, cerebral necrosis, and brain atrophy, can be seen on computed tomographic (CT) scans or magnetic resonance imaging (MRI) of the head. Other findings can include radiographic bone lucencies, intrauterine growth retardation, limb hypoplasia, aplasia cutis, cutaneous pigmentary abnormalities, skin ulceration, hepatosplenomegaly, optic atrophy, retinal dysplasia, persistent intraocular fetal vasculature, cloudy corneas, and cataracts. About 30% have seizures during the neonatal period. The mortality rate is 40%, and about one-half of the survivors have significant long-term residual problems, such as psychomotor retardation, seizure disorders, spasticity, blindness, or deafness (253,254,255,256,257,258,259). Most cases are caused by HSV-2.

The National Institute of Allergy and Infectious Diseases Collaborative Antiviral Study Group (NIAID CASG) reported their experience with 186 acyclovir-treated newborns with HSV infection enrolled between 1981 and 1997. Neonates with HSV were often born at or before 37 weeks of gestation (35%) and had fetal scalp electrodes placed (40%). Their mothers tended to be young (mean age, 22 years) and to have one or no previous children (65%). Their mean birth weight was 2.95 kg, 69% were white, and 52% were boys (260).

About 10% of infants with neonatal HSV infection became sick within the first day of life, and about 30% are ill by the fifth day of life. Because of the nonspecific nature of the initial symptoms, the average time from disease onset to diagnosis is 5 to 7 days. Despite heightened awareness and physician concerns about neonatal herpes infections, the interval from onset of disease symptoms to initiation of antiviral therapy did not become shorter between 1981 and 1997 (260). Thus, a high index of suspicion is needed so that HSV-infected infants can be identified and treated earlier to reduce the risk of progression to more serious disease manifestations. The signs and symptoms of 186 neonates with HSV infection at diagnosis and initiation of therapy are depicted in Fig. 48-1.

Infections resulting from the intrapartum acquisition of HSV may not manifest until about 10 to 12 days of age, with disease localized to the skin, eyes, or mouth (10,260). Cutaneous lesions include discrete vesicles, grouped vesicles, large bullae, or denuded skin (Fig. 48-2). New vesicles typically continue to appear early into therapy. Ulcerative mouth lesions without skin disease may sometimes occur. Eye disease includes keratoconjunctivitis and chorioretinitis. Recurrent mucocutaneous herpes develops in some of these infants. Neurologic abnormalities eventually develop in 25% of infants with recurrent mucocutaneous herpes, even though CNS involvement may not have been evident during the acute illness.

A second group of infants presents at 15 to 19 days of age with localized CNS involvement, with or without skin, mouth, or ocular lesions. Fever may be seen in 44% of infants and, on occasion, it is the sole presenting sign (260,261). Hypothermia in a neonate with irritability, hypotonia, lethargy, apnea, or other neurologic signs and symptoms should raise concerns about HSV CNS disease (262). Skin lesions may be absent in a third of these neonates. The mortality rate is 15% for newborns with HSV-2 CNS disease, and almost none for those with HSV-1 infection. Prematurity and seizures at initiation of therapy are potential risk factors for death. Only 30% of survivors have normal development at one year of age, and this is somewhat worse for infants with HSV-2 infection (260).

A third group presents at 9 to 11 days of age with disseminated disease. CNS involvement is found in about two-thirds of these infants. Other organs that are severely affected are the adrenal glands, gastrointestinal tract, liver, heart, pancreas, and kidneys. Without appropriate therapy, about 80% die. With acyclovir therapy, the mortality rate is about 55%, and about 25% of survivors have severe neurologic impairments (260).

Figure 48-1 Signs and symptoms of neonatal herpes simplex virus infection at diagnosis and initiation of therapy. Abbreviations: SEM, skin, eyes, or mouth; CNS, central nervous system; DIC, disseminated intravascular coagulopathy. Adapted from Kimberlin DW, Lin C-Y, Jacobs RF, et al. Natural history of neonatal herpes simplex virus infections in the acyclovir era. *Pediatrics* 2001;108:223, with permission.

P.1288

In an earlier trial comparing vidarabine with acyclovir, the NIAID CASG studied 202 infants younger than 1 month of age with HSV infection (263,264,265). About 4% of infants had congenital HSV infection, and 40% had disease confined to the skin, eyes, or mouth. CNS disease occurred in 34%, and 22% had disseminated infections. Two-thirds of the isolates were HSV-2. In contrast, HSV-1 is the predominant isolate in countries such as the Netherlands where this viral type accounts for 73% of all cases of neonatal herpes (266).

The clinical manifestations of herpes encephalitis in the newborn includes focal or generalized seizures, lethargy, hypothermia, apnea, opsoclonus, and pyramidal tract signs (262,267,268). Eventual loss of gag and suck reflexes is common. Skin vesicles may be absent in about 30% to 40% of infants. CSF analysis reveals mononuclear pleocytosis, elevated protein concentrations (as high as 1,000 mg/dL), and either normal or slightly decreased glucose levels (267). Rarely, the CSF may show a predominance of neutrophils or be completely normal (269). Focal or generalized electroencephalographic abnormalities are common (260,267,270). About 8% of surviving infants have CNS relapse within 1 month of completing therapy (263). As many as 40% of infants will have a local skin or CNS relapse within two months of stopping therapy, and this risk is higher for newborns with HSV-2 infection (271).

Figure 48-2 Localized cutaneous herpes simplex virus type 2 infection in a neonate. Notice the coalescing vesicular lesions on the back and right arm. The vesicles are surrounded by an erythematous border.

Ocular herpetic infection may be an isolated problem, but it is more likely to occur in infants with CNS disease. Eye abnormalities include keratitis, conjunctivitis, chorioretinitis, necrotizing retinitis, optic atrophy, and cataracts. Long-term follow-up studies of survivors of neonatal HSV infection indicate that 40% (94% in patients with neurologic impairment; 20% in patients who are neurologically normal) have persistent abnormalities, such as cataracts, corneal scars, optic atrophy, and chorioretinal scars. About 44% have disturbed oculomotor control (272,273).

HSV pneumonia usually presents between days 3 and 14 of life with gradually worsening respiratory distress (274,275,276,277). Chest roentgenograms reveal perihilar infiltrates that gradually progress into severe diffuse interstitial and alveolar disease (i.e., "white-out" lungs) (278). Other findings include thrombocytopenia, neutropenia, jaundice, and hyperammonemia (279). The mortality rate of neonatal HSV pneumonia is about 80%, and almost 100% if infants have disseminated intravascular coagulopathy (264).

P.1289

Diagnosis

Neonatal HSV infections are best diagnosed by isolating the virus from a vesicular lesion. The virus can be recovered from 25% to 40% of CSF specimens obtained from infants with CNS disease. Cultures of urine, feces, blood, nasopharyngeal secretions, and conjunctivae may yield the virus in some patients. Collection of duodenal aspirates may help in the diagnosis of HSV-related hepatitis and necrotizing colitis. Serology is not useful in neonatal HSV infections because of the presence of transplacentally-acquired maternal HSV IgG antibodies. DFA staining of scrapings from the base of fresh vesicles may reveal HSV antigens (254,280,281).

PCR assays for the detection of HSV DNA are valuable diagnostic tools and have become the gold standard for the diagnosis of HSV encephalitis, despite interlaboratory variabilities in assay performance (265,282). In the NIAID CASG trials, HSV DNA was detected in the CSF of 26 (76%) of 34 infants with CNS disease, in 13 (93%) of 14 infants with disseminated infection, and in 7 (24%) of 29 infants with disease seemingly limited to the skin, eyes, or mouth. One of seven PCR-positive patients with disease limited to the skin, eyes, or mouth later developed severe neurologic impairment (283). PCR assays can detect HSV in serum in as many as two thirds of infected patients, including some whose CSF PCR is negative (284). PCR assays on serum and CSF may remain positive for 1 to 2 weeks after starting antiviral therapy (285).

Viral load measurements using a real-time PCR assay has been described for infants with HSV infection. Neonates with disseminated disease had the highest viral loads in their sera and lower levels in their CSF. Newborns with CNS disease had higher viral loads in the CSF than in the serum. Infants who die from their infection have significantly higher viral loads in serum and CSF than those who survive. In one study, CSF viral load did not differ significantly in surviving infants with or without long-term neurologic impairment (286).

Treatment

Antiviral therapy with acyclovir or vidarabine is the mainstay of treatment. In earlier NIAID CASG reports, infants treated with acyclovir (30 mg/kg per day for 10 days) or vidarabine had comparable morbidity and mortality rates (263). No deaths occurred among 85 infants with localized skin, eyes, or mouth disease; about 94% seemed developmentally normal after 1 year. The mortality rates for the encephalitis and the disseminated HSV groups were 14% and 54%, respectively, and 40% to 70% of the survivors were neurologically impaired. Factors influencing mortality included level of consciousness at the start of treatment, prematurity, disease classification, pneumonia, and disseminated intravascular coagulopathy (264). Cutaneous HSV recurrences occurred in 46% of survivors by 6 months after the end of therapy, and the rates were similar for infants treated with acyclovir or vidarabine. Seventy-five percent of survivors with disease caused by HSV-2 were impaired compared with 27% of infants with HSV-1 infection. This is explained partially by the greater *in vitro* susceptibility of HSV-1 to acyclovir (237).

Because of the considerable mortality and long-term neurologic morbidity associated with disseminated or localized CNS HSV disease despite acyclovir therapy, the NIAID CASG studied the impact of higher acyclovir doses on the outcome of these infections. Seventy-two neonates studied between 1990 and 1997 received 60 mg/kg per day of acyclovir for 21 days; 50% had disseminated disease and 35% had localized CNS infections. Acyclovir-induced neutropenia developed in 20% of infants.

The 24-month mortality rate for disseminated disease was 31%, and this beneficial effect was most pronounced for newborns with aspartate aminotransferase (AST) elevations 10 or more times the upper limit of normal. At

one year of follow-up, 83% of survivors were developing normally (287).

The 24-month mortality rate for CNS disease was 6%, but this was not statistically different than the outcome of infants who had received the lower acyclovir dose (30 mg/kg per day for 10 days only). Only 30% of infants were developing normally at one year of age, and this was also not statistically different for the infants receiving the higher or lower acyclovir dosage regimens. However, when adjustments were made for the virus type, prematurity, and seizures, there appeared to be 6.6-fold increased likelihood of normal development at one year in infants receiving the higher acyclovir dose (287). HSV has been shown to cause direct injury to neurons leading to apoptotic neuronal death, which may partially explain the frequent development of long-term neurologic dysfunction (288).

Infants receiving acyclovir shed lower virus titers than those on vidarabine. Given its ease of administration compared with vidarabine, its fairly benign toxicity profile, and its efficacy against HSV, intravenous acyclovir (60 mg/kg per day divided in three daily doses) has become the standard regimen for suspected or proven neonatal HSV infections. The duration of therapy is 14 days if the disease is limited to skin, eye, and mouth, and 21 days for disseminated or localized CNS HSV infections. The use of chemical mediators such as bradykinin analogs to increase the permeability of the blood-brain barrier can augment the uptake of acyclovir by two- to three-fold and lower the viral titers in the brains of experimental animals, and this may eventually enhance the efficacy of treatment for neonatal CNS HSV infections (289).

Dosage reductions are needed for infants with renal or hepatic dysfunction (290). The dose of acyclovir should be lowered in infants with reduced creatinine clearance. For serum creatinine levels of 0.8 to 1.1 mg/dL, acyclovir should be administered at a dose of 20 mg/kg every 12 hours. For infants with serum creatinine levels of 1.2 to 1.5 mg/dL, the dose is reduced to 20 mg/kg every 24 hours, and for newborns with creatinine concentrations greater than 1.5 mg/dL or have a urine output less than 1 mL/kg per hour, the dose is lowered to 10 mg/kg every 24 hours (287).

P.1290

Neonatal infections caused by acyclovir-resistant HSV strains have been encountered, but are very rare (291). Acyclovir resistance in HSV is principally as a result of a mutation that leads to viral thymidine kinase deficiency. Another recognized, but less common, mechanism of resistance is the production by the virus of a thymidine kinase with decreased ability to phosphorylate acyclovir. A third mechanism of resistance is a mutation within the viral gene encoding DNA polymerase. Acyclovir triphosphate is formed but is unable to block viral transcription because of poor affinity for the viral DNA polymerase (292,293).

Topical antiviral agents, such as the ophthalmic preparations of 1% to 2% trifluorothymidine, 3% vidarabine, or 0.1% iododeoxyuridine, should be used in newborns with ocular involvement, in addition to parenteral acyclovir. The use of commercial intravenous γ -globulin preparations for HSV postexposure prophylaxis or treatment of neonates is not recommended, although evidence gleaned from animal studies suggests that the administration of monoclonal or polyclonal neutralizing antibodies given as late as 3 days after HSV infection can decrease mortality and morbidity (294,295).

Seizure control, fluid and electrolyte management, ventilatory support, and treatment of shock and disseminated intravascular coagulation is required for many HSV-infected neonates (292). Contact precautions are needed if mucocutaneous lesions are present (296).

Neuroimaging studies are often utilized in the care of infants with HSV encephalitis, and approximately 65% show abnormalities (260). Ultrasound of the head early in the course of illness may be normal or show areas of increased echogenicity (297). Initial head CT scans may be abnormal in as many as half of newborns with HSV CNS disease. Involved areas of the brain may be hypo-intense (T1-weighted sequences) or hyperintense (T2-weighted sequences) using MR imaging. Abnormal signal intensities can reflect edema, infarction, or calcifications. In contrast to older children and adults, involvement of the medial temporal or inferior frontal lobes is uncommon (298). Diffusion-weighted imaging appears to be more sensitive than conventional MRI early in the course of HSV encephalitis (299).

A repeat lumbar puncture at the end of 21 days of acyclovir therapy has been recommended by some investigators. If the CSF HSV PCR were still positive, then intravenous acyclovir would be continued until the test becomes negative (254). Whether this approach alters long-term outcome for these infants is unknown.

Given the frequency of cutaneous or CNS recurrences after completion of antiviral therapy, some investigators have tried using oral acyclovir for posttreatment prophylaxis (300,301). The NIAID CASG conducted a phase I/II trial of oral acyclovir prophylactic therapy at a dose of 300 mg/m²/dose given two or three times daily for 6

months to newborns recovering from HSV-2 infections limited to the skin, eyes, or mouth. Of 16 infants taking the thrice daily acyclovir regimen, 13 (81%) had no recurrences over the ensuing 6 months. This compared favorably with the 54% rate observed for historic control patients. The number of infants on the twice daily regimen was too small to permit any meaningful conclusions on its effectiveness as prophylaxis. Although acyclovir suppressive therapy appears able to limit cutaneous recurrences, its effectiveness in improving neurologic outcome for these infants is not known. Half the infants became neutropenic (absolute neutrophil counts less than 1,000 cells/ μ L) while on acyclovir therapy. One infant had an acyclovir-resistant HSV-2 mutant isolated from a skin recurrence that occurred 36 hours after the conclusion of the 6-month suppressive regimen (301). Given the current limitations of available data, it cannot yet be recommended that neonates with HSV infection be routinely placed on oral acyclovir suppressive regimens after completion of their intravenous therapy (302).

Prevention

Because of the enormous morbidity and mortality rates of neonatal HSV infections despite the early initiation of antiviral therapy, the focus of many research groups has been the development of effective prevention strategies. In a detailed decision analysis study, Libman and colleagues used published data to theoretically evaluate nine different obstetric approaches for the prevention of neonatal HSV disease. The investigators concluded that, given the state of technology, physical examination at the time of labor was the most reasonable strategy. This tactic would be expected to reduce the number of neonatal HSV cases by 36% although increasing the rate of cesarean sections by only 3%. The strategy of obtaining genital HSV cultures at weekly intervals from women with a history of recurrent genital herpes and then delivering by cesarean section those whose most recent culture results were positive by onset of labor would result in 547 additional cesarean sections performed to prevent less than one case of neonatal HSV infection (rates per 100,000 deliveries) (303).

Studies on women with histories of recurrent genital herpes have demonstrated that weekly antepartum cultures fail to predict the risks to their infants of HSV exposure at delivery and that most infants exposed to asymptomatic HSV shedding at delivery are born to women without a history of recurrent genital herpes infection (304,305). Garland and co-workers showed that the positive predictive value of a positive antepartum HSV culture for intrapartum viral shedding is only 59% when the interval between visits was two days or less, and dropped to 19% when the days between visits was more than two days (306). Similarly, the practice of screening pregnant women for the presence of type-specific HSV antibodies in an effort to prevent neonatal infection is not recommended (307,308).

Roberts and colleagues were able to reduce the HSV-related cesarean section rate at their institution by 37% (without adverse neonatal consequences) by questioning women in labor about prodromal symptoms of genital HSV infection followed by careful visual inspection of the

P.1291

lower genital tract. Previously, the strategy at their institution had incorporated the use of weekly HSV cultures beginning at 34 weeks of gestation and delivering by cesarean section those whose last genital cultures were positive or unavailable (309).

Cesarean section should be performed on women with signs and symptoms suggesting genital HSV infection at the onset of labor. It is not known whether cesarean delivery can reduce the risk of neonatal herpes when the membranes have been ruptured for longer than 4 to 6 hours, but the American College of Obstetricians and Gynecologists recommends the procedure for women in labor with active HSV genital lesions, irrespective of the duration of premature rupture of membranes (296,310). In a study of 202 women from whom HSV was isolated at time of labor, cesarean delivery reduced the HSV transmission rate by about 85% (311). The same study showed that the risk of transmission of HSV to newborns was increased for first-episode maternal genital infection, for women with no HSV antibodies, when HSV was isolated from the cervix rather than only the vulva, for HSV-1 viral type, when delivery occurred before 38 weeks of gestation, or when invasive monitoring was done (311). Vacuum extraction techniques causing scalp laceration increase the risk of neonatal HSV infection for women who are shedding the virus asymptotically at delivery (312).

Contact precautions are needed for infants delivered through an infected birth canal, and those delivered by cesarean sections to mothers with herpetic genital lesions (296). The risk of invasive HSV infection is small for infants delivered vaginally to women with recurrent genital herpes who are asymptomatic but shedding the virus at the time of labor (310,313). Cultures of urine, stools, and mucous membranes (e.g., rectum, eyes, mouth, nasopharynx) should be obtained at 24 to 48 hours of life. Earlier positive cultures may reflect transient contamination and not true infection. If the cultures are positive for HSV, antiviral therapy should be started,

even if the infant is asymptomatic. Infants who are symptomatic at birth (e.g., scalp lesions, symptoms suggestive of sepsis) should be treated with acyclovir after specimens for HSV culture and PCR (including CSF and blood buffy coat) are obtained. Animal data suggest that acyclovir therapy concomitant with HSV inoculation could inhibit acute viral replication and decrease the number of neurons with latent infection (314).

A number of studies have assessed the potential benefits of suppressive acyclovir therapy for pregnant women with recurrent genital herpes. Various acyclovir doses were tried and started at 36 weeks of gestation. The results of these trials were not in complete agreement, but all showed decreases in viral shedding and clinical recurrences, and a probable decline in the cesarean section rates for these women (315,316,317). A study of once daily valacyclovir in late pregnancy did not demonstrate any improvements at delivery for any of these parameters (317). Despite the lack of data on whether suppressive therapy in late pregnancy reduces the rate of vertical-fetal HSV transmission, the American College of Obstetricians and Gynecologists has suggested that antiviral therapy be considered for women at or beyond 36 weeks of gestation who have either a first-episode of genital herpes infection during the pregnancy or are at risk for recurrent HSV (310). For women who are seronegative for HSV-2 but whose sexual partners have recurrent genital herpes, education regarding safer sexual practices and use by the male partner of valacyclovir (500 mg once daily) can reduce the likelihood of infection by approximately 45% (318,319).

The detection of HSV DNA by PCR assays in the amniotic fluid of pregnant women with symptomatic genital HSV may not reflect intrauterine infection (320). Thus, pregnancy termination without other indicators of disease such as an abnormal fetal ultrasound would be unwarranted.

Numerous HSV candidate vaccines (e.g., subunit vaccines, DNA vaccines) are currently at various stages of development. None are available commercially (196,321).

Cytomegalovirus Infections

CMV is the most common congenital viral infection of humans in the United States and is one of the most important opportunistic pathogens causing serious illness and death in immunocompromised patients (322,323,324). CMV infections are benign for most adults. However, when CMV infection occurs during pregnancy, the virus can be transmitted to the fetus and result in either symptomatic neonatal disease or subclinical congenital infection that may later manifest with hearing loss or learning disabilities.

CMV is an enveloped, double-stranded DNA virus that belongs to the herpes family of viruses (323). It has a restricted host range and only human cells are productively infected by this virus (325). CMV is not eradicated after resolution of the primary infection. It persists in the body in a low-grade chronic infection form or in a latent state with periodic reactivations (325). CMV transmission occurs primarily by direct or indirect person-to-person spread of infected oropharyngeal secretions, sexual intercourse, blood transfusions, or transplacental spread from mother to fetus.

Maternal Infection

Serologic surveys in the United States and Great Britain have shown that antibodies to CMV can be found in the sera of 40% to 60% of adults of middle or upper socioeconomic status, and in as many as 80% of those in lower socioeconomic groups (326). CMV seroprevalence is as high as 90% to 100% in pregnant women from Brazil, Chile, Korea, Japan, and the Ivory Coast (322,327). The higher the prevalence of maternal CMV antibody in a population, the greater is the rate of congenital CMV infection (326). Factors correlating with CMV seropositivity in pregnant women in the United States include non-Caucasian race, unmarried status, lower educational and income levels, and increasing parity (328,329). Sexual activity is an important risk factor for CMV infection in adolescents and

P.1292

young adults, and coinfection with bacterial vaginosis, trichomoniasis, gonorrhea, or other pathogenic organisms increases the odds of intrauterine CMV transmission (330,331,332,333,334).

Intrafamilial CMV transmission from young children to their seronegative pregnant mothers can occur. The risk of CMV seroconversion for a seronegative mother with an infected child is estimated at 10% to 30% per year and is even higher if the child is younger than 20 months of age (326,335). Annual seroconversion rates

for seronegative day care providers is about 8% to 12% (336,337). Health care workers with CMV-infected patient contact do not appear to be at increased risk of CMV acquisition compared with persons without patient contact (338).

About 0.7% to 4.1% of susceptible women acquire primary CMV infection during pregnancy, a risk comparable to that of nonpregnant women (322). Seropositive women can reactivate their latent CMV infection during pregnancy or, less commonly, become reinfected by an exogenous CMV strain. Cervical and urinary CMV excretion increases as pregnancy advances from the first to the third trimester (339). Pregnant women may shed CMV from the cervix, urinary tract, throat, and breast milk in the postpartum period (10).

Primary and recurrent maternal CMV infection can result in transmission of the virus to the fetus. This occurs in about 40% (range 24% to 75%) of pregnancies complicated by primary CMV infection (338). The presence of maternal antibodies to CMV in women with recurrent infection does not prevent viral transmission to the fetus, but it does reduce the risk of fetal infection and protects against major fetal damage by CMV (340,341). Severe congenital CMV after maternal reactivation or reinfection by other strains can occur, but is infrequent (342,343,344,345,346,347,348,349,350). For women who seroconvert between deliveries of successive infants, the risk of transmission of CMV to their offspring is 25%, 10%, and 4.2% when the interval is 24 months or shorter, 25 to 48 months, and more than 48 months, respectively (351).

Most women (90%) with primary CMV infection are asymptomatic, and the rest usually have illnesses resembling infectious mononucleosis (352). In a series of 102 pregnant women with primary cytomegalovirus infection referred to a tertiary care center in Rome, Italy, common symptoms noted were fever (42%), weakness (31%), myalgias (21%), and influenza-like illness (24%). Relative lymphocytosis of 40% or higher was found in 39%, and mild elevations in at least one aminotransferase level was measured in a third of the women (353). Other manifestations are rare but include interstitial pneumonia, myocarditis, aseptic meningitis, encephalopathy, retinitis, hepatitis, colitis, thrombocytopenia, and hemolytic anemia (354,355). Primary CMV infection during the first trimester of pregnancy does not cause fetal loss (356).

Infection can be documented by isolating the virus from urine, saliva, buffy coat, or cervical secretions (357). Viral isolation, however, does not differentiate between primary and recurrent CMV infections. Measurement of CMV-specific IgM antibodies is useful for the diagnosis of primary infection, but this antibody can persist in serum for 4 to 8 months (358). Furthermore, CMV-specific IgM can appear after primary and reactivated infection (357). CMV-specific IgG antibody levels are helpful if seroconversion or a fourfold titer rise can be demonstrated. The IFA and ELISA are the most practical and reliable methods for detecting CMV antibodies. CMV-specific IgG avidity is low (mean 30%) when measured within the first 14 weeks after seroconversion, and it increases over time (mean 88% for

patients with remote infections). This assay may be helpful in the diagnosis of primary CMV infection during pregnancy and may even be able to identify women who would deliver a CMV-infected infant (359,360). Rapid diagnosis of CMV infection is possible using antigen assays or molecular biological techniques such as the PCR (357). One needs to be aware that interlaboratory variability exists in the results of CMV PCR assays, especially for specimens containing lesser quantities of viral DNA (361). In a cohort of asymptomatic adolescents with primary CMV infection, CMV DNA was detected in buffy coat samples by PCR in 75% to 80% within 16 weeks of infection, and this declined to 0% to 25% after 48 weeks; lower recovery rates were noted in plasma specimens (362). Quantitation of CMV DNA in buffy coat, plasma, or serum is available, but this is mostly utilized in the management of immunosuppressed and organ transplant patients (357,363).

Several drugs are currently available for the treatment of CMV infection in the immunocompromised host, but they are almost never used in pregnant women (364,365,366). The drugs have a number of associated problems such as toxic side effects, poor oral bioavailability, and potential for emergence of drug-resistant virus strains (365). Ganciclovir, an acyclic nucleoside analogue of acyclovir, has excellent inhibitory activity against CMV (367). As with acyclovir, ganciclovir has to be phosphorylated initially by a viral enzyme. It is then eventually converted to the triphosphate form by cellular enzymes. Ganciclovir concentrations are at least ten-fold higher in CMV-infected cells than in uninfected cells (367). Ganciclovir is both mutagenic and teratogenic in pregnant experimental animals. The drug crosses the placenta into the fetal compartment passively without being metabolized (368,369). Valganciclovir is a prodrug of ganciclovir that is given orally (364). Foscarnet (phosphonoformate), another anti-CMV drug, inhibits the DNA polymerase of CMV. Like ganciclovir, foscarnet is used only in the immunosuppressed patient with CMV disease (367). Cidofovir is a nucleotide analogue that inhibits viral DNA polymerase. It has a long intracellular half-life, which allows its administration to adults once every 1 to 2 weeks. It is active against ganciclovir- or foscarnet-resistant CMV isolates. Its use currently is limited to immunocompromised adults, especially those with CMV retinitis (367,370).

Congenital Infection

Congenital infection with CMV occurs in 0.4% to 2.3% of all live births (326). About 10% are symptomatic, and the

rest have subclinical infections. It is thought that CMV in women with primary infection is transmitted to the fetus via maternal leukocyte-associated viremia and infection of uterine endothelial cells, with subsequent hematogenous spread to the fetus. Local reactivation of CMV-infected macrophages can lead to infection of

placental villi and retrograde spread to the fetus in CMV-seropositive mothers (371). In one study, 30% of placentas from CMV-seropositive women had CMV DNA and this was localized mostly to the villi (372).

Infants with symptomatic congenital CMV have a mortality rate of 15% to 30%, and most survivors have long-term sequelae (10,373-376). Petechiae, jaundice, and hepatosplenomegaly are found in two-thirds of patients, although conjugated hyperbilirubinemia and thrombocytopenia are found in about 80% of cases (340,373). Neurologic abnormalities such as seizures and hypotonia are common, and microcephaly occurs in about 50% to 75% of infants. Intracranial calcifications are seen on the CT scans of one-half of the patients (Fig. 48-3). At autopsy, evidence of multiorgan involvement is apparent (373, 377). Neuropathologic findings include periventricular necrosis, intraventricular hemorrhage, calcifications, cerebellar hypoplasia, periventricular leukomalacia, hydrocephalus, and porencephalic cyst (376,378,379). Hearing loss and neurologic impairment (e.g., psychomotor and mental retardation) develop in one-half of the survivors (374,375). Infants whose cranial CT scans are abnormal at birth have a 90% risk of developing at least one long-term sequela such as mental or psychomotor retardation, seizures, cerebral palsy, or hearing loss. In contrast, only 29% of infants with symptomatic congenital CMV infection and normal cranial CT scans at birth have similar long-term residual problems (380).

Figure 48-3 Computerized axial tomogram of a microcephalic 3-month-old boy with symptomatic congenital CMV following primary maternal gestational CMV infection. Shown are subependymal periventricular calcifications, enlarged ventricles and CSF spaces, and loss of periventricular and subcortical white matter volume.

Chorioretinitis is the most frequent eye abnormality, followed by optic atrophy

(10). The chorioretinitis is typically seen in infants with symptomatic congenital CMV, but it can occasionally be the only manifestation of infection. It can also develop several weeks after birth (381,382). Spontaneous resolution of the retinitis has been reported (383). Visual impairment in infants with symptomatic congenital CMV may be as a result of optic atrophy, chorioretinal scars, or damage to the visual cortex (381). Microphthalmia, cloudy cornea, corneal opacities, optic nerve hypoplasia, optic nerve coloboma, nystagmus, strabismus, anophthalmia, and cycloopia also occur. Eye abnormalities are common in infants with intracranial calcifications (10,381,382).

Unilateral or bilateral sensorineural hearing loss that can vary from mild to profound develops in as many as half of infants with symptoms at birth, and in 7% to 13% of those with subclinical infections. Hearing loss may be present at birth in otherwise asymptomatic infants, and it subsequently deteriorates in more than one-half of the patients with a median age at first progression of 18 months (range 2-70) (384,385,386). In one study, the presence of petechiae or intrauterine growth retardation were predictive of the development of hearing loss; microcephaly and other neurologic abnormalities were not (387). Some patients have normal hearing for the first several years of life, but they subsequently develop sudden or fluctuating hearing loss (385,388). CMV has been shown to be responsible for a substantial percentage of sensorineural hearing loss cases in children. In a study from Italy of 130 children with hearing loss of more than 40 dB, CMV was the culprit for 10% of those detected within the first two months of life, 34% of children with deafness of unidentified cause, and 42% of those with hearing loss more than 70 dB (389).

Intellectual deficits are common, particularly in infants with symptomatic congenital CMV. Microcephaly and an abnormal CT scan are respectively the most specific and sensitive predictors of mental retardation and major motor deficits (390). Some infants with subclinical disease may develop mental or behavioral problems, but a few recent studies have shown no differences in intelligence quotients or neuropsychological test results between patients with asymptomatic congenital CMV and healthy controls or uninfected siblings (391,392). Children with asymptomatic congenital CMV who are developmentally normal at 1 year of age are unlikely to be at increased risk of subsequent neurodevelopmental or intellectual impairments (393).

Dental defects can be found in 40% of the survivors of symptomatic neonatal disease but in only 5% of asymptomatic

P.1294

cases (394). A variety of other congenital anomalies have been described in infants with congenital CMV infection, but these probably reflect coincidental associations rather than true cause-and-effect relationships (395). Reported associations include atrial and ventricular septal defects, tetralogy of Fallot, congenital mitral stenosis, aortic arch thrombosis, congenital lobar emphysema,

Mondini deformity of the temporal bone (congenital anomaly of osseous and membranous labyrinth characterized by aplastic cochlea, and deformity of the vestibule and semicircular canal with partial or complete loss of auditory or vestibular function), stuck twin syndrome, renal agenesis, diabetes insipidus, inguinal hernia, hip dislocation, clubfoot, esophageal atresia, megacolon, and extrahepatic biliary atresia (10,396-403).

Maternal CMV antibodies protect the fetus against major CMV-related pathology. Fowler and colleagues found that 18% of 125 infants born to women with primary CMV during pregnancy had symptomatic neonatal disease compared with none of 64 infants born to women with reactivated CMV infection. After a 5-year follow-up period, 13% of infants born to mothers with primary infection had mental impairment (i.e., intelligence quotient ≤ 70) compared with none in the recurrent infection group. Sensorineural hearing loss was found in 15% and 5% of infants born to mothers with primary and recurrent CMV infections, respectively. Bilateral hearing loss occurred only in the primary infection group (340).

Discordant fetal outcomes are possible after primary maternal CMV infection in twin pregnancies. CMV usually affects both twins if they are monozygotic with a monochorionic placenta. In dizygotic twins with a dichorionic placenta, one twin can be severely affected whereas the other completely escapes infection (404). In one report of a quadruplet pregnancy complicated by primary maternal CMV infection, one infected fetus died antenatally, another died at 3 months of liver failure, one had hearing loss and developmental delay, and the fourth infected infant was normal at his last evaluation at age 18 months (405). CMV viral loads in amniotic fluid of discordant twins have been found to be higher in those born with symptomatic congenital CMV than in their twin with asymptomatic infection (406).

Congenital infection can be diagnosed by isolation of CMV from the urine or saliva within the first 2 weeks of life. Positive cultures from specimens obtained after 3 weeks of age may reflect perinatal CMV acquisition. Congenitally infected infants shed CMV in their urine for many years. The use of shell vial cultures hastens viral isolation. CMV can be also detected in urine by electron microscopy or ELISA. CMV DNA can be detected in clinical specimens such as urine or serum using sensitive hybridization or PCR methods. CMV-specific IgM is detected in many of the infected newborns. IgM detection by radioimmunoassay or ELISA is superior to immunofluorescence (326,357, 407-411). Compared to CMV isolation from urine, Revello and colleagues found that the sensitivities of assays detecting CMV DNA in serum, CMV viremia, antigenemia, and CMV-specific IgM to be 100%, 28%, 43%, and 71%, respectively (412). CMV viral loads are higher in urine than in cord vein blood or cerebrospinal fluid in congenitally infected infants (413). PCR assays on blood collected on Guthrie cards have been successfully employed in a number of studies to make retrospective diagnoses of congenital CMV infection in infants with unexplained sensorineural hearing loss or CNS malformations (389,414).

Guthrie cards are saved in various State Laboratories for periods that range from weeks to years. Storage conditions are highly variable and may allow for cross contamination by blood from other cards.

Ganciclovir has been evaluated as treatment for symptomatic congenital CMV infection. Ganciclovir suppresses viral replication in immunocompromised patients with serious CMV infections. Several problems are associated with ganciclovir use, including the resumption of viral replication on discontinuation of therapy, emergence of ganciclovir-resistant CMV strains after prolonged use in immunosuppressed patients, and drug toxicity (e.g., neutropenia, thrombocytopenia) (367,415). With the exception of one study, information on the utility of ganciclovir for infants with symptomatic congenital CMV infection comes from individual case reports, small case series, and uncontrolled trials utilizing more than one dosage regimen for the drug (326,413,416-429). From these studies, it appears that ganciclovir can lessen or stop viral multiplication and inhibit its shedding; however, viremia resumes on discontinuation of therapy. Regimens that used higher individual doses (7.5 instead of 5 mg/kg) given twice daily and for longer periods (6 to 12 weeks or longer instead of 2 to 3 weeks) were associated with improved short-term outcomes. Drug-related hematologic toxicities (e.g., neutropenia, thrombocytopenia) develop in the majority of treated infants.

A randomized, but not placebo-controlled, trial of intravenous ganciclovir (6 mg/kg per dose every 12 hours) vs. no therapy for 6 weeks enrolled 100 newborns with symptomatic congenital CMV involving the CNS between 1991 and 1999 (415). To be included in the study, infants had to be one month of age or younger, have a gestational age of at least 32 weeks, weigh 1200 grams or more at birth, and be HIV-negative. CNS disease was considered present if infants had one or more of the following: microcephaly, intracranial calcifications, hearing deficits, chorioretinitis, or abnormal CSF findings. A major limitation of the study was that only 42 infants were evaluable at the six-month follow-up. Nevertheless, the investigators found that ganciclovir prevented hearing deterioration at six months. At or beyond one year of age, fewer ganciclovir-treated infants had worsened hearing as compared to baseline (21% vs. 68%). Two-thirds of treated infants developed significant neutropenia requiring dosage adjustment or treatment with granulocyte colony stimulating factor (415).

The optimal treatment for congenital CMV infection remains to be defined. For symptomatic infants with severe disease, ganciclovir needs to be considered. The duration

P.1295

of therapy should be between three and six weeks, depending on clinical response and cessation or reduction of virus replication. Some investigators have suggested treatment durations of 3 months to 3 years. Oral valganciclovir has not yet been studied in newborns, but it might offer options in the future for the treatment of

symptomatic congenital CMV or asymptomatic infants with demonstrated hearing deficits (428,430).

Intrauterine therapy for CMV infection was attempted for one fetus at 27 weeks of gestation by infusing ganciclovir once daily into the umbilical vein for 12 days. There was initial improvement in the fetal platelet count and liver enzyme concentrations, and a reduction in the amount of virus in the amniotic fluid and fetal urine, and clearance of CMV from fetal blood. However, viral replication promptly resumed on discontinuation of the drug, and the fetus died in utero at 32 weeks of gestation. Disseminated CMV was demonstrated at autopsy (431). CMV hyperimmune globulin used in conjunction with ganciclovir has improved the survival of bone marrow transplant recipients with CMV pneumonia. The combination was not beneficial in one infant in whom it was tried (418). CMV hyperimmune globulin was injected into the abdominal cavity of another CMV-infected fetus with ascites at 28 and again at 29 weeks of gestation (432). The fetus was delivered at 34 weeks because of fetal distress. The ascites was still evident at that time but disappeared by the fourth day of life. CMV hyperimmune globulin was given intravenously to a mother of twins with only one infected fetus who had intrauterine growth retardation, placental thickening, and umbilical cord edema; a dose of the immunoglobulin was also injected into the amniotic cavity. The affected fetus was developmentally normal at the two-year follow-up, with no visual or auditory impairments (433). There is no published experience with foscarnet or cidofovir in the treatment of congenitally infected infants.

Perinatal Infection

Infants can acquire CMV during passage through an infected birth canal or by ingestion of CMV-positive breast milk (434,435). CMV is found in the milk of 20% to over 90% of seropositive mothers for up to 12 weeks postpartum, and 60% to 80% of infants receiving CMV-containing milk will become infected. However, a report from Japan of 30 preterm infants fed CMV-positive breast milk showed that only three (10%) became infected and none developed symptoms (436). Another study of 22 preterm infants infected with CMV postnatally by breast-feeding found that none had sensorineural hearing loss at 2 to 4.5 years of age, and they did not differ from a CMV-negative preterm comparison group with respect to psychomotor development (437). One of the components of human milk, sialyllactose, has been found to consistently increase the titer of CMV in tissue culture systems at concentrations found in milk. The addition of another component of breast milk, lactoferrin, negates the effects of sialyllactose on CMV growth (438,439). Pasteurization of breast milk inactivates CMV, although freezing it at -20°C will decrease viral titers.

In contrast to congenital disease, perinatally acquired CMV infection usually is benign. Most infections are subclinical. A self-limited, infantile pneumonitis is the clinical abnormality encountered most commonly among symptomatic term

infants. Premature infants, and rarely term babies, may have severe illness, including pneumonia, hepatitis, enteritis, anemia, thrombocytopenia, and neutropenia (429, 440,441). Those born to CMV-seronegative mothers are at risk of acquiring CMV through blood transfusions from CMV-positive donors (440). CMV infection does not appear to be a co-factor for the development of bronchopulmonary dysplasia in preterm infants (442). The long-term prognosis for intellectual abilities and intact hearing for infants with perinatal CMV infection is excellent (443).

Prevention

Termination of the pregnancy can be considered for women who develop a primary CMV infection during gestation. With primary infection, the overall risk of delivering an infant with symptomatic congenital infection is about 5%.

Prenatal diagnosis of fetal CMV infection is feasible and can be accomplished by a variety of invasive methods such as cordocentesis and amniocentesis (371). Fetal blood can be cultured and PCR assays for CMV DNA can be performed. Additionally, fetal blood can be analyzed for the presence of CMV-specific IgM, liver enzyme elevations, anemia, and thrombocytopenia. Amniotic fluid can be tested by culture and PCR assays for evidence of CMV infection. The experiences with hundreds of pregnant women with primary CMV infection in whom prenatal diagnosis was attempted have been described in the literature (371,444-473). In the aggregate, these studies revealed that fetal blood testing is not as sensitive as amniocentesis in establishing the diagnosis of intrauterine CMV infection, and that symptomatic fetuses have higher CMV viral loads and higher CMV-specific IgM levels (371). Patients with positive results with the CMV-specific IgM assay, fetal blood culture, or fetal blood PCR testing also are positive when their amniotic fluid is examined, but the reverse is not true. Fetal blood sampling for CMV infection should only be used for confirmatory tests.

Amniocentesis is easier to perform and carries less risk to the mother and her baby. Studies have shown that neither culture methods nor PCR assays on amniotic fluid are 100% sensitive, and that false-negative results are more likely to be encountered if testing is done shortly after the diagnosis of maternal primary CMV infection is made (454,461,463,466,469). The influence of time between primary CMV infection and prenatal diagnostic tests diminishes when the most sensitive PCR techniques are employed (371). Positive PCR results on amniotic fluid may not necessarily reflect fetal infection. In one study of 82 women with primary CMV infection, PCR detected viral DNA in the amniotic fluid of 27; in only 12 was a congenital

infection documented after birth (positive predictive value of 48%) (458). However, other investigators consider the detection of even small amounts of CMV

DNA by PCR as an indicator of fetal infection (371). A false-positive amniotic fluid culture or PCR result is possible if contamination occurs with maternal blood or during performance of the assay. In general, higher CMV viral loads are found in the amniotic fluid of fetuses with symptomatic involvement as compared to those with subclinical infection (459,464,470). CMV DNA is not detected by PCR in the amniotic fluid of women who do not have CMV infection (474). Isolation of CMV from the amniotic fluid by culture implies intrauterine infection but does not provide information regarding the severity of fetal disease (454). PCR assays have been used to detect CMV DNA in chorionic villi, but the sensitivity, specificity, and positive and negative predictive values of the method are not known (475).

Ultrasonographic fetal abnormalities in women with gestational primary or recurrent CMV infection generally indicate more severe fetal disease. A variety of sonographic findings have been reported, including microcephaly, ventricular dilation, periventricular pseudocysts, hypoplastic corpus callosum, ascites, hyperechogenic fetal bowel, hepatomegaly, splenomegaly, hydrops, pleural and pericardial effusions, oligohydramnios, intrauterine growth retardation, and intracranial and abdominal calcifications (371,444,457,476-483).

Live attenuated and subunit CMV vaccines are in clinical trials and not yet available in the United States (484,485). Routine CMV serologic screening of pregnant women is not currently recommended (486).

Because blood from seropositive donors contains leukocytes that are latently infected with CMV, many blood banks now screen the blood for CMV antibodies, use leukocyte filters, or use washed erythrocytes. The practice of giving only CMV-negative blood or blood products to ill neonates has greatly reduced or eliminated the occurrence of transfusion-acquired CMV infections in many nurseries. Disseminated CMV infection after extracorporeal membrane oxygenation has been described; CMV screening of blood had not been done (487).

Varicella

Varicella (chickenpox) and herpes zoster (shingles) are caused by varicella-zoster virus (VZV). VZV is an enveloped, double-stranded DNA virus. Only one serotype is known, but there are a few genetically distinct strains (488).

Maternal Infection

About 95% of women of childbearing age in the United States have serologic evidence of past VZV infection. The proportion of seropositive women is smaller in those from tropical or semitropical countries (489). Varicella is a highly communicable and usually benign disease of childhood. Its incubation period is usually 14 to 16 days, with a range of 10 to 21 days. Before licensure of the varicella vaccine in 1995, children younger than 15 years of age accounted for more than 90% of cases and fewer than 2% of reported cases occurred in those 20 years of age or older (490). Vaccination coverage rates were about 80% in U.S. children by the year 2000, but disease activity and hospitalizations had declined by 76% to 87% (491). Although the greatest decrease in incidence has been in children 1 to 4 years of age, cases declined in all age groups including infants and adults (492). The estimated incidence of gestational varicella before vaccine availability was 1 to 7 per 10,000 pregnancies, but there have been no revised estimates to date (493,494). Zoster results from reactivation of latent VZV and is encountered more frequently in elderly or immunosuppressed patients. Its incidence in pregnancy is unknown, but it is probably lower than that of varicella. One estimate placed the incidence at about 0.5 per 10,000 pregnancies (493).

Less than 5% of primary VZV infections are subclinical (495). The typical illness consists of fever, malaise, and a pruritic rash. The exanthem is mostly truncal in distribution and is characterized by crops of maculopapules that rapidly evolve into vesicles. The vesicles gradually crust over. New lesions continue to appear for 3 to 5 days, producing the distinctive finding of cutaneous lesions in various stages of evolution. Complications of varicella include pneumonia, encephalitis, arthritis, bacterial cellulitis, retinal vasculitis, and bleeding diathesis. The risk of incurring complications from varicella in otherwise normal adults may be up to 25-fold greater than that for normal children (490,496,497). Pregnancy

is generally not considered a risk factor for maternal complications, but there may be an increased prevalence of varicella pneumonia in the third trimester (497). Immunity after varicella is usually long lasting, but recurrent VZV infections can occur in immunocompetent persons (498,499). Zoster is characterized by pain localized to the area of distribution of one or more sensory nerve roots. The rash is unilateral in most patients and follows the same evolutionary pattern seen in varicella except for its restricted distribution.

Varicella and herpes zoster usually are diagnosed clinically, and laboratory confirmation is needed infrequently. The virus can be isolated from vesicular fluid by inoculating freshly collected specimens onto human diploid cell lines. The VZV-specific antigens can be detected in vesicular fluid by immunofluorescence staining of smears of cell scrapings collected from the base of fresh vesicles (500). VZV DNA can be detected in vesicle samples, including most crusted lesions, by PCR methodologies (501,502). PCR assays have also been used to detect VZV DNA in CSF, genital lesions, and other clinical specimens (503,504). Quantitative VZV DNA measurements in blood and skin lesions show that viral loads are higher in patients with varicella than in those with herpes zoster (505,506).

Several serologic assays are available for the detection of antibodies to VZV. These include complement fixation, neutralization, IHA, immune adherence hemagglutination, radioimmunoassay, immunoblot, latex agglutination,

P.1297

fluorescent antibody against membrane antigen (FAMA), indirect fluorescent antibody (IFA), and ELISA. These tests can be used to diagnose VZV infections or to ascertain the susceptibility status of an individual (507). Complement fixation antibodies develop within 10 days of onset of varicella and peak at 2 to 3 weeks. These antibodies appear earlier in herpes zoster. Complement fixation antibodies tend to disappear with time. By 1 year after infection, about two-thirds of persons do not have detectable complement fixation antibody titers. The complement fixation test is relatively insensitive compared with FAMA or ELISA, and it is now rarely used in clinical laboratories. The FAMA test is very sensitive and is considered to be the gold standard for VZV antibody measurements. However, FAMA is

arduous to perform and is not readily available. The ELISA test is more frequently used for VZV antibody measurements. The IFA methods appear to be as sensitive as FAMA.

Two serum samples collected 1 to 2 weeks apart can provide a retrospective diagnosis of VZV infection if a fourfold or greater rise in antibody titer is demonstrated. If the first sample is collected late in the course of the illness, a single high titer indicates a recent primary or a reactivated VZV infection.

Measurement of VZV-specific IgM antibodies is useful for documenting a recent infection with this virus. VZV-specific IgM antibodies can be detected in serum for several weeks after varicella and may be transiently found after herpes zoster.

For uncomplicated varicella, symptomatic treatment with antipruritics and cleansing of lesions is adequate. Analgesics are needed for pain control in herpes zoster. Early therapy of varicella within the first day of illness with oral acyclovir (800 mg given orally five times per day for 7 days) or valacyclovir (1000 mg given orally three times daily for 5 days) hastens resolution of fever and shortens the time period to complete crusting of the lesions (508,509). Acyclovir and valacyclovir are not recommended for use during pregnancy, but can be given for the treatment of severe or life-threatening VZV complications such as pneumonia.

There have been several reports of pregnant women with varicella pneumonia who were treated with acyclovir (510,511,512,513,514,515,516,517). The drug was used at doses ranging from 5 to 18 mg/kg every 8 hours, and the treatment results generally have been favorable. It is currently recommended that women who need intravenous acyclovir therapy for varicella pneumonia should get 10 mg/kg every 8 hours for 5 days.

Transmission to the Fetus

VZV transmission to the fetus occurs primarily through the transplacental route. Congenital malformations after maternal infection during the first half of pregnancy occur infrequently. VZV antigens and its DNA have been detected in fetal tissues from pregnancies complicated by varicella using immunohistochemical staining methods and PCR, respectively (518,519,520,521,522).

About one-fourth of newborns delivered to mothers who contract varicella during the last 3 weeks of pregnancy develop clinical infection (516). Paryani and Arvin (523) used several clinical and immunologic criteria to document intrauterine transmission of VZV in 43 pregnancies complicated by varicella and 14 others complicated by herpes zoster. These criteria included malformations consistent with the congenital varicella syndrome, acute varicella of the newborn, detection of VZV-specific IgM in the neonatal period, specific lymphocyte transformation to VZV antigen, persistence of anti-VZV IgG, and the occurrence of herpes zoster in infancy. The rate of intrauterine transmission was 24% after maternal varicella and 0% after maternal herpes zoster (523).

Fetal Infection

Varicella during pregnancy is not associated with an increased incidence of prematurity or fetal death (523- 525). Chromosomal abnormalities have occurred after VZV infections in experimentally infected human diploid fibroblasts and in the peripheral leukocytes of patients with acute varicella (526,527). Leukocyte chromosomal breaks were described in one child whose mother had gestational varicella (528). An increased risk of leukemia in the offspring of women with gestational varicella has been found by some investigators, but the numbers are too small to confirm the association (529).

Numerous case reports published over the past 58 years have described the occurrence of congenital malformations in the progeny of women who acquire chickenpox during pregnancy (521,522,523,524,530,531,532,533,534,535,536,537,538,539,540,541,542, 543,544,545,546,547,548,549,550,551,552,553,554,555,556,557,558,559, 560,561,562,563,564,565,566,567,568,569,570,571,572,573,574,575,576, 577,578,579,580,581). With the exception of a few infants with congenital anomalies after maternal varicella at 24 to 32 weeks of gestation, these infections usually occurred during the first half of gestation, and mostly between weeks 8 and 20 of pregnancy (582,583,584,585). Abnormalities are primarily cutaneous, musculoskeletal, neurologic, and ocular (Table 48-5).

The risk of fetal or congenital varicella syndrome after maternal chickenpox during pregnancy is low. Pastuszak and colleagues (586) studied 106

women with varicella in their first 20 weeks of pregnancy and found a 1.2% risk (95% confidence interval [CI] of 0%-2.4%) of varicella embryopathy. Enders and associates (587) studied 1,373 women with gestational varicella between 1980 and 1993 and found the risk of fetal varicella syndrome to be 0.4% (95% CI of 0.05%-1.5%) for infections occurring between weeks 0 to 12 of pregnancy, and 2% (95% CI of 0.8%-4.1%) for those occurring between weeks 13 to 20 of pregnancy. Jones and colleagues (588) found that 2 of 146 infants born to women with gestational varicella had abnormalities consistent with the fetal varicella syndrome; four others had a single major malformation. Harger and associates found the frequency of definite congenital varicella syndrome to be 0.4% in a cohort of 347 pregnant women with varicella evaluated between 1993 and 1996 (585). No infants were born with the fetal varicella

P.1298

syndrome to 57 women described in two other similar studies (589,590).

TABLE 48-5 ABNORMALITIES IN NEWBORNS AFTER MATERNAL GESTATIONAL VARICELLA

Timing of Maternal Varicella	Neonatal Clinical Abnormalities
Weeks 0 to 20 of pregnancy	Cicatricial skin lesions, denuded skin, herpes zoster, limb hypoplasia, rudimentary digits, muscle atrophy, intrauterine growth retardation, psychomotor retardation, microcephaly, cerebellar and cortical atrophy, hydrocephalus, seizures, intracranial and extracranial calcifications, sensory deficits, Hornersyndrome, spinal cord atrophy, anal sphincter dysfunction, dysphagia, intestinal atresia, neurogenic bladder,

	renal dysplasia, recurrent aspiration pneumonia, clubfoot, microphthalmia, optic atrophy, hypoplasia of optic disc, chorioretinitis, chorioretinal scars, cataract, nystagmus
5 days antepartum to postpartum day 2	Fever, vesicular exanthem, hemorrhagic rash, respiratory distress, cyanosis, pneumonia, widespread necrotic lesions of the viscera (in fatal cases)

Cicatricial lesions are the most common skin abnormalities (Fig. 48-4). Cutaneous scars usually occur on hypoplastic extremities, but they can extend to the trunk or opposite extremity. Limb hypoplasia usually is unilateral and most commonly involves the leg. The arm, mandible, or hemithorax can be affected. Rudimentary digits are common on hypoplastic extremities. Detailed clinical and histopathologic studies of some patients suggest that limb abnormalities after intrauterine VZV infection probably is as a result of a neuropathy resulting from damage to dorsal ganglia and anterior columns of the spinal cord (555,557).

CNS pathology is common and includes microcephaly, cortical and cerebellar atrophy, psychomotor retardation, seizures, and focal brain calcifications. Autonomic dysfunction, manifested by loss of bowel and urinary sphincter control, dysphagia, intestinal obstruction, and Horner syndrome, is observed in some patients. Unilateral or bilateral ocular anomalies are common; the eye may be the only organ affected in fetal VZV infection. The literature contains references to a few infants born with congenital malformations after maternal herpes zoster during pregnancy (591,592,593,594). Reported birth defects include microcephaly, microphthalmia, cataracts, and talipes equinovarus. These rare cases probably represent chance occurrences rather than true associations. Paryani and Arvin (523) prospectively followed 14 pregnancies complicated by herpes zoster and were unable to uncover any clinical or immunologic

evidence of intrauterine VZV infection. Enders and associates (587) found no evidence of intrauterine VZV infection in infants of 366 women who developed herpes zoster during the first 36 weeks of pregnancy.

Figure 48-4 Newborn with congenital varicella after maternal infection at about week 13 of pregnancy. Notice the ulcerated area with surrounding scars over the knee; a second scar is visible distally, over the tibia. Despite an otherwise normal physical examination, computerized tomography of the head revealed multiple areas of cerebral infarction and diffuse intracranial calcifications.

Neonatal Infection

About 25% of newborns become infected when maternal varicella occurs during the last 3 weeks of pregnancy (516). The most important determinant of the severity of neonatal disease is the time of onset of maternal varicella relative to delivery. If maternal infection occurs within 5 days before and 2 days after delivery, varicella lesions in neonates usually appear at 5 to 10 days of age. The illness may be mild, with only a few cutaneous lesions, or may become severe, with fever, hemorrhagic rash, and generalized visceral involvement (see Table 48-5). The mortality rate is about 30%, and death usually is caused by severe

pulmonary disease. If maternal varicella occurs 5 to 21 days before delivery, lesions in newborns typically appear in the first 4 days of life and the prognosis is good, with no associated mortality. The mild course probably is as a result of the production and transplacental passage of maternal antibodies, which modify the course of the illness in newborns. Passive transfer of maternal VZV antibodies across the placenta at titers considered to be protective can occur as early as 24 to 28 weeks of gestation (595). Investigators from the Netherlands have shown that the most important determinant of neonatal antibody titers to VZV is the mother's VZV IgG level, and that birth weight or gestational age are less predictive than previously believed (596).

The diagnosis can be confirmed by viral isolation or VZV antigen detection. Infected newborns may have VZV-specific IgM, but these usually disappear shortly after birth. Newborns with varicella should be kept in strict isolation if they require hospitalization. Acyclovir is used for infants with severe disease (597). Although there are no studies to support current practice, the suggested dose of acyclovir is 500 mg/m² per dose every 8 hours. Dosage adjustments are needed for premature infants with renal or hepatic dysfunction. If started early in the illness, acyclovir usually leads to more rapid resolution of disease symptoms and signs. Varicella-zoster immune globulin (VZIG) is not beneficial after clinical disease has developed.

Prevention

Management of persons exposed to VZV is critical because varicella is a highly communicable infection that can adversely affect pregnant women and their offspring. Exposed susceptible persons can be protected by passive immunization with VZIG. VZIG is prepared from plasma of normal blood donors found to have high IgG antibody titers to VZV. VZIG can prevent or modify clinical varicella in susceptible persons if given shortly after exposure.

Pregnant women exposed to varicella who have negative or uncertain prior histories of this infection should be tested for VZV susceptibility if sensitive assays are available and the results can be obtained rapidly. About 80% to 95% of these women are immune to varicella, as indicated by positive FAMA, IFA, or ELISA test results (490,598). If a pregnant woman has

significant exposure to varicella and is susceptible or if the laboratory test result cannot be obtained in a timely fashion, VZIG should be administered for the purpose of preventing or modifying the infection in the mother to avoid complications. It is not known whether passive maternal immunization can prevent fetal VZV infection (490). VZIG is most efficacious when given as soon after exposure as is feasible, but not later than 96 hours.

A history of previous varicella infection is not always reliable. In a study of 184 military personnel with acute varicella, 20 (10.8%) reported a prior history of chickenpox. Sera from 19 of these individuals collected 3 days to 34 months earlier and stored at -70° were available for testing; none had VZV-specific IgG (599).

Discordant results with respect to fetal infections are possible in multiple gestation pregnancies. Borzyskowski and collaborators (534) reported a set of female identical twins sharing a single placenta whose mother developed varicella at 10 weeks of gestation. The first twin was normal, and the second had congenital defects consistent with intrauterine VZV infection. Prenatal diagnosis by detection of VZV-specific IgM in fetal blood was successful in one fetus evaluated at about 32 weeks of gestation, approximately 12 weeks after his mother developed chickenpox (538). Anti-VZV IgM could not be detected in cord blood samples obtained at 27 and 35 weeks of gestation of another fetus whose mother developed chickenpox at 12.5 weeks of gestation; later testing of stored amniotic fluid was positive for VZV DNA by PCR (600). Isada and colleagues (601) attempted to diagnose intrauterine VZV infection in two patients by chorionic villus sampling and PCR. Tissues from both mothers were PCR positive but culture negative. One mother elected to terminate her pregnancy at 23 weeks; examination of the fetal brain by Southern blot hybridization was negative. The second woman continued her pregnancy to term, and her newborn infant was clinically normal. Tests for VZV-specific IgM in cord blood and viral placental cultures were negative. Thus, the detection of VZV DNA sequences in chorionic villus samples did not equate with fetal infection (601). Amniotic fluid viral culture done at 22 weeks of gestation (11 weeks after maternal varicella) confirmed the diagnosis in another infected fetus; concomitant testing of fetal blood failed to detect VZV-specific IgM (602). Amniotic fluid testing using PCR confirmed the diagnosis of fetal varicella

infection in 9 of 107 women who had chickenpox before week 24 of gestation; none had detectable VZV-specific IgM in fetal blood (603). A variety of antenatal sonographic abnormalities have been described for VZV-infected fetuses. These include hypoplastic extremities, clubfoot, flexed limbs, ventriculomegaly, porencephalic cyst, oligohydramnios, polyhydramnios, hydrops, ascites, and calcifications of the lungs, myocardium, liver, and spleen (603,604,605,606).

Mattson and colleagues reported on 84 children born to women infected with varicella during pregnancy, only one of whom had features of the congenital varicella syndrome. They were able to show that the children without congenital varicella syndrome were normal when tested with age-appropriate neuropsychological tests at age 3 to 15 years (607).

Children born to mothers who develop varicella within 5 days before and 2 days after delivery should receive 125 U of VZIG as soon as possible. VZIG does not reduce the clinical attack rate in treated newborns, but these infants generally contract milder infections than untreated neonates (490,571,608). Because severe varicella can develop in newborns despite timely administration of

P.1300

VZIG, some clinicians have advocated the use of acyclovir prophylaxis in these infants (609,610).

Although a few cases of severe neonatal varicella after exposure to mothers who developed the infection more than 2 days after delivery have been described, routine VZIG administration is not recommended, because this group of infants is not regarded as being at increased risk of varicella complications (490,611). Investigators from Taiwan reported on 24 newborns whose mothers developed chickenpox within 14 days before and after delivery. They were able to show that the use of prophylactic intravenous acyclovir (5 mg/kg every 8 hours for 5 days) started 7 days after onset of maternal rash, coupled with one dose of intravenous gammaglobulin either at birth or after postnatal contact, could prevent neonatal varicella infection (612).

Pregnant women with varicella at the time of delivery should be isolated from their newborns until all vesicles have crusted. Neonates with varicella lesions should be isolated from other infants but not from their mothers.

Hospitalized premature infants may be candidates for VZIG if a significant exposure to chickenpox has occurred. All infants less than 28 weeks gestation or with a birth weight of $\geq 1,000$ grams should receive VZIG. Premature infants born at 28 weeks gestation should get VZIG if their mothers have no reliable history of chickenpox or lack serologic evidence of protection (613).

A live, attenuated varicella vaccine (VARIVAX) was licensed in the United States in March 1995. The vaccine should not knowingly be administered to susceptible pregnant women. The vaccine manufacturer established a Pregnancy Registry for VARIVAX (telephone number 1-800- 986-8999) to collect data on the pregnancy outcomes of inadvertently immunized women. There were 701 reports of inadvertent exposure to the vaccine from 3 months before or at any time during the pregnancy between March 17, 1995 and March 16, 2000; 362 prospective and 21 retrospective reports were available for analysis. There was no evidence of the congenital varicella syndrome in newborns, including those delivered to seronegative women who received the vaccine during the first or second trimester of pregnancy (614). Seronegative women receiving postpartum varicella vaccination have been shown not to shed the vaccine virus in their breast milk when samples were tested by PCR assays (615).

Screening of pregnant women for varicella susceptibility is not recommended at the present time. Some obstetricians routinely screen their gravid patients who have negative or uncertain histories of past varicella infections, but this approach is felt not to be cost effective (616). One cost-effectiveness analysis concluded that serologic testing of women without prior history of chickenpox, if coupled with postpartum vaccination of susceptibles, could prevent about 43% of adult varicella and at a reasonable cost to the health care system (617). These analyses notwithstanding, the varicella vaccine has already had a major impact on the epidemiology of VZV infections in the United States, and this will inevitably modify our current thinking about the management of this problem in pregnant women and their infants.

Other Herpesvirus Infections

Epstein-Barr Virus

Primary Epstein-Barr virus (EBV) infections during pregnancy are rare because $\geq 95\%$ of adults have serologic evidence of past infection. Estimates place the risk at 0.0% to 0.2% (10). However, the frequency of primary EBV infection was found to be 7% among 46 pregnant women who were susceptible early in gestation (618). Reactivation of latent EBV is common during pregnancy (10).

The majority of primary EBV-infected individuals are asymptomatic. Infectious mononucleosis is the most common clinical manifestation of infection.

Complications such as meningoencephalitis, Guillain-Barré syndrome, airway obstruction, or rupture of the spleen are infrequent, but can be severe (10).

Diagnosis typically is made with serologic tests. Heterophile antibodies are usually present in most women at onset of symptoms, and decline to undetectable levels within 3 months. Persistence of heterophile antibodies for as long as one year can occur. The measurement of antibodies to the EBV viral capsid antigens (VCA), early antigen (EA), and EBV nuclear antigen (EBNA) can be used to make a specific diagnosis of primary EBV infection. EBV-VCA IgM is usually present at onset of symptoms. It is rarely detected with EBV reactivations. EBV-VCA IgG is generally present early and four-fold titer rises are detected in 20% or fewer patients. Anti-EA is found in 80% of patients with primary EBV, but it can also be detected with virus reactivations. IgG antibodies to EBNA usually appear after 3 or 4 weeks, and remain detectable indefinitely (619).

Transplacental transmission of EBV is rare. Maternal oropharyngeal EBV shedding may increase the risk of maternal-fetal transmission of HIV-1 (620). EBV acquisition during passage through the birth canal is theoretically possible because cervical shedding of this virus has been demonstrated (10). A study of 100 healthy women showed that 46% of women shed EBV in their breast milk, and that the shedding was highest at 3 to 12 weeks postpartum (621).

A variety of congenital defects have been described in the offspring of women with documented EBV infection or infectious mononucleosis. Abnormalities included low birth weight, micrognathia, congenital heart disease, biliary atresia, cataract, microphthalmia, hip dysplasia, and central nervous system malformations. However, there is no specific pattern to these findings and they likely represent chance occurrences (10).

Human Herpesvirus 6

Human herpesvirus 6 (HHV-6) is an enveloped double-stranded DNA virus that is separated into two variants (HHV-6A and HHV-6B) on the basis of differing genetic, immunologic, and biologic properties (622). Most children become infected by two years of age, but seropositivity decreases with age. Transmission is believed to be by

P.1301

infected oral secretions, but the virus is also found in the cervixes of some pregnant women in late gestation (622,623).

HHV-6 antibodies were found in 100% of 569 pregnant and nonpregnant women attending a family planning clinic in San Antonio, Texas. HHV-6 genital shedding was found in 2% of the pregnant women, and 3.7% of those who were not pregnant (624). A study of pregnant women in Japan similarly found a 100% prevalence of IgG antibodies to HHV-6, and 1.6% of women had significant increases in these titers suggesting virus reactivation. HHV-6 DNA was found in the genital tract of 3.7% of pregnant women in the first trimester and in 12.2% of the same women in their third trimester (625). Serosurveys of other countries show that the prevalence of HHV-6 antibodies can vary from a low of 50% in Morocco, to 76% in France, and 90% in Ecuador and Congo (626).

Roseola infantum is the clinical illness most often associated with HHV-6 (usually HHV-6B) in children, but most symptomatic HHV-6 infections in infants are non-specific febrile illnesses. Primary infection in healthy adults is rare and may manifest with rash, hepatitis, lymphadenopathy, or encephalitis. In immunosuppressed individuals, especially posttransplantation, HHV-6 (usually HHV-6A) reactivates and is associated with pneumonitis and encephalitis. A variety of unproven disease associations such as Bell's palsy, drug-induced hypersensitivity syndrome, multiple sclerosis, sarcoidosis, and lymphoproliferative disorders have been described for HHV-6 (622).

Diagnosis of HHV-6 is by culture of peripheral blood mononuclear cells or, preferably, by PCR methods. Specimens can include blood cells and other fluids such as CSF. Because of the potential for virus reactivations, the detection of HHV-6 DNA by PCR is only 57% predictive of a primary infection. However, absence of HHV-6 IgG antibodies or the demonstration of a high viral load are strongly suggestive of a primary infection. Positive HHV-6 IgM measurements are suggestive of a primary infection but are subject to cross-reactions with other herpesviruses and can be detected with reactivations. Fourfold rises in HHV-6 IgG titers are also suggestive of a primary infection, but this is more likely to be seen in infants than in adults. Immunohistochemical tests allow the detection of HHV-6 antigens in formalin-fixed, paraffin-embedded tissues (622). HHV-6 antibodies are readily passed through the placenta, and paired mother-infant samples show higher virus titers in cord blood than maternal serum (627).

Treatment of HHV-6 infections is reserved for immunocompromised patients and

otherwise healthy individuals with serious complications. Cidofovir is the most active drug against this virus, but ganciclovir is the drug for which there is more clinical experience. Foscarnet is also active against HHV-6, but acyclovir is not. There is no experience with antiviral therapy of pregnant women with serious HHV-6 infections (622).

Maternal-fetal transmission of HHV-6 can occur. HHV-6 antigens were detected in spontaneously aborted villous tissues of 2 of 3 women who were positive for HHV-6 IgM (628). Another study from Japan reported on the detection of HHV-6 DNA in 2 of 8 fetuses with hydrops fetalis but in none of 10 non-hydrotic dead fetuses (629). Dunne and Demmler found that 2 of 799 cord blood sera were HHV-6 IgM positive but DNA negative by PCR (630). By contrast, a study of 110 pregnant women in Japan showed that women who had HHV-6 DNA (none of whom had a positive HHV-6 culture result) in vaginal samples collected early in pregnancy did not transmit the virus to their offspring. Infant blood and saliva was collected at birth and again at one month, and all samples were negative by PCR (631). In another study, 7% of HIV-negative infants born to HIV-infected women had HHV-6 DNA in their blood during the first month of life (632). A study of cord blood specimens of 305 babies from Germany found that 1.6% contained HHV-6 DNA suggesting intrauterine infection (633).

Neonatal HHV-6 infections may include severe hepatitis, thrombocytopenia, seizures, aseptic meningitis, fever, or rash (634,635,636). One newborn with non-febrile seizures was found to have HHV-6B in the CSF; neurologic sequelae such as psychomotor retardation, strabismus, and hypertonia were found at 18 months of age (636). It is not known whether treatment with ganciclovir or other antiviral agents is of any benefit.

Human Herpesvirus 7

Like HHV-6, human herpesvirus 7 (HHV-7) is ubiquitous and can be recovered from the blood and saliva of most adults (637,638,639). It has been associated with fever, roseola infantum, seizures, hemiplegia, aseptic meningitis, and hepatitis (639,640,641,642).

Antibodies to HHV-7 are readily transferred through the placenta, and higher titers are found in cord blood than in maternal sera (627). A study of 72 cervical swabs from pregnant women found 2.7% to be positive for HHV-7 DNA (623). In another study, 2.4% of Japanese women had significant increases in HHV-7 antibody titers (but no HHV-7 IgM) during their pregnancies. HHV-7 DNA was detected in the genital tracts of 2.7% and 9.6% of these women during their first and third trimesters, respectively (625). The clinical relevance of these observations to newborns is not known.

Human Herpesvirus 8

Human herpesvirus 8 (HHV-8), also known as Kaposi sarcoma-associated herpesvirus, has been associated with several tumors including Kaposi sarcoma, multicentric Castleman disease, and one type of non-Hodgkin's lymphoma. In the few known examples of primary HHV-8 infection, clinical presentations included non-specific febrile illnesses, maculopapular rash, splenomegaly, cervical lymphadenopathy, and bone marrow failure in a kidney transplant recipient (643).

Seroprevalence studies from North America show that 0.0% to 20% of the general population have antibodies to

P.1302

HHV-8, but this is much higher in geographic regions where Kaposi sarcoma is common (643). The seroprevalence of HHV-8 among HIV-infected pregnant women from Italy, Haiti, and Zambia is 39%, 10%, and 51%, respectively (644,645,646). It is only 11% among Italian women undergoing amniocentesis for genetic screening (647).

It is unclear how HHV-8 is transmitted. Sexual contact appears to be the primary mode in North America, but horizontal transmission is frequent in developing countries (643). It is believed that horizontal spread occurs by infected saliva. Bloodborne transmission is possible, but this is less efficient than for HIV, HCV, or HBV (648). Vertical spread from infected mothers to their offspring is rare (647,649,650). Two of 12 Zambian infants infected with HHV-8 during the first year of life had HHV-8 DNA in their peripheral blood mononuclear cells at birth (650). Preliminary data suggest that there may be a higher risk of abortion among women with high HHV-8 antibody titers (651). The clinical relevance of intrauterine, perinatal, or postnatal HHV-8 infection remains to be elucidated.

Parvovirus B19 Infections

Human parvovirus B19 was discovered fortuitously in the mid-1970s by British scientists evaluating new laboratory methods for the improved detection of HBsAg in blood donor sera (652). B19 has since been etiologically linked to a variety of conditions, including erythema infectiosum (i.e., fifth disease), aplastic crises in sickle-cell anemia and other hemolytic diseases, chronic anemia in immunocompromised patients, acute arthritis, and fetal hydrops. Less commonly recognized B19-related conditions are myocarditis, hepatitis, aseptic meningitis, and virus-associated hemophagocytosis (653).

B19 is a small, nonenveloped, single-stranded DNA virus. Despite its many genotypes, only one B19 antigenic type is currently recognized. The B19 genome encodes two structural proteins (VP1 and VP2) and one nonstructural protein. The virus does not grow in conventional cell lines, but it can best be propagated in erythroid progenitor cells (653).

B19 causes a lytic infection of human erythroid progenitor cells. The erythroid tropism of B19 is as a result of the tissue distribution of globoside (erythrocyte P antigen), its major cellular receptor. Globoside is a neutral glycopospholipid of red blood cell membranes. Persons who do not have P on their erythrocytes (i.e., p phenotype) are naturally resistant to infection with B19. The frequency of the p phenotype is 1 per 200,000 persons (654). Globoside also can be found on megakaryocytes, endothelial cells, placenta, fetal liver, and heart cells. B19 binds not only to globoside but also to several tissue-specific neutral glycopospholipids, such as those found in granulocytes, kidneys, liver, and bowel tissue (655).

Cessation of erythrocyte production, manifesting as reticulocytopenia, does not cause symptomatic anemia in otherwise healthy persons. However, patients who have reduced erythrocyte lifespans (e.g., sickle-cell anemia, thalassemia major) may develop transient aplastic crises. The nonstructural protein of B19 is cytotoxic and causes the death of erythroid progenitors. Patients with congenital or acquired immunodeficiency disorders may fail to clear the acute infection; a persistent B19 infection ensues, which results in chronic anemia (653).

Establishment of a persistent infection sometimes can occur in persons without recognized immune deficiency disorders; a qualitatively or quantitatively aberrant immune response is thought to be responsible for this phenomenon (656). The rash and arthropathy seen in B19 infections are immune-mediated manifestations and are not directly related to the lytic infection of erythrocyte progenitor cells (653).

Maternal Infection

Serologic surveys have found that 30% to 60% of adults in the United States have serum antibodies against B19, indicating prior infection (657,658). Surveys of pregnant women in other countries show B19 seroprevalence rates of 35% in Barcelona, Spain, 40% in Japan, 53% in Kuwait, 64% in Melbourne, Australia, 65% in Denmark, and 81% in Stockholm, Sweden (659,660,661,662,663,664). The virus is transmitted primarily by B19-infected respiratory secretions. Transmission through transfusions of blood or blood products such as pooled factor VIII or IX concentrates is uncommon. B19 is found in the blood of 1 in 20,000 to 1 in 50,000 donors, but the incidence can be as high as 1 in 260 during epidemic years (665). To reduce the risk of iatrogenic transmission, major producers of plasma derivatives have voluntarily started quantitative measurements of B19 DNA to keep it under 10,000 genome copies per mL in the manufacturing pools (653,665). The incubation period of parvovirus B19 is 4 to 14 days, but it can be as long as 21 days. Infections are more common in late winter and spring in temperate climates, and epidemics usually occur every 4 or 5 years (666).

About 1% of susceptible pregnant women without known exposure to B19-infected persons seroconvert each year in the United States. Rates of 1.5% to 6.8% for acute gestational B19 infections have been reported from other countries (659-661,667). Higher rates are encountered during epidemic periods (661). During a large erythema infectiosum outbreak in Connecticut, pregnant women were tested for serologic evidence of recent B19 infection. Infection rates among exposed susceptible pregnant women were 16% for school teachers, 9% for day care workers, and 9% for homemakers (668). Attack rates of 36% to 38% were documented among susceptible nursing staff who were exposed to patients with sickle-cell anemia and aplastic crisis at a children's hospital (669). However, another study of health care workers under similar circumstances showed no transmission of B19 from patients to susceptible staff members (670).

A study of 30,946 pregnant women from three regions in Denmark conducted between November 1992 and June

P.1303

1994 found that the presence of B19 IgG correlated with a woman's number of siblings, having a sibling close in age (within 2 years), number of children, and occupational exposure to children. The risk of seroconversion to B19 during pregnancy increased by threefold to sevenfold depending on the number of children at home, and having children 6 to 7 years of age was associated with the highest rate of gestational B19 infection (661).

Half or more of acute B19 infections of adults are subclinical (653,666). Erythema infectiosum is the most commonly identified B19-related condition. This illness is seen primarily in children, and its most characteristic feature is a facial exanthem (i.e., slapped-cheek appearance). The rash is lacy or reticulated, spreads to the trunk and extremities, and fades within 2 weeks. Recrudescence of the rash is observed with stimuli such as temperature changes, sunlight, or emotional stress.

Pruritic, petechial, purpuric, vesicular, or erythema multiforme types of rashes are possible with acute B19 infection (653,666,671,672).

In addition to erythema infectiosum, acute B19 infections in otherwise healthy adults can manifest with influenza-type illnesses and symmetric polyarthropathies (e.g., polyarthralgias, polyarthritides). B19-associated joint disease is more common in women, affecting 50% to 80% of those with symptoms (673). The hands are most often involved, but pain, stiffness, and swelling can also involve the wrists, ankles, and knees (653,666). Rheumatoid factor may be positive transiently; therefore the illness could be misdiagnosed as early rheumatoid arthritis (674). B19 infections in compromised patients can result in transient aplastic crises, chronic anemia, and viral-induced hemophagocytic syndrome (653).

A diagnosis of acute or recent B19 infection can be made by detecting B19-specific IgM using enzyme immunoassays. These antibodies are present in the serum of more than 90% of patients by the third day of illness. B19-specific IgM can persist for 4 months or longer in more than 75% of patients, rendering the distinction between acute or recent B19 infection on serologic grounds alone difficult (675). B19-specific IgG usually is formed by the end of the first week of the illness, and it persists for life. The detection of B19-specific IgG antibodies with negative IgM test results is considered evidence of past infection and, probably, immunity to B19 reinfections. There are reports of rare instances of B19 reinfection of women known to be previously seropositive for this virus that have led to hydrops fetalis and fetal demise (676).

B19 DNA can be detected in serum and tissues by nucleic acid hybridization techniques and PCR assays (653). B19 DNA can be found in serum for 2 to 6 months after the onset of illness, but it has persisted for years in a few patients (675,677). B19 antigens can be detected by immunofluorescence, immunoperoxidase, or enzyme immunoassays, but these methods are not widely available (678).

There is no specific treatment for B19-associated illnesses. Immunosuppressed patients with chronic anemia secondary to persistent B19 infections have benefited from the infusion of commercially available intravenous immune globulins (653). Scant evidence suggests that high doses of intravenous immune globulins may be beneficial in preeclamptic B19-infected women with hydropic fetuses (679). Patients with erythema infectiosum are not contagious to others after the rash becomes evident, but those with aplastic crises continue shedding their viruses during the first few days of their hospitalization and require contact isolation.

Fetal Infection

Maternal B19 infection during pregnancy can have an adverse effect on pregnancy outcome, but most fetuses escape infection. Fetal infection can lead to hydrops

fetalis or death. B19 is responsible for 8% to 18% of nonimmune hydrops cases (657,663,680-682). Immunohistochemical analysis of placental villous trophoblast cells from women with B19 infection and a poor fetal outcome shows increased apoptosis within these cells (683). The histo-pathology of fetal B19 infection consists principally of infected erythroblasts with eosinophilic intranuclear inclusions, which are found mostly in the liver, spleen, and bone marrow (680,684).

Gestational B19 infections are associated with a less than 10% risk of pregnancy loss from spontaneous abortion, stillbirth, or delivery of a hydropic infant. In a British prospective study of 190 pregnant women found to be positive for B19-specific IgM during the period 1985 to 1988, the B19-related fetal death rate was estimated at 9% (685). A follow-up study of 274 pregnant women diagnosed between 1992 and 1995 again found the excess rate of B19-related fetal loss to be about 9%, but this risk was confined to the first 20 weeks of gestation. The risk of fetal hydrops in this study was 2.9%, with a 95% CI of 1.2% to 5.9% (686). More recent data from Sweden suggest that B19 may be responsible for 14% and 7.5% of intrauterine fetal deaths occurring at more than or equal to 22 weeks of gestation and the third trimester, respectively (687,688). Most infants with B19-related intrauterine fetal death do not manifest with hydrops fetalis (689). In a case control study conducted in the United States, it was shown that B19 was not a common cause of fetal death in the general population (690).

B19 suppresses fetal bone marrow erythrocyte production, leading to chronic anemia. This is not well tolerated by the fetus because of its rapidly expanding cell volume and its immature immune system, which fails to rapidly contain the B19 infection. Congestive heart failure ensues, usually secondary to the severe anemia. Direct infection of cardiac muscles by B19 can occur and may contribute to cardiac dysfunction (691,692,693). Using transmission electron microscopy, O'Malley and colleagues were able to demonstrate the presence of intranuclear virions in erythroid precursor cells and in cardiac myocytes of three fetuses with B19-related fatal hydrops fetalis (693).

Koch and colleagues (694) reported on 43 pregnant women with primary B19 infection who were followed to

P.1304

delivery. None of the infants was hydropic. Twenty-two (51%) of the 43 infants had evidence of congenital infection as determined by finding B19 DNA, B19-specific IgM, or B19-specific IgA; one infant tested negative at birth but became positive on all three assays at 6 weeks of age. A 20% rate of intrauterine infection among asymptomatic newborns was noted by Miller and co-workers (686). A study from Japan found an intrauterine B19 transmission rate of about 23% among 57 mother-infant pairs, about two-thirds of whom were asymptomatic (695). Thus, intrauterine B19 infection after primary B19 infection in the mother occurs commonly, but serious complications such as fetal hydrops or stillbirth are

infrequent. Congenital anemia and transient erythroblastopenia of the newborn are uncommon manifestations of intrauterine B19 infection (696,697). A few reports of twin pregnancies complicated by maternal B19 infection indicate that it is possible for one fetus to be severely affected by the virus although the other fetus can remain asymptomatic or escape infection altogether (698,699).

Congenital malformations after intrauterine B19 infection rarely have been described, and they may represent chance occurrences rather than a true teratogenic effect of B19. Hartwig and colleagues (700) described a 9-week-old embryo whose tissues were positive for B19 DNA and who had abnormalities of the eyes and damage to skeletal and smooth muscles. Rodis and associates (701) described an electively terminated pregnancy in which the B19-infected fetus had anencephaly. Tiessen and co-workers (702) found B19 DNA in several tissues by PCR in an aborted fetus with cleft lip and palate, micrognathia, webbed joints, and multifocal degenerative changes of skeletal and smooth muscles. Katz and colleagues (703) described two infants with congenital malformations after maternal B19 infection. One infant had myocardial infarction, hepatic and splenic calcifications, and mild hydrocephalus, whereas the second infant had moderate hydrocephalus with dysplasia of the cerebral cortex and glial overgrowth. If B19 were a true teratogen, the associated risk would have to be very small. One case report described a hydropic fetus that died at 24 weeks of gestation after his mother had developed primary B19 infection (704). The fetus had a flat nose and low implanted deformed ears. On detailed examination, these dysmorphic features were found to be as a result of a partial trisomy 3q and a partial monosomy 11q resulting from a balanced translocation between chromosomes 3 and 11 in the mother. This report suggests that some of the rare congenital malformations noted in the offspring of B19-infected women may be related to small chromosomal abnormalities that can be missed unless a careful evaluation is undertaken. Some infants without obvious dysmorphic features had ileal stenosis or atresia with resultant meconium peritonitis after maternal B19 infection (698, 705). Neuropathologic abnormalities consisting of perivascular calcifications and B19-positive multinucleated giant cells were noted in the cerebral white matter of a fetus at postmortem examination (706).

The diagnosis of intrauterine B19 infection in a newly born infant is difficult and rests on detection of B19-specific IgM in serum or B19 DNA in the fetal blood or tissues. Parvovirus particles can be observed in tissues by electron microscopy (682,707-709).

Management of hydropic newborns is supportive and often includes packed erythrocyte transfusions. There are no recognized long-term sequelae for healthy infants born to mothers with gestational B19 infection (686,710). Infants with B19-related hydrops fetalis who recover after treatment with intrauterine transfusion of packed red blood cells do not seem to be at risk for persistent B19 infection, joint problems, or neurodevelopmental delay (711,712). One infant who

developed hydrops fetalis at 22 weeks of gestation, with spontaneous resolution by 26 weeks, manifested with angioedema of the face, trunk, and extremities within hours of birth and this faded by the fifth day of life (713).

Prevention

Pregnant women who sustain a significant exposure to a B19-associated illness at home (e.g., erythema infectiosum in a child) and whose B19 antibody status is unknown can be informed that their overall risk of fetal death is at most 2.5%. This figure can be arrived at by multiplying the rate of susceptibility (about 50%), the rate at which exposed susceptible persons acquire B19 infection (maximum of 50%), and the estimated rate of death in documented infection (9%). Had the exposure taken place in a school or day care setting, the risk would decline to less than 1.5%.

Some investigators have suggested the use of intravenous gammaglobulin for postexposure prophylaxis of B19-susceptible pregnant women (666,714). Commercial intravenous gammaglobulin preparations contain anti-B19 IgG antibodies, and they have been shown to be helpful in the treatment of immunosuppressed patients with B19-induced chronic anemia. There are no data to support or refute the use of IGIV for the prevention or amelioration of B19 infection.

If acute or recent B19 infection is confirmed in the pregnant woman by a positive B19-specific IgM assay, serial ultrasound examinations should be performed for the detection of early signs indicative of fetal hydrops or, rarely, meconium peritonitis (698,705,715). Maternal serum alpha-fetoprotein elevations have been observed in pregnancies with B19-related adverse fetal outcomes such as hydrops, but this has been an inconsistent finding (716,717).

Published experience suggests that the prenatal diagnosis of fetal B19 infection is possible and accurate (718- 727). B19 can be demonstrated in fetal blood by electron microscopy, molecular biological techniques, or detection of B19-specific IgM antibodies. Török and colleagues (721) used a PCR assay to detect B19 DNA in amniotic fluid and fetal blood. Fifteen mothers who were positive for B19-specific IgM were evaluated. Eight of 15 fetuses were positive for B19 DNA only, and the other seven were positive for B19 DNA and B19-specific IgM. Nine (60%) fetuses

P.1305

had hydrops. Ten infants were born healthy, including four found to have hydrops at 17 to 23 weeks of gestation, which resolved without specific intervention. PCR detected B19 DNA in the sera of 20% of mothers with negative B19-specific IgM assay results, with or without B19-specific IgG; one-half of the fetal specimens corresponding to this group of mothers were B19 DNA positive by PCR (721).

Zerbini and associates (724) studied 18 fetuses with B19-related hydrops fetalis and could detect B19 DNA by nested PCR in nine maternal sera. The less sensitive dot blot hybridization assay failed to detect B19 DNA in any of these specimens. For the 18 hydropic fetuses, B19 DNA was detected in blood obtained at cordocentesis in 62% by PCR and 40% by dot blot hybridization. However, 100% of cell smears prepared from fetal blood were positive for B19 DNA using in situ hybridization. In contrast, only 15% of fetal blood samples were positive for B19-specific IgM. When amniotic fluid was tested for B19 DNA, 83% were found to be positive by PCR, 20% by dot blot hybridization, and 70% by in situ hybridization (724). Thus, a combination of virologic and serologic tests may be needed to ensure an accurate diagnosis of intrauterine B19 infection.

B19 DNA can be detected in chorionic villus samples of some women (726). One study suggested that viral DNA levels are generally higher in the fetus than the mother's blood (727).

Some B19-infected pregnant women may remain negative for B19-specific IgM and IgG antibodies, despite the detection of B19 particles in serum and saliva using electron microscopy or the detection of B19 DNA using PCR or other techniques (721,728). B19 infection of their newborns may or may not be symptomatic.

Fetal therapy with intrauterine blood transfusions has been attempted in many infants, and digitalization in a few (657,711,712,718-720,729-734). The indications for intrauterine transfusion are not well defined (666). The degree of fetal anemia can be determined by cordocentesis (732,733). A recent report suggested that noninvasive Doppler ultrasonography showing increased fetal middle cerebral artery peak systolic velocity could predict fetal anemia with good accuracy (735). Fetal hydrops can resolve spontaneously before birth in as many as one-third of patients without specific intervention. These infants typically remain well after birth and during several months of follow-up (721,733,736-739). This indicates that fetal hydrops is not uniformly fatal if not treated and that some fetuses are capable of eventually resolving their B19 infection and reversing the observed pathophysiologic abnormalities. Intrauterine transfusions of packed red blood cells are typically administered into the umbilical vein, but intraperitoneal blood transfusions have been suggested as an alternative (732,734).

Routine screening of pregnant women for B19 infection is not recommended at present (666,740). Candidate B19 vaccines are in development, but none are commercially available (653).

Hepatitis Virus Infections

Hepatitis A

Hepatitis A virus (HAV) is a small, nonenveloped RNA virus that belongs to the picornavirus family. There are several genotypes of HAV, but only one known serotype. Its incubation period averages four weeks, with a range of 15 to 50 days. HAV replicates in the liver, and then is transported through the biliary tree and shed in the stool. Fecal excretion of the virus begins 1 to 2 weeks before the onset of the illness, and continues for at least 1 week after that. Infants and children can shed HAV in the stools for several months (741,742).

HAV infections are very common in early life in developing countries. In the United States, there were an estimated 90,000 persons with symptomatic hepatitis A and another 90,000 persons with subclinical infection in 1997. A third of reported cases are in children less than 15 years of age. There are geographic variations within the United States with regards to disease incidence, with higher rates in western states such as Arizona, Alaska, Oregon, and New Mexico. HAV infection rates are also highest for American Indians and Alaskan Natives, and lowest for Asian Americans (742).

Transmission of HAV is primarily by person-to-person contact through fecal contamination and oral ingestion of the virus during communitywide outbreaks (742). The virus is highly communicable. Approximately 16% to 30% of an inoculum of HAV can be recovered from infected hands after 4 hours (743). The most commonly reported source of HAV infection in the United States is household or sexual contact with a person with hepatitis A in 12% to 26% of instances. Other sources of exposure are day care attendance or employment, international travel, food or waterborne outbreaks, and injecting or noninjecting drug use (742). A study from Israel found that certain occupations such as yeshiva students, day care center and kindergarten staff, food industry workers, teachers, physicians, and dentists were at increased risk of hepatitis A infection (744).

Neonatal intensive care unit outbreaks of hepatitis A have been described (745,746,747,748). The initial infection in some outbreaks occurred through transfusion of neonates with blood or fresh frozen plasma from donors with hepatitis A viremia during the prodromal phase of their illness (746,747,748). In one nursery outbreak, 20% of infants, 24% of nurses, and several nonnursing staff and household contacts were affected. The study found that having long fingernails, not wearing gloves for certain procedures, smoking, and drinking beverages in the nursery facilitated direct hand-to-mouth contact (747). Other risk factors for spread of hepatitis A to new infants and nursery personnel includes asymptomatic infection, prolonged fecal virus shedding, frequent contact with

soiled diapers, and breaks in infection control measures.

Most children younger than 6 years of age have asymptomatic or anicteric HAV infections, whereas most adults have symptomatic disease (742). The typical clinical illness seen

P.1306

in over 80% of symptomatic individuals begins abruptly with fever, malaise, headache, anorexia, nausea, vomiting, and diarrhea; dark urine, clay-colored stool, and jaundice appear a week or two later (741,742). Other disease forms include relapsing hepatitis A, cholestatic hepatitis A, and fulminant hepatitis A. Extrahepatic manifestation such as vasculitis, arthritis, hemolytic anemia, or cryoglobulinemia are infrequent (741). In contrast to hepatitis A and hepatitis B, there is no chronic carrier state for HAV. About 100 persons in the United States die each year as a result of acute liver failure due to hepatitis A (742).

Approximately 33% to 38% of the US population are positive for HAV IgG (741,749). The incidence of acute hepatitis A in pregnancy is 1:1000 or less. Pregnant women are not more susceptible to HAV, nor do they have a worse clinical outcome, than nonpregnant women (749).

Serologic testing is needed to establish a diagnosis of acute hepatitis A. IgM antibodies to HAV are found 5 to 10 days before the onset of symptoms and for 3 to 6 months after that. HAV IgM is measurable for a longer time in patients with symptomatic hepatitis A than in those with asymptomatic infection (750). HAV RNA can be detected by PCR in serum, stool, or other body fluids during the acute phase of infection, but this test is rarely needed and is not readily available (741,742).

Treatment of hepatitis A is supportive. Management of infection usually includes bed rest, nutrition, avoidance of alcohol and hepatotoxic medications (741).

A number of published case reports suggest that intrauterine and perinatal transmission of HAV does occur, with resultant symptomatic disease in the neonate (751- 756). In some of these reports, the mothers developed hepatitis A shortly before or immediately after delivery (751,752,753). Other reports describe women with acute hepatitis A several weeks before parturition. One mother developed hepatitis A at 20 weeks of gestation; an abdominal ultrasound at 27 weeks of gestation showed polyhydramnios and fetal ascites. Cordocentesis allowed the detection of HAV IgM in fetal blood. Meconium peritonitis subsequently developed at 35 weeks of gestation, which required surgical intervention after delivery (754). In another report, a mother developed hepatitis A at week 13 of gestation and her fetus was noted to have ascites at 20 weeks; meconium peritonitis was found at 33 weeks of gestation. The infant was delivered at 35 weeks gestation and a perforated distal ileum was found (755). Another mother whose hepatitis A occurred during her fourth month of pregnancy had protracted jaundice until she delivered at 36 weeks of gestation. The neonate

was small for age and subsequently developed acute hepatitis A infection at 4 weeks of age. HAV RNA was detected in the mother's serum obtained at 4 months of pregnancy and the infant's serum at the age of 4 weeks (756).

The prevention of hepatitis A can be accomplished by both passive and active immunization. Intramuscular immune globulin (IGIM) at a dose of 0.02 mL/kg given within 2 weeks of last exposure confers greater than 85% protection. Pregnancy is not a contraindication to IGIM administration, but only thimerosal-free preparations should be used. Two inactivated hepatitis A vaccines are available in the United States, and one combined inactivated hepatitis A and hepatitis B vaccine. Although the hepatitis A vaccines are not approved for use during pregnancy, the theoretical risk to the fetus should be weighed against the risk of hepatitis A to susceptible women at high risk of exposure to HAV (742). Hepatitis A vaccine is immunogenic in infants, but it is currently approved for use in persons 2 years of age or older. Placental transfer of HAV IgG occurs in both term and preterm newborns, and its presence has been shown to lower the antibody response to the vaccine in these infants (757,758).

Hepatitis B

HBV afflicts nearly 335,000 persons in the United States each year, about 5% of whom become chronic carriers of the virus (759,760). Estimates place the number of chronic, infectious HBV carriers in the United States at more than 1.25 million people (759). Globally, a third of the world population (about 2 billion) have been infected with HBV. The number of chronic HBV carriers worldwide is greater than 400 million, three-quarters of whom are Chinese, according to estimates by the World Health Organization (761). As many as 1 million people die each year from HBV-related acute and chronic hepatic disease (762). More than one-fourth of all carriers develop HBV-related chronic active hepatitis, liver cirrhosis, or hepatocellular carcinoma (759). Women who are chronic carriers of this virus can transmit HBV to their offspring during pregnancy; as many as 90% of perinatally infected infants become chronic carriers themselves (759).

The complete HBV is known as the Dane particle and consists of an outer lipid-containing envelope and an inner core or nucleocapsid. On the surface of the outer coat is the hepatitis B surface antigen (HBsAg), an antigenically complex glycoprotein. HBsAg has many antigenic epitopes that permit the identification of several HBV subtypes; the subtyping scheme is valuable as an epidemiologic tool, but it has no correlation with disease severity. The surface envelope contains three proteins (major, middle, and large S proteins) coded for by the HBV DNA genome. Variations in the major protein account for the subtype determinants, and the middle and large proteins are implicated in receptor-mediated virus uptake by hepatocytes (762).

The virus inner core consists of hepatitis B core antigen (HBcAg), hepatitis B e

antigen (HBeAg), hepatitis B x antigen (HBxAg), a partially double-stranded DNA molecule, a DNA-dependent DNA polymerase enzyme with reverse transcription activity, and a protein kinase. HBcAg is found primarily in the nuclei of infected hepatocytes. In serum, HBcAg is found only as a component of circulating Dane particles, but it is never found in free form. HBeAg is a prematurely terminated polypeptide product of the same gene that codes for HBcAg; its presence in serum indicates infectivity. The function of HBeAg is not known. HBxAg directly and indirectly

P.1307

affects host and viral gene expression, and the X protein is essential for *in vivo* replication and spread of HBV. HBV DNA is a partially double-stranded DNA, and HBV DNA polymerase repairs the single-stranded HBV DNA region to form a complete double-stranded molecule (762,763).

With very sensitive assays, HBsAg can be detected in the blood within 1 to 2 weeks of exposure to HBV. However, clinical disease usually occurs 1 to 3 months, and occasionally 6 months, after exposure. HBeAg can be detected late in the incubation period, usually coinciding with or within days of HBsAg appearance. HBV DNA polymerase and HBV DNA are measurable at this stage and generally peak by the latter part of the incubation period. Viral titers during the acute stage of the infection can reach 10^9 to 10^{10} virions/mL. In patients who recover, HBsAg usually can no longer be detected at about the time of clinical resolution (764).

The earliest antibodies to appear are those directed against HBcAg (anti-HBc), typically 2 to 4 weeks after HBsAg is first detected. Anti-HBc titers increase during the acute stage of infection and persist for many years. Antibodies to HBeAg (anti-HBe) appear immediately after or within several weeks of HBeAg clearance and usually while HBsAg is still present. A window period that occasionally can be as long as 20 weeks follows HBsAg clearance from the circulation, during which neither HBsAg nor anti-HBs are detectable. However, specific IgM and IgG anti-HBc antibodies usually are present. The patient is contagious during this period. After anti-HBs antibodies become measurable, their titers continue to increase for approximately 6 to 12 months (762,764). Low levels of HBV DNA may persist in the blood for years, despite the appearance of anti-HBs (763). HBV DNA can be found in liver biopsies of patients with self-limited hepatitis B, including those with negative serum HBV assays (765). Anti-HBs antibodies persist for life and protect against future HBV reinfections. Antibodies to HBxAg (anti-HBx) can be detected in only 17% of patients with acute HBV infection and usually appear 3 to 4 weeks after onset of clinical symptoms; their clinical significance is not yet defined (766).

Patients who continue to have detectable serum HBsAg for 20 weeks or longer, or HBeAg for 10 weeks or longer, are likely to become chronic HBsAg carriers. Their serum anti-HBc titers usually are high, and IgM anti-HBc tends to persist for a long time. Approximately 25% to 50% of chronic carriers are HBeAg positive, and the remainder have anti-HBe. Persons who are positive for HBeAg, HBV DNA

polymerase, or HBV DNA are highly contagious. Chronically infected patients clear HBV particles from their plasma with a half-life of about 1 day, and about 10^{11} virus particles are released daily into the periphery from HBV-infected cells (767). Among persistently infected patients, about 5% to 10% convert each year from being HBeAg-positive to having anti-HBe (763). Over a period of about 10 years, more than 70% will clear HBeAg from their serum (768). Most chronic carriers remain HBV infected for life, but 1.5% to 2% of carriers spontaneously lose their HBsAg each year.

Young age is an important risk factor for developing the chronic carrier state; 70% to 90% of infected newborns become carriers, compared with 25% to 50% of children infected before their fifth birthday and 5% (range of <1%-12%) of adults. Other risk factors include a positive HIV-1 antibody status, hemodialysis, other immunodeficiencies, Down syndrome, and male gender (769). Virus-specific T cell responses in chronic carriers are attenuated in comparison to individuals who clear HBV after their acute infection (763). Reactivation of chronic HBV infection can occur during pregnancy, but this is rare (770).

There are several HBV genotypes (A to H), each with a characteristic geographic distribution and some differences in disease profiles (761). Naturally occurring HBV variants that are unable to produce HBeAg are recognized; these patients have high HBV DNA but no detectable HBeAg during the acute infection, and often have fulminant disease (771).

Clinical Manifestations

Most HBV infections are subclinical, particularly in children. Symptomatic infections can be mild and anicteric or be severe enough to produce encephalopathy, coagulopathy, and death. Fulminant hepatitis is more common in adults than in children and in those infected with certain mutant HBV strains or coinfecting with the hepatitis C or D viruses (762,772-774). Extrahepatic disease may manifest as a serum sickness-type illness in patients with acute infections, polyarteritis nodosa, membranous glomerulonephritis, infantile papular acrodermatitis (Gianotti-Crosti syndrome), or cryoglobulinemia (762,775).

Approximately two-thirds of chronic HBsAg carriers develop chronic persistent hepatitis. They usually are healthy but have persistent or recurrent serum transaminase elevations. The remaining third eventually develop chronic active hepatitis, a progressive disorder that ultimately results in postnecrotic liver cirrhosis. Primary hepatocellular carcinoma, a common malignant tumor in certain parts of the world such as southeast Asia, Japan, Greece, and Italy, may be as much as 100 to 400 times more common in HBsAg-positive individuals than in their HBsAg-negative counterparts (776). Patients positive for both HBsAg and HBeAg are at highest risk for developing hepatocellular carcinoma (777). Primary hepatocellular carcinoma develops after an average of 35 years of HBsAg

carriage; coexisting cirrhosis is found in 60% to 90%.

Most neonates and infants who acquire HBV from their mothers remain asymptomatic; those with symptoms typically have benign illnesses. Fulminant disease is rare. Most infected infants become chronic carriers and have a 25% or greater lifetime chance of dying of primary hepatocellular carcinoma or liver cirrhosis.

Modes of Transmission

HBsAg has been found in blood, blood products, urine, feces, bile, saliva, tears, sweat, semen, vaginal secretions, gastric contents of newborns, breast milk, cord blood, CSF, synovial fluid, and wound exudate (778). Many routes for

P.1308

HBV spread are possible, but the most significant are percutaneous or permucosal exposure to infected blood or body fluids during birth or sexual intercourse or by contaminated needles.

HBV-infected blood can enter the body through contaminated needles shared by drug users, if health care providers mistakenly puncture themselves, or if other persons reuse unsterilized devices in medical or dental offices, acupuncture clinics, or tattooing parlors. Contaminated blood can be introduced through mucous membranes, open wounds, or abrasions. Screening of blood and blood products for HBsAg has almost eradicated transfusion-acquired HBV infection.

HBV can spread to sexual partners of chronic HBsAg carriers or patients with acute hepatitis B. HBV infection is more likely in persons with multiple sex partners, more years of sexual activity, and histories of other sexually transmitted diseases. Heterosexual transmission now accounts for 25% of new HBV cases in the United States, a 38% increase from the early 1980s. It is the most important risk factor for women, with parenteral drug abuse in second place. Close, long-term contact with chronic carriers, as happens in households or institutions for the developmentally disabled, is a risk factor. Intrafamilial nonsexual transmission accounts for 2% of new HBV infections in the United States each year.

Transplanted organs are uncommon vehicles of HBV spread to susceptible recipients. About 30% to 40% of all patients have no identifiable risk factors (779).

Perinatal Epidemiology

About 0.2% of American Caucasians and 0.9% of African Americans are HBsAg-positive. The prevalence is notably higher in certain high-risk groups, such as immigrants from areas of high HBV endemicity (13%), Alaskan Natives or Pacific Islanders (5% to 15%), clients in institutions for the developmentally disabled (10% to 20%), users of illicit parenteral drugs (7%), household contacts of an

HBV carrier (3% to 6%), health care workers with frequent blood contact (1% to 2%), and heterosexuals with multiple partners (0.5%) (780).

The rate of vertical transmission from mother to infant hinges on several factors. For women with acute HBV infection, the risk is about 76% if infection occurs during the third trimester or shortly after delivery, but it is only about 10% if it takes place during the first or second trimester. For HBsAg carrier mothers, the risk of mother-to-infant transmission depends on their HBeAg/anti-HBe status. The rate is estimated to be 70% to 90% for those who are HBeAg-positive, 31% for those who are negative for HBeAg and anti-HBe, and 10% or less for those who are positive for anti-HBe. About one-third of HBsAg-positive pregnant women in the United States also are HBeAg positive. Other variables that enhance vertical transmission are high maternal HBsAg and anti-HBc titers and a high HBV DNA concentration (778,781). In one study of HBsAg-positive pregnant Taiwanese women, the odds ratio of having a persistently infected infant climbed from 1.0 to 147 as the maternal serum HBV DNA level increased from less than 0.005 to 1.4 ng/mL (782). HBsAg chronic carriers who are HBeAg-positive usually have higher HBV DNA levels than HBeAg-negative women (783). Carrier mothers can transmit HBV to infants born after sequential pregnancies.

Mother-to-infant transmission occurs during delivery in most cases through transplacental microhemorrhages or from ingestion of contaminated maternal secretions. Intrauterine infection is uncommon but may account for 5% to 15% of cases for HBeAg-positive mothers (784). However, a recent study of 59 HBsAg-positive mothers from China found evidence of intrauterine transmission in 40%. These investigators were able to find HBV DNA in 48% of amniotic fluid samples and 52% of vaginal samples, and could detect HBsAg and HBcAg in placentas from these mothers (785). Studies of placentas from HBsAg-positive women have found that HBV infection rates were not the same for all placental layers, and generally decreased from the maternal to the fetal side (785,786). The closer an infected placental cell layer is to the fetal side, the greater the likelihood of intrauterine HBV infection (786). Intrauterine HBV infection has been associated with the development of fetal ascites, abdominal calcifications, and meconium peritonitis in a few infants (787,788). HBsAg is found commonly in breast milk samples from carrier mothers, but no differences in antigenemia rates are found between breast-fed and bottle-fed infants born to infected mothers. There appears to be no added risk of HBV transmission to infants from breast milk, especially in those receiving appropriate immunoprophylaxis at birth (789).

Unimmunized infants who acquire HBV infection from their mothers usually have no detectable serum HBsAg until 1 to 4 months later. Passively acquired low levels of HBsAg may be detected in the peripheral blood of some neonates, and they do not necessarily imply HBV infection. Cord blood should not be used for HBsAg testing because it can be contaminated with maternal blood.

Immunoprophylaxis

Two preparations have been used for passive immunization against HBV: immune serum globulin and hepatitis B immunoglobulin (HBIG). Immune serum globulin has anti-HBs titers of 1:16 to 1:1,000. HBIG, a hyperimmunoglobulin product, has anti-HBs titers of 1:100,000 to 1:250,000. HBIG is prepared from plasma obtained from HIV and HCV antibody-negative donors with a high anti-HBs titer, and its administration does not interfere with the host's immune response to hepatitis B vaccines.

Plasma-derived and recombinant hepatitis B vaccines have been used for active immunization. The plasma-derived vaccine, Heptavax-B, is no longer distributed in the United States. Two recombinant hepatitis B vaccines are available: Recombivax HB and Engerix-B. These vaccines are prepared by insertion of a plasmid containing the HBsAg gene into common baker's yeast, followed by

P.1309

lysis of yeast cells after the intracellular production, assembly, and accumulation of HBsAg polypeptides. HBsAg is later separated from disrupted yeast cell components; less than 5% of the final product is yeast-derived protein.

Recombivax HB contains 10 mcg of HBsAg protein per milliliter (a 40 mcg/mL product is available for use in selected adults), and Engerix-B contains 20 mcg/mL (790). A hepatitis A and hepatitis B combined vaccine (Twinrix) is available on the U.S. market, but it is only approved for use in persons 18 years of age or older.

The usual regimen for primary hepatitis B vaccination consists of three intramuscular doses given at 0, 1, and 6 months. The three-dose schedule induces a good antibody response in more than 90% of healthy adults and more than 95% of pediatric patients (newborn through 19 years of age). Hepatitis B vaccines have a protective efficacy of 80% to 95% when given to susceptible recipients. The duration of protection is unknown, but appears to persist even after anti-HBs is no longer detectable (790).

Susceptible pregnant women with accidental percutaneous or permucosal exposure to HBV-infected blood or who had sexual contact with a chronic HBV carrier or an acutely infected man should receive immunoprophylaxis. After exposure to HBV-contaminated blood, immunoprophylaxis should consist of two doses of HBIG (0.06 mL/kg given intramuscularly; maximum 5 mL). The first dose of HBIG should be given as soon as possible or within 24 hours of exposure; its effectiveness when given after 7 days of exposure is unknown. The second dose is given 1 month later. This regimen has not been specifically evaluated in pregnant women, but it is about 75% effective in preventing infection in healthy persons. If the physician decides to use the hepatitis B vaccine, which is the preferred approach, only one HBIG dose needs to be given. The vaccine should be administered intramuscularly at a site different from that used for HBIG, and the first dose can be given concomitantly with HBIG or within 7 days of exposure. For

sexual HBV exposure, the prophylactic regimen is similar, except that immunization can begin within 14 days of the last sexual encounter (790).

Pregnancy is not a contraindication to hepatitis B vaccination. However, vaccine manufacturers advise against their use during pregnancy for liability reasons. Avoidance of vaccination in early pregnancy (i.e., period of embryogenesis) is recommended by some experts. No fetal or maternal risks from hepatitis B vaccination are known, and the limited available data suggest that its use in early or late pregnancy is safe (790,791,792,793).

Prevention of Perinatal Hepatitis B Virus Transmission

The CDC estimates that 22,000 births per year occur to HBsAg-positive women in the United States and, unless immunoprophylaxis is given at birth, about 6,000 of these newborns would become chronic HBV carriers (778). The administration of HBIG and the initiation of hepatitis B vaccination is 85% to 95% effective in preventing the development of the chronic carrier state in these infants (784).

The CDC initially recommended in 1984 that all high-risk women be screened for HBsAg during pregnancy. However, targeting women in high-risk groups identifies only about 35% to 65% of HBsAg carriers (794,795). The guidelines were later revised, and universal prenatal screening for HBsAg was recommended beginning in 1988 (796). All pregnant women should be routinely screened for HBsAg during an early prenatal visit. HBsAg-negative women at high risk of infection (e.g., those with other sexually transmitted diseases or illicit drug users) should be retested late in pregnancy. Screening of all pregnant women and reporting of the results to health care providers is not complete in many geographic areas, and perinatal screening for women whose HBsAg status is not known is not consistently practiced. This can lead to failure to identify HBsAg-positive women and to administer appropriate immunoprophylaxis to their newborns (797, 798). A year 2000 survey of birthing hospitals in 14 states showed that 96% of pregnant women were screened for HBsAg. Of 10,192 infants born to HBsAg-positive women, 90% had received HBIG and their first dose of the hepatitis B vaccine before discharge from the hospital (794).

Infants born to HBsAg-positive mothers should be bathed as soon as possible to remove HBV-infected blood and other secretions. Suctioning of the stomach contents, if needed, should be performed gently to avoid mucosal trauma that could promote HBV entry into the blood. Delivery by elective cesarean section has been advocated by some as a way to reduce maternal-to-infant HBV transmission; this approach is not recommended because of the lack of evidence to support the practice and because of the efficacy of immunoprophylaxis.

HBIG at a dose of 0.5 mL intramuscularly should be given as soon as possible

after birth and no later than 12 hours of life. An HBIG dose given at 12 to 48 hours of life probably is effective, but this has not been proved. The first vaccine dose should be given within the first week of life, preferably within the first 12 hours, and at a different anatomic site; the intramuscular dose is 0.5 mL (5 mg of Recombivax HB or 10 mg of Engerix-B). Later doses are given at 1 and 6 months of age. For preterm infants with a birth weight less than 2000 grams, four vaccine doses are needed (0, 1, 2-3, and 6-7 months of age). Breast-feeding should be allowed for infants who have started immunoprophylaxis (799).

The CDC and the American Academy of Pediatrics (AAP) currently recommend universal hepatitis B vaccination of all infants, regardless of the maternal HBsAg status (794,799). Infants born to HBsAg-positive women are given HBIG and the vaccine as outlined earlier. Infants born to women admitted in labor and whose HBsAg status is unknown should receive the first dose of the vaccine within 12 hours of birth; maternal HBsAg testing should be immediately performed and, if positive, the infant should receive HBIG (0.5 mL) as soon as feasible after birth and no later

P.1310

than 7 days of age. Preterm infants weighing less than 2000 grams at birth should get both HBIG and their first dose of the hepatitis B vaccine by 12 hours of age. Household contacts and sex partners of HBsAg-positive women should be vaccinated against hepatitis B; prevaccination susceptibility testing should be done in adults whenever possible, but is not required in children because of low rates of HBV infection in that age group and the lower costs of smaller individual vaccine doses.

Infants born to HBsAg-negative mothers do not need HBIG administration. They can receive their first dose of vaccine at birth or within the first 2 months of life at routine health maintenance visits. Hepatitis B virus vaccines can be given concurrently but in different syringes with inactivated poliomyelitis, diphtheria-tetanus-pertussis, measles-mumps-rubella, and pneumococcal or *Haemophilus influenzae* type b conjugate vaccines. The use of hepatitis B-containing combination vaccines can begin at the age of 6 to 8 weeks (799).

A study from Taiwan of infants born to HBsAg-positive but HBeAg-negative mothers showed that those receiving both HBIG and the hepatitis B vaccine, as compared to newborns receiving hepatitis vaccine alone, were more likely to have protective anti-HBs titers at 2 months of age (98% vs. 57%, respectively) and their geometric mean titers of this antibody were higher. By 7 months of age, however, just as many infants receiving the hepatitis B vaccine alone had protective anti-HBs levels and the geometric mean titer of anti-HBs in this group was significantly higher than those receiving both HBIG and the vaccine (800). Another study from Italy of 522 children born to HBsAg-positive mothers from 1985 to 1994, and who had received HBIG and the hepatitis B vaccine at birth, found that 79% still had protective anti-HBs levels 5 to 14 years later (801).

Preterm infants generally will respond well to the hepatitis B vaccines if the first dose is given at 1 month of age or at hospital discharge. Anti-HBs titers tend to be lower than those elicited in vaccinated term infants. Very-low-birth-weight infants ($\leq 1,500$ g) who receive their first dose of vaccine within the first 72 hours of life are less likely to have protective anti-HBs levels after the third dose of the vaccine is given than infants of similar weight and gestation who receive their first vaccine dose at 1 month of age (802,803,804,805).

Infants who become chronic HBV carriers despite correct immunoprophylaxis may have been infected *in utero*, or their mothers may have had a high virus load or were infected with vaccine-escape virus mutants (801,806-808). Infants who fail immunoprophylaxis do not become HBsAg-positive until 6 to 9 months of age. Immunized infants born to HBsAg-positive mothers should be tested at the age of 9 months or later for HBsAg and anti-HBs. Those who test negative for both should receive a fourth vaccine dose and be tested again 1 month later, and infants found to be HBsAg-positive should be monitored closely to determine whether a chronic carrier state has developed (784).

The United States Public Health Service and the AAP recommended in July 1999 to defer the first dose of hepatitis B vaccine until the age of 2 to 6 months for infants born to mothers who were HBsAg-negative. This stemmed from concerns over mercury exposure contained in thimerosal, a vaccine preservative. Infants born to HBV carrier mother were to continue receiving HBIG and the hepatitis B vaccine as before. The restriction was lifted after preservative-free hepatitis B vaccine became available in September 1999. Hepatitis B vaccination of infants born to women with unknown HBsAg status declined precipitously after the recommendations were issued, but did not rebound to its baseline level until the cohort of infants born 7 to 12 months after the suspension was lifted (809,810,811,812,813,814). It is estimated that this brief and well-intentioned transient change in recommendations resulted in 750,000 fewer newborns getting vaccinated in 2000 as compared to 1998, and 182,000 children remaining undervaccinated for hepatitis B at 19 months of age (814).

Universal hepatitis B vaccination of newborns has been implemented in over 60% of countries worldwide (815). Dividends from these policies have already become apparent. In Taiwan, the incidence of hepatocellular carcinoma among children 6 to 14 years of age has decreased by 50% and the average mortality from fulminant hepatitis B in infants has declined by 68% (815,816). Other studies have shown that the prevalence of HBsAg among children decreased in Taiwan (10.5% to 1.7%), American Samoa (7.5% to 0%), and The Gambia (10.3% to 0.6%) after programs for universal infant hepatitis B vaccination were started (815,817). It is estimated that perinatal HBV infections in the United States decreased by about 75% between 1987 and 2000 based on existing vaccine coverage rates (794).

Three antiviral agents (alpha interferon, lamivudine, adefovir dipivoxil) are licensed at the present time for the treatment of chronic hepatitis B and numerous others (DNA vaccines, ribozymes, emtricitabine) are under development (818,819,820). Lamivudine, a nucleoside analogue that inhibits the RNA-dependent DNA polymerase of HBV, is a potent suppressor of HBV replication and leads to a 3 to 4 log reduction in HBV DNA level in a treated chronic carrier (763,818). Its chief limitation is the frequent emergence of lamivudine-resistant HBV strains, although these drug-resistant variants are thought to be less fit than their wild-type counterparts. The rate of resistance approaches 20%, 40%, and 67% after 1, 2, and 4 years of therapy, respectively (763). Lamivudine has been used during pregnancy to reduce maternal viremia in an effort to decrease the rate of perinatal HBV transmission (821,822). In one trial of 8 women with chronic hepatitis B, lamivudine was prescribed during the last month of pregnancy. Additionally, newborns received HBIG and hepatitis B vaccine. Maternal HBV DNA levels decreased with lamivudine treatment. One infant (12.5%) became a chronic hepatitis B carrier compared with 28% of a control group of infants who received immunoprophylaxis at birth but whose mothers did not receive lamivudine (822). The role, if any, of maternal antiviral therapy as a supplement to immunoprophylaxis for the prevention of perinatal HBV infection is unknown at present.

P.1311

Hepatitis C

Hepatitis C is currently the most common chronic bloodborne infection in the United States. Antibodies to HCV are detected in about 1.8% of the US population, of whom 75% (over 2.7 million people) are believed to have chronic infection (823). Globally, chronic HCV infection afflicts more than 170 million people and was the cause of at least 20% of the 1.4 million deaths from chronic liver disease worldwide in 2001 (824).

HCV is an enveloped, single-stranded RNA virus whose genome encodes for both structural and nonstructural proteins. The structural proteins include two envelope proteins (E1 and E2), which contain neutralizing epitopes, a nucleocapsid core protein (C), and a small protein (P7) whose function is unknown. The nonstructural proteins are essential for viral multiplication and include a helicase (NS2), viral protease (NS3), RNA-dependent RNA polymerase (NS5B), and membrane-binding protein (NS5). There are at least nine known HCV genotypes, which are divided further into more than 90 subtypes; 70% of HCV-infected persons in the United States are infected with genotype 1 (with subtype 1a predominating). Genotypes 1 to 3 circulate in western countries and Asia, genotype 4 in the Middle East and Africa, genotype 5 in South Africa, and genotypes 6, 7, 8, and 9 in Southeast Asia. Viruses circulating within an individual may show nucleotide variability (quasispecies). Quasispecies arise as a result of

ongoing host immune surveillance and mutations occurring during viral replication. Antibodies elicited by one virus type may not recognize another HCV type; therefore, patients are not protected against reinfection by either the same or different HCV genotypes. A consequence of the genetic diversity of HCV is its ability to escape host immune surveillance leading to a high rate (greater than 80%) of chronic infections (23,775,825,826).

Epidemiology

The highest incidence of acute HCV infection occurs in persons 20 to 39 years of age. There is great variation in the seroprevalence of HCV within the United States. The highest rates are found in persons with repeated or large percutaneous exposure to blood, such as injecting drug users (72% to 86%) or persons with hemophilia treated with products made before 1987 (74% to 90%). Lower rates are found in other groups, such as chronic hemodialysis patients (10%), persons receiving blood transfusions before 1990 (6%), and persons with a history of a sexually transmitted disease (6%) (23). Approximately 1% to 2% of pregnant women in the United States are positive for HCV antibodies, about 5% of whom pass the virus to their newborns (827).

HCV also can spread via organ transplantation from HCV-infected donors, tattoos, body piercing, sexual activity with an infected person, and nonsexual household contact (23,828). Intrauterine transfusion of HCV-infected blood was shown to be the source of maternal infection in one report (829). These sources account for a very small fraction of all HCV infections in the United States. Only 10% of patients have no identifiable source of infection (23,828). Although HCV RNA can be detected in breast milk from infected mothers (in lower amounts than in maternal serum), infection acquired through breast-feeding has not been documented definitively (830).

Clinical Manifestations

The incubation period of hepatitis C infection is 7 weeks on average, with a range of 2 to 30 weeks. Acute HCV is mostly asymptomatic. Jaundice is seen in 25%, and fulminant hepatitis is rare (825).

Most patients (85%) develop chronic HCV infection. Symptoms are vague and nonspecific (arthralgias, fatigue). Serum aminotransferase concentrations are either persistently or intermittently elevated, and tend to be lower during the third trimester only to return to their prepregnancy levels in the first 3 to 6 months postpartum (14). Aminotransferase concentrations correlate poorly with the degree of liver injury, but individuals with abnormal levels are more likely to have significant hepatic histologic abnormalities (61%) than those with persistently normal ALT levels (19%) (831). Extrahepatic manifestations include mixed cryoglobulinemia, glomerulonephritis, lichen planus, and porphyria cutanea tarda.

Cirrhosis develops in as many as 20% within 10 to 20 years of infection. One to four percent of HCV-infected patients are at risk of developing hepatocellular carcinoma (825). Chronic hepatitis C infection does not seem to have adverse pregnancy outcomes such as increased rates of spontaneous abortion, gestational diabetes, or maternal hypertension, or lower birth weight of neonates (14).

Diagnosis

Serologic tests permit the detection of antibodies to HCV (anti-HCV) but do not allow differentiation among acute, chronic, or resolved infections. Two Food and Drug Administration-approved enzyme immunoassays and one enhanced chemiluminescence immunoassay are available in the United States for anti-HCV screening. Sensitivity of these tests is greater than 97% in high-prevalence populations, and the specificity is more than or equal to 99%. Positive results on screening immunoassays usually require confirmation with a supplemental test such as the recombinant immunoblot assay (RIBA) or nucleic acid tests, but this is seldom done by clinical laboratories. RIBA uses both HCV-encoded recombinant antigens and synthetic peptides and can be performed on the same serum sample screened for anti-HCV (832,833).

Very sensitive RNA detection tests are commercially available. Qualitative tests such as the reverse transcriptase PCR (RT-PCR) detect the presence of circulating HCV RNA. These tests are positive as early as 1 to 3 weeks after exposure. Their lower limit for detection is 50 IU/mL. Because some HCV-infected patients are only intermittently HCV RNA-positive, a single negative test result is not considered conclusive. False-positive

P.1312

and false-negative results can occur. Quantitative assays for measuring HCV RNA titers also are available from commercial laboratories. The two most commonly used assays are the quantitative RT-PCR (threshold of 500 viral genome copies per milliliter) and a branched DNA signal amplification assay (threshold of 200,000 genome equivalents per milliliter); both are less sensitive than the qualitative RT-PCR. Patients with chronic hepatitis C infection usually have from 10^5 to 10^7 genome copies per milliliter of circulating virus. The quantitative tests are mostly utilized to assess the response of chronically infected patients to antiviral therapy (23,825,832,833).

It is also possible to group HCV by genotype and subtype using commercially available assays that are not yet approved by the Food and Drug Administration. The clinical utility of these assays is limited at present to possibly altering the length of antiviral therapy, depending on a person's specific HCV genotype (23,832).

Treatment

The goals of treatment are to eradicate HCV and stem the progression of liver injury. Alpha interferons are the mainstay of therapy. These agents have antiviral, antiproliferative, and immunomodulatory effects. Attaching an inert polyethylene glycol (PEG) polymer to interferon leads to a molecule with a longer half-life. At present, the combination of peginterferon- α -2a or peginterferon- α -2b plus ribavirin is the treatment of choice for non-pregnant adults. The dosage and treatment duration depends primarily on the patient's genotype, with the shortest length of treatment (24 weeks) used for genotypes 2 or 3. The overall sustained virologic response is only about 56%, but some patients with good prognostic factors achieve responses of 80% to 95%. Ethnicity is a determinant of treatment outcome, even after adjustment for other factors affecting response to medications. Asians have the best response to therapy, and African Americans the worst. A good response to therapy is seen within 12 weeks (834,835,836,837).

Pregnant women with hepatitis C are rarely treated with antiviral agents. Ribavirin is teratogenic in animals. Interferon has not been shown to be teratogenic in humans or experimental animals, possibly because of its large molecular size which limits its ability to cross the placenta (837).

Susceptible HCV-infected women should be vaccinated against both hepatitis A and hepatitis B viruses after delivery of their infants. Superinfection by either virus may lead to a severe illness in HCV-infected persons.

Vertical Transmission

The risk of HCV infection for infants born to women with anti-HCV has been assessed in numerous studies (14,23,838-848). The average transmission rate for HCV-infected but HIV-negative women is 5%, with a range from 0% to 25%. The presence of HCV RNA in the mother at delivery is the most consistent factor associated with vertical transmission. Limited data suggest that women with higher HCV RNA titers at delivery may be more likely to infect their newborns (14,23,849-852). Infants tend to have less HCV nucleotide variability than their mothers, thus suggesting that not all clones of a quasispecies are vertically transmitted. After several weeks, nucleotide variability in infants increases, but the evolution differs from what occurs in their mothers (852,853,854,855,856,857,858).

The average HCV infection rate for infants born to women coinfecting with HIV-1 is higher and estimated at 19%, with a range from 5% to 36% (14,23,859). The delivery route (i.e., vaginal or by cesarean section) seems not to have an appreciable impact on the risk of HCV infection for infants. Elective, but not emergency, cesarean section may lower the rate of vertical HCV transmission, but the data are limited and not sufficient to recommend this route of delivery for HCV-infected women (14). Nevertheless, elective cesarean section may be partially protective for infants of HCV-infected women who are co-infected with

HIV (860). The specific maternal HCV genotype does not affect the risk of vertical transmission. There is no increased risk of HCV transmission in subsequent pregnancies (861). Invasive procedures such as amniocentesis or fetal scalp monitoring have been examined as potential risk factors for HCV vertical transmission, but the data are inconclusive. They are best avoided unless definitely necessary (14).

Perinatal Management

Routine screening of all pregnant women for HCV infection currently is not recommended. Testing should be limited to women who have high-risk exposure histories. Examples of women for whom screening is suggested are those who are HIV-positive or HBsAg-positive, current or previous intravenous drug users, have current or past sexual partners known to have been intravenous drug users, have a history of transfusion of blood or blood products prior to 1992, were incarcerated, have undergone anonymous donor *in vitro* fertilization, have a history of body piercing or tattooing, have elevated serum aminotransferase levels, or are patients or employees at hemodialysis units (14,861).

Postexposure prophylaxis with immune globulin preparations or antiviral agents for infants born to HCV-infected mothers also is not recommended. Because passively acquired transplacental IgG antibodies against HCV can persist for several months, it is recommended that infants not be tested for anti-HCV before 18 months of age (23,827,861). If earlier diagnosis is desired, RT-PCR for HCV RNA can be performed after the first month of life and repeated at 6 months of age; HCV RNA detected in the first month of life may reflect only transient carriage (861,862). Cord blood should not be used for HCV diagnosis because of the potential for its contamination with maternal blood.

Infants and children found to be infected with HCV require periodic monitoring. Most remain asymptomatic, but half will be persistently viremic and an almost equal number of infants will have HCV RNA intermittently in their sera. Alanine aminotransferase values vary from normal

P.1313

to high. Liver biopsies performed within the first 10 years of life reveal minimal or moderate hepatic inflammation in 20% of perinatally-infected infants (863,864). However, a recent report of a 35-year follow-up of a cohort infected at birth with blood transfusions from a single donor with genotype 1b showed that 89% were HCV RNA-positive, but that the majority of those who underwent liver biopsies had either no or mild portal fibrosis (865,866).

Hepatitis D

Hepatitis D virus (HDV) is a defective RNA virus that causes disease only in

persons infected with hepatitis B virus. It can occur as a co-infection with acute hepatitis B or as a superinfection in persons who are chronic HBV carriers. Persons co-infected with HBV and HDV are at high risk for chronic hepatitis, cirrhosis, and liver failure. Diagnosis is made by serologic assays for HDV-specific IgM and IgG. Perinatal transmission is possible, but rare. Measures aimed at prevention of hepatitis B virus infection are effective against HDV (749).

Hepatitis E

Hepatitis E virus (HEV), previously known as enterically transmitted non-A, non-B hepatitis, is a small RNA virus that is transmitted by the fecal-oral route. It causes a self-limited disease that resembles hepatitis A. There is no chronic carrier state associated with HEV infection. Genomic analysis shows that there are several geographically distinct strains of HEV (867).

HEV has caused large outbreaks of disease in India, Nepal, and China, and smaller ones in the Middle East, Africa, and Mexico. The highest attack rates during outbreaks occur among young adults. Pregnant women, especially those in their third trimester, have high mortality rates (15% to 25%). Sporadic HEV infections have been described in numerous countries including Egypt, Italy, Greece, and the United States (867). Seroprevalence studies have shown that HEV antibodies are detectable in as many as 37% in Nepal, 64% in India, 62% in Pakistan, 27% in Bangladesh, 38% in Vietnam, 8% in Nicaragua, 2.2% in Greece, 0.8% in southern Italy, and 0.4% in Ireland (868,869,870,871,872). Studies from the United States showed seroprevalence rates of 5.7% in Iowa and 21% in Baltimore, Maryland (873,874).

Outbreaks are generally related to the ingestion of fecally contaminated drinking water and often follow heavy rains and floods. Person-to-person transmission during outbreaks is uncommon (867). Zoonotic reservoirs (deer, sheep, cows, rodents) for HEV are suspected (872,875,876). In the United States, domestic swine may be the reservoir for HEV (872).

The incubation period is 2 to 10 weeks. Diagnosis of HEV infection is made by detection of HEV-specific IgM in serum or by finding HEV RNA in serum or stools. IgM antibodies disappear after a few months, but specific IgG antibodies can persist for several years (867).

It is not known why pregnant women are at such high risk for death from acute HEV infection. Fulminant hepatitis did not develop in pregnant rhesus monkeys or swine experimentally inoculated with HEV (877).

Vertical transmission of HEV is known to occur at rates of 50% to 100% (878,879,880). Infected infants can develop either icteric or anicteric hepatitis. Others may suffer from hypothermia and hypoglycemia, and can die within 24 to 48 hours of birth (878,879).

Treatment is supportive. Passive immunoprophylaxis with immune globulin prepared in the United States is not effective. Prevention is best accomplished by use of clean drinking water and proper sanitation (867).

Hepatitis G

Hepatitis G virus (HGV), also known as hepatitis GB virus (GBV-C), is an RNA virus that causes persistent human infection, but no known disease. It appears to be transmitted by blood or blood products, and by sexual contact with infected persons. Vertical transmission occurs in as many as 90%. HGV is associated with decreased mortality among patients co-infected with HIV. The virus appears to replicate in lymphocytes, but not hepatocytes. Its incubation period is not known. Treatment is neither available nor indicated (845,881).

Transfusion-Transmissible Virus

Transfusion-transmissible virus (TTV) is a non-enveloped single stranded DNA virus that has also been associated with posttransfusion hepatitis. Like HGV, it is a virus that causes persistent infection, but no known disease. TTV DNA can be found circulating in the blood of a high percentage (37%-90%) of healthy individuals, but the likelihood of detecting it is higher in those with a history of blood transfusions. Its presence is not associated with liver damage, even in patients who are carriers of HBV or HCV (882,883).

TTV has also been found in feces, saliva, breast milk, and in the cervixes of pregnant women. In one study of 100 pregnant Chinese women without a history of blood transfusions, TTV DNA was detected in 66% of the cervical samples (884). Although vertical transmission does occur, it appears that infants are more likely to acquire TTV postnatally. TTV infection becomes persistent in most infants, but without evidence of liver impairment (885,886,887).

Lymphocytic Choriomeningitis Virus

Human infections by lymphocytic choriomeningitis virus (LCMV) have been recognized since 1933. LCMV is an RNA virus that belongs to the family *Arenaviridae*, and its reservoir in nature is rodents such as mice and hamsters. Pregnant wild mice that become viremic can transmit LCMV transplacentally. Mice infected *in utero* are unable to

P.1314

mount an effective immune response to the virus and they remain asymptotically infected. LCMV is shed in their nasal secretions, saliva, milk, urine, semen, and feces. Horizontal transmission to other rodents such as hamsters further spreads the virus. Humans acquire LCMV by inhaling aerosolized virus or by direct contact with contaminated fomites (888). Although arenaviruses are generally not very pathogenic for rodents, they are capable of causing serious or fatal infections such as aseptic meningitis, liver disease, and hemorrhagic fever in humans, primates, and guinea pigs (888,889,890).

LCMV infections of humans are asymptomatic or mild in about a third of individuals. Half the symptomatic patients have aseptic meningitis or meningoencephalitis. The typical LCMV infection is biphasic with an initial illness consisting of fever, malaise, headache, photophobia, sore throat, emesis, and cough, followed by defervescence and resolution of symptoms, with subsequent development of CNS symptoms. Mononuclear CSF pleocytosis is noted on the lumbar puncture. Complications of LCMV can include eighth nerve deafness, transverse myelitis, hydrocephalus, Guillain-Barré syndrome, pneumonia, myocarditis, parotitis, and dermatitis. Contact with rodents raises the index of suspicion for LCMV infection. The diagnosis can be established by isolating the virus or by using PCR (serum, CSF), but serologic methods (ELISA, IFA, complement fixation) that detect LCMV-specific IgG and IgM antibodies are generally employed (888,891).

There have been over 50 published cases of congenital LCMV infections from diverse geographic areas, including the United States. Chorioretinitis is the most common findings in infected infants, with peripheral chorioretinal scars next in frequency. Other ocular abnormalities include optic atrophy, nystagmus, conjunctivitis, esotropia, microphthalmos, and cataract. About 40% of the infants are microcephalic, and a third are macrocephalic. Neuroimaging studies reveal hydrocephalus or intracranial calcifications in the majority of affected infants. Other abnormalities such as hearing loss, hepatosplenomegaly, or thrombocytopenia are occasionally noted. Long-term neurologic deficits such as mental retardation, seizures, or decreased visual acuity are expected in the majority. There is no available therapy for LCMV-infected infants, but ribavirin has been used for other arenavirus infections (888,891,892).

West Nile Virus

West Nile virus (WNV) was first isolated from an infected woman in 1937 in the West Nile district of Uganda, and has since been found to be a fairly common human pathogen in Africa, the Middle East, Asia, Australia, and temperate areas of Europe (893,894). The first documented cases of WNV encephalitis were in New York City in 1952 when patients with advanced malignancies were experimentally inoculated with an Egyptian strain of this virus for its possible oncolytic effect (895). Naturally acquired WNV was initially recognized in North America in August 1999 when an unusual cluster of cases of meningoencephalitis and muscle weakness in New York City was carefully investigated (896). The virus has since spread throughout much of the United States, and cases in Canada and the Caribbean region have been diagnosed (895,897,898). The number of human WNV infections reported to the CDC peaked at 9,122 (with 223 deaths) in 2003; 2,313 cases (with 79 deaths) were reported for the following year through November 16, 2004 (895,898). Outbreaks of WNV have been described for many countries, including Romania, Russia, Israel, South Africa, and the United States (898).

WNV is a single-stranded RNA virus of the family Flaviviridae, genus *Flavivirus*. It is classified within the Japanese encephalitis virus antigenic complex, which also includes other human pathogens such as Japanese encephalitis, Murray Valley encephalitis, Kunjin, and St. Louis encephalitis viruses (899,900). Mosquitoes (primarily *Culex* species) serve as the vector for WNV although birds are the most common amplifying hosts (893,899). Infected birds usually survive WNV infection and become immune, but the infections can be virulent in crows and jays. The virus can be recovered from the oral secretions and feces of birds, and bird-to-bird transmission can occur in the laboratory in the absence of mosquitoes (900). Most vertebrates are susceptible to WNV, and natural infection has been demonstrated in humans, horses, skunks, cats, rabbits, squirrels, chipmunks, and a few bat species (899). The WNV strains isolated in New York in 1999 are most closely related to an isolate obtained from the brain of a dead Chilean flamingo in Israel in 1998, but how this virus was imported into the United States is not known (901).

Human infections are the result of mosquito bites, usually in the summer and early fall (899). Other modes of transmission to humans have also been recognized since the appearance of WNV in the United States. These include intrauterine transmission from mother to fetus, transfusion of blood or blood products, breast feeding, percutaneous inoculation among laboratory workers, receiving an organ-transplant from a viremic donor, and possibly hemodialysis (900,902).

The incubation period is from 2 to 14 days, but can be as long as 21 days after organ transplantation (900). Most infections are asymptomatic (894). In the 1999 New York City outbreak, about 2.6% of the population at the outbreak's epicenter became infected, but only a fifth had exhibited symptoms consisting of mild febrile illnesses (903). The typical WNV illness is mild and lasts 3 to 6 days. Symptoms have a sudden onset, and include fever (usually $>39^{\circ}\text{C}$), malaise, anorexia, nausea, vomiting, eye pain, headache, myalgias, and rash (899,900). Only about 1 in 150 WNV infections result in meningitis or meningoencephalitis (894). Muscle weakness is common in WNV encephalitis. Other neurologic manifestations encompass poliomyelitis-like acute flaccid paralysis, optic neuritis, cranial nerve abnormalities, seizures, tremor, myoclonus, and parkinsonism (900,904-907). Case-fatality rates of 4% to

P.1315

18% have been observed among hospitalized patients, with advanced age proving to be the most important risk factor. Persistent abnormalities such as fatigue, memory loss, gait problems, depression, and muscle weakness are common one year after recovery from acute WNV encephalitis (894).

Definitive diagnosis requires the detection of IgM antibodies in serum or CSF using the IgM antibody-capture enzyme-linked immunosorbent assay. CSF IgM is positive by the third to fifth day of the illness, and at least 3 days before serum IgM is detectable. Serum IgG usually appears about 5 days after WNV-specific IgM is detectable (895). False-positive IgM results may be seen in recent recipients of the yellow fever or Japanese encephalitis virus vaccines or persons recently infected with another flavivirus such as St. Louis encephalitis or dengue virus. Plaque reduction neutralization assays can help distinguish cross-reactions from true WNV infection. WNV IgM can be detectable in the blood of most patients for over a year, and this can complicate interpretation of test results. A fourfold or greater increase in WNV-specific neutralizing antibody titers in acute and convalescent phase serum samples confirms acute infection. Viral cultures or detection of WNV RNA in serum and CSF can be helpful, but the sensitivity of these tests is low because of the low magnitude and transient nature of the viremia (894,900,908). Nucleic acid amplification tests in serum and CSF are usually negative by 3 to 5 days of illness (895). WNV nucleic acid amplification tests have been used to screen donated blood in the United States since June 2003 (900,909).

Treatment of WNV infection is supportive. A variety of agents such as ribavirin, interferon- $\alpha 2\text{b}$, and steroids have been tried, but none in a controlled trial (900). An intravenous gammaglobulin preparation with high WNV antibody titers obtained from healthy Israeli blood donors was effective both prophylactically and therapeutically in experimentally-infected mice and in anecdotal reports of human infection (895,910). The product is currently being evaluated in human trials in the United States. An inactivated WNV vaccine is available for horses, but not yet

for humans. Prevention is best accomplished by applying insect repellents on skin and clothes, draining standing water in which mosquitoes may breed, and avoiding being outdoors during peak mosquito feeding times at dawn and dusk (900,911).

The CDC is compiling data on pregnancy outcomes of over 70 women with WNV infection during pregnancy. In 2002, four cases of WNV infection during pregnancy were investigated. Three infants were born at term and were normal and had no laboratory evidence of WNV infection (911). A fourth infant was delivered at 38 weeks gestation after the 20-year-old mother developed WNV encephalitis at 27 weeks of gestation. The infant had chorioretinal scars and severe white matter loss in the temporal and occipital lobes on brain neuroimaging studies. The infant had positive WNV-specific IgM in the serum and CSF, but the lumbar puncture was traumatic. Nucleic acid amplification assays did not yield consistent results when placental and umbilical cord tissues were tested (912,913). Another infant was delivered at 32 weeks gestation after her mother developed WNV encephalitis at week 16 of gestation. The infant had low birth weight, but no attempt was made to diagnose fetal WNV infection (914).

Probable WNV transmission through breast milk was demonstrated after a woman in Michigan received transfusions in the immediate postpartum period that were later shown to harbor WNV. She developed WNV meningoencephalitis 12 days after delivery. Her breast milk on postpartum day 16 was positive for WNV by nucleic acid amplification methods, and for WNV-specific IgG and IgM. Her term infant had started breast-feeding within a few hours of birth and remained well. However, a serum sample from the infant at 25 days of age was positive for WNV-specific IgM. The infant had minimal outdoor exposures and no known mosquito bites (915). This case was not considered sufficient by the CDC to restrict breast-feeding for women infected with WNV.

The CDC does not recommend screening of pregnant women for WNV infection. Women diagnosed with WNV encephalitis during pregnancy should have a fetal ultrasound within 2 to 4 weeks of disease onset. Amniotic fluid, chorionic villi, or fetal serum can be tested for WNV infection but the sensitivities and specificities of these tests are not established. Infants born to infected women should be examined carefully, and have their sera tested for WNV-specific IgG and IgM. If clinical or serologic evidence of neonatal infection is found, an ophthalmologic examination, lumbar puncture, and CT scan of the brain should be performed. Histopathologic examination and testing for WNV RNA should be done, if available. Hearing screens at birth and again at six months are also encouraged (911).

Human Immunodeficiency Virus Type 1 Infection

The global impact of HIV-1 infection is staggering. The WHO has estimated that, as of the end of 2003, approximately 37.8 million people were living with HIV-1 around the world, two thirds of whom resided in Africa. Approximately 20 million people have died of AIDS since the start of the AIDS pandemic. In 2003 alone, 4.8 million people were newly infected with HIV-1, and 2.9 million others died of AIDS. About 1.1% of all persons between 15 and 49 years of age worldwide are now infected with this virus. In some African countries such as Botswana, 37% of adults are HIV-positive (916).

In the United States, the estimated number of persons diagnosed with AIDS between the start of the epidemic and the end of 2002 is 886,575, of whom 501,669 have died (917). About 950,000 people are currently living with HIV-1 in the United States (916). Females account for 29% of persons 13 years of age or older with HIV-1 infection, 66% of whom are African American and 10% Hispanic (918).

P.1316

There were between 520,000 and 680,000 HIV-1-infected people living in western Europe at the end of 2003. Since the recognition of AIDS, about 259,000 persons had been diagnosed with this condition as of the end of June 2003, of whom 152,000 had died (919).

The region hardest hit is sub-Saharan Africa where most HIV-1-infected persons are found. The median HIV-1 seroprevalence among women attending antenatal clinics there was about 24% in 2002. The highest rates are found in southern African countries such as Botswana, Lesotho, Zimbabwe, Swaziland, and South Africa (920). South Africa, with a total population of about 44 million people, has 5.3 million HIV-1-infected persons living there (916, 920).

Asian countries such as China, Vietnam, and Indonesia are currently experiencing a growing HIV-1 epidemic, largely driven by sex workers and injecting drug use (921). Estimates place the number of people living with HIV-1 at 570,000 in Thailand, 330,000 in Myanmar, and 220,000 in Vietnam. Imprecise estimates suggest that between 430,000 to 1.5 million Chinese are HIV-infected, and that between 2.2 million to 7.6 million individuals in India are HIV-positive (916).

More than 2 million HIV-infected women around the world give birth each year, and 630,000 infants acquire the virus from their mothers. For 2003 alone, the World Health Organization estimates that about 490,000 children 15 years of age or younger died of AIDS, 90% of whom were from sub-Saharan Africa. AIDS as of the end of 2003 had orphaned at least 12 million children in sub-Saharan Africa (916).

There were 9,300 pediatric (children <13 years of age) AIDS cases diagnosed in the United States through the end of 2002. This accounted for 1% of the 886,575 total AIDS cases reported to the CDC between the start of the epidemic and the end of 2002. Perinatal acquisition of HIV-1 was responsible for 8,629 (93%) of these infections. The major maternal risk factors for perinatal HIV-1 infection were injection drug use (38%), having sex with an injection drug user (17%), sex with an HIV-infected person whose risk status is unspecified (17%), sex with a bisexual male (2%), sex with a person with hemophilia (0.4%), and receipt of blood or blood product transfusions (1.8%). The risk factors are not known for 22% of all mothers of children with AIDS (917). Between 1999 and 2002, heterosexual transmission accounted for 64% of all new HIV-1 infections among females 13 years of age or older; 89% of all heterosexually acquired HIV-1 infections in persons 13 to 19 years of age were female (922).

A disproportionate number of children with perinatal AIDS in the United States have been African American (59%) or Hispanic (23%). White children have accounted for 17% of the cumulative number of cases through 2002. With the success of programs for the interruption of mother-to-infant transmission of HIV-1 and the availability of improved antiretroviral drug regimens for HIV-1-infected children, the number of children diagnosed with AIDS in the United States has steadily declined from 952 in 1992 to a low of 92 in 2002. About 55% of all children 13 years of age or younger diagnosed with AIDS since the start of the epidemic have died (917).

HIV-1 is one of several known human retroviruses. It is a single stranded, enveloped RNA virus that is composed of inner core proteins (p18, p24, p27), surface proteins (gp120, gp41), genomic RNA, and enzymes such as reverse transcriptase and protease. The virion contains three structural genes (*gag*, *pol*, and *env*) and regulatory genes (*tat*, *vif*, *nef*, *vpu*, *vpr*, and *rev*). HIV-1 requires a cell-surface glycoprotein known as CD4 for viral entry into cells. CD4 is found on the subset of T lymphocytes referred to as helper T cells, and on macrophages and other cell types (e.g., placenta, CNS cells). Other cell surface molecules (chemokine receptors) serve as co-receptors for HIV-1 entry into cells. Genetic variants of HIV-1 may preferentially bind to different co-receptors. For example, HIV-1 variants that induce syncytium formation depend on the receptor molecule CXCR4, whereas the nonsyncytium-inducing variants use CCR5 co-receptors. The density of receptors on cells, and the relative densities of co-receptors and CD4 in membrane microdomains, are major determinants of infection (923- 926). The absence of CCR5 in about 1% of Caucasians, as a result of homozygosity for a 32-nucleotide deletion in the coding region (*CCR5D32* allele), protects against HIV-1 transmission and delays disease progression (927). Other chemokine receptors such as CCR-2b, CCR-3, and CCR-8 are used by HIV-1 as well (925,928). Patients considered to be long-term non-progressors also tend to have lower amounts of circulating HIV-1 RNA, and their activated CD8 lymphocytes may help suppress viral replication through the release of inhibitory chemokines such as RANTES, MIP-1a, and MIP-1b (925).

Although HIV-1 infects a relatively small number of CD4+ T lymphocytes, there is gradual but massive depletion of these cells over time. This renders patients susceptible to a variety of opportunistic infections and malignancies. Studies have suggested that HIV-1 gp120-induced intracellular activation plays a role in inducing apoptosis of uninfected cells as well (926).

Antibody responses to HIV-1 show only weak neutralizing activities against primary HIV-1 isolates. Most of the antibodies produced are non-neutralizing and directed against virion debris. Neutralizing antibodies do not have much impact on HIV-1 replication, but they do exert immune selection pressure. For control of HIV infection, virus-specific CD8+ cytotoxic T lymphocytes (CTL) are pivotal. These cells can be found in a variety of locations including peripheral blood, spleen, lymph nodes, skin, and bronchoalveolar spaces. CTL lyse HIV-1-infected cells and interfere with virus multiplication. However, HIV-1 replication is error-prone and this allows evasion from virus-specific CTL (929,930).

Major strides have been made in the prevention of perinatal HIV-1 infection in the last decade. The most crucial has been the demonstration that the risk of vertical transmission can be reduced significantly by administration of zidovudine during pregnancy, at delivery, and to newborns (931).

P.1317

As a result, the CDC recommended use of zidovudine to reduce perinatal transmission of the virus (932). Numerous studies followed and showed the feasibility of using alternative regimens of zidovudine, or of other drugs such as nevirapine, to prevent vertical HIV-1 transmission (933). Use of PCR assays has allowed the diagnosis of HIV-1 infection early in infancy, and the availability of antiviral drugs active at various sites in the viral replication cycle has allowed more potent drug combinations to be administered to infected patients. Viral load monitoring now provides a measure of how successful a therapeutic regimen is in suppressing viral replication for an individual patient, and HIV-1 strains can be examined for mutations associated with resistance to specific antiretroviral agents (934,935,936,937,938).

Maternal Infection

Epidemiology

Female adults or adolescents have accounted for 18% of all AIDS cases reported to the CDC through 2002. However, the proportion of women among persons newly diagnosed with AIDS has risen to 25% for the years 1998 through 2002. Heterosexual contact with a high risk person was the route of infection for more than half of these women (917). AIDS incidence and deaths have declined since the mid-1990s across all racial and ethnic groups (918). Of women who were living with AIDS at the end of

2002, 59% were African American and 19% were Hispanic (917). HIV-1 seroprevalence among women of child-bearing age varies by state. It ranges from a low of about 0 per 1,000 in Wyoming to highs of 6.9 and 5.2 per 1,000 for the District of Columbia and New York State, respectively. Seroprevalence rates for African American women are 15- to 20-fold higher than for white women, with intermediate rates noted for Hispanic women (939). The risks of HIV-1 infection grow as the number of high-risk behaviors practiced increases. Such behaviors encompass the use of crack cocaine, multiple sexual partners, sexual intercourse with a high-risk partner, having other sexually transmitted diseases, and low level of condom use (940,941,942).

HIV-1 screening programs targeted at patients who acknowledge high-risk behavior generally fail to identify most HIV-1-infected pregnant women (943,944). It is currently recommended that screening be offered to all pregnant women (4). With proper education, the majority of women offered antenatal HIV-1 testing agree to getting screened for this virus (945,946). It has been suggested that in high-risk populations, pregnant women who were initially HIV-1-negative should be screened again during the third trimester (947). However, 15% of HIV-infected women receive no or minimal prenatal care, and another 20% do not seek care until the third trimester (4). Rapid testing for HIV-1 antibodies for women in labor has been evaluated. These tests take about 20 minutes to perform and can provide results within 45 to 120 minutes of blood collection, thus allowing the identification of HIV-1-infected women and instituting intrapartum and postpartum zidovudine prophylaxis (948,949). With nondirective counseling about options for terminating or continuing pregnancy, 85% of HIV-1-infected women elect to continue their pregnancies (943,950).

Many studies have examined the effects of HIV-1 infection on pregnancy outcome, and most have found no significant effects of the virus *per se*. Adverse pregnancy outcomes were common in a cohort of 634 HIV-1-infected women who delivered after 24 weeks of gestation. These included preterm birth (20%), low birth weight (19%), and small-for-gestational age newborns (24%) (951). Comparable outcomes have been described in other studies, especially those conducted in resource-poor countries (952). With the increased cesarean delivery rates for HIV-infected women, a rise in postpartum and post-cesarean section complications has been observed (952). Maternal HIV-1 infection may increase the rate of spontaneous fetal loss, but this has not been a consistent finding (924, 953,954). Pregnancy itself has a marginal effect, if any, on accelerating the progression of HIV-1 infection in women (924,955-958). In one study of 160 HIV-1-infected women, HIV-1 RNA viral loads did not change significantly during the pregnancy (957).

Mother-to-Infant Transmission

Vertical transmission of HIV-1 can occur *in utero*, intrapartum, or postpartum (through breast-feeding). Most infants in the United States acquire HIV-1 infection at the time of delivery (959).

Intrauterine transmission accounts for about 30% of all vertically infected infants, and about two thirds of these occur during the last two weeks before delivery (4). Second-trimester fetal blood sampling performed on HIV-1-infected women scheduled for elective pregnancy termination has confirmed the low rate of early *in utero* HIV-1 fetal infections (960,961).

Many studies have examined maternal and obstetric factors that increase the risk of vertical HIV-1 transmission. Not all risk factors have been consistently identified as such in every study, but there are definite patterns that have been observed. Maternal factors that enhance the risk of HIV-1 transmission to infants include advanced stage of maternal infection, low CD4⁺ absolute cell count or percentage, elevated CD8⁺ cell count or percentage, high viral load, p24 antigenemia, illicit drug use, co-infection by other sexually transmitted diseases, low titers or avidity of maternal HIV-1 antibodies, and infection by certain HIV-1 genotypes or phenotypes. Maternal vitamin A deficiency is a risk factor for vertical HIV-1 transmission in developing countries. Obstetric factors favoring HIV-1 vertical transmission include premature delivery, vaginal delivery, cervicovaginal HIV-1 viral load, maternofetal blood transfusions, longer (more than 4 hours) durations of membrane rupture, chorioamnionitis, and use of invasive fetal monitoring devices (959,962-974). Maternal plasma HIV-1 viral load is the strongest single predictor of mother-to-

child transmission (974). For twins born to HIV-1-infected mothers, the first infant delivered, whether vaginally or by cesarean section, appears to be at least twice as likely to be infected as the second-born twin (975). This may be as a result of more intense exposure of the first born to HIV-1-infected genital secretions. de Martino and associates could not confirm these observations in their studies of twins born to HIV-1-infected mothers. They did observe that, if the first-born twin became infected, 42% of their second-born siblings were infected as well. If the first-born twin escaped HIV-1 infection, only 13% of the second-born siblings got infected (976).

An infant is considered to have early (i.e., *in utero*) infection if the HIV-1 genome is detected by PCR or if HIV-1 is isolated from blood within 48 hours of birth. Positive results should be confirmed with at least one sample obtained after the neonatal period. An infant is considered to have late (i.e., intrapartum) infection if diagnostic studies (e.g., HIV-1 isolation, PCR, serum p24 antigen assays) are negative in blood samples obtained during the first week of life but become positive during the period from day 7 to 90, and the infant has not been breast-fed. Care should be exercised to avoid contaminating cord blood with maternal blood (977).

In the United States, breast-feeding of infants by infected mothers is not recommended. Postnatal HIV-1 transmission rates by breast-feeding are 8% to 18%, but can be as high as 13% to 39% (mean 26%) when mothers acquire their HIV-1 infection while lactating (978,979). Several factors have been associated with higher rates of transmission through breast milk: RNA viral load in milk or plasma, low maternal CD4¹ count, breast pathology (mastitis, cracked nipples, abscess), and duration of breast feeding. Because HIV-1 transmission can occur at any time during lactation, longer durations of breast feeding increase the overall risk for HIV-1 infections of infants (979). Both HIV-1-infected cells and cell-free virus are found in breast milk (978,979,980,981). Cell-free virus more commonly is found in mature milk than in colostrum (980). The PCR assay can detect HIV-1 RNA in whole milk or its components (breast milk cells, skim milk, lipid fractions), but the sensitivity appears greatest when whole breast milk is used for testing (981,982). After ingestion of infected breast milk, the virus can be transmitted to the infant through gut mucosal surfaces or tonsillar tissues (979).

In 1998, the WHO recommended that HIV-1-infected women in developing countries be provided information about the benefits and risks of breast-feeding so that they can make an informed decision regarding nutrition for their infants. A study of 371 infants born to HIV-1-infected mothers in Nairobi, Kenya, and randomized to breast- or bottle-feeding revealed comparable two-year mortality rates, even after adjusting for HIV-1 status. Both groups had similar rates of diarrhea or pneumonia during their first two years of life. HIV-1-infected infants had a ninefold higher risk of dying by the age of two years when compared to HIV-1-uninfected infants (983).

Vertical HIV-1 transmission has been reported to occur at various rates in different areas of the world. A report by the 19-center European Collaborative Study provided a rate of 14.4% among a cohort of 721 children followed for 18 months or longer (984). A similar rate of 14% to 20% was observed in a nationwide study of a cohort of 286 children born to HIV-1-positive mothers in Switzerland (985). The rate is about 25% to 30% in the United States for women not receiving zidovudine prophylaxis (931, 986). Rates as high as 50% have been reported from African countries such as Zaire and Kenya (987).

Multiple HIV-1 variants exist in infected persons. These variants arise through errors in reverse transcription and by recombination during retroviral replication. Because of the high turnover rate in the HIV-1 population (more than 10 billion virions are generated daily) and the high error frequency during replication, a large number of variants is produced. These variants subsequently undergo selective pressure from cellular tropism, host immune responses, and antiretroviral therapy. Only a small subset of the HIV-1 variants is transmitted from the mother to her infant, but it can include HIV-1 strains that carry specific drug-resistance mutations (988,989,990,991,992,993). In one study of the first viral isolate from a cohort of 91 HIV-1-infected infants born in New York in 1998 and 1999, 12.1% were shown to harbor zidovudine-resistance mutations (994). There are also concerns that pregnant women with zidovudine resistant HIV-1 strains may transmit the virus more readily to their offspring (993).

Treatment

Women should receive antiretroviral therapy appropriate for their stage of infection without regard to whether or not they are pregnant. Highly active antiretroviral therapy (HAART) is recommended for pregnant women with HIV-1 RNA levels greater than 1,000 copies/mL. However, most experts are of the opinion that HIV-1-infected pregnant women should be treated with potent antiretroviral drugs regardless of their CD4⁺ count or viral load because of the possibility of vertical transmission, even at relatively low HIV-1 RNA levels (4,995,996). In a review of several European and US prospective studies, Ioannidis and colleagues found 44 instances of HIV-1 transmission from mother to infant among 1,202 pregnant women whose viral load at delivery or one measured closest to delivery was less than 1,000 RNA copies/mL, and observed a 1% transmission rate among treated women compared to 9.8% for the untreated mothers (997). The downside of such a recommendation includes the potential teratogenicity of some of the medications and the risk for emergence of drug-resistant HIV-1 strains, especially among women who do not adhere adequately to the treatment regimen. Circulating resistant strains would impact future treatments for mothers and their infected infants. Women who are in their first trimester of pregnancy and who are not already receiving antiretroviral agents may consider delaying initiation of therapy until after 10 to 12 weeks of gestation (4,995,996). HIV-1-infected women who are already

P.1319

on antiretroviral agents when they become pregnant can expect their HIV-1 viral load to increase, and their CD4⁺ count to decrease, should they choose to discontinue their medications during the first trimester (998).

At least 20 different drugs have been approved by the Food and Drug Administration for the treatment of adults with HIV-1 infection, but data on their safety in pregnant women is limited for most of these agents (Table 48-6). These antiretrovirals act by inhibiting viral reverse transcriptase or protease, or by interfering with gp41-mediated fusion. Fixed combinations of certain drugs are available in the United States (e.g., zidovudine-lamivudine, emtricitabine-tenofovir disoproxil fumarate) and of others in countries such as India.

Some antiretroviral agents such as zalcitabine, efavirenz, and delavirdine should not be used because of their significant teratogenic potential. Insufficient data exist for tenofovir, amprenavir, fosamprenavir, atazanavir, and enfuvirtide to recommend their use in pregnant women. The recommended drugs are zidovudine, lamivudine, nevirapine, nelfinavir, and the saquinavir-ritonavir combination. The remaining medications listed in Table 48-6 are considered alternate agents that can be used when needed (999,1000).

It has been suggested that the use of combination antiretroviral therapy in pregnancy may be associated with preterm birth, but the data are inconclusive. Nevirapine-induced hepatic toxicity associated with rash has been observed in persons on chronic treatment with this medication, but not in those receiving the two-dose regimen for prevention of perinatal HIV-1 transmission. Nucleoside analogues interfere with mitochondrial replication by inhibiting γ DNA polymerase, resulting in mitochondrial DNA depletion and dysfunction. The most potent of these nucleoside analogues is zalcitabine, followed by didanosine, stavudine, zidovudine, lamivudine, abacavir, and tenofovir. Mitochondrial dysfunction can manifest with neuropathy, myopathy, pancreatitis, hepatic steatosis, and lactic acidosis. The frequency of lactic acidosis with microvascular hepatic steatosis in pregnant HIV-1-infected women treated with these drugs is not known, but it has been described in a few infants with intrauterine or neonatal exposures to these drugs (1000).

Zidovudine was the first antiretroviral agent shown to reduce the risk of perinatal HIV-1 transmission. The safety and efficacy of zidovudine as a chemoprophylactic agent against the vertical transmission of HIV-1 was demonstrated in a double-blind, placebo-controlled trial known as the Pediatric AIDS Clinical Trials Group (PACTG) Protocol 076 (931,1000). Pregnant women who were HIV-1 positive and whose CD4⁺ T-lymphocyte counts were higher than 200 cells per cubic millimeter were enrolled if they had no other indication for antiretroviral therapy and were between 14 and 34 weeks of gestation. Zidovudine

(or matching placebo) was given antenatally at a dose of 100 mg orally five times daily followed by intravenous zidovudine during labor (2 mg/kg of body weight given over 1 hour, followed by 1 mg/kg/h until delivery). The newborns received zidovudine at a dose of 2 mg/kg orally every 6 hours beginning at 8 to 12 hours of age, and this was continued for 6 weeks. The final analysis of this study included 402 mother-infant pairs. The rate of HIV-1 transmission was 7.6% (95% CI of 4.3%-12.3%) with zidovudine treatment and 22.6% (95% CI of 17%-29%) with placebo. The difference was very significant statistically (1001). The study noted that women in the placebo group with large viral burdens were more likely to transmit HIV-1 to their newborns (41% risk for those with more than 15,700 HIV-1 RNA copies per milliliter using the RT-PCR assay or more than 7,530 HIV-1 RNA copies per milliliter using a second-generation branched-chain DNA signal amplification assay). The rate of transmission in the zidovudine-treated cohort was lower than that for the placebo group for women with comparable HIV-1 RNA viral load measurements. Interestingly, the reduced vertical transmission noted with zidovudine was found not to be as a result of a reduction of viral RNA from baseline to delivery (1001).

After the results of PACTG 076 became available, zidovudine use during pregnancy and in newborns has steadily increased (946,1002). Several studies have confirmed that pregnant women receiving zidovudine are less likely to transmit HIV-1 to their offspring (1002,1003,1004,1005,1006,1007). A prospective trial (PACTG 185) evaluated pregnant women with advanced HIV-1 infection and low CD4⁺ count who were already on antiretroviral therapy, a quarter of whom had previously been treated with zidovudine. These women received the same zidovudine regimen used in PACTG 076, plus either standard intravenous immunoglobulin or a hyperimmune HIV-1 immunoglobulin. Although the advantage of one immunoglobulin preparation over the other could not be established, PACTG 185 demonstrated the efficacy of zidovudine for women with advanced disease and low CD4⁺ count (1007). Further reductions of perinatal HIV-1 transmission rates are possible with the addition of either lamivudine to the maternal and infant zidovudine regimen, or protease inhibitors to the maternal treatment regimen (1000).

The New York State Department of Health examined the risks of perinatal HIV-1 transmission for 939 exposed infants whose mothers received abbreviated zidovudine treatment regimens during pregnancy. The study found that the risk of HIV-1 infection for infants whose mothers received no zidovudine was 26.6% (95% CI of 21.1%- 32.7%). When treatment was started antenatally, the risk of perinatal HIV-1 transmission dropped to 6.1% (95% CI of 4.1%-8.9%). When zidovudine was started intrapartum, the rate increased to 10% (95% CI of 3.3%- 21.8%), and when it was started within the first 48 hours of life or at 72 hours of age or later, the rates were 9.3% (95% CI of 4.1%-17.5%) or 18.4% (95% CI of 7.7%- 34.3%), respectively. Zidovudine should thus be given during labor or the early neonatal period even to women who received no antenatal therapy (1008).

A randomized, placebo-controlled trial of zidovudine prophylaxis for the prevention of perinatal HIV-1 infection was performed in Thailand using a simpler and less

P.1320

P.1321

expensive protocol. Pregnant women received zidovudine at a dose of 300 mg orally twice daily beginning at 36 weeks of gestation until onset of labor, followed by 300 mg orally every 3 hours from onset of labor to delivery. Women were advised not to breast-feed their infants. Interim analysis of the data on 397 women revealed that the risk of perinatal HIV-1 transmission was 18.6% (95% CI of 13%-24%) in the placebo recipients compared with 9.2% (95% CI of 5%-13.5%) in the zidovudine-treated mothers, representing a 51% decrease in HIV-1 transmission (1009). Another study conducted in Africa (PETRA trial) showed that using a combination of zidovudine and lamivudine starting at 36 weeks gestation, intrapartum, and for one week to the mother and infant in the postpartum period reduced vertical transmission of HIV-1 by 63%, despite breast feeding (1010). The HIVNET 012 study, performed in Uganda, showed that a single 200 mg oral dose of nevirapine given to the mother at onset of labor followed by a single 2 mg/kg oral dose of the same drug administered to the breast-feeding infant at 48 to 72 hours of age was more effective than a short course of zidovudine prophylaxis (600 mg orally at labor onset and 300 mg every 3 hours until delivery, and 4 mg/kg twice daily for 7 days

given to the babies). The gain was an estimated 41% reduction in HIV-1 transmission rate, and this was sustained through 18 months of age (1011,1012). However, the benefits of the HIVNET 012 protocol were not realized when it was implemented in Kenya (1013). Another trial (PACTG 316) investigated whether combining the HIVNET 012 and PACTG 076 protocols could further reduce HIV-1 perinatal transmission, but found no difference in outcome compared with the standard zidovudine prophylactic regimen (1014).

TABLE 48-6 ANTIRETROVIRAL AGENT USE IN PREGNANCY

Drug	FDA Pregnancy Category*	Placental Passage	Breast Milk Passage	Teratogenicity or Carcinogenicity
<i>Nucleoside and nucleotide analogue reverse transcriptase inhibitors:</i>				
Abacavir	C	Yes ¹	Yes ¹	Decreased fetal body weight, fetal anasarca, and skeletal malformations in rats treated with very high doses during organogenesis; malignant tumors of liver, thyroid, and genital tract of rats with high doses of drug
Didanosine	B	Yes (0.35) ^{2,3}	Yes ¹	None
Emtricitabine	B	Not known	Not known	Not teratogenic in rats or rabbits exposed to 60- to 120-fold higher doses than used in humans; carcinogenicity studies not completed
Lamivudine	C	Yes (1.0) ^{2,3}	Yes ³	None
Stavudine	C	Yes (0.5–0.8) ^{1,3,4}	Yes ¹	Minor skeletal ossification delays in rats; benign and malignant liver and bladder tumors in rats and mice receiving 250-fold to 732-fold usual human doses
Tenofovir DF	B	Yes (0.17) ⁴	Yes ¹	Osteomalacia in juvenile animals receiving high doses; carcinogenicity studies not completed

Zalcitabine	C	Yes (0.5–0.6) ⁴	Not known	Hydrocephalus in rodents receiving 1,000-fold higher dose than used in humans; decreased fetal weight, skeletal defects, and thymocyte cytotoxicity; thymic lymphoma in rodents
Zidovudine	C	Yes (0.85) ³	Yes ³	Vaginal squamous tumors in adult rodents; lung, liver, and female reproductive tumors in offspring of mice treated with 50 times usual human dose; fetal malformations after near-lethal doses (350-fold higher than human dose)
Non-nucleoside reverse transcriptase inhibitors:				
Delavirdine	C	Not known	Yes ¹	Ventricular septal defects in rats given high doses; non-carcinogenic in rats; hepatocellular adenoma and carcinoma in mice; bladder tumors in male mice
Efavirenz	C	Yes (1.0) ^{1,4,5}	Not known	Anencephaly, cleft palate, anophthalmia, and microphthalmia in monkeys; liver and lung tumors in female mice
Nevirapine	C	Yes (1.0) ³	Yes ³	Hepatocellular adenomas and carcinomas in rats and mice; decreased fetal weight in rats receiving high doses
Protease inhibitors:				

Amprenavir	C	Not known	Yes ¹	Hepatocellular adenomas and carcinomas in male mice and rats at doses 2- to 4-fold higher than for humans; abortion in rabbits; deficient bone ossification in rabbits and rats
Atazanavir	B	Not known	Not known	Carcinogenicity studies not completed; not teratogenic in rabbits or rats exposed to doses comparable to those used in humans
Fosamprenavir	C	Not known	Yes ¹	Benign and malignant liver tumors in male rats and mice; increased rate of abortion in pregnant rabbits
Indinavir	C	Yes ^{1,6} ; minimal in humans	Yes ¹	Thyroid adenomas in male rats; no teratogenicity in rabbits or dogs; extra ribs in rats
Lopinavir+ritonavir	C	Not known	Yes ¹	Carcinogenicity studies not completed; delayed skeletal ossification in rats
Nelfinavir	B	Minimal in humans	Yes ¹	Thyroid follicular adenomas and carcinomas in rats; minor skeletal ossification delay with high doses
Ritonavir	B	Yes ¹ ; minimal in humans	Yes ¹	Liver adenomas and carcinomas in male mice; cryptorchidism in rats; decreased body weight and ossification delays after toxic maternal doses in rats
Saquinavir	B	Minimal ^{1,3,5}	Yes ¹	Carcinogenicity studies not completed; no teratogenicity in animals studies
Fusion inhibitors:				

Enfuvirtide	B	Not known	Yes ¹	Long-term carcinogenicity studies not done; not teratogenic in rats or rabbits at up to 27-fold higher doses than used in humans
-------------	---	-----------	------------------	--

Abbreviations: FDA = Food and Drug Administration; DF = disproxil fumarate

* Pregnancy categories: B = Animal reproduction studies fail to risk to the fetus, but adequate well-controlled studies of pregnant women have not been conducted; C = Safety in human pregnancy has not been determined; animal studies are either positive for fetal risk or have not been conducted, and the drug, and the drug should not be used unless the potential benefit outweighs the potential risk to the fetus.

Recommendations for use of antiretroviral drugs in pregnant HIV-1-infected women for maternal health and interventions to reduce perinatal HIV-1 transmission in the United States, June 23, 2004 [online]. Available from <http://www.aidsinfo.nih.gov/>. Accessed August 28, 2004, with permission.

A study of 1,844 pregnant HIV-1-infected Thai women who were receiving zidovudine therapy during the third trimester, and conducted between 2001 and 2003, compared three nevirapine regimens: mothers and infants each received a single nevirapine dose, mothers received one nevirapine dose and infants got one dose of placebo, or both mothers and infants were given a placebo. All infants were given zidovudine for one week, and they were formula fed. Women not receiving nevirapine transmitted HIV-1 to 6.3% of their infants, although those getting a single dose of nevirapine transmitted the virus to 1.9% and 2.8% of the infants getting nevirapine or placebo, respectively (1015). The WHO recommends this combination approach (zidovudine beginning at 28 weeks of pregnancy and an intrapartum dose of nevirapine, plus zidovudine for one week and a single dose of nevirapine given soon after birth to infants) for women in resource-limited settings who do not require antiretroviral therapy for themselves (1016). For antiretroviral treatment-naive women who are administered a single intrapartum dose of nevirapine, the use of a single nevirapine dose alone for infants was similar in outcome to one dose of nevirapine plus one week of zidovudine in terms of mother-to-child HIV-1 transmission (1017). Nevirapine should be given to mothers at least one hour before delivery to be effective (1018).

Concerns over the use of nevirapine for prevention of mother-to-child transmission revolve around the emergence of nevirapine-resistance mutations in treated women (1016). In the PACTG 316 protocol, HIV-1-infected pregnant women received a single 200 mg nevirapine dose during labor. Nevirapine-resistance mutations were present in 2.3% of women before receipt of study drug, and in 15% at 6 weeks postpartum (1019). Women receiving intrapartum nevirapine prophylaxis are more likely to have virologic failure if they are subsequently treated with nevirapine-containing antiretroviral drug regimens (1020).

Elective cesarean delivery performed before onset of labor and rupture of membranes has been shown to reduce the rate of mother-to-child HIV-1 transmission. The combined use of elective cesarean delivery and zidovudine provides additive protective effects, reducing the rate of vertical HIV-1 transmission to about 1%. The American College of Obstetricians and Gynecologists recommends that HIV-1-infected pregnant women with HIV-1 RNA levels greater than 1,000 RNA copies/mL near the time of delivery be considered candidates for delivery by elective cesarean section at 38 weeks of gestation. HIV-1-infected women with undetectable viral loads are unlikely to benefit from a scheduled cesarean section, and the morbidity from the procedure outweighs any potential benefits (1000). A Thai study using a combination of zidovudine and lamivudine beginning at 34 weeks of gestation, a scheduled cesarean section at 38 weeks of gestation, preoperative intravenous zidovudine, and 4 weeks of neonatal zidovudine therapy showed that mother-to-child HIV-1 transmission still occurred (1021).

Despite the efficacy of protocols aimed at preventing mother-to-child transmission of HIV-1, there were missed opportunities for perinatal HIV-1 prevention for over half of the infected infants born between 1996 and 2000 at 6 U.S. sites (1022). A survey of 982 U.S. pediatricians found that the maternal HIV-1 status was unknown for 41% of neonates they evaluated in the 3 months before the survey, but that a discussion about screening for this infection was undertaken for only 10% of these infants (1023). Reasons cited for not addressing the need to screen for HIV-1 included low prevalence of disease in a pediatrician's area of practice (65%), parents who do not fit an "at risk" profile (56%), fear of offending the parents (50%), parental lack of understanding about the importance of screening (50%), and lack of sufficient time for counseling (44%). For infants of HIV-1-infected mothers who are prescribed zidovudine, adherence to the neonatal prophylactic regimen is decreased for women who are asymptomatic and lack a social support network (1024).

It is currently recommended that all HIV-1-infected pregnant women be treated with appropriate antiretroviral regimens suitable for their stage of disease. At a minimum, antenatal and intrapartum maternal zidovudine prophylaxis and treatment of newborns with zidovudine for 6 weeks, using the dosage regimens utilized in PACTG 076 as outlined earlier, is recommended (1000). Women who do not receive antenatal zidovudine because of nonlife-threatening serious drug-related toxicity or personal choice should still receive the drug intrapartum and their newborns should be treated. *In utero* exposure of infants to zidovudine has been associated with the occurrence of mild anemia and lower levels of other hematologic parameters, and a possible increased rate of early first febrile seizure (1025,1026,1027). Zidovudine dosing for premature newborns (34 weeks or less of gestation) should be 1.5 mg/kg given intravenously or 2.0 mg/kg given orally every 12 hours, then increased to every 8 hours at 2 weeks of age for those with a gestational age of at least 30 weeks, or at 4 weeks of age for those whose gestational age is 29 weeks or less (1028).

HIV-1-exposed newborns should have a complete blood count done before zidovudine initiation and again at 1 and 2 months of age at a minimum. If anemia develops, a repeat hemoglobin measurement at 12 weeks of age usually shows resolution of zidovudine-related hematologic toxicity. Transient lactic acid elevations have been observed. Mitochondrial dysfunction can occur, but is infrequent. Infants should be assessed at 1, 2, and 6 months for symptoms and signs of mitochondrial toxicity such as encephalopathy, non-febrile seizures, developmental delay, cardiomyopathy, or hepatitis (933,1029).

Prophylaxis for *Pneumocystis jirovecii* (formerly *P. carinii*) should begin at 4 to 6 weeks of life, on completion of zidovudine therapy. The preferred regimen is trimethoprim-sulfamethoxazole (given at a dose of 150 mg/m²/d of the trimethoprim component in two divided doses, and administered three times per week on consecutive days). The total daily dose of trimethoprim-sulfamethoxazole also can be given as a single dose (instead of two divided doses), or it can be given 7 days per week (instead of on three days of each week), or it can be given in two divided daily doses but administered three times per week on alternate days. Oral dapsone at a dose of 2 mg/kg once daily or 4 mg/kg given once a week, can be prescribed to infants intolerant of trimethoprim-sulfamethoxazole. Intravenous pentamidine (4 mg/kg every 2 to 4 weeks) or atovaquone (30 mg/kg for infants 1 to 3 months of age, or 45 mg/kg for infants 4 to 24 months of age) can be given orally once daily as alternative regimens. These regimens are continued until the diagnosis of perinatal HIV-1 infection is excluded, which usually requires two negative virologic assays done after 1 month of age (933).

HIV-1-exposed infants in the United States should not breast-feed, even if their mothers are on effective antiretroviral drug regimens. Potential exposures to other infectious agents that could be transmitted vertically (e.g., HBV, HCV, HSV, CMV, *T. pallidum*) should be evaluated and managed accordingly.

Fetal and Neonatal Infection

Congenitally infected infants usually are asymptomatic during the neonatal period, although detectable subtle signs such as lymphadenopathy and hepatosplenomegaly have been observed in 2% to 8% of cases, and some infants have been born with evidence of cerebral atrophy (1030,1031). Kaposi sarcoma presenting within the first month of life has been described rarely in HIV-1-infected infants (1032). The clinical latency period to development of AIDS is shorter than that for adults. About one-fourth of all perinatally infected infants develop AIDS by 1 year of age, and 40% to 50% do so by age 3 to 4 years; 33% of all perinatally infected patients remain free of AIDS by 13 years of age. About 10% of all HIV-1-infected infants die by age 1 year, and 25% to 30% by age 5 years (1033,1034,1035). Median survival for perinatally-infected Thai children is

P.1323

estimated at 60 months, but is only 6 months for African infants (1036,1037). The mortality rates for infants infected perinatally with HIV-1 in the United States are 9% and 13% at 12 and 36 months, respectively, after a diagnosis of AIDS is made (917). Higher HIV-1 viral loads and lower CD4⁺ percentages or absolute counts have been shown to correlate with more rapid progression to AIDS and to death (1038,1039). The slowest progression occurs in infants with low viral loads (plasma RNA levels of less than 10,000 copies per milliliter) and high CD4⁺ counts (1039,1040,1041,1042,1043). Infants with intrauterine HIV-1 infection are 2.5-fold (95% CI of 1.1-5.8) more likely to progress to AIDS or death than those with intrapartum HIV-1 infection (1044).

The diagnosis of HIV-1 infection during the neonatal period or early infancy can be difficult (933). Measurement of HIV-1-specific IgG is not useful because of passive transplacental passage of this antibody and its persistence for several months. The median age to clearance of passively acquired HIV-1 antibodies is 13 months (range 10 to 16) (1045). Positive HIV-1 antibody test results in those younger than 18 months of age indicate maternal infection but cannot diagnose infection in the infant (933). Although positive HIV-1 antibody test results in toddlers 18 months of age or older generally are considered indicative of infection, the reverse may not be true. Some infants with virologic evidence of HIV-1 infection can have negative or indeterminate serologic test results at 18 to 24 months of age (1046). A few infants who serorevert to an HIV-1-seronegative status in early infancy may actually be HIV-1 infected, and close follow-up is required (1047, 1048). Virus co-culture methods, p24 antigen detection, immune complex dissociation, and HIV-1-specific IgM and IgA measurements are all hampered by low sensitivities in the first weeks of life (1049,1050,1051,1052,1053). Assays for HIV-1-specific IgA during the first month of life detect fewer than 10% of HIV-1-infected infants, but their sensitivities increase to 60% for 3-month-old infants and to 77% to 100% at 6 months of age or later (1051,1052).

The early diagnosis of HIV-1 infection can be accomplished by using DNA or RNA PCR assays (933). HIV-1 DNA PCR has a sensitivity and specificity of 96% and 99%, respectively, by 28 days of age for HIV-1 subtype B (the most common subtype in North America). The assay is less sensitive for non-B subtypes, such as subtype C that predominates in regions of Africa and India or subtype E that predominates in southeast Asia (1039). HIV-1 RNA can be measured in plasma by a variety of assays. HIV-1 RNA assays are at least as sensitive and specific, if not more so, than HIV-1 DNA assays (933,1054). The sensitivity and specificity of PCR is somewhat higher in older infants than in neonates (1054,1055). For infants at low risk of perinatal HIV-1 transmission, the positive predictive value for PCR is about 56% for neonates and 83% for older infants. Approximately 30% to 50% of HIV-1-infected infants are DNA PCR positive at birth, which suggests intrauterine infection, and about 50% to 70% of infected infants have negative DNA PCR results at birth but become positive after 7 days of age, which suggests intrapartum transmission of the virus (1056). The PCR can be falsely positive if

contamination with maternal blood occurs or if there is cross-contamination from other blood specimens in the laboratory.

Infants exposed to HIV-1 should be tested by PCR or other virologic assays at birth, at 4 to 6 weeks of age, and at 2 to 4 months of age. Cord blood should not be used for PCR assays. If either test result is positive for HIV-1, it should be repeated immediately for confirmation. A negative test result at 4 months of age or later provides more than 95% assurance that the infant is not infected with HIV-1. Continued follow-up serologic testing should be performed until disappearance of passively transferred maternal antibodies. An exposed infant is considered uninfected when there are no physical findings suggestive of HIV-1 infection, virologic test results are negative, immunologic test results (CD4⁺ count and percentage) are normal, and, after the infant is 12 to 18 months of age or older, two or more HIV-1 antibody test results are negative (933). Follow-up of HIV-1-uninfected infants who were exposed *in utero* to maternal zidovudine prophylactic therapy have shown no drug-related ill effects 3 to 5.6 years later (1057).

Antiretroviral treatment should be started in all HIV-1-infected infants younger than 1 year of age as soon as the diagnosis is confirmed, regardless of clinical or immunologic status or viral load results, because they are considered to be at high risk of disease progression. By 12 months of age, about 50% of infants with perinatal HIV-1 infection develop moderate immune suppression, and another 20% have severe immune suppression (1039). Moderate and severe immune suppression for infants less than 12 months of age is defined as absolute CD4⁺ count (and percentage) of 750 to 1,499 (15%-24%) and less than 750 (<15%), respectively. Treatment with three drugs (preferably two nucleoside reverse transcriptase inhibitors and one protease inhibitor) is recommended, as this affords the infected infant the best opportunity to preserve immune function and delay disease progression by maximally suppressing viral replication, preferably to undetectable levels (1039,1058,1059). Treated infants need close monitoring for medication-related adverse effects and adherence issues, virologic and immunologic responses to therapy, and emergence of drug-resistant HIV-1 strains (938,1029,1039,1060-1062).

The most common AIDS-defining conditions in pediatric patients are *P. jiroveci* pneumonia, lymphoid interstitial hyperplasia, recurrent bacterial infections, HIV-1 wasting syndrome, candidiasis, and HIV-1 encephalopathy (1033,1035-1037,1063). Other problems may include *Mycobacterium avium-intracellulare* infections, tuberculosis, CMV retinitis, disseminated HSV infection, herpes zoster, toxoplasmosis, extrapulmonary cryptococcosis, and cryptosporidiosis. *P. jiroveci* pneumonia can occur at any age, but it is diagnosed most commonly in young infants not receiving appropriate prophylaxis. Lymphoid interstitial hyperplasia is a chronic lung disease that results from the

P.1324

proliferation of lymphoid tissue in the interstitium of the lungs leading to tachypnea, hypoxia, and digital clubbing (1064). Progressive encephalopathy can be the first manifestation of HIV-1 infection in 10% to 15% of patients, and can range in severity from minor developmental delays to severe CNS involvement. Ventricular enlargement is the most common finding, followed by cortical atrophy, attenuation of periventricular white matter, and cerebral calcifications (1065). Cognitive decline sometimes occurs despite viral suppression and immunologic stability (1066). Cardiomyopathy can be present in HIV-1-infected children, and may be reversible with highly active antiretroviral therapy (1067).

Impaired linear growth occurs early and appears to be more pronounced in infants with higher viral loads, and this may not improve after virologic suppression (1068- 1071). Altered pancreatic endocrine secretion manifested as increased insulin, glucagon, C-peptide, and glucose measurements is common in HIV-1-infected children not receiving protease inhibitors, and this is associated with growth problems (1072). Parotitis occurs in one-third of children surviving for 5 years or longer (1073).

Children with AIDS are also at increased risk of developing cancer. The most common malignancy is non-Hodgkin lymphoma (Burkitt lymphoma being the most frequent), followed by Kaposi sarcoma, leiomyosarcoma, and Hodgkin lymphoma. Varied proliferative and neoplastic disorders such as papillomavirus-related genital lesions, acute lymphoblastic leukemia, and other sarcomas have also

been described. Non-Hodgkin lymphoma develops a median of 14 months after AIDS is diagnosed, but leiomyosarcomas take longer to manifest (1074,1075).

Infusions of IGIV every 4 weeks can reduce the risk of serious and minor viral and bacterial infections (1076). HIV-1-infected infants in the United States should receive all childhood immunizations with the possible exception of the varicella vaccine. However, this vaccine can be considered in those who are asymptomatic or mildly symptomatic and have no evidence of immune suppression. The live, attenuated measles-mumps-rubella vaccine can be given to HIV-1-infected infants who are not severely immunodeficient based on their absolute CD4⁺ cell count or percentage. The inactivated influenza vaccine, but not the cold-adapted trivalent live vaccine, should be given every season for infants 6 months of age or older (1077).

Toxoplasmosis

Toxoplasmosis is a common zoonosis, afflicting approximately one in three people worldwide. Infections of immunocompetent hosts are typically asymptomatic or benign, but intrauterine infections and illnesses in immunosuppressed patients can be severe or fatal. The causative organism, *T. gondii*, is an obligate intracellular protozoan that can be encountered in the form of a tachyzoite, tissue cyst, or oocyst. In addition to humans, *T. gondii* can infect other warm-blooded animals such as cats, dogs, sheep, swine, and some birds; cats and other felines are the only known complete hosts for this parasite (15).

The life cycle of *T. gondii* usually is divided into an enteroepithelial sexual phase that occurs only in felines and an extraintestinal asexual phase that takes place in definitive (e.g., cats) and intermediate (e.g., humans) hosts. Susceptible cats can acquire *Toxoplasma* infection by ingesting oocysts or parasite-harboring tissues of other animals. Some of the organisms released in cat intestines invade gut epithelial cells and undergo sexual differentiation into microgametes and macrogametes; the gametocytes later fuse to produce a zygote. After a rigid wall forms around the zygote, it is excreted in feces as an oocyst. Acutely infected cats generally shed millions of oocysts in their feces daily for periods of 1 to 3 weeks. Parasites that do not undergo sexual differentiation may instead penetrate the gut wall and spread to other tissues by way of the blood and lymphatics; this extraintestinal or asexual stage can occur in humans and other susceptible animals as well (1078).

The tachyzoite is the actively proliferating form that is encountered in organs during the acute stage of infection. Tachyzoites gain entry into the cytoplasm of host cells and multiply rapidly. Infected cells subsequently burst and release progeny parasites that go on to attack neighboring host cells, which leads to the formation of necrotic areas that are surrounded by an inflammatory cellular reaction. This process eventually is curtailed by specific cellular and humoral host immune responses. In immunodeficient persons, the acute infection can continue relentlessly and cause serious illnesses.

After the host develops specific immunity against *T. gondii*, the organism can remain in organs in a viable, clinically inapparent tissue cyst form. *T. gondii* tissue cysts most commonly are found in the brain, eyes, myocardium, and skeletal muscles, and can be detected as early as 6 to 12 days postinfection in experimentally infected animals (1079). Each cyst can contain many thousands of slowly propagating or dormant parasites (bradyzoites). Encysted organisms can reactivate and cause serious illnesses, such as encephalitis and pneumonia, in patients who become immunodeficient later in life because of malignancy, AIDS, or immunosuppressive therapy (e.g., organ transplants).

There are three main clonal lineages (or strain types) of *T. gondii*, designated types I to III. Types I and II have generally been recovered from congenitally-infected infants, type II from patients with AIDS, and type III from animals. Sexual recombination between clonal lines occurs in nature (1080,1081).

T. gondii is transmitted to humans primarily through the ingestion of oocyst-contaminated water or food or the consumption of cyst-containing raw or undercooked beef, pork, mutton, or chicken. Unwashed hands can serve as vehicles for the transport of contaminating oocysts from the soil, dust, or cat litter box material into the mouth. Transmission occasionally can occur by eating raw infected eggs, transfusion of infected blood or blood products, or accidental self-inoculation of laboratory workers who are

P.1325

in contact with infected animals, needles, or glassware. Direct human-to-human transmission occurs primarily in the context of transplacental spread of the parasite to a developing fetus and, much less often, after an organ (e.g., heart, kidney) is transplanted from a seropositive donor into a seronegative recipient (1081,1082).

Maternal Toxoplasmosis

Epidemiology

The prevalence of anti-*Toxoplasma* antibodies among women of child-bearing age varies geographically, ranging from none to more than 90%. A seroprevalence of 39% was found in a large study of 22,845 pregnancies from diverse parts of the United States conducted between 1959 and 1966 (1083). Another survey of 17,658 sera from persons 12 years of age or older conducted in the United States between 1988 and 1994 showed that the overall age-adjusted prevalence was 22.5%. The overall prevalence was highest in the Northeast (29%) and lowest in the West (17.5%). Among women between 15 and 44 years of age, 15% had antibodies to *T. gondii*. Risk factors for seropositivity were increased age, birth in a foreign country, lower educational level, living in crowded conditions, and working in soil-related occupations. Current cat ownership did not increase the overall likelihood of having antibodies to this parasite (1084). A study of 4,234 persons 12 years of age or older conducted in 1999 and 2000 in the United States found that 15% of women had antibodies to *T. gondii*, with a higher prevalence among African Americans (1085). Seventh Day Adventists, who follow a diet that contains no meat, have a likelihood of being seropositive for *T. gondii* that is only 20% of that for a control group of other healthy adults living in the same area (1086). The average seroprevalence among HIV-1-infected women from New York, California, Washington, D.C., and Illinois is about 15%. HIV-1-infected women 50 years of age or older and those born outside the United States have

seroprevalence rates of 32% to 41% (1087). Examples of seroprevalence figures for women of child-bearing age from other countries are India (Delhi), 2%; Australia (Melbourne), 4%; Taiwan, 9%; China (Lanzhou), 7%; China (Chengdu), 39%; southern Finland, 20%; Saudi Arabia, 30%; France (Strasbourg), 36%; Poland, 36%; Italy, 40%; Belgium, 46%; Germany, 46% to 68%; Greece, 52%; Panama, 63%; and Ethiopia, more than 75% (15,1082).

The incidence of acute *T. gondii* infection during pregnancy varies by locale. Reported frequencies per 1,000 pregnancies include Alabama with 0.6, Finland with 2.4, Australia with 5, New Zealand with 6, Germany with 7.5, and Belgium with 14.3 (15,1088-1090). The risk of infection is greatest for pregnant women leaving a region with a low incidence of toxoplasmosis to reside in an area in which the infection is prevalent (1088). Specific risk factors for acquisition of *T. gondii* infection in pregnancy may include consumption of cured pork and raw meat (including tasting raw meat while preparing food), eating unwashed raw vegetables or fruits, infrequent washing of hands or kitchen utensils after preparation of raw meat before handling another food item, contact with soil, and cleaning cat litter boxes (1091,1092,1093,1094).

Clinical Manifestations

Acute toxoplasmosis is asymptomatic in 80% to 90% of pregnant women. Individuals with clinically evident illnesses most commonly present with lymphadenopathy, primarily of the head and neck region; a single node is involved in about two-thirds of patients (1095). *T. gondii* causes about 1% to 5% of infectious mononucleosis cases and should be considered a likely etiologic agent in patients with negative heterophile antibody test results (1096). Complications such as hepatitis, pneumonia, myocarditis, encephalitis, and deafness are rare in immunocompetent women (1082,1097,1098). Ocular involvement manifests mainly as retinochoroiditis and retinochoroidal scars, but lesions such as neuroretinitis, retinal vascular occlusions, and scleritis also occur (1099,1100,1101). It is thought that severe ocular disease will occur in the immunocompetent patient if the infecting parasite is type I (1100). Psychiatric complications such as psychoses with schizophreniform features, anxiety, and depression have been encountered on rare occasions (1102,1103). Fulminating illnesses are common in immunosuppressed patients (1098,1104).

T. gondii spreads transplacentally to involve the developing fetus in 25%, 54%, or 65% of pregnant women with untreated primary toxoplasmosis during the first, second, or third trimester, respectively (1082). Proper maternal therapy reduces the overall incidence of fetal infection by more than 50%, and fewer infected infants manifest with severe congenital toxoplasmosis (1105,1106). These data underscore the importance of accurate and timely diagnosis of acute toxoplasmosis in pregnant women.

Diagnostic Tests

A clinical diagnosis of toxoplasmosis should be considered dubious unless supported by appropriate laboratory test results. *T. gondii* can be isolated from infected blood, CSF, aqueous humor, amniotic fluid, or homogenized tissues (e.g., placenta, brain, muscle) by inoculating these specimens into the peritoneal cavities of mice or onto tissue cultures. Tissue culture techniques are faster but less sensitive than intraperitoneal inoculation methods, but neither method is practical for clinical purposes. Tachyzoites can be visualized in tissue sections or smears of body fluids, especially if labeled specific anti-*Toxoplasma* antibodies are used for staining; their presence denotes acute infection. The demonstration of tissue cysts on histopathology can be consistent with an acute or a chronic *Toxoplasma* infection (619).

Other immunologic techniques that have been used for the diagnosis of toxoplasmosis include intradermal skin tests and transformation of lymphocytes on exposure to

P.1326

Toxoplasma antigens, both of which connote chronic infection (1082). *Toxoplasma* antigens can be detected in CSF, urine, serum, or amniotic fluid using enzyme-linked immunosorbent assays (ELISA) or immunoblotting methods. A positive antigen test result indicates that the infection is recent. This is particularly helpful in newborns and immunodeficient persons in whom antibody responses to infection may be absent or unpredictable (15,1107). The antigen test is not available commercially. The PCR has been used successfully for the direct detection of *T. gondii* DNA in clinical samples by amplification of the *P30* or *B1* genes of the parasite; amplification of TGR1E (a repetitive DNA sequence) and a part of the small subunit ribosomal DNA (rDNA) also have been used (1108,1109,1110,1111,1112,1113,1114).

The diagnosis of toxoplasmosis most often rests on serologic confirmation. The Sabin-Feldman dye test, traditionally the reference test against which newer methods are compared, requires the use of live parasites. Positive titers are usually in the 1:256 to 1:128,000 range. Most laboratories have abandoned the dye test in favor of simpler techniques that use killed antigens, such as the IFA, ELISA, agglutination, and indirect hemagglutination (IHA) tests.

Toxoplasma-specific IgM antibodies can be measured by IFA, ELISA, or IgM immunosorbent agglutination assay (IgM-ISAGA). False-positive IgM-IFA or IgM-ELISA are encountered in sera containing rheumatoid factor or the IgM can be directed against sphingolipids or ceramides that co-migrate with a low molecular weight antigen of the parasite during lipid extraction; these problem are circumvented if a double-sandwich IgM-ELISA (DS-IgM-ELISA) is performed (1111,1115). Specific IgM antibodies usually become positive within 1 to 2 weeks of infection and continue to be detectable for months or years, especially when

measured by very sensitive assays such as DS-IgM-ELISA or IgM-ISAGA. The detection of specific IgM antibodies should not be considered proof that an infection is acute. In a British study of 446 *Toxoplasma*-infected women, specific IgM antibodies were detected for median periods of 13 and 10 months using ISAGA or IFA methods, respectively (1116). Persistent IgM responses for longer than 2 years were seen in 27% of women using ISAGA and in 9% using IFA (1116). IgM antibodies have been detected for as long as 12 years after acute infection in rare instances (1111).

High specific IgM titers suggest acute infection, especially if accompanied by high specific IgG titers of about 1:1,000 or greater as measured by IFA or the Sabin-Feldman dye test. Low specific IgM titers measured by DS-IgM-ELISA or IgM-ISAGA generally are encountered in patients whose infections occurred several months earlier. IgM-IFA tests are considerably less sensitive than DS-IgM-ELISA or IgM-ISAGA and are positive in only 60% to 70% of patients with acute infections and 25% to 50% of infants with congenital toxoplasmosis. It is important to know the type of assay used to measure specific IgM antibodies in pregnant women to interpret correctly the significance of positive and negative results (15,619). Commercially available test kits for *Toxoplasma* IgM measurements unfortunately are unreliable as the sole determinant of recent *T. gondii* infection during pregnancy, and reliance on a single test result can lead to misdiagnoses and possibly inappropriate interventions (FDA Public Health Advisory: Limitations of *Toxoplasma* IgM Commercial Test Kits, July 25, 1997).

Anti-*Toxoplasma* IgG antibodies usually appear early during an infection. IgG titers peak at about 2 months, gradually drop thereafter, but remain detectable for years. The predominant IgG antibody response is of the IgG1 subclass (1117). A single high specific IgG titer is considered only suggestive of an acute infection. The strength of the binding of specific IgG to multivalent *Toxoplasma* antigens (IgG avidity) has been shown to be low in acute infections and high in chronic infections. Low IgG avidity can persist for as long as a year (1113). This test is being refined with the use of recombinant *Toxoplasma* antigens instead of lysed whole cell antigen, because rates of affinity maturation of IgG antibodies differ for specific parasitic antigens (1118). IgG avidity greater than 20% indicates that the infection occurred at least 20 weeks earlier. Thus, detection of high-avidity IgG antibodies to *Toxoplasma* antigens in pregnant women during the first half of their pregnancies can provide reassurance that their infections were remote in relation to the pregnancies (1119,1120).

Anti-*Toxoplasma* IgA antibodies directed against the major surface protein of tachyzoites (P30) are present in more than 95% of patients with acute infections (619). These antibodies are detected at the end of the first month of infection and usually disappear within 4 to 7 months, but can last up to 12 months or occasionally longer (619,1111,1121). Specific IgA antibodies are found rarely in patients with chronic infections (1121).

Specific serum IgE antibodies are present in about 86% of women who seroconvert during pregnancy. They appear shortly before or concomitantly with specific IgA antibodies. Specific IgE antibodies usually persist for less than 4 months, but are occasionally detectable for up to 8 months (619,1122).

Antibodies detected by IHA are different from those measured by the dye test, ELISA, or IFA. The titers take several weeks before becoming positive, making the test unsuitable for diagnosis of acute toxoplasmosis during pregnancy (15).

The differential agglutination test (AC/HS test) compares IgG titers obtained using acetone- or methanol-fixed (AC) tachyzoite antigens with those measured using formalin-fixed (HS) tachyzoite antigens. AC antigens detect acute phase-specific IgG antibodies. The AC-to-HS ratio is used to determine the timing of the primary infection. The test can show an acute pattern for up to 14 months (666,1123).

Serologic Diagnosis of Maternal Infection

Acute infection in immunologically normal women can be diagnosed if seroconversion or a fourfold or greater rise in antibody titers occurs when serum samples are collected 3

P.1327

to 6 weeks apart (1082). The absence of *Toxoplasma*-specific IgM antibodies as measured by the DS-IgM-ELISA or IgM-ISAGA essentially excludes the diagnosis of acute toxoplasmosis. Elevated titers obtained by these assays are considered suggestive of the diagnosis, especially if specific IgG titers are high as well. Positive IgM-IFA results are more likely to represent recent infection. Specific antibodies detected by IgM-ISAGA or DS-IgM-ELISA usually persist at low levels for months or years after infection. High levels measured many years after the acute infection are rare (1111). The detection of *Toxoplasma*-specific serum IgA or IgE antibodies indicates a recent infection; conversely, absence of these antibodies in a seropositive woman suggests that the infection is old (619,1121,1124).

A panel of tests referred to as the Toxoplasma Serological Profile (TSP) is available from the Toxoplasma Serology Reference Laboratory of the Palo Alto Medical Foundation (<http://www.pamf.org/serology/>). TSP includes DS-IgM-ELISA, ELISA IgA, ELISA IgE, the Sabin-Feldman dye test, and the differential agglutination test (AC/HS test). Of 811 women who had positive *Toxoplasma* IgM test results performed at hospital or commercial laboratories, only 40% were shown to have a recent illness using TSP (1111,1113, 1125).

Immunodeficient women with acute *T. gondii* frequently are unable to mount a specific IgM response, and their IgG responses may be absent or low. Use of the more sensitive antibody assays may be helpful, but direct detection of the parasite or its components (e.g., antigen, DNA) in body fluids or tissues is sometimes the

only means of establishing the diagnosis of acute toxoplasmosis (1082, 1111).

Diagnosis of Intrauterine Infection

Estimation of the duration of maternal *T. gondii* infection usually is difficult, and, consequently, assessment of the true risk to the fetus is often fraught with uncertainties. The parasite can be transmitted to the developing fetus at any stage of pregnancy and, in some cases, at or shortly before conception (15,1126,1127). The risk of fetal infection is estimated to be less than 1% if the initial stages of maternal infection occur before conception (1127,1128). This creates considerable anxiety for parents, who may choose an unwarranted end to the pregnancy or unnecessary maternal chemotherapy with potentially toxic drugs.

Prenatal diagnosis of fetal toxoplasmosis can be achieved safely and reliably. Pregnant women shown to have acquired acute *Toxoplasma* infections during the course of their pregnancies can undergo amniocentesis and ultrasound-guided cordocentesis. Parasite isolation studies, if available, include inoculation of these clinical samples into mice or onto tissue cultures. Fetal blood should be shown to be free of maternal blood contamination, using the Kleihauer-Betke stain or hemoglobin electrophoresis, before it is assayed for *Toxoplasma*-specific IgM antibodies or other nonspecific indicators of fetal infection (e.g., leukocyte and differential cell counts, platelet count, total IgM content, lactic dehydrogenase level, gamma-glutamyltransferase concentration). Serial ultrasound examinations should be done at 2-week intervals to detect ventricular dilation, cerebral or hepatic calcifications, ascites, hydrops, or other fetal abnormalities (1082,1129-1131).

Daffos and colleagues (1132) applied this approach to prenatal diagnosis to 746 women with gestational toxoplasmosis occurring within the first 25 weeks of pregnancy. All mothers were treated with spiramycin. Fetal infection occurred in 42 pregnancies, and 39 (93%) were successfully identified prenatally. The most sensitive test in this study proved to be parasite isolation from amniotic fluid or fetal blood (81%). Despite the use of the sensitive IgM-ISAGA assay, only 21% of infected fetuses tested positive. Serial ultrasound examinations showed abnormalities in 45% of fetuses. Among nonspecific tests, gamma-glutamyltransferase or total IgM contents of fetal blood were elevated in more than one-half of the patients. Results of prenatal testing led to pregnancy terminations in 62% of cases; the diagnosis was confirmed postnatally in the remainder. No false-positive diagnoses of fetal toxoplasmosis were made in this study, although other investigators have encountered this problem (1132,1133,1134).

Because maternal IgA and IgE antibodies do not cross the placenta, fetal serum IgA and IgE have been explored as possible markers for intrauterine *T. gondii* infection. Decoster and colleagues (1135) were able to detect specific IgA

antibodies in fetal blood as early as 23 weeks of gestation. The sensitivity of the assay was only 50%, slightly higher than that for *Toxoplasma*-specific IgM. No false-positive results were obtained. The sensitivity and specificity of *Toxoplasma*-specific fetal serum IgA measurement was 77% and 96%, respectively, in another study of 286 patients (1136). *Toxoplasma*-specific IgA antibodies found in amniotic fluid is probably of maternal origin and is not useful for the diagnosis of fetal toxoplasmosis (1137). Pinon and colleagues were unable to detect specific anti-*Toxoplasma* IgE antibodies in fetal blood (1138).

PCR methods have been used in prenatal diagnosis of fetal toxoplasmosis (1139,1140,1141,1142,1143,1144,1145,1146). Cazenave and colleagues (1140) studied 80 women with documented acute toxoplasmosis during pregnancy. PCR analysis (using *P30* gene amplification) of the amniotic fluid was negative in 70 cases without intrauterine infection and positive for all ten with fetal toxoplasmosis. In this study, the PCR was considerably more sensitive than recovering the parasite from amniotic fluid using culture methods (40%) or detection of specific fetal IgM (40%). Similarly, Grover and associates (1139) amplified the *B1* gene and found the PCR method to be more sensitive than the traditional techniques used for the prenatal diagnosis of toxoplasmosis. Hohlfeld and coinvestigators (1142) evaluated 339 consecutive women with gestational toxoplasmosis using PCR analysis (*B1* gene amplification) of their amniotic fluids and found that 37 of 38 infected fetuses had positive amniotic fluid test results; no false-positive results were encountered. The PCR was more sensitive than the conventional methods used for prenatal diagnosis of fetal

P.1328

toxoplasmosis (97.4% vs. 89.5%, respectively). Other researchers found their PCR assays on amniotic fluid to have lower sensitivities than indicated by these reports (1141,1143). Because the PCR test for *Toxoplasma* DNA is not standardized, interlaboratory variability in test results can be encountered (1147). The PCR can provide results within hours compared with tissue cultures, which require a minimum of 4 days, or animal inoculation techniques, which take at least 5 weeks to complete (1140). A real-time quantitative PCR assay used by Romand and co-workers revealed that high parasite concentrations in the amniotic fluid were associated with more serious fetal outcomes (1146). The sensitivity and versatility of PCR analysis, coupled with its rapidity, has made it valuable as a diagnostic tool (1145).

Treatment

Acute toxoplasmosis in the healthy, nonpregnant woman usually requires no specific therapy because of its benign, self-limited nature. Drugs used to treat toxoplasmosis are active against tachyzoites, but they generally have no effect on the encysted form of the parasite.

The option of pregnancy termination should be confined to women who become infected during the first one-half of their pregnancies. Although the risk of transmission of the parasite to the fetus is at its lowest during this stage, the severity of fetal disease is usually at its greatest. Acutely infected women who elect to proceed with their pregnancies should be treated with spiramycin as soon after diagnosis as possible (1081). Spiramycin is a macrolide antibiotic that is active against *T. gondii* and can cross the placenta to enter the cord blood and amniotic fluid (1148). It achieves high tissue levels, especially in the placenta. However, the measured concentrations of spiramycin and neospiramycin (a major metabolite) in maternal serum, fetal serum, placental tissues, and amniotic fluid appear to be below the levels needed to inhibit the parasite (1149). The main adverse effects of spiramycin are nausea, vomiting, and diarrhea. Although some studies do not confirm benefits from spiramycin, the drug is believed to reduce the risk of intrauterine transmission of the parasite, but it does not alter fetal pathology after infection has developed (1081). Spiramycin is only available by request from the Food and Drug Administration; the adult dose is 1 g per dose, given orally three times daily without food (1150). It is not known whether clarithromycin or azithromycin are effective alternatives to spiramycin in preventing intrauterine *T. gondii* infection.

If prenatal diagnosis is attempted and a fetus is shown to be infected, drugs such as pyrimethamine and sulfadiazine are added. Pyrimethamine, an antimalarial drug, is a folic acid antagonist. Its half-life in adults is about 100 hours, and it achieves tissue concentrations (e.g., brain) that are higher than in serum (1082). The drug causes bone marrow suppression with resultant anemia, granulocytopenia, and thrombocytopenia; severe pancytopenia occasionally occurs (1151). Other side effects include a bad taste in the mouth, headache, and gastrointestinal discomfort. Pyrimethamine has been shown to be teratogenic in animals receiving massive doses of the drug early in organogenesis, and it should not be used before the fifth month of pregnancy (1082). Sulfadiazine (and its hydroxylated metabolites) or the trisulfapyrimidines act synergistically with pyrimethamine against *Toxoplasma* tachyzoites; other sulfonamides show less synergy and are not used (1152). These drugs are folic acid antagonists. Side effects include bone marrow suppression, rashes, crystalluria, hematuria, and reversible acute renal failure (1082). Treatment protocols vary between medical centers, but a report from the Cochrane Pregnancy and Childbirth Group concluded after reviewing over 3,300 papers that it is still not known whether antenatal treatment of women with toxoplasmosis actually reduces congenital transmission of *T. gondii* (1153). The Cochrane report notwithstanding, one suggested regimen used to treat pregnant women with an infected fetus incorporates monthly courses of a combination of pyrimethamine (100 mg/d in two divided doses for 2 days, then 50 mg/d), sulfadiazine (75 mg/kg per day in two divided doses for 2 days, then 100 mg/kg per day in 2 divided doses, up to a maximum of 4 g/d), and leucovorin supplements (10-20 mg/d), alternating with monthly spiramycin (1 g every 8 hours) (15). Leucovorin (folinic acid) is used to

counteract the bone marrow suppressive effects of pyrimethamine and sulfadiazine. This treatment regimen is thought to reduce the occurrence of severe congenital infection and increase the proportion of infants born with asymptomatic toxoplasmosis. A multicenter European study could not demonstrate a beneficial effect of antenatal treatment started less than 4 weeks after diagnosis of maternal toxoplasmosis as compared to therapy prescribed at 4 to 7 weeks or after 8 weeks (1154).

Prevention

A vaccine against *T. gondii* is not yet available. Primary prevention rests on educating susceptible pregnant women on how to avoid becoming infected with this parasite. Cats that are kept indoors and only eat dried, cooked, or canned food are unlikely to get infected and shed oocysts. Contact with cat feces should be avoided; disposable gloves should be worn when handling cat litter boxes or while gardening. Cat litter boxes should be emptied of cat feces daily and disinfected by adding boiling water to the empty box for 5 minutes. Covering children's sandboxes decreases the risk of contamination. Meat should be cooked at 66°C or higher temperatures, smoked, or cured in brine. Hands should not touch the eyes or mouth when handling raw meat, and they must be washed thoroughly afterward. Kitchen surfaces should be cleaned carefully. Fruits and vegetables may have oocysts on their surfaces and should be washed or peeled before being eaten (666). Prenatal health education programs can bring about changes in personal behavior that reduce a susceptible woman's risk of acquiring toxoplasmosis by as much as two-thirds (1155,1156).

P.1329

Secondary prevention entails the identification and treatment of pregnant women who are acutely infected. Because about 90% of patients with acute toxoplasmosis have minimal or no symptoms, a systematic serologic screening program would be needed. A national prevention program for congenital toxoplasmosis that mandates monthly serologic screening of all seronegative pregnant women has been in place since 1976 in France (1157). A comparable policy for routine screening does not exist in the United States, because it generally is regarded as not being cost effective and can lead to adverse pregnancy outcomes (in view of the difficulties associated with interpreting serologic test results), not the least of which is the termination of several pregnancies with uninfected fetuses per case of congenital toxoplasmosis prevented (1158,1159,1160,1161).

Women found to be seronegative early in pregnancy should be advised to follow the hygienic measures outlined earlier. Retesting at 18 to 22 weeks of gestation can identify women who seroconverted during the first one-half of their pregnancy, affording them the opportunity to consider options such as maternal

chemotherapy, prenatal diagnostic procedures, or elective pregnancy termination (1162,1163). Seronegative women gain from testing at the end of pregnancy; this helps to identify asymptomatic newborns with toxoplasmosis that may derive benefit from treatment during the first year of life.

Women found to be seropositive early in gestation should be evaluated further to exclude a recent *Toxoplasma* infection. As a group, infants born to seropositive pregnant women with IHA titers of 1:256 to 1:512 have double the predicted frequency of deafness, a 60% increase in microcephaly, and a 30% increase in the occurrence of intelligence quotients less than 70 (1083). Fetal infections after reactivation of latent toxoplasmosis or following reinfection of immunocompetent seropositive women are known to occur, but are very rare (1164,1165,1166,1167,1168). In twin pregnancies, monozygotic twins are more likely to be concordant with respect to their infection status than dizygotic twins (1169).

Congenital Toxoplasmosis

Epidemiology

The true incidence of congenital toxoplasmosis is unknown. Reported figures underestimate its occurrence. Published rates vary by locale, but they range from 0 to 10 per 1,000 live births. Representative incidence estimates per 1,000 live births include New York City with 0.7, Birmingham, Alabama, with 0.12, Mexico City with 2, Paris with 3, and Austria with 8.3 (1082). Prospectively collected data from Massachusetts and New Hampshire, where all heelstick blood specimens adsorbed onto a filter paper card for routine neonatal screening for metabolic and endocrine disorders also are tested for intrauterine *T. gondii* infection using an IgM capture immunoassay, have shown the rate of congenital toxoplasmosis to be about 1 per 10,000 newborns (1170). Using a similar approach, Brazilian investigators documented the rate of congenital toxoplasmosis to be 1 per 1,867 newborns (1171).

As treatment of acutely infected pregnant women becomes more commonplace, the occurrence of congenital toxoplasmosis should decline. Trimester-specific *T. gondii* transmission rates decrease with proper maternal chemotherapy from 25% to 8% for the first trimester, from 54% to 19% for the second trimester, and from 65% to 44% for the third trimester (1082).

Clinical Manifestations

At least two-thirds of infants with congenital toxoplasmosis have inapparent disease at birth; however, one-third of all asymptomatic neonates who undergo detailed examinations are found to have abnormalities such as CSF pleocytosis or

elevated protein content (20%), chorioretinitis (15%), or intracranial calcifications (10%) (1082,1170). Several weeks or months later, untreated infants develop signs or symptoms of disease.

Symptomatic *Toxoplasma* infection of the newborn can be mild, moderate, or severe. It can involve multiple organ systems or present as isolated abnormalities such as hydrocephalus, hepatosplenomegaly, or prolonged hyperbilirubinemia. Approximately 25% to 50% of symptomatic infants are delivered prematurely. Only 10% of infected infants have severe disease at birth. Systemic manifestations such as fever, jaundice, anemia, hepatomegaly, splenomegaly, or chorioretinitis may predominate in some infants, and neurologic abnormalities such as encephalitis, seizures, hydrocephalus, or intracranial calcifications may be prominent in others. About 10% of congenitally infected infants who have severe disease die, and most surviving infants are left with major neurologic sequelae, such as mental retardation, seizures, spasticity, and visual deficits (15).

CNS involvement is common. Parenchymal lesions may extend to surrounding blood vessels, leading to vasculitis with thrombosis and infarction. Substantial destruction of brain parenchyma can lead to obstruction of the aqueduct of Sylvius with resultant secondary enlargements of the third and lateral ventricles and, ultimately, hydrocephalus. Hydrocephalus can be the sole manifestation of congenital toxoplasmosis. It may be present at birth or develop later in infancy, and it may be static or gradually worsen to the point of requiring shunt placement. Diffuse intracranial calcifications occur in 10% to 20% of infants with congenital toxoplasmosis, but they can be found in 30% to 70% of those with symptomatic disease at birth (Fig. 48-5) (1082,1170,1172). They may increase in number and size over time. However, about 75% of these intracranial calcifications decrease or resolve within 1 year in adequately treated infants (1172). Other neurologic findings encountered in this infection include bulging anterior fontanelle, encephalitis, hydranencephaly, hypotonia or paralysis, spasticity, microcephaly, opisthotonus, swallowing difficulties, or proteinorachia (1173). Radiologic CNS findings may be consistent with an old insult (e.g., hydrocephalus, porencephaly, encephalomalacia,

P.1330

cortical atrophy) or, less commonly, with an acute process (e.g., single or multiple hypodense lesions with contrast ring enhancement) (1174,1175).

Figure 48-5 Computerized axial head tomogram of a 5-month-old girl with congenital toxoplasmosis. Notice the diffuse parenchymal calcifications and the prominent subarachnoid space bilaterally.

Manifestations of active congenital ocular toxoplasmosis may include chorioretinal scars, chorioretinitis, iritis, leukocoria, microphthalmia, nystagmus, optic atrophy, optic coloboma, retinal folds and traction detachments, granulomas in the posterior pole, strabismus, small cornea, and cataracts (15,1176-1179).

Chorioretinal scars are the most common eye findings and are most likely to be found in the periphery. Macular scars are noted in 75% of untreated infants and are bilateral in about 23%; visual acuity can be markedly reduced in these patients (1178). On ophthalmoscopy, the typical findings are single or multiple yellow-white, fluffy necrotic lesions with indistinct margins that arise at the borders of preexisting, healed, hyperpigmented retinochoroidal scars (Fig. 48-6). Other findings may include retinal hemorrhages, iridocyclitis, vitreous haziness, papillitis, and papilledema. Untreated infants who were asymptomatic at birth are at great risk of subsequent development of chorioretinitis (about 50% for patients older than 10 years) (15).

Sensorineural hearing loss may occur in 15% to 25% of congenitally infected infants, and educationally significant hearing loss afflicts 10% to 15% of infected infants (1180). *T. gondii* has been found in the mastoid and middle ear at autopsy of some infants. Gastrointestinal disturbances such as feeding difficulties, diarrhea, and vomiting are common. The liver and spleen may be enlarged, and hepatic calcifications may be found. Conjugated hyperbilirubinemia sometimes takes months to subside. Biliary atresia associated with congenital toxoplasmosis has been reported (1181). Myocarditis, nephrotic syndrome, hydrops fetalis, interstitial pneumonia, and skeletal metaphyseal lucencies occur infrequently. Cutaneous lesions include ecchymoses, petechiae, purpura, and maculopapular rashes.

Figure 48-6 Active chorioretinitis in a 5-month-old boy with untreated congenital toxoplasmosis.

Hematologic abnormalities include anemia, eosinophilia, and thrombocytopenia (1182). Transient quantitative (e.g., neutropenia) and qualitative (e.g., enlarged, vacuolated lymphocytes) changes in the leukocytes are common (1182). Total CD4⁺ lymphocyte counts and CD4⁺-to-CD8⁺ ratios usually are depressed (1183). Compared with adults, infants with congenital toxoplasmosis have no or reduced lymphocyte blastogenic responses on exposure to *Toxoplasma* lysate antigens, with failure to produce interferon- γ or interleukin-2; however, they do respond normally to nonspecific stimulators such as concanavalin A (1184). The severe organ damage seen in congenital toxoplasmosis may be as a result of specific deficits in cell-mediated immune responses to *Toxoplasma* antigens.

Diagnosis

Congenital toxoplasmosis is diagnosed if the parasite is recovered from the placenta. *T. gondii* can be isolated from the blood of asymptomatic or symptomatic infants; isolation rates peak at 71% during the first week of life and then decline to 33% at 2 to 4 weeks of age. Attempts at recovering the parasite from the blood of older infants generally are fruitless. The detection of *Toxoplasma* antigens or DNA in body fluids such as urine, CSF, or serum is considered diagnostic (15,1185,1186).

Specific IgM antibodies can be detected in the serum of 25% of congenitally infected infants with the IFA method and in as many as 75% with the DS-IgM-ELISA technique (1082). The sensitivity of the IgM-ISAGA test probably is even

greater (1187). Passively transferred maternal anti-*Toxoplasma* IgG antibodies can suppress an infant's specific IgM response. Gross and colleagues (1185,1188) have shown that about 5% of sera have strain-specific immune responses. Unless antigens from more than one *T. gondii* strain are used in the assay, the sera would have no detectable specific antibodies in one test but be positive in another (1188). IgM antibodies can persist for more than 1 year when measured by very sensitive assays (1187). Rarely, intrathecal production of anti-*Toxoplasma* IgM is demonstrable despite the absence of specific antibodies in the serum of congenitally infected infants with CNS involvement (1185).

Levels of anti-*Toxoplasma* IgG antibodies of maternal origin typically drop at a rate of 50% per month in the infant's serum, but they may continue to be detectable for about 1 year. Active congenital infection should be suspected if specific IgG titers do not show the anticipated decline, or if they increase. Untreated infants begin synthesizing their own anti-*Toxoplasma* IgG antibodies by 3 months of age. The intrathecal production of specific IgG is demonstrable in about 2% of infants with CNS involvement (1082).

Toxoplasma-specific serum IgA antibodies are detectable in most congenitally infected infants, significantly more often than IgM antibodies (1121). Specific IgA antibodies were found in the CSF of the few infants in whom it had been measured (1189). Specific serum IgE antibodies can be measured from birth in some patients, especially infants with complications such as hydrocephalus or chorioretinitis (1138).

Research is ongoing to refine existing serologic methods for the diagnosis of congenital toxoplasmosis. Newer techniques that are still considered investigational include IgG, IgA, and IgM immunoblotting which appears to be more sensitive and specific than traditional serologic assays, and serial measurements of IgG avidity to *Toxoplasma* antigens in sera of infants (1113,1190-1194).

Transformation of lymphocytes on exposure to *Toxoplasma* antigens is a sensitive and specific indicator of congenital infection if performed on symptomatic or asymptomatic infants 3 months of age or older (15,1195). The observed blastogenic response is lower in infants than in infected adults (1184).

Treatment

Controlled trials examining the benefits of various treatment protocols are lacking. Drug regimens have been arrived at empirically, and conclusions about their efficacies are based on comparisons with historic data.

The treatment of symptomatic infants during the first 12 months of life usually consists of a combination of pyrimethamine, sulfadiazine, and leucovorin supplements. After an initial loading dose of 2 mg/kg per day for 2 days,

pyrimethamine (1 mg/kg orally in one or two divided doses) is given daily (first 6 months of life) or every other day (at 7 to 12 months of age). Sulfadiazine at 100 mg/kg per day is given in two divided oral doses for 12 months. Leucovorin (10 mg) is injected intramuscularly three times per week (1081). In some medical centers, the regimen is modified after the first 6 months of treatment to include 1-month courses of spiramycin alternating with 1-month courses of pyrimethamine, sulfadiazine, and leucovorin supplements for an additional 6 months. Spiramycin is given daily at a dose of 100 mg/kg per day in two divided oral doses (15,1081,1196,1197).

Corticosteroids such as prednisone or methylprednisolone (1.0-1.5 mg/kg per day orally in two divided doses) are used in infants with chorioretinitis or CSF protein elevations (≥ 1 g/dL) to reduce the inflammatory response (1082,1198). They should be used concurrently with anti-*Toxoplasma* drugs.

Infants with asymptomatic congenital toxoplasmosis are treated for 1 year. They receive an initial 6-week course of pyrimethamine, sulfadiazine, and leucovorin supplements, followed by alternating courses of spiramycin for 6 weeks and the pyrimethamine, sulfadiazine, and leucovorin combination for 4 weeks.

Healthy infants born to mothers with gestational toxoplasmosis and for whom serologic tests have not provided definitive answers regarding the presence or absence of infection can be treated with a 4-week course of pyrimethamine, sulfadiazine, and leucovorin followed by 4 to 6 weeks of spiramycin. If the diagnosis of congenital toxoplasmosis is later established, chemotherapy is continued as delineated earlier for infants with subclinical *T. gondii* infection. For healthy infants born to mothers with high Sabin- Feldman dye test titers and undetermined timing of maternal infection, a 1-month course of spiramycin usually is prescribed. Therapy is extended if clinical or laboratory evidence of congenital toxoplasmosis is uncovered (15).

Pyrimethamine serum levels do not vary significantly with age during infancy; they are comparable for infants receiving the drug daily or every other day. Pyrimethamine serum concentrations and half-life may be reduced in infants concomitantly treated with phenobarbital. The drug achieves CSF concentrations that are 10% to 25% of concurrently measured serum levels. Seizures have been observed in patients with pyrimethamine overdose (1199).

Clindamycin and trimethoprim-sulfamethoxazole have been used effectively for the treatment of ocular toxoplasmosis in older patients (1081). There are no data on their efficacies in congenital infection. Photocoagulation of active lesions and of normal retinal tissues immediately bordering chorioretinal scars may be helpful in reducing recurrences (1200). Treatment with pyrimethamine, sulfadiazine, and leucovorin (with corticosteroids during the phase of active inflammation) currently is preferred for ocular toxoplasmosis, primarily because of the limited body of data on the efficacy of alternative regimens. Therapy should be continued for 2 weeks

active ocular inflammation (1197). Active lesions usually become quiescent after 10 to 14 days of therapy (1178).

Infants treated with pyrimethamine and sulfadiazine should be closely monitored. One or two blood and platelet counts should be done every week for the early detection of pyrimethamine-related adverse effects. The frequency of monitoring can be reduced to one or two times per month for infants receiving pyrimethamine on an every-other-day basis. The leucovorin dose is increased if the absolute neutrophil count falls below 1,000 cells/ μ L. If the absolute neutrophil count falls below 500 cells/ μ L, pyrimethamine should be withheld temporarily until the neutropenia resolves (1197).

Prognosis

Most infants with severe symptomatic congenital toxoplasmosis who survive beyond the neonatal period suffer from serious long-term residual problems, such as mental retardation and blindness (15,1088). The majority of those born with subclinical infection who are not treated develop eye problems, and about half will suffer neurologic sequelae (15).

Short-term follow-up studies indicate that maternal therapy during gestation, followed postnatally by treatment of all congenitally infected infants, improves prognosis by reducing the frequency and severity of late-appearing disease sequelae. In the study by Hohlfeld and colleagues (1105), congenital infection remained subclinical in 76%. Almost all treated infants developed normally and were neurologically normal. Peripheral chorioretinitis that did not impair vision developed in about 10% between 5 and 17 months of age (1105). In another study, early institution of anti-*Toxoplasma* therapy may have prevented the occurrence of sensorineural hearing loss in congenitally infected infants (1180). Guerina and associates (1170) reported that only one of 46 congenitally infected but treated infants identified through their neonatal screening program had a neurologic deficit (hemiplegia), and 10% of those followed for 1 to 6 years had eye lesions.

TABLE 48-7 ADVERSE FETAL AND NEONATAL OUTCOMES CAUSED BY OTHER GESTATIONAL VIRAL AND PROTOZOAL INFECTIONS

Pathogen	Fetal and Neonatal Effects
Viruses:	
Cache Valley virus (1208)	Congenital macrocephaly (?)
Measles virus (2, 82, 1209, 1210, 1211)	Prematurity; fetal loss; sporadic reports of congenital heart disease, cleft lip, pyloric stenosis, and cyclopia; congenital or perinatal measles; Crohn's disease (?)
Mumps virus (1212, 1213, 1214, 1215, 1216, 1217)	Fetal loss; endocardial fibroelastosis; multicystic encephalomalacia; hydrocephalus; chorioretinitis; bilateral corneal opacities; malformations of the external ear; urogenital abnormalities; intestinal atresia; neonatal pneumonia; parotitis; splenomegaly; thrombocytopenia
Papillomaviruses (1218, 1219, 1220)	Juvenile laryngeal papillomatosis; anogenital condylomata; giant cell hepatitis
Smallpox virus (1221)	Congenital smallpox (10%); prematurity; neonatal death; stillbirth
Vaccinia virus (1222)	Fetal vaccinia (skin lesions and internal organ involvement); premature birth; fetal loss
Protozoa:	
Malaria (1223, 1224)	Placental infection; stillbirths; low birth weight; prematurity; neonatal death; congenital malaria (fever, anemia, and splenomegaly)
African trypanosomiasis (1225, 1226)	Prematurity; abortion; stillbirth; central nervous infection; fever; hepatosplenomegaly
American trypanosomiasis or Chagas' disease (1225, 1227)	Placental infection; spontaneous abortion; stillbirth; neonatal death; meningoencephalitis; seizures; anemia; jaundice; hepatosplenomegaly; cataract

Long-term follow-up studies of infants with symptomatic or subclinical congenital toxoplasmosis suggest that most patients develop chorioretinitis or chorioretinal scars by 10 to 20 years of age, but treatment may reduce the frequency and severity of adverse sequelae (1201-1206). The prognosis of infants with symptomatic congenital toxoplasmosis treated for 1 year with the pyrimethamine,

sulfadiazine, and leucovorin regimen appears to be much better than that of historic untreated controls (1172,1178,1196,1207). All untreated patients develop chorioretinal scars, but this is seen in only 75% of those treated for 1 year. Among treated patients, peripheral chorioretinal scars and macular scarring are seen in 40% to 60% (compared with 82% and 76%, respectively, of untreated historic controls). Thirteen percent of treated infants and 44% of controls later have recurrences of ocular toxoplasmosis. The median time to ocular recurrence is 5 years (range 3 to 10) in treated infants; new lesions can occur in previously normal-appearing retina and contiguous to old scars (1178,1206).

P.1333

Neurologic and developmental outcomes of 36 infants with treated congenital toxoplasmosis were assessed by Roizen and colleagues (1207). Tone and motor abnormalities were present on the initial examinations of 20 infants, and these resolved in 12 of them by 1 year of age. Six infants had perinatal seizures; four could be taken off their anticonvulsant medications within a few months. Low cognitive functioning as measured by a score of less than 50 was found in 21%. Seven children with a score above 50 on the Mental Developmental Index were compared to their siblings who served as controls; patients scored lower than their uninfected siblings (87 vs. 112). Sequential IQ tests done at intervals of at least 1.5 years showed no deterioration over time for congenitally infected children. Seventeen of 18 patients without hydrocephalus, and six of eight children with obstructive hydrocephalus that responded to shunt placement, were neurodevelopmentally normal or near normal; those with more severe CNS involvement did not fare as well. Intracranial calcifications in treated infants may diminish or disappear in as many as 75%, and remain unchanged in the rest (1172).

Miscellaneous Viral and Protozoal Pathogens

Table 48-7 is a summary of some known and putative fetal and neonatal ill effects of a few additional viruses and protozoa that can infect pregnant women. Some of the published observations are individual case reports that may represent associations and not necessarily true cause-and-effect relationships

(1208,1209,1210,1211,1212,1213,1214,1215,1216,1217,1218,1219,1220,1221,1222,1223,1224,1225,1226,1227).

Chapter 49

Healthcare-Associated Infections

Jukka K. Korpela

Joyce Campbell

Nalini Singh

Like birth itself, survival of the premature newborn is a miracle. The improved survival of the very low birth weight neonate is possible due to advancement in neonatal intensive care. However, this high-risk population of neonates is also at-risk of nosocomial, or healthcare-associated infections due to invasive monitoring and supportive care (1,2,3,4,5 and 6).

The impact of this adverse event is estimated to affect 2 million patients each year in the United States, contributing to 90,000 deaths and adding \$4.5 to \$ 5.7 billion per year to the costs of patient care in the United States (7,8). Twenty five percent of healthcare-associated infections occur in intensive care units, and 70% of these infections are caused by resistant strains of bacteria (9,10). Neonates and young children are among the hospitalized patients at highest risk for acquiring healthcare-associated infections. Infants <1500 g experience a disproportionate share of healthcare-associated infections (~75%) compared to other newborns in the neonatal intensive care unit (NICU) (11). Thus, infection control is a crucial component of patient safety and optimal survival of the newborns hospitalized in the NICU. In this chapter we are attempting to outline the epidemiology of major healthcare-associated infections, the emerging problem of multi-drug resistance organisms, and evidence-based infection control efforts.

EPIDEMIOLOGY

The epidemiology of healthcare-associated infections among neonates in NICUs has been described from the National Nosocomial Infection Surveillance (NNIS) system of the Centers for Disease Control and Prevention (CDC) from January 1992 to June 2004 (12). Device-associated bloodstream infections, followed by ventilator-associated pneumonia, are the most common healthcare-associated infections in the NICU. These infection rates increase with decrease in birth weight and age (13,14,15 and 16). Reports published by the CDC-NNIS provide information on pooled means and percentiles of the distribution of device-associated infection rates by birth weight category and device utilization ratios (Tables 49-1 and 49-2) (12). Pediatric Prevention Network's point prevalence study of NICUs also reports frequency of other infections in the lower respiratory tract(12.9%), urinary tract (8.6%), and ear-nose-throat (8.6%) (11). NICU surveillance is conducted in various methodologies including reporting of site-specific rates by birth weight in the United States (17). The frequency of healthcare-associated infections in individual NICUs varies from 6% to 25% in the United States and 8% to 10% in Europe based upon multicenter studies data (18,19,20,21 and 22).

In a multicenter study from National Institutes of Child Health and Human Development (NICHD) Neonatal Research Network of 5447 patients, the increased use of intrapartum antimicrobial therapy, for prevention of group B streptococcal disease, was associated with a decrease in the incidence of early-onset (<3 days) group B Streptococcal sepsis (from 5.9 to 1.7 per 1000 live births) but was associated with a proportionate increase in sepsis with ampicillin-resistant *Escherichia coli* isolates (from 3.2 to 6.8 per 1000 live births) (23). In high-risk infants there may also be an increase in the incidence of healthcare-associated infections due to multi-drug resistant gram-negative organisms. This increase in gram negative organisms has been seen in many national and international centers (24,25,26,27,28,29,30,31,32,33 and 34).

Identifying neonates who are at greatest risk of developing nosocomial sepsis can be complex, but is important so that prompt, accurate diagnosis can be made, appropriate management modalities can be instituted and unnecessary use of broad-spectrum antimicrobial agents can be avoided. Various scoring systems have been developed in an attempt to provide objective criteria to diagnose

P.1358

nosocomial sepsis. Recently, the Nosocomial Sepsis Prediction score for neonates (NOSEP) attempts to do this, based on clinical and laboratory parameters. This model has been validated in five regional NICUs in Europe (35). The NOSEP-NEW- II score includes: (a) body temperature >38.1°C, (b) C-reactive protein ≥30 mg/L, thrombocytopenia, ≤190×10⁹, and neutrophil fraction >63%, and (c) total parenteral nutrition, ≥15 days. The

incorporation of additional factors in this score such as surgery, maternal hypertension, and ventilation at the time of sepsis work up, increased the discriminative performance (A_z of receiver operating characteristic curve from 0.71 to 0.82). The NOSEP-NEW-II score (range 0-19 points) was significantly higher in patients with healthcare associated sepsis (median, 9) than with patients without sepsis (median, 6), $p= 0.008$. The calibration curve of the NOSEP score shows a very good correlation between predicted risk and observed prevalence of nosocomial sepsis (Spearman's correlation coefficient $\rho < .005$). No discrepancy was seen between the predicted and observed outcomes (Hosmer-Lemeshow goodness-of-fit chi square $p=.48$). There was also very good uniformity of fit (similar fit across different strata). A model to predict a future event such as the risk of developing a healthcare associated infection should incorporate both intrinsic and extrinsic risk factors as was done in the pediatric nosocomial infection risk model (36). Limiting factors of these models are applicability differences in case-mix, the diversity of the patient population with varying risk factors (e.g., access to care) and availability to limited laboratory resources developing countries (37).

TABLE 49-1 MEDIAN NICU BSI AND VAP NI RATES AMONG ALL BIRTH-WEIGHT GROUPS IN PEDIATRIC PREVENTION NETWORK, 1997

Population Survey	Median
All patients NI/1000 patient-days	8.9
BSI/1000 CVC-days	8.6
VAP/1000 ventilator-days	2.5

VAP 1501–2500 grams	1.1	1.9
VAP >2500 grams	0.9	1.4

BSI—bloodstream infection
VAP—Ventilator associated pneumonia

HEALTHCARE-ASSOCIATED INFECTION RATE

Surveillance of healthcare-associated infection rates is used to evaluate the infection trends in NICUs and to compare different patient populations. These rates are the basic statistical tools for infection control. A comprehensive infection surveillance, prevention, and control program can be a part of the performance-improvement program in the hospital and annual planning for strategies to meet specific hospital needs and priorities (38). Many of the difficulties in comparing intra-hospital and inter-hospital rates can be decreased using standardized definitions and taking risk factors into account (15).

The CDC-NNIS System defines a nosocomial infection as a localized or systemic condition (1) that results from an adverse reaction to the presence of an infectious agent(s) or its toxin(s) and (2) that was not present or incubating at the time of admission to the hospital (39). For determination of the presence and classification of

healthcare-associated infections, a combination of clinical findings and results of laboratory tests should be used. These definitions have been developed by CDC to provide uniform criteria to compare infections within hospitals and between different data systems. For infections in infants and neonates, whose clinical manifestations differ from those in older persons, specific criteria are used. These criteria are used according to the listing of major and specific site codes and descriptions. For example laboratory-confirmed primary bloodstream infection in infants or neonates must meet at least one of the following criteria:

- Patient has a recognized pathogen cultured from one or more blood cultures and the organism cultured from the blood is not related to an infection at another site.
- Patient ≤ 1 year of age has at least one of the following signs and symptoms: fever ($>38^{\circ}\text{C}$), apnea, or bradycardia and at least one of the following:
 - common skin contaminant (e.g., diphtheroids, *Bacillus* species, *Propionibacterium* species, coagulase negative staphylococci, or micrococci) cultured from two or more blood cultures drawn on separate occasions
 - common skin contaminant (e.g., diphtheroids, *Bacillus* species, *Propionibacterium* species, coagulase-negative staphylococci—CONS, or micrococci) cultured from at least one blood culture from a patient with an intravascular line, and the physician institutes appropriate antimicrobial therapy
 - positive antigen test on blood (e.g., *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Neisseria meningitidis*, group B *Streptococcus*) and signs and symptoms and positive laboratory results are not related to an infection at another site.

P.1359

The evaluations and comparisons of healthcare-associated NICU sepsis caused by CONS have failed partly due to the lack of uniformity in the definition of sepsis (40). Recently using mathematical modeling, the predictive value of a single and two positive blood cultures for CONS was estimated to be 55% and 98% respectively (41). From a surveillance point of view, this may require improving current CDC definitions as follows:

- Criterion 2 (a) for two positive culture results, should not require clinical signs or symptoms because their diagnostic value is unknown and the positive predictive value when ≥ 2 cultures are positive is high.
- Criterion 2 (b) should exclude single positive blood cultures where ≥ 2 cultures are performed.
- The definition should account for whether culture was obtained through a central line or a peripheral vein.

Findings from this mathematical modeling are also consistent with recommendations from the Vermont Oxford Neonatal National Evidence-based Quality improvement collaborative for Neonatology (42).

The accuracy of reporting healthcare-associated infections data also varies according to the type of infection (43). In nine participating NNIS hospital intensive-care units, the CDC epidemiologists determined the reported bloodstream infections, pneumonias, surgical-site infections and urinary tract infections. Primary bloodstream infection was the most accurately identified with sensitivity of 85% and specificity of 98.3%, in comparison to the other infections, pneumonia, surgical-site infection and urinary tract infection with a sensitivity of 68%, 67%, and 59% and specificity of 97.8%, 97.7%, and 98.7% respectively. When these CDC-NNIS hospitals reported a healthcare-associated infection, the infection most likely was a true infection.

The CDC-NNIS System collects data from infection control professionals on nosocomial infections in NICU patients. All body sites are included in this data. Site-specific infection rates can be calculated by using as a denominator the number of patients at risk or patient-days, and/or device days (umbilical catheter/central line

or ventilator use) for each of the four birth-weight categories (≤ 1000 g, 1001 to 1500 g, 1501 to 2500 g, and > 2500 g) (12). Birth weight specific rates of bloodstream infection and ventilator-associated pneumonia are shown in Tables 49-1 and 49-2. The incidence of bloodstream infections and ventilator-associated pneumonia is inversely proportional to the birth weight. Birth weight can also be a marker of severity of illness and a predictor of mortality in very low birth weight infants (44).

The device utilization days are widely used in calculating risk-adjusted infection rates in NICU. Device utilization is calculated as follows: Number of umbilical and central line-associated bloodstream infections per number of umbilical and central-line days multiplied by 1000. Another useful measure of device use in a NICU is the device utilization ratio (12). This is calculated as number of device-days per number of patient-days. Device utilization stratified by birth weight group and device utilization ratio are essential for valid inter-hospital NI rate comparisons (17). Increase in device utilization can reflect either higher severity of illness in infants requiring increased use of invasive devices or healthcare provider's patient care practice. Under these circumstances targeted efforts to decrease infection rates may require efforts to decrease use of devices. CDC-NNIS rates can serve as an external benchmark and NICUs can be compared using the percentiles of site-specific infection rate and device utilization ratios. If the infection rates are above the 90th percentile, it may indicate a problem in the infection control or higher severity of illness in patients requiring more device use. If they are below 10th percentile, it may reflect of underreporting of infections or infrequent or/and short duration of device days (12).

The effect of infection control interventions for a NICU should be evaluated at least annually using a risk-adjusted healthcare-associated infection rate. Risk should be adjusted for device use such as central venous catheters and birth weight category (45). Overall impact of an infection control program can be easily estimated within the hospital over a period of time (38). Continuous quality control improvement processes by multidisciplinary teams in a NICU can be evaluated using bloodstream infections rates over the time period in focus (46). Reduction of infection rates will encourage the efforts and show the right direction of control measures.

Many risk factors are not accounted for in the CDC-NNIS High-Risk Nursery surveillance components (47,48 and 49). Besides birth weight and use of invasive devices, length of stay in NICU and severity of the co-morbidities and use of total parenteral nutrition may contribute to increased incidence of healthcare-associated infections (50,51). Use of dexamethasone and neonatal neutropenia and maternal hypertension should also be considered important risk factors under specific maternal conditions (52,53). High-risk infants acquire nosocomial pathogens either endogenously or exogenously. Exogenously parents can also serve as a vector for transmission of organisms like *Pseudomonas aeruginosa* and *Staphylococcus aureus* (54). This vertical and horizontal transmission of microorganisms can be confirmed by use of molecular epidemiological tools (55).

P.1360

LATE-ONSET SEPSIS

The frequency of healthcare-associated or late-onset sepsis varies from 11% to 30% (56). The number of sepsis episodes increases with decreasing birth weight. Inter-center variability is also seen in the incidence of late onset sepsis in multi-institutional studies (6,57,58). CONS are the most common pathogens responsible for late-onset nosocomial sepsis in the NICU (6). It is still difficult to determine which blood culture isolates of CONS reflect true infections and which are contaminants. CONS are part of the patient's endogenous flora. Oral mucosa and/or skin are colonized with CONS (59). The NICHD Neonatal Research Network reports that Gram-positive organisms specifically CONS were the most common pathogens causing late-onset > 3 days) bloodstream infections in neonates. CONS was isolated from 43.4% of cases with late onset sepsis in very low birth weight infants in the NICHD Neonatal Research Network and 54% in Pediatric Prevention Network (6,60). In a prospective NICU incidence study CONS bacteremia are reported to be 12.4 per 1000 device days (61). Infants with late-onset sepsis have significantly increased length of stay in the hospital (79 days vs 60 days; $p < .001$) and mortality (18% vs 7%; $< .001$) (6). CONS infections usually present between 7 and 14 days of age (62). It is not a significant cause of mortality (less than 1%) (63).

Prolonged hospital stay and complications with prematurity, such as patent ductus arteriosus, prolonged ventilation, prolonged use of intravascular access, bronchopulmonary dysplasia and necrotizing enterocolitis are associated with an increased rate of late-onset sepsis (6). Persistent infections with CONS occur in significantly smaller and less mature infants than with non-CONS, but generally mortality is not higher. Infants with persistent infection should undergo aggressive evaluation for focal complications (64). Primary osteomyelitis and suppurative arthritis with CONS in preterm neonates have been also described in the absence of any indwelling

central catheters (65). Most CONS isolates causing sepsis are frequently predominantly antibiotic resistant CONS types (66).

The role of CONS as causative pathogens or contaminants in cultures from blood and cerebrospinal fluid is difficult to determine (67). Procedures to help to differentiate CONS positive blood cultures from CONS contaminants include drawing of at least two blood cultures, using optimal skin antisepsis and catheter disinfection before drawing blood samples, and using adjunctive tests, such as IL-6 and CRP (42,60,68). CONS are the predominant organism, consisting of 44% versus approximately 25% of various Gram-negative bacteria in randomly collected environmental samples in NICU (3). The possible increase of CONS infections after twice-daily petrolatum ointment application indicates that routine ointment practices may colonize skin. Thus ointment routines remain controversial, especially in babies with intact skin (69).

Another cause for possible therapeutic failures in the NICU, is the emergence of vancomycin heteroresistant *Staphylococcus capitis* strains (70). Occurrences of endemic strains require careful evaluation of existing treatment regimens and therapeutic responses. Heteroresistance to vancomycin should be suspected in a NICU where CONS positive bloodstream infections treated with vancomycin and appropriate replacement of intravenous catheters fail to respond to treatment. There is an urgent need for evaluation of clinical practice guidelines for safely decreasing vancomycin use in NICUs (60).

In a recent CDC-NNIS surveillance report 89% of CONS were resistant to methicillin (12). Resistant *Staphylococcus epidermidis* clones to penicillin, gentamicin and erythromycin with the *mecA* gene can be significant nosocomial pathogens that can be transmitted between babies in the NICU (71). Usually predominant antibiotic resistant CONS types are detectable in neonates and staff of neonatal units, suggesting cross-contamination (66).

A recent study by NICHD Neonatal Research Network revealed that only one-third of patients with late-onset meningitis had meningitis in the absence of sepsis. Cerebrospinal fluid cultures were performed only half as often as blood cultures, suggesting that meningitis may be under-diagnosed among very low birth weight infants. CONS was recovered from 29% of cases when meningitis occurred (72,77).

Enterococci have also been recognized as clinically important pathogens in high-risk, hospitalized children (73,74,75,76,77). Neonatal nosocomial enterococcal infections are being recognized with increased frequency (78,79,80,81,82,83,84,85). The Pediatric Prevention Network's point prevalence study of NICUs also reports enterococci as the second most frequent (15%) nosocomial pathogen among neonates admitted to the NICU in 1999 and third most common (7.8%) in NICHD Neonatal Research Network studies (11). Most of these were bloodstream infections, but enterococci were isolated in 13.4% of cases with meningitis in NICHD Neonatal Research network studies (86). Enterococci are indigenous to the normal flora in humans and are known to colonize the intestines, gastrointestinal tract, and female genital tract. There are two major species of Enterococci that infect humans, *Enterococcus faecalis* (*E. faecalis*) and *Enterococcus faecium* (*E. faecium*). During the 1980s, *E. faecalis* was responsible for 80% to 90% of all isolates and *E. faecium* had accounted for only 5% to 15% (87).

In one case controlled study risk factors for nosocomial enterococcal infection in neonates are non-umbilical central lines (71% vs 32%), duration of indwelling central lines (26.5 vs 6.5 days), and bowel resection (29% vs 4%) (83). The mean gestational age was 27 weeks and the mean birth weight was 913 grams. Similarly, risk factors in another case-control study of young children also showed that central line and bowel resection are important risk factors, as well as duration of antimicrobial therapy (median duration of use was approximately one week) (88). A mortality of 14 to

P.1361

17.6% and an attributable mortality of 8.0% were observed with enterococcal bacteremia patients (73,78). To prevent occurrence of nosocomial enterococcal infections, clinicians should carefully monitor the use and duration of antimicrobial agents. Rational delivery of antimicrobial therapy is critical, especially during an era of increasing rates of antimicrobial resistance in enterococci.

Gram-Negative Sepsis

With a significant improvement in the survival of premature and very low birth weight infants, increased incidence of Gram-negative healthcare-associated sepsis is seen in these infants (6,25). The increasing incidence of Gram-negative rods bacteremia has been reported by many NICUs (26,89). The NICHD Research network reported that although Gram-positive organisms caused the majority of late-onset (>3 days) sepsis in very low birth weight neonates (<1500 grams), mortality was highest with Gram-negative sepsis (6). Increase

in mortality to 36% and a fulminant clinical course has been reported in these very low birth weight hospitalized infants (6,63,90). Epidemics of multi drug-resistant *Klebsiella pneumoniae* and acinetobacter sepsis have been reported in some nurseries (91,92,93). Environmental sources, such as cots, incubators and various equipments yield growth of several pathogens, bacteria and fungi. The presence of Gram-negative pathogens, such as *Pseudomonas aeruginosa* and *Serratia marcescens*, varies in different environments and poses a potential threat for infection. In an era of increasing incidence of antimicrobial resistance, the empiric treatment of clinical sepsis in high-risk neonates, should include adequate antimicrobial coverage for resistant Gram-negative rods.

Enterobacter sakazakii has also been reported as a rare cause of invasive infection with high mortality rates in neonates (94). These neonates can present with intestinal colonization, or more invasive disease such as sepsis and meningitis with cerebral infarction (95,96,97). *E. sakazakii* has neurotropic qualities and should be considered as a part of differential diagnosis of central nervous system abscess and/or infarction along with *Citrobacter diversus* (98,99,100). Outbreaks of necrotizing enterocolitis have been seen in premature infants (101). This infection has been reported with ingestion of contaminated commercial formula in healthcare settings (102,103,104,105). Infection with *E. sakazakii* has also been reported with the use of contaminated spoons or blenders and with ready-made formula kept warm in bottle heaters (106,107). Powdered milk is not sterile and can contain low numbers of *E. sakazakii*. Formula made from powder should be prepared daily and kept in the refrigerator no longer than 30 hours.

Fungal Sepsis

Candida species are the third most common cause of late onset sepsis in NICU patients, affecting approximately 20% of babies weighing <1000 grams (25,108-111). The crude mortality for candidemia has been reported to vary between 15 and 50% (6,86,108). Although Gram-positive organisms caused the majority of late-onset sepsis (>3 days) in very low birth weight neonates (<1500 grams), mortality was highest with Gram-negative and fungal sepsis (6,86). In this multicenter study of 6215 patients, very low birth weight infants were more likely to die if they had infection with fungi (32%; odds ratio fungi vs other organisms 2, $p < .01$).

Prior colonization of body sites (gastrointestinal tract, skin, respiratory tract) is an important risk factor for invasive disease (112,113). The gastrointestinal tract appears to be the earliest, most common site of colonization (108,114). Approximately one-half of very low birth weight infants colonized with $>8 \times 10^6$ colony-forming units of *Candida* species in their gastrointestinal tract developed feeding intolerance and/or bloody stools; 29% of these infants developed *Candidemia*. Colonization of the gastrointestinal tract in NICU patients has been associated with the use of antibiotics, particularly third generation cephalosporins, central catheters, intravenous lipids and H₂ blockers (108). Invasive *Candida* infection in preterm infants has been attributed to intrinsic factors, such as the immaturity of their immune system, increased permeability of skin and mucosal barriers, delayed enteral feedings and extrinsic factors, such as the prolonged use of antimicrobials, mechanical ventilation, parenteral nutrition, and central vascular access (108,115-119). Necrotizing enterocolitis, gastrointestinal tract, respiratory tract or skin colonization of neonates with *Candida* species have also been associated with invasive disease (113,115,120,121). Loss of normal gastrointestinal tract flora secondary to antimicrobial treatment and delayed enteral feedings may facilitate *Candida* species colonization, while skin colonization may occur through horizontal transmission from the hands of health care workers not used again (119,122).

Skin colonization of neonates with *Candida* species, particularly *Candida parapsilosis*, has been shown to occur by horizontal transmission (from person to person) through the hands of health care workers (123,124 and 125). Use of molecular typing methods has confirmed horizontal transmission of *Candida parapsilosis* *Candidemia* (122).

Empiric antifungal therapy for at-risk very low birth weight neonates has been proposed based on the clinical predictive model with a sensitivity of 85% and a specificity of 47% (126). In this multicenter study, investigators propose empiric antifungal treatment if neonates are <25 weeks gestational age, have thrombocytopenia or have a history of third-generation cephalosporins or carbapenem exposure in the past 7 days, at the time of obtaining blood culture.

Malassezia furfur is lipid-dependent yeast that can cause colonization and also systemic infections in neonates (127,128 and 129). It is usually seen in neonates receiving intravenous lipid emulsions. Eighty percent of neonates

appears that 51% of very low birth weight neonates are colonized with *Malassezia furfur* by two weeks of age (130). Colonization, however, does not predict infection and the predictive value of surveillance cultures is poor (127,130). Peripheral thromboembolism associated with *M. furfur* has been reported in a premature infant (131). Consideration should be given to detection of this lipophilic yeast when neonates receiving intralipids develops signs of catheter related sepsis. The yeasts usually grow slowly in blood culture media but readily when subcultured onto Sabouraud's medium coated with sterile olive oil (129).

VENTILATOR-ASSOCIATED PNEUMONIA

Critically ill, premature neonates in NICUs require ventilator support. The care of these hospitalized neonates contributes to increased rates of ventilator-associated pneumonia (11,13,15,17). Diagnosis of ventilator-associated pneumonia, however, is difficult in neonates with bronchopulmonary dysplasia due to underlying radiographic changes (132). A positive blood culture along with radiographic changes makes diagnosis of ventilator-associated pneumonia with greater specificity and sensitivity (39, 133). The rate of ventilator-associated pneumonia disproportionately affects very low birth weight neonates (Table 49-2) (134). In pediatric intensive care units, ventilator associated pneumonia is also the second most common nosocomial infection and *P. aeruginosa* is the most common cause of these infections, accounting for 22% of the cases (14).

Airway colonization of in-patients begins within 3 days to two weeks of the start of mechanical ventilation and may be due to either endogenous or exogenous organisms. In young children bacterial colonization and infection occurs more frequently in patients ventilated through a tracheotomy. During endotracheal ventilation, lower airway colonization occurs after two weeks of mechanical ventilation (135). Very low birth weight infants are at-risk of airway colonization with Gram-negative bacilli and also bloodstream infections (132,136). Airway colonization with Gram-negative rods may also be associated with severity of bronchopulmonary dysplasia (137). Systemic antimicrobial treatment does not eradicate Gram-negative rod airway colonization. This may be in part, to the presence of foreign bodies (tracheal or endotracheal tube), low levels of antimicrobial concentration in respiratory secretions, or translocation of bacteria from the gastrointestinal tract (138). Topical antibiotic combinations of polymyxin E and tobramycin in a 2% paste applied four times a day to the tracheostoma in young children (median age 4 months) were found to be effective in reducing the exogenous route of colonization of the lower respiratory tract (139). High case-fatality rates (30-50%) with *P. aeruginosa* invasive infections has been seen in patients with compromised host defenses and in very low birth weight infants (140,141). Of note, tracheal culture can be negative preceding invasive infections. Ventilator-associated pneumonia is usually present when tracheal culture and blood culture simultaneously grow *P. aeruginosa*. In a retrospective study of 1571 very low birth weight infants, 751 patients were on a ventilator for longer than a week. *P. aeruginosa* colonization occurred in 33 patients and of these, 15 patients also developed bloodstream infections. Thirteen of the 15 infants with bloodstream infections and none of the 33 with tracheal colonization died within two days of positive culture (134).

Care processes in ventilated neonates vary and account for the different rates of ventilator-associated pneumonia. Most neonates are subject to frequent suctioning to maintain patent airways that can easily be blocked by excessive bronchial secretions. There has been increased use of closed endotracheal suctioning systems that permit continuous ventilation of patients instead of open systems that require disconnection from ventilators. In adults, closed endotracheal suctioning systems are associated with increased rates of bacterial colonization without an increased incidence of nosocomial pneumonia (142). Closed endotracheal suctioning systems have a theoretical advantage for use due to fewer physiologic disturbances and suction-induced complications (143). An outbreak of a healthcare-associated acute Gram-negative rod pneumonia suggestive of *P. aeruginosa* on autopsy was seen in one NICU concomitant with the increase use of closed endotracheal suctioning systems with a mortality rate of 33% (10/30) in patients (144). It is possible the catheters of closed endotracheal suctioning systems were not changed every 24 hours in this outbreak, as is recommended. This report differs from that of Cordero et al., who failed to show increased colonization and nosocomial *P. aeruginosa* pneumonia and bloodstream infections among patients undergoing closed endotracheal suctioning systems (145). Guidelines for prevention for nosocomial pneumonia has been recently published (146).

P. aeruginosa is also ubiquitous in the hospital environment and is found on moist surfaces such as sinks, toilets, floor mops and respiratory equipment (141,147,148). Environmental reservoirs have been implicated as sources of transmission of *P. aeruginosa* to patients in NICUs via the use of hand lotion and on contaminated fingernails of health care workers (147,149). Warm tub bath during a term labor was associated with neonatal *P. aeruginosa* meningitis and bacteremia in an 11-day-old neonate in Germany. Genotyping revealed clonal similarity between the blood culture isolate and the shower tubing used to clean the bathtub (150).

URINARY TRACT INFECTIONS

Healthcare-associated urinary tract infection in the neonate continues to be a source of morbidity and prolonged

P.1363

hospital stay. Prevalence of urinary tract infection in the hospitalized neonate ranges from 4 to 25% (151). While the prevalence of urinary tract infections in non-hospitalized infants was only 0.1 to 1% (152). These studies demonstrated that prematurity, low birth weight and male gender contributed to increased risk for urinary tract infection in the hospitalized neonate. With improved survival of low birth weight infants, increased risk of urinary tract infection may also be seen in neonates <1000 grams (153). Incidence of vesicourethral reflux is also low in very low birth weight infants (154). In earlier studies neonatal urinary tract infection often occurred in association with sepsis (151). The exact mechanism of urinary tract infection in the very low birth weight is unknown, as they usually do not have in-dwelling catheters.

INFECTIONS DUE TO MULTI-DRUG RESISTANT ORGANISMS

Multi-drug resistant organisms such as methicillin resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococcus (VRE), and antimicrobial-resistant *Enterobacteriaceae* have emerged as major causes of healthcare-associated infections. According to the CDC-NNIS, recent analysis shows a continuing increase in the incidence of multi-drug resistant organisms in intensive care units in hospitals in the United States. As of 2004, almost 28.5% of enterococcal isolates were VRE, 59% of *Staphylococcus aureus* isolates were MRSA, and 89% of CONS were resistant to methicillin (12). The increase is continuing despite the implementation of standard infection control measures. There are no specific resistance rates for neonates and young children admitted to intensive care units. Clinical manifestations of healthcare-associated infections with multi-drug resistant organisms or susceptible organisms are indistinguishable, which makes it more challenging to diagnose these infections and treat them promptly. The next section discusses the historical perspective of specific multi-drug resistant organisms, epidemiology and interventions.

Methicillin-Resistant *Staphylococcus aureus*

MRSA is an important nosocomial pathogen. It was first reported in the United Kingdom in the 1960s, and in the United States in 1968. In 2004, 59% of *Staphylococcus aureus* isolates causing nosocomial infections among patients hospitalized in intensive care units reporting to the CDC-NNIS System were resistant to methicillin (12). This represented an 11% increase over the average percent of *Staphylococcus aureus* isolates that were resistant to methicillin during the four years from 1998 to 2002. However, a low prevalence of MRSA in NICUs (>3%) was demonstrated in a point prevalence survey conducted by the Pediatric Prevention Network (155). MRSA can cause a high morbidity and mortality in high-risk infants.

Severity of MRSA outbreaks in neonates varies in non-invasive and invasive disease. Some neonates may be colonized, others may acquire superficial infections, such as conjunctivitis and impetigo with high attack rates, but only a few of these patients develop invasive infections (156,157). Others may present with severe, invasive disease, such as bacteremia and meningitis (158,159,160,161,162). An outbreak of MRSA transmitted from a mother to 3 of her preterm quadruplet infants postnatally has been reported (163). Nasal cultures from three of the quadruplets and 2 additional unrelated infants grew the same clone of MRSA. The mother's only identified risk factors for MRSA acquisition were (1) prepartum hospitalizations related to multiple gestation and (2) treatment with ampicillin and erythromycin one week before delivery for ruptured membranes.

Healthcare-associated transmission of community acquired-MRSA infections was also documented in postpartum women in the same NICU (164). The major mode of transmission of MRSA in hospitals is by spread from one patient to another on the hands of hospital personnel (165,166,167). Asymptomatic patients who carry MRSA can also be a source of infection for other patients because healthcare workers contaminate their hands while caring for these patients and do not adequately disinfect their hands before continuing work in the unit (168). An association between overcrowding and understaffing, and the rate of MRSA infections in a NICU and in an intermediate-care nursery has been reported (169). In this nursery, the outbreak ended when overcrowding and understaffing were temporarily reduced, triple dye was applied to the umbilical cords of all infants, and an infection control nurse was dedicated to the NICU.

Intervention for Control of Methicillin-Resistant *Staphylococcus*

aureus

In the NICU baseline prevalence of MRSA should be assessed and efforts should be intensified when there is a case of healthcare-associated infection. Active surveillance for MRSA when epidemiologically appropriate is also proposed in recent guidelines for prevention and control of MRSA (170). Given the seriousness of MRSA infections in the NICU, considerable efforts should be made to identify the reservoir. Active surveillance is cost effective and should be initiated to assess the reservoir of patients who are colonized with MRSA after a single MRSA infection has been identified in a NICU. Cost of weekly active surveillance and isolation of patients with MRSA is 19 to 27-fold less costly than attributable costs of MRSA bacteremia from a new outbreak in the NICU (171). Active surveillance and increased use of alcohol-based hand antiseptic solution for hand hygiene is associated with a significant reduction in the transmission rate of MRSA (172).

Active surveillance and enhanced use of barrier precautions is effective in controlling MRSA (173). When appropriately implemented, contact precautions, weekly surveillance

P.1364

cultures, attempts to eradicate carriage in some patients, and surveillance cultures of personnel who had contact with new cases have decreased the risk of nosocomial transmission in the NICU (174). Use of cohort nursing and intranasal mupirocin may be necessary (158,162,165). Molecular epidemiological tools can be used to assess horizontal transmission. A multifaceted approach to prevent and control of MRSA is often necessary and a variety of interventions may have to be implemented concurrently.

Vancomycin-Resistant Enterococcus

In the United States, during late 1989, VRE infections from *E. faecium* were identified in the Northeast and from *E. faecalis* in the Midwest United States (175). In the United States in 2004, CDC-NNIS, analysis shows 12% increase in VRE from the preceding four years (12). Although the rate of VRE colonization among patients in the intensive care units is increasing, the incidence reported from NICUs is low, with relatively few reports related to VRE (144,176,177,178 and 179). This may be due, in part, to lack of invasive infections with this organism and also to the limited number of pediatric facilities implementing active surveillance programs for detection of multi-drug resistant organisms such as VRE.

VRE has become an important concern in public health because of the strong potential for the *vanA* gene of vancomycin resistance to transfer to virulent pathogens such as *Staphylococcus aureus* (180,181,182,183 and 184). This is a growing threat to medical facilities (185). Clinical manifestations of vancomycin-resistant and susceptible enterococcal infections are similar. Although prevalence of VRE in NICUs is low, spread is of significant concern, especially in NICUs with a large population of very low birth weight infants requiring longer duration of stay. These neonates are prime targets for the spread of VRE because of lack of bowel control and close proximity of patients; any breach in infection control practices can lead to horizontal spread. Infections due to VRE have been associated with higher health care costs, prolonged morbidity, and greater mortality rates in adults (186,187). Vancomycin-resistant *E. faecium* and vancomycin-resistant *E. faecalis* strains are increasingly being recognized as serious pathogens. *E. faecium* is also more predominant than *E. faecalis* in its resistance to both vancomycin and ampicillin, making it difficult to treat. The risk for developing a VRE infection/ colonization is inversely related to birth weight (177). Overall, patients who stay longer in the NICU are at a greater risk for acquiring VRE, which may be due to the increased risk for exposure to a possible carrier and/or prolonged use of antimicrobial therapy (176). Colonized infants are at risk for infections and serve as reservoirs for transmission (144). Multiclonal transmission of VRE strains has occurred in a NICU (178). Active surveillance cultures yielded 65 cases of VRE colonization/infection among the 1820 patients admitted to the NICU. Repetitive sequence PCR was performed on 60 of the VRE isolates and identified three clusters. Members of cluster one included isolates from 21 patients and four isolates from the environment of the index case. Cluster two and cluster three included isolates from 23 and three patients, respectively. The similarity coefficients among the members of each cluster were $\geq 93\%$ (Table 49-3). This outbreak illustrates that spread of VRE can occur easily in a NICU setting.

VRE is known to survive in an environment for as long as 5 weeks. Additionally, patients with a compromised immune system are susceptible to other illness, such as gastrointestinal dysfunction, resulting in higher risk for VRE colonization (188,189). VRE can be transferred via hands of health care workers, thermometers, physical therapy equipment, and hospital beds (178,185,190,191). VRE can be transferred from one patient to another via the contaminated gloves of healthcare workers and the environment (176,192).

Patients colonized with VRE do not always acquire infection; however, they do have a greater risk of infection

(193). VRE colonized children generally carry the bacteria in their bowel flora for long periods of time without manifesting any clinical signs and symptoms (178,194,195 and 196). These infected or colonized patients serve as a reservoir for spread of this organism to other hospitalized patients.

Interventions for Control of Vancomycin-Resistant Enterococci

In 1995, the Hospital Infection Control Practices Advisory Committee (HICPAC) of the Centers for Disease Control and Prevention published guidelines for health institutions to follow in preventing the spread of vancomycin resistance (197). These guidelines include the proper use of vancomycin, education of healthcare workers on the threat of VRE, optimal methods for screening for VRE, and implementation of control measures. However, efforts to prevent VRE colonization and to restrict vancomycin usage in these facilities have been unsuccessful, and the incidence of VRE continues to increase in ICUs in the United States (12). These HICPAC guidelines are being revised (198). The Society of Healthcare Epidemiology has recommended active surveillance for VRE (170). In NICU baseline prevalence of VRE should be assessed and efforts should be intensified when there is a case of healthcare-associated infection.

Hand hygiene should be emphasized at all times. Healthcare workers contaminate their hands after contact with a VRE colonized or infected patient regardless of whether or not gloves are worn (193). In a study, 17 (34%) of 50 healthcare workers had VRE isolates on their gloves; and 5 out of 17 of those workers who wore gloves had VRE on their hands. All health care workers should be trained to enforce appropriate isolation precautions.

As environment plays an important role in transmission of VRE, schedules for routine cleaning of rooms should be strictly adhered (192). Additionally, potentially infectious waste must be disposed of in such a manner to prevent

P.1365

P.1366

contamination of the environment and minimize the risk of exposure to hospital personnel and patients. For patients colonized or infected with VRE dedicated individual use of non-critical equipment such as thermometers and blood pressure cuffs should be mandatory. Molecular epidemiological tools can be used to assess infant-to-infant transmission.

TABLE 49-3 DENDROGRAM OF VANCOMYCIN RESISTANT ENTEROCOCCI STUDY ISOLATES. REP-PCR WAS PERFORMED ON 60 VRE ISOLATES AND IDENTIFIED THREE GENETICALLY-RELATED CLUSTERS USING THE UPRIME DT PRIMER SET

Antimicrobial-Resistant Enterobacteriaceae

Third generation cephalosporin resistant enteric Gram negative rods are an important cause of healthcare-associated infections in ICUs (24,155). NICU patients frequently acquire intestinal colonization with antimicrobial resistant enterobacteriaceae. Intestinal colonization serves as an important source for transmission to the environment (199). Colonization with these organisms has been detected as early as on the first day of hospitalization (200,201,202). This colonization may follow transmission from other patients in the unit or may evolve endogenously from the selective pressures afforded by antimicrobial therapy. Approximately 10% of colonized neonates are at risk for development of healthcare-associated systemic infections (203). Clinical manifestations of infants with resistant enterobacteriaceae are similar to the healthcare-associated infections with susceptible pathogens.

Colonization with resistant Gram-negative rods seen in a European NICU was related to empiric use of amoxicillin and cefotaxime (204). In this crossover study, neonates who were given intravenous amoxicillin-cefotaxime therapy were 18 times more likely to harbor resistant Gram-negative rods than neonates who were given penicillin and tobramycin. The combination of amoxicillin and cefotaxime may exert selective pressure encouraging emergence of extended-spectrum beta-lactamase (ESBL) producing bacteria. Cefotaxime may also select for de-repressed *amp C* mutants among the colonizing enterobacteriaceae. The appearance of ESBL-producing Gram-negative rods causes many concerns. These isolates are clinically resistant to all penicillins, cephalosporins, and monobactam agents, making therapeutic intervention difficult. Detection of such isolates is problematic for the clinical microbiology laboratory. Special procedures, such as the triple disk approximation test or the methods described by the National Committee on Clinical Laboratory Standards must be employed by the laboratory to recognize ESBL producers. The spectrum of enterobacteriaceae capable of ESBL production is broadening. In particular, *Enterobacter* species, *Serratia* species and *Citrobacter* species have been found capable of ESBL production (205,206).

Interventions for Control of Antimicrobial-Resistant Enterobacteriaceae

When an endemic problem with antimicrobial resistant enterobacteriaceae exists, multiple interventions are needed. The focused use of barrier precautions and restricting use of cephalosporins, along with provision of educational programs, helped reduce colonization and healthcare-associated infections with antimicrobial resistance enterobacteriaceae in a Brazilian neonatal unit from 32% to 11% (207,208). Molecular epidemiological tools can be used to assess infant-to infant transmission.

VIRAL INFECTIONS

Viruses account about 5% of all healthcare-associated infections and up to 23% in children (209,210). These viral infections are most common in neonates and young infants. The infections are associated with extended length of hospital stay and have considerable morbidity and mortality. The intensive care environment allows for efficient spread of viral pathogens (211). The spectrum of nosocomial viruses is wide including respiratory, enteric, and blood-borne viruses among others. This section outlines the epidemiology of these viruses and the control measures used to limit exposure.

Respiratory Viruses

This section focuses on the common viruses causing respiratory illness such as respiratory syncytial virus (RSV), influenza virus, adenovirus, and parainfluenza viruses. In a substantial number of cases of respiratory illness when no virus can be cultured, the possibility of metapneumovirus should be considered. Recently, a newly discovered coronavirus associated with severe acute respiratory syndrome (SARS) and metapneumoviruses have also been described in infants and children (212,213 and 214).

RSV causes severe morbidity and high mortality in premature infants (215). Nosocomial RSV infections are common when the community is also experiencing a high rate of respiratory viral illness during winter months (216). Neonates acquire these infections from family members and HCWs with mild respiratory illness. Neonates can present with a clinical picture consistent with sepsis, including apnea, lethargy, feeding difficulties and chest x-ray evidence of pulmonary infiltrates. Diagnosis is made by detection of antigen using a rapid viral diagnostic kit. Infections spread by secretions and large droplets. RSV remains infective in fomites for up to 12 hours (215). Prophylactic measures, such as RSV immunoglobulin or humanized monoclonal antibody (palivizumab) are cost-effective only in high-risk patients (215,217). Both of these products are licensed for prevention of RSV disease in infants with bronchopulmonary dysplasia or in preterm birth (<35 weeks) (218). Both of these agents can be given once a month, beginning just before the onset of the RSV season, and subsequently 4 more doses given monthly. No safe vaccine is currently available for use in infants. Control measures during the increase in community onset RSV include early identification of patients with respiratory symptoms who are infected with RSV and prompt

P.1367

institution of contact isolation. During large outbreaks cohorting patients and staff may be needed. Exclusion of staff and family members with respiratory tract illness may also be necessary.

Other respiratory viruses, including influenza and parainfluenza, cause healthcare-associated infections less commonly in the NICU (219,220,221,222). Although influenza A infection has been rarely described in the neonatal period, it has to be considered one of the possible causes of nosocomial infection during the winter season in the NICU (223). Diagnosis is made by detection of antigen using a rapid viral diagnostic kit. Influenza A is readily transmissible; amantadine has been used to treat symptomatic neonates and for prophylaxis of NICU staff (219). Influenza A prevention by immunization is a priority for those caring for high-risk NICU patients (221). Community acquired influenza A infections are common in children; recommendations for reducing healthcare-associated influenza virus infections include vaccination programs for both healthy children aged 6 to 23 months and health care workers and family members in contact with high-risk patients (224,225).

Parainfluenza viruses are the second most common cause of bronchiolitis and pneumonia in infants. Simultaneous outbreak of RSV and parainfluenza virus 3 has been seen in a newborn nursery (226). Respiratory viral illness due to parainfluenza virus 3 infections in neonates can be seen during summer months. Diagnosis is made by detection of antigen using a rapid viral diagnostic kit. An outbreak of parainfluenza virus 3 was seen in infants with respiratory symptoms and the chest x-ray showed pulmonary infiltrates. Significant morbidity was seen in three of the six neonates requiring ventilator support. Healthcare workers ill with respiratory symptoms were the vehicles of transmission and the nursery was understaffed during this outbreak (220).

Adenoviral pneumonia occurs in approximately 10% of cases and can be more severe than RSV (227,228 and 229). Clinical manifestations include findings consistent with clinical sepsis, including decreased feeding, lethargy, apnea, retractions, and progressive pneumonia. Diagnosis is made by detection of antigen using a rapid viral diagnostic kit.

Human coronavirus (HCoV, strains 229E and OC43) has been shown to cause healthcare-associated viral infections in 11% of neonates in a prospective study (230). The incidence rate for other viruses such as RSV, influenza A and B, paramyxoviruses 1,2, and 3 and adenovirus were shown to be less prominent pathogens in the study period (230). Risk factors included prolonged duration of hospitalization, parenteral nutrition, and antibiotic treatment.

SARS, a newly diagnosed respiratory disease caused by a novel coronavirus SARS-CoV, has been seen in a 56-day-old ex-30 week gestation infant in Hong Kong (212,213,231). This infant, upon admission to hospital, presented with hypothermia and respiratory distress. Laboratory and microbiologic results were similar to those found in other pediatric patients with SARS. Lymphopenia and elevation of enzymes such as AST, ALT, CK and LDH was seen at the time of admission to the critical care unit. Chest radiograph showed focal consolidation. Nasopharyngeal aspirate revealed SARS-CoV by reverse transcriptase-polymerase chain reaction (RT-PCR). This

patient was seen during an on going SARS outbreak in regions of China and in Hong Kong.

Human metapneumovirus infection has been recently shown to be one of the leading causes of respiratory tract infections in the first years of life (214). Human metapneumovirus infection produces clinically similar symptoms to RSV infection. In a study using nasal wash samples obtained over a 25-year period, 20 percent of the all previously virus-negative lower respiratory track illnesses were attributable to human metapneumovirus (215). Clinical manifestation included cough (90%), coryza (88%), fever (52%) and other constitutional symptoms. The mean age of human metapneumovirus infected children was 11.6 months. In a substantial proportion of viral infections in NICUs the etiological agent responsible for the disease cannot be found, the possible role of human metapneumovirus remains to be seen.

Parvovirus B19

Parvovirus B19 is the etiologic agent of fifth disease in children. Droplets in household contacts readily spread this virus and infection rates are high (232). Although transmission in healthcare settings has occurred, the risk of healthcare worker transmission is low (233,234). Nosocomial infection has occurred among hospital staff after contact with infected patients with sickle cell disease and aplastic crisis (235). Nosocomial transmission from chronically infected immunocompromised patients can also occur (236). Susceptible healthcare workers are at risk of seroconversion to B19-specific IgM and IgG during community outbreaks of fifth disease (237). Transmission from infected HCWs to patients has been documented, prior to the implementation of standard and isolation precautions practiced for at least past two decades. Transmission of parvovirus in a healthcare setting is less likely to occur with use of stringent infection control practice and good hand hygiene. Pregnant healthcare workers should be informed of the potential risk to the fetus from parvovirus B19 and the preventive measures.

Enteroviruses

Healthcare-associated enteroviral infections are usually associated with community outbreaks during summer and autumn; they spread by the fecal-oral and respiratory routes, and from mother to neonate in the peripartum period. Enteroviruses survive on an environmental surface for a prolonged period of time, with a potential for transfer of infection through fomites. Echovirus type 22 has been identified in nosocomial necrotizing enterocolitis outbreaks (238). Echovirus type 11 was the most common type found in neonatal echovirus infections at a

P.1368

non-mucosal site in the review of 16 outbreaks in nurseries (239,240).

A RT-PCR can detect the presence of enteroviruses- echovirus and coxsackie (241). PCR can be helpful in detecting outbreaks, and in cohorting patients with enteroviruses (*Coxsackie B4*) meningitis and myocarditis (242). Standard and isolation precautions with strict hand hygiene practice after diaper change should minimize exposure to enteroviruses.

Coxsackie B virus infections are also frequent, with attack rates of 22 to 54% (243). They may cause myocarditis, hepatitis and meningitis (242,244). *Coxsackie A* infections are rare, but herpangina and aseptic meningitis have been described (245).

Studies using DNA markers have showed that, in the NICU environment, the most consistently positive sites for Coxsackie B detection included blood gas analyzers, computer mice, telephone receivers, medical charts, ventilator knobs, door handles, radiant warmer control buttons, patient monitors, and the hands of personnel (246). The information revealed by these techniques help in assisting and enforcing cleaning procedures, and educational intervention programs to decrease nosocomial infections.

Other Viruses

Hepatitis A virus (HAV) has been reported to occur as a vertical transmission from a mother with an acute infection (247). Horizontal spread among premature infants by nurses and asymptomatic infected premature infants can be a source of hepatitis A outbreak in nursery infants and personnel and in the community (248). Infants exposed to perinatal HAV may benefit from immunoglobulin, although its efficacy has not been established (249).

Herpes simplex virus (HSV) transmission to the neonate occurs during vaginal delivery from symptomatic or asymptomatic mothers. The incidence of neonatal herpes virus is 1 in 3000 to 20,000 live births. Nosocomial

transmission of HSV is very rare (250,251). Interfamilial transmission of HSV infants has been reported and is also rare. Neonates born to mothers with active disease or mucocutaneous lesions should be placed on contact isolation in addition to standard precautions.

Human immunodeficiency virus (HIV) is transmitted vertically, and healthcare-associated transmission of HIV is also reported. Prospective studies of HCWs have estimated that the average risk for HIV transmission after a percutaneous exposure to HIV-infected blood is approximately 0.3% (95% confidence interval=0.2%-0.5%) and after a mucous membrane exposure is 0.09% (95% CI =0.006%- 0.5%) (252). HIV infection predisposes to neonatal septicemia and congenital infection. Maternal HIV infection has been estimated to increase the stillbirth rate by 1.6 times and neonatal mortality rate by 2.7 times (253). Standard precautions to prevent parenteral, mucous membrane, and non-intact skin exposure to HIV should be used for all patients.

Varicella-zoster virus (VZV) can cause serious morbidity and mortality in neonates if the mother develops varicella from 5 days before to 2 days after delivery. The airborne route readily transmits varicella and prophylactic varicella-zoster immune globulin should be considered for exposed premature infants (254). Indications include: (1) newborn infant whose mother had onset of chicken pox within 5 days before or 48 hours after delivery (2) hospitalized premature infant (≥ 28 weeks of gestation) whose mother lacks a reliable history of chicken pox or serologic evidence of protection against varicella (3) hospitalized premature infant (≤ 28 weeks of gestation or ≤ 1000 grams birth weight), regardless of maternal history of chicken pox. Oral acyclovir has been administered prophylactically to preterm infants in contact with a varicella patient and has been suggested to prevent hospital-acquired VZV infections in situations where VZV immunoglobulin is not available (255). Healthcare workers should be screened for VZV immunity and receive vaccine as needed, unless contraindicated (256).

Cytomegalovirus (CMV) infection can occur either vertically from the mother or horizontally from household members or childcare centers. Transfusion-acquired CMV infection of low birth weight neonates of seronegative mothers has been reported (257). Seropositive healthy donors have latent CMV in their leukocytes and blood transfusion can result in viral transmission. Transmission of CMV has been virtually eliminated by the use of CMV antibody negative donors (258). Cells are frozen in glycerol before administration, either the buffy coat is removed, or cells are filtrated to remove the leukocytes. Use of pasteurized milk or freezing of human milk can also decrease the risk of transmission. If human milk is used, infants born to CMV antibody-negative mothers should receive milk only from CMV antibody-negative women. The prevalence of CMV excretion by patients in a neonatal intensive care unit is about 1%. The majority of CMV excreters are symptomatic. Pregnant health care workers are especially concerned, because CMV infection can be associated with significant neurological injury to the fetus. Healthcare-associated transmission from patient to health care worker has not been documented (259). A review of cytomegalovirus excretion in hospitalized patients and prospective evaluations of primary infection in hospital personnel do not support frequent occurrence of cytomegalovirus infection despite ample opportunity for exposure. Adherence to proper isolation techniques and good hand hygiene should be adequate to prevent nosocomial transmission of the cytomegalovirus. However, pregnant healthcare workers should be counseled about the potential risks of acquisition and urged to practice good hand hygiene.

Good hand hygiene, barrier precautions such as gloving, gowning, masks and goggles to prevent person-to-person viral transmission are the key elements in controlling nosocomial spread of viruses in the NICU (260). In specific situations, prophylactic antiviral or specific immunoglobulin is also used, as described above.

P.1369

INFECTION CONTROL MEASURES

New technologies and better approaches are rapidly changing concepts about infection management. Today, one third of all hospital-acquired infections could be prevented by effective, readily available programs that monitor, prevent and control infections (261,262). Such programs require substantial changes in NICU culture, from the current focus on early detection to a full commitment to prevention and to a multi-step management program that incorporates: (1) surveillance, (2) prevention and control including (i) isolation precautions, (ii) hand hygiene, (iii) oral and skin care, (iv) catheter care, (v) accuracy of diagnosis, and (vi) equipment care, (3) staffing and nursery design, (4) educational and feedback (5) an infection control practitioner (ICP) and availability of a trained infection control physician (hospital epidemiologist) (261,263). In addition, the care of pre-term infants requires specialized knowledge of infectious disease processes and methods to reduce infection.

Surveillance

A key component of infection control is surveillance: the collection, management and organization, analysis

(interpretation) and reporting of relevant data. Active surveillance is essential to identify alterable risk factors and detect system problems. Although the patient may be the source of contamination, healthcare workers, invasive devices, and hospital equipment continue to be important vectors promoting the spread of organisms within the nursery. Without effective surveillance, it is not possible to mount effective efforts to prevent infection (9).

Ideally, the progress of each infant would be followed from admission to discharge from an infection control perspective. Methods of active surveillance and detection vary but include clinical case review, review of laboratory results, and retrospective chart review. Patient and environmental risk factors, procedures, and culture results must be recorded and interpreted by the ICP and epidemiologist.

Surveillance also includes monitoring all central lines from insertion to removal. Insertion sites must be inspected. Record the operator's name and the date of catheter insertion, dressing changes and catheter removal, along with signs of infection (fever, hypothermia, apnea, and bradycardia). Surveillance also includes monitoring other risk factors including length of parenteral nutrition and intralipids infusions and device days (Table 49-4).

Not only must the course of each individual infant be followed, but also the entire NICU population must be tracked for multi-drug resistant organisms colonization and infection rates, risks and trends. These observations provide important and practical tools to guide clinical practice and change-efforts as well as measures of quality improvement. Any significant change in the rate of infection or with a particular microbe should be investigated. Identify the microorganism along with its reservoir and risk factors for transmission. Present ICP and epidemiologist recommendations to the NICU staff.

As ICPs monitor each infant's care from the unique perspective of infection control, the practitioner's responsibility is to understand the risk factors identified, and to question closely the characteristics affecting any situation she/he does not understand.

Prevention and Control

Understanding the source of each infection and its mode of transmission is the essential basis for determinations of appropriate control measures (264). Infection risks related to the patient, the personnel, the procedures and devices all must be considered. Neonatal patient risks also include premature rupture of membranes, maternal illness, gut colonization, and mechanical ventilation and each may be important, even those that cannot be modified (58). Often, a combination of strategies to minimize infection can be effective by focusing only on known modifiable risk factors. These include but are not limited to hand hygiene, oral and skin care, catheter care, accurate diagnosis of infection, enhanced isolation precautions, and care of equipment (265).

Successful prevention strategies also include limiting nurse-to-patient ratios and avoiding overcrowding, educating and providing feedback to nursery personnel, and continuously monitoring infection rates.

Isolation Precautions

Guidelines for isolation precautions, revised in 2004/2005, suggest ways control the spread of microorganisms that are transmitted to infants through direct contact with infected or colonized persons, indirect contact with contaminated objects, droplet contact in the air and through contaminated products. It is important to monitor infants for multi-drug-resistant organisms colonization and/or infection and to take appropriate special precautions to prevent transmissions.

Cohorting of patients colonized or infected with multi-drug resistant organisms is appropriate. Treatment for these patients includes aseptic technique, hand hygiene and appropriate antimicrobial usage. Patients colonized with multi-drug-resistant organisms require use of isolation precautions to prevent cross-colonization; a single negative culture does not prove that the infant is no longer colonized with the resistant microorganism.

Hand Hygiene

Lack of hand hygiene is the most frequent (and, most important) source of pathogens in health care facilities, and the institution of strict hand hygiene is the easiest,

fastest and most effective corrective measure. Although neonatal healthcare workers typically believe that they

applied to wet both the tops and bottoms of each hand, between the fingers and under the nails. It is important to rub the hands together after application until all the alcohol has evaporated. Also, these products are not effective when hands are visibly dirty.

The drying effect of alcohol can be reduced or eliminated by adding 1 to 3% glycerol or other skin conditioning agents (266). Health care workers with respiratory allergies may poorly tolerate alcohol-based products with fragrances. Alcohol-based products cause substantially less skin irritation and dryness than soaps or antimicrobial detergents and are consistently associated with improvements in skin health and improved compliance with hand hygiene when compared with traditional hand washing products (270,271).

Approximately 25% of nurses report symptoms of dermatitis on their hands and 85% give a history of skin problems (272). Frequent and repeated use of hand hygiene products, especially soap and water, is the primary cause (273). Using hot water for hand washing (especially in winter months) also contributes to dermatitis, but allergic dermatitis from alcohol-based hand rubs is uncommon. It is important to provide chlorhexidine-compatible lotion for healthcare workers. Hand lotion can increase skin hydration and replace depleted skin lipids that contribute to the barrier function of normal skin. Skin irritation leads to dryness and cracking of the skin. Skin breakdown can lead to less hand washing and more frequent colonization by staphylococci and Gram-negative bacilli (274). Lotion decreases skin irritation, dryness and cracking, and twice-a-day use of lotion can prevent irritant contact dermatitis caused by hand hygiene products (275). It is important to insure easy access for hand hygiene materials. Sinks must be accessible, along with antiseptic products and paper towels. Dispensers for alcohol-based hand rubs must be accessible and monitored to ensure proper function.

The initial hand wash before entering the NICU should be done with antimicrobial soap and water up to the elbow. Brushes do not seem to be more effective than antiseptic soap alone, are no longer recommended for hand hygiene, and may even be harmful since they lead to sloughing of skin and contribute to dermatitis (276).

The CDC recommends health care workers wear gloves to (1) reduce the risk of personnel acquiring infections from patients, (2) prevent workers' flora from being transmitted to patients and (3) to reduce contamination of the hands of personnel by flora that can be transmitted from one patient to another (277). One study demonstrates that wearing gloves prevented personnel from acquiring VRE on their hands when touching contaminated environmental surfaces (278). Another, involving personnel caring for patients with *C. difficile*, found that gloves effectively prevented hand contamination among a majority of personnel having direct contact with patients (278). However, gloves do not provide complete protection and it is important to wash hands after removing gloves (279).

Artificial nails are a particular hazard. Routine cleaning does not effectively remove bacteria and their use should be banned for direct caregivers in the NICU. There is no longer any question that hand hygiene in health care settings is fundamentally effective. Research findings are abundant on the topic, and they are convincing. Specific guidelines for workers to follow are equally important to help facilitate system improvements and include requirements for detailed monitoring to: (1) periodically record the number of hand-hygiene episodes by personnel compared to the number of hand-hygiene opportunities and provide feedback to personnel regarding their performance, (2) record the volume of alcohol-based hand rub used per 1,000 patient-days, (3) record adherence to policies concerning artificial nails, (4) when outbreaks of infection occur, assess the adequacy of health-care worker hand hygiene. Improvements in compliance tend to be short-lived without ongoing monitoring. The possibility of including parents as partners ensuring compliance with hand decontamination in NICUs needs to be studied.

Skin Care and Oral Hygiene

Very low birth weight infants have inadequate epidermal barriers, so that their risk of infection is elevated. Care should be taken to avoid damage to the newborn skin. While there is no consensus concerning the most effective skin care practice for these infants it is recognized that newborns should be washed with warm water, that may include mild non-medicated soap, immediately after birth (280). Thereafter, whole-body bathing and antiseptic

P.1372

agents are not necessary for routine care but may be indicated during outbreaks. When antiseptic agents are needed, chlorhexidine is a safe choice; it is less toxic than hexachlorophene and cutaneous absorption is negligible (281). Iodophors may not be safe for bathing because of absorption of iodine (282,283). Chlorhexidine cord care has been effective in reducing colonization and infection in some centers. A recent study shows no decreased risk of infection to infants receiving Aquaphor, a topical emollient, in fact there may be an

increase in the risk of CONS infection with this practice (284,285).

Recent studies demonstrate that CONS colonize mucosal sites including the gut, nares, and throat of preterm infants. It is possible that mucosal colonization leads to translocation of CONS from mucosal sites to the bloodstream through the mesenteric lymph nodes (59). It is therefore possible that the gut, in addition to the skin, may be an important source of CONS bacteremia. Few studies have been done to support this data, but these findings raise important questions related to infection control practices. Studies in the adult population show that aspiration of oropharyngeal organisms is associated with hospital acquired pneumonia. Nasogastric tubes, endotracheal tubes, mechanical ventilation, enteral feeds and surgery put patients at risk for hospital-acquired pneumonia. Strategies aimed at decreasing CONS mucosal colonization, including nasal and gut colonization, may help prevent hospital-acquired pneumonia and bloodstream infections.

Probiotic supplements have been suggested to play a role in retaining the normal micro flora in the colon of infants and thus preventing bloodstream infections and late-onset sepsis. The normal intestinal bacterial colonization of very low birth weight infants is disturbed by several factors, such as cesarean section and parenteral nutrition, low modulation of immunity and increased gut permeability allowing bacterial translocation from gut to tissues, and antibiotic treatment (286,287 and 288). In a recent prospective double-blind study with lactobacillus treatment no statistical significance in reducing bacterial sepsis was found (289). However, this field remains controversial, and more studies are needed in very low birth weight infants to show possible benefits of probiotics in prevention and control of nosocomial sepsis.

Catheter Care

Most serious catheter-related bloodstream infections (CRBSI) are associated with central venous catheters, especially those placed in ICU patients colonized with hospital acquired organisms. These catheters are used for extended periods of time and are manipulated several times each day to administer fluids, drugs and blood products. The catheters are also accessed to obtain blood, increasing the potential for contamination and subsequent infection (290). Such infections are both costly and dangerous, with cost per infection ranging from \$34,508 to \$56,000 and mortality rates between 12% and 15% (291,292,293).

Migration of skin organisms found at the insertion site into the cutaneous catheter tract, with colonization of the catheter tip, is the most common route of infection for short-term peripherally inserted catheters. Contamination of the catheter hub contributes substantially to intra-lumina colonization of long-term catheters (42). Catheters can also become hematogenously seeded from another focus of infection. Infusate contamination is less common, but leads to catheter-related bloodstream infection.

Extensive research convincingly demonstrates the risk for infection declines following standardization of aseptic catheter care. Specialized IV teams are highly effective in reducing incidence of catheter-related infections (294). Improvements are noted when a limited team of skilled persons consistently performs central line insertions.

Most umbilical and central venous catheters are available with a heparin-bonded coating and impregnated with benzalkonium-chloride, to provide them with both antimicrobial activity and an anti-thrombotic effect (295,296). Other catheters coated or impregnated with antimicrobial or antiseptic agents can decrease the risk for CRBSI. However, these catheters are currently not available for infants weighing less than 3 kg.

The risk of catheter colonization and bloodstream infection for umbilical vein catheters and umbilical artery catheters are similar and high for some newborns. In one study, neonates with very low birth weight receiving antibiotics for > 10 days were at an increased risk for umbilical artery CRBSI while those with higher birth weight receiving parenteral nutrition were at increased risk for umbilical vein CRBSI (297). Ideally umbilical catheters should be removed as soon as possible when no longer needed, but umbilical artery catheters can be left in place for 5 days and umbilical venous catheters for 14 days if managed aseptically (290). No relationship has been found between the duration of catheterization and the daily probability of infection, suggesting that routine replacement of most central venous catheters does not reduce the incidence of catheter-related infection (298).

To prevent infection, all central catheters should be inserted using sterile technique including sterile gowns, gloves, masks, large sterile sheets and appropriate skin disinfection (process measure forms Tables 49-5 and 49-6). Avoid small sterile drapes that do not provide an adequate sterile field for catheter insertion in neonates. Maximal sterile precautions (large sheets) help reduce central venous catheter bacteremia in neonates. Two-percent chlorhexidine is the preferred skin antiseptic, but is not yet approved for infants less than two months of age (299). Seventy percent alcohol or ten percent povidone-iodine can be used for these young infants. The skin

must be scrubbed for at least 30 to 60 seconds and must be allowed to dry completely. Ten-percent povidone-iodine takes at

least 2 to 3 minutes to air dry, and is not effective until it is thoroughly dry.

TABLE 49-5 CENTERS FOR DISEASE CONTROL SAMPLE CENTRAL LINE DATA COLLECTION RECORD (To be completed by nurse assisting with insertion)

The rate of colonization among catheters dressed with transparent dressings (5.7%) is comparable to the colonization of those dressed with gauze (4.6%); there are no substantial differences in the incidence of catheter colonization or phlebitis (300). The catheter-site dressing requires changing when it becomes damp, loose, or visibly soiled. Replace gauze dressings every two days and transparent dressings every seven days except for patients in which the risk of dislodging the catheter outweighs the benefit of changing the dressing (301). Clean or sterile gloves must be used when changing dressings. The chlorhexidine-impregnated sponge (Biopatch) can be used for infants greater than 26 weeks gestation or greater than 7 weeks of age, and cuts infection rates in older children and adults. One study of neonates showed a substantial decrease in colonized catheter tips but no difference in the rates of CRBSI and bloodstream infections without a source (302). Infants in this study with gestational age less than 26 weeks and less than 8 days of age were at increased risk for localized contact dermatitis with the Biopatch dressing. Of the 98 neonates with very low birth weights, 15% developed localized contact dermatitis.

Topical antibiotics or creams at the catheter insertion site are not recommended because they promote fungal infections and antimicrobial resistance (303). Rates of catheter colonization with *candida* species appear to be increased with ointments that have no fungicidal activity (304).

Peripheral venous catheters should be left in place in children until intravenous therapy is completed, unless complications occur (290). Promptly remove any catheter that is no longer essential. Line setups should be designed to limit the number of ports and connections, since each is an independent opportunity for contamination. Hub contamination can be prevented by maintaining catheter sterility during line changes and by effective hand washing, use of a sterile field under the hub, wiping the injection ports with 70% alcohol and friction and allowing the alcohol to dry before accessing the systemD. Use ports that do not require opening to access. Access ports should be covered with a silicone membrane to reduce risk of contamination. Microorganisms found colonizing the catheter hubs are frequently the same

organisms as those isolated from the bloodstream in patients with CRBSI (305). Unneeded components and stopcocks should be excluded whenever possible. Replacing intravenous administration sets no more frequently than 72 hours after initiation is safe and cost-effective (306). When a fluid that enhances microbial growth is

infused (e.g., lipid emulsions and blood products) more frequent changes of administration sets are indicated, because these products are independent risk factors for CRBSI (305). Exposure to lipids is an independent risk factor for development of coagulase-negative staphylococcal bacteremia, and in very low birth weight infants the risk of infection with *candida* or lipophilic fungus such as *Malassezia furfur* is also increased (307,308,309,310). All tubing used to administer blood, blood products or lipid emulsions should be replaced within 24 hours of administering the infusion. Infusions of lipid-containing solutions should be completed within 24 hours and blood or blood-products within 4 hours. One port should be designated exclusively for parenteral nutrition if a multi-lumen catheter is used (51,290).

TABLE 49-6 CENTERS FOR DISEASE CONTROL SAMPLE CVC DAILY INDICATION FOR USE FORM

Accuracy of Diagnosis

Accurate diagnoses are essential to support correct remediation. Perhaps the most important step toward accuracy is avoiding false-positive cultures. Antiseptic skin preparation is essential along with aseptic cleansing of the catheter hub. Coagulase negative staphylococcus, a normal skin/oral flora, can lead to false-positive blood cultures. False-negative blood cultures also occur when an inadequate amount of specimen is obtained (311). For example, one mL is the optimal sample volume for blood culture in the NICU. Obtaining two blood cultures with each sepsis evaluation improves the accuracy of diagnosis and allows better antibiotic decisions (41). One culture can be obtained through the central line and the other culture from a peripheral puncture (42).

Equipment Care

Every piece of equipment used in the NICU is a potential source of infection, directly or indirectly. Ventilators, monitor leads, radiology cassettes, thermometers, isolettes, breast pumps and antiseptic solutions are examples (264). All equipment in direct contact with skin or mucous membranes of newborns must be decontaminated with a high-level disinfectant or sterilized between patients. Equipment should be reserved for one patient or decontaminated with alcohol between patients.

Organisms such as *pseudomonas*, *serratia* and *flavobacterium* are prevalent in the inanimate environment and grow readily at room temperature in water and moist environments such as incubators, humidifier reservoirs and respiratory nebulizers and tubing. Respiratory support equipment such as resuscitation bags, masks, and laryngoscope blades should be decontaminated and replaced periodically according to the Centers for Disease Control's guidelines (<http://www.cdc.gov>).

Staffing and Nursery Design

Outbreak investigations clearly associate infection and understaffing or overcrowding, probably because of poor adherence to hand hygiene (170,266). For example, when results are adjusted for confounding factors, the patient-to-nurse ratio remains a significant independent risk factor for bloodstream infection, implying that nursing staff reduction below a critical threshold may jeopardize adequate catheter care (see also Chapter 6) (312).

In one example, during an outbreak of *Enterobacter cloacae* in a neonatal intensive care unit, the daily number of hospitalized neonates was above the maximum capacity of the unit. The number of staff was substantially less than the number recommended and there was a reduced attention to basic infection control measures. Adherence to hand hygiene practices before device contact declined to 25% during the workload peak, but increased to 70% after the end of the understaffing and overcrowding (313). Such results not only demonstrate the link between workload and infection, but they also highlight the intermediate cause of antimicrobial spread: poor adherence to hand hygiene policies.

Understaffing and overcrowding, inexperienced staff and float-pool nurses appear to increase the risk of cross contamination of organisms (314). Nursery design should provide adequate space for care of the infant and necessary equipment as well as strategically placed sinks. The American Academy of Pediatrics recommends that NICUs have a minimum of 150 net square feet of floor space per infant, with at least 6 feet between incubators and 8-foot aisles (315). There should be at least one sink for every three to four patients. Ventilation in the NICU should provide positive pressure airflow from a ceiling entry to a floor return, pulling dust downward and out. There should be a minimum of 6 to 10 air changes per hour. One nurse for every one to two patients is recommended.

Educational Programs and Feedback to Healthcare Workers

Education of the entire health care team is essential to success in reducing healthcare-associated infection in pre-term infants. To an important degree, preventing hospital-acquired infection depends on influencing and changing the unit culture. Where infection rates are low, the staff tends to be aware and proud of their success. They believe infections are preventable, and are willing to invest the necessary time and effort to insure that result. Where staff do not understand the importance of new procedures, change is not possible. Educational programs teach staff how and why new practices minimize the risk of infection. They include hand washing, catheter care, accurate diagnosis of bloodstream, and standard and enhanced transmission-based precautions. The entire health care team learns the best way to avoid cross-colonization and infection. Educational efforts include developing infection control policies and procedures, staff education modules, skills laboratories and competency tests.

Compliance with the new procedures improves when staff has adequate training, adequate supplies, and ongoing programs to encourage and monitor implementation. Infection control is everyone's responsibility. Staff education must be persistent, but can be offered as infrequently as twice a year for full-time staff and at the beginning of each resident rotation. Feedback needs to be part of all educational activities. Widespread staff involvement and acceptance require frequent communications. Disseminate information through e-mail, in-service sessions, regularly scheduled staff meetings, newsletters, open discussion and posters.

Role of the Infection Control Practitioner

Benchmarking and reliance on well-supported procedures is essential to build institutional confidence in the effectiveness of specific practices that cut infection rates. The ICP and epidemiologist must keep abreast of the most current research and take steps to use those practices that have proved effective. The presence of the infection control practitioner in the NICU increases awareness of the importance of basic infection control principles at the same time it helps control health care related infections and the ICP's presence helps focus medicine, nursing, respiratory therapy and pharmacy on their need to be involved in infection control by providing a line of communication between and among the disciplines. The ICP serves as a resource not only for

the medical and nursing staff, but also the consultants, management, ancillary staff and families.

A significant element of effective control of health-care related infections is the understanding that continuing vigilance and effort rather than single interventions are required, and depend on the creation of an effective control system, as well as planned interventions in many disciplines over an extended time frame. Four key habits integral to

P.1376

preventing health-care related infections were identified by the Vermont Oxford National Evidenced-Based Quality Improvement Collaborative for Neonatology in 2003: (1) the habit for change, (2) the habit of systems thinking, (3) the habit of collaborative learning, and (4) the habit of evidenced-based medicine (316).

An additional success factor in infection control is staff conviction regarding the importance of changing practices to improve outcomes. In many cases, small changes can affect the larger process and lead to effective strategies for lowering infection rates. Sharing experiences with other centers (NICUs) is critically important to encourage the team, keep the process exciting and push the improvement process forward. Evidence from randomized trials is not always available. Collaborating with an infection control expert helps place neonatal literature review in the larger framework of healthcare-related infections in medical care. Benchmarking offers the best opportunity to find which practices have the greatest impact. The number one finding common to all benchmark sites in the Vermont Oxford study was the practitioners' attitude regarding their role in lowering infection rates. Practitioners that believe infection rates can be lowered by changes in practice had the most success and the lowest infection rates.

ICPs are able to assist staff in cohorting patients as necessary and to insure that proper isolation precautions are instituted; they review current literature to share with staff members, and are available to give timely feedback related to infection control practice issues in the clinical setting. ICPs play an integral part in reviewing policies and procedures and standardizing patient care, and they help to change the culture of the NICU so that physicians, nurses and other staff members are aware of the vital importance of infection control.

Chapter 50

Neurological and Neuromuscular Disorders

Alan Hill

In the context of dramatic improvements in obstetric care and in the treatment of neonatal respiratory disorders and infection, neurologic problems remain a major cause of morbidity and mortality in the newborn. In this chapter, an approach to the neurologic assessment of the newborn is outlined, and practical aspects of diagnosis and management of the most common neurologic and neuromuscular problems of the newborn are reviewed (e.g., seizures, hypoxic-ischemic cerebral injury, intracranial hemorrhage, traumatic birth injury, spinal muscular atrophy, muscular dystrophies and myopathies). Major bacterial and viral infections, metabolic derangements that affect the central nervous system (CNS), and cerebral dysgenesis are discussed in other chapters.

NEUROLOGIC EVALUATION OF THE NEWBORN

History and Physical Examination

The importance of a detailed history and neurologic examination for assessment of the newborn with suspected neurologic problems cannot be overemphasized (1). Such history must include details of the family history and complications encountered during pregnancy, labor, and delivery, because many neurologic abnormalities that present during the neonatal period actually originate antenatally.

The format of the neurologic examination in the newborn is similar to that used in older patients. However, observations must be interpreted in the context of the level of cerebral maturation at different gestational ages (1,2). The examination should not be prolonged unnecessarily to avoid hypothermia and fluctuations in arterial blood pressure that may be associated even with routine handling, especially in premature newborns.

Neurologic observations also are influenced considerably by the level of alertness of the infant. After 28 weeks of gestation, infants are able to awaken spontaneously or may be roused for several minutes by stimulation. Distinct sleep-wake patterns may be recognized by 40 weeks of gestation.

In an examination of the cranial nerves, pupillary constriction to light and the blink reflex may be elicited as early as 28 weeks of gestation. Pupillary responses are consistent by 31 to 32 weeks. Consistent visual tracking of a bright light and optokinetic nystagmus can be elicited consistently in the awake infant at term. Fundoscopy may reveal retinal hemorrhages in 20% to 50% of newborns following vaginal delivery, but these rarely indicate significant CNS injury. Dysconjugate and jerky eye movements are common in premature infants and may persist to some extent for several months after term. Full extraocular eye movements to doll's-head maneuver or to caloric stimulation may be elicited after 32 weeks of gestation. Facial muscle weakness may be of central or peripheral origin. Hearing may be difficult to assess, although infants startle to loud noises as early as 28 weeks of gestation. The act of feeding requires coordination of breathing, sucking, and

swallowing, which involve principally cranial nerves V, VII, IX, X, and XII. Therefore, observation of feeding provides valuable information regarding function of these cranial nerves and the brainstem in general.

The major features of the motor examination include evaluation of limb posture, spontaneous and elicited movements, muscle power, tendon reflexes, and primitive neonatal reflexes. Muscle tone may be assessed by careful observation of the infant's posture at rest and during various maneuvers of passive manipulation. With increasing gestational age, there is development of predominance of flexor tone in all limbs. Asymmetry of muscle tone and spontaneous limb movements may indicate focal cerebral lesions or peripheral injury, e.g., brachial plexus injury. Tendon reflexes can usually be elicited in the term newborn. Undue emphasis should not be placed on brisk tendon reflexes, ankle clonus, or crossed adductor responses

P.1385

in the absence of corroborative abnormal neurologic signs. Muscle strength may be assessed by gently pinching the infant's distal extremities and eliciting the recoil flexor response.

Careful evaluation of sensory function is particularly important in the evaluation of spinal cord or peripheral nerve injury. A useful aspect of sensory evaluation is the determination of habituation, i.e., the normal dampening of responses to multiple (e.g., 5-10) stimulations. Habituation indicates a high level of response that appears to require input from cerebral hemispheres. It is characteristically absent in anencephalic infants.

Neurodiagnostic Techniques

Because the neurologic examination is often limited by concomitant systemic illness and the requirement for complex life-support systems, a variety of noninvasive neurodiagnostic techniques, e.g., neuroimaging, electroencephalography, evoked potentials, often are used as adjunctive methods for the evaluation of neurologic problems. The clinical applications of various techniques will be discussed in the context of specific neurologic conditions.

NEONATAL SEIZURES

Seizures are the most distinctive manifestation of significant CNS disease in the newborn. Prompt diagnosis and intervention are indicated because not only do seizures often indicate serious underlying disease, they also may interfere with supportive care, e.g., ventilation and alimentation. Repeated seizures are often associated with hypoventilation and apnea which, in turn, may result in cardiovascular collapse and ischemic brain injury. Furthermore, the hypercapnia, in combination with increased lactate and an adaptive rise in systemic blood pressure, may result in an abrupt rise in cerebral blood flow with associated risk of intracranial hemorrhage especially in premature infants (3). Additionally, experimental animal studies suggest that neonatal seizures may have a deleterious effect on the developing brain by depleting cerebral glucose levels, which, in turn, may interfere with deoxyribonucleic acid (DNA) synthesis, glial proliferation, differentiation, and myelination (4,5). Although the relevance of data from experimental animal studies to the human newborn is not entirely clear, the significance of neonatal seizures has been corroborated by in vivo studies with magnetic resonance spectroscopy (MRS) (6). In terms of management, the possible detrimental effects of neonatal seizures must be balanced against the

potentially deleterious effects of anticonvulsants on the developing brain (7).

Clinical Features

Neonatal seizures differ considerably from seizures observed in older children, principally because the immature brain is less capable of propagating generalized or organized electrical discharges. The principal types of neonatal seizures are summarized in Table 50-1 (8). Although individual seizure types are not indicative of specific varieties of brain injury, certain seizure types are associated more commonly with some conditions. For example, generalized tonic seizures, which may represent brainstem release phenomena or posturing, have been observed with major germinal matrix hemorrhage/intraventricular hemorrhage (GMH/IVH). Focal clonic seizures may be associated with focal cerebral infarction or traumatic cerebral contusion.

Differentiation of seizures from nonepileptic movements may be difficult in the newborn. Clonic seizures may be particularly difficult to differentiate clinically from jitteriness or tremulousness, particularly because both occur

P.1386

frequently in similar clinical contexts, e.g., hypoxic-ischemic encephalopathy, metabolic derangements, and drug withdrawal. However, jitteriness is classified as a movement disorder that may be associated with good outcome. Benign jitteriness often resolves within weeks. The distinction between jitteriness and seizures may be made clinically as follows:

- Jitteriness is not accompanied by abnormal eye movements.
- Jitteriness may be spontaneous or stimulus sensitive.
- The flexion and extension phases of the tremor are equal in amplitude compared to the unequal phases observed with clonic seizure movements.
- Jitteriness may be stopped by passive flexion or repositioning of the affected body part.

Infants with severe dysfunction of the CNS may have stimulus-sensitive myoclonus, which may be associated with spike or sharp wave discharges on the electroencephalogram (EEG) (9).

TABLE 50-1 CLINICAL FEATURES OF NEONATAL SEIZURES

TABLE 50-1 CLINICAL FEATURES OF NEONATAL SEIZURES

Seizure Type	Major Clinical Manifestations
Subtle	Repetitive blinking, eye deviation, staring Repetitive mouth or tongue movements Apnea Bicycling-rowing movements
Tonic (i.e., generalized or focal)	Tonic extension of limb or limbs Tonic flexion of upper limbs, extension of lower limbs
Clonic (i.e., multifocal or focal)	Multifocal, synchronous, or asynchronous limb movements Repetitive, jerky limb movements Nonordered progression Localized repetitive clonic limb movements with preservation of consciousness
Myoclonic (i.e., generalized, focal, multifocal)	Single or several flexion jerks of upper limbs (common) and lower limbs (rare)

Benign neonatal sleep myoclonus occurs during active sleep in healthy premature and term newborns. Myoclonus may be florid and consists of either bilateral synchronous or asynchronous or asymmetric movements that are not stimulus sensitive, but which cease on arousal from sleep. They are not associated with epileptiform or background disturbances on the EEG. Benign sleep myoclonus usually resolves over several months (10,11).

Simultaneous video and EEG monitoring has raised major issues concerning the incidence, classification, pathophysiology, and management of neonatal seizures. Some stereotypic, paroxysmal clinical phenomena, e.g., oral-buccal-lingual movements, generalized tonic, or extensor posturing are not associated consistently with epileptiform discharges on EEG recordings performed using surface electrodes. Subtle clinical phenomena correlate more frequently with simultaneous abnormal EEG discharges in premature than in term newborns (1,8).

Etiology

Neonatal seizures are rarely idiopathic in origin. Thus, when neonatal seizures occur, immediate attention must be directed toward the identification of an underlying etiology to permit rapid and appropriate intervention (when available) and meaningful prediction of outcome (8). Although neonatal seizures may be as a result of numerous underlying causes, most result from a relatively few causes, e.g., hypoxic-ischemic cerebral injury, intracranial hemorrhage, or metabolic derangements. The most important causes of neonatal seizures and their prognostic significance are listed in order of relative frequency in Table 50-2.

Seizures are a distinctly uncommon manifestation of withdrawal from passive addiction to narcotics, e.g., heroin, methadone, or barbiturates. In contrast, maternal cocaine abuse may be associated more commonly with epileptiform EEG abnormalities or seizures in newborns exposed in utero or by breast-feeding. This may relate to direct neuronal excitotoxicity, teratogenic effects, or destructive ischemic and hemorrhagic lesions (1).

Intoxication with local anesthetic after inadvertent injection into the infant's scalp during

placement of pudendal, paracervical, or epidural blocks is a rare cause of severe but self-limited neonatal seizures (12). Characteristically, severe, tonic seizures begin during the first hours of life, associated with coma and loss of brainstem reflexes, e.g., apnea and severe hypoventilation, bradycardia, hypotonia, fixed and dilated pupils, and absence of extraocular movements in response to the doll's-head maneuver. The early onset of the latter two features during the first six to eight hours of life is useful for distinguishing such local anesthetic intoxication from hypoxic-ischemic encephalopathy. Evaluation involves careful inspection of the scalp for evidence of injection. Management consists of vigorous support and removal of the drug by diuresis, acidification of urine or exchange transfusion.

Neonatal seizures, which begin after several days of age, are a common manifestation of inborn errors of metabolism.

P.1387

There is increasing evidence that accurate diagnosis requires analysis of specific metabolites in cerebrospinal fluid and in serum (13).

TABLE 50-2 ETIOLOGY AND PROGNOSIS OF NEONATAL SEIZURES^a

Etiology	Gestational Age		Time of Onset (d of Age)		Outcome Normal (%)
	Premature	Term	0–3	4–10	
Hypoxic-ischemic encephalopathy	+	+	+		50
Intracranial hemorrhage					
Intraventricular hemorrhage	+	-	+		<10
Subarachnoid hemorrhage	-	+	+		90
Hypoglycemia	+	+	+		50
Infection	+	+		+	<50
Cerebral dysgenesis	+	+		+	0
Hypocalcemia					
Early onset	+	+	+		50
Late onset	-	+		+	100

^a From Volpe JJ. Neurology of the newborn. Philadelphia: WB Saunders, 2001, with permission.
+, common; - rare.

In addition to the underlying etiologies listed in Table 50-2, there are several recognized epilepsy syndromes that may present during the newborn period. These include two benign syndromes, i.e., "fifth day fits" and benign familial neonatal seizures. The latter often present as frequent seizures on the third day of life and usually are linked to autosomal dominant gene loci on chromosomes 20 or 8 (14,15). Additionally, there are several recognized severe epilepsy syndromes. Early myoclonic encephalopathy (EME) presents within hours of birth with severe, fragmentary, refractory myoclonus, which often is worsened by handling or stimulation. Infants often have a high-arched palate. The initial neuroimaging is normal, but diffuse cerebral atrophy develops and affected infants frequently die in the first 2 years of life. Another entity, early infantile epileptic encephalopathy, also termed "Ohtahara's syndrome," may present with structural cerebral

lesions (dysgenesis or destruction) and a severe burst-suppression pattern on the EEG (16).

Diagnosis

Diagnostic evaluation must begin with a careful history and physical examination. Obtaining a maternal history of drug abuse, intrauterine infection, and genetic or metabolic conditions is critical, and it should be obtained directly from the mother whenever possible.

Although the EEG may be useful for confirmation of suspected seizures and for establishment of prognosis, it is rarely helpful for the identification of a specific etiology. Continuous EEG monitoring may be of value for identifying seizures in infants who are paralyzed pharmacologically or those who have electrographic seizures only.

Initial laboratory investigations should address treatable causes (e.g., hypoglycemia, hypocalcemia, hypomagnesemia). Lumbar puncture may identify intracranial infection or hemorrhage. Additionally, cerebrospinal fluid (CSF) analysis may also prove to be critical for identifying inborn errors of metabolism, e.g., folinic-acid responsive seizures and disorders of glucose transport, with low CSF glucose concentration and normal blood glucose concentration which, when treated with the ketogenic diet, may minimize long-term neurologic sequelae (13,17). If the initial screening investigations fail to identify a specific etiology, additional studies should be considered, including neuroimaging, metabolic investigations, e.g., serum amino acids, lactate, ammonia, urine organic acids, screening for drugs, and investigation for congenital viral infections. In some instances, several underlying factors may be operative in the same patient.

Treatment

Treatment of neonatal seizures is directed toward minimizing physiologic and metabolic derangements and preventing the recurrence of seizures. This should involve immediate support of ventilation and perfusion, if required, and correction of hypoglycemia, hypocalcemia, or other metabolic derangements. If seizures persist, a single loading dose of phenobarbital (20 mg/kg) should be administered intravenously, which may be followed by additional doses of 5 mg/kg to a total of 40 mg/kg (including loading dose) as required, if there is no cardiac decompensation. If seizures are still uncontrolled, a single loading dose of phenytoin (20 mg/kg) or possibly fosphenytoin (1.5 mg of fosphenytoin yields 1.0 mg of phenytoin) may be administered slowly with concomitant careful monitoring of cardiac function. If seizures remain refractory to therapy, the use of a benzodiazepine may be considered, e.g., lorazepam (0.05-0.1 mg/kg), or diazepam infusion (0.3 mg/kg/hr). Midazolam may have harmful effects in the newborn and should be avoided. Additionally, there are anecdotal reports of the value of other anticonvulsants for refractory seizures, e.g., primidone, carbamazepine, lamotrigine, and thiopentone (1).

Pyridoxine dependency should be considered if there are recurrent seizures without obvious explanation. This condition may be diagnosed by a therapeutic trial of intravenous pyridoxine (100 mg) with EEG monitoring or oral treatment (100-200 mg daily) which should be continued for approximately 2 weeks.

Several major issues regarding the ongoing treatment of neonatal seizures remain unresolved. These include the optimal maintenance doses and therapeutic ranges of serum levels of anticonvulsants, the importance of eliminating electrographic seizures, and the optimal duration of anticonvulsant therapy. The duration of therapy should be guided by the

underlying etiology and the risk of seizure recurrence. Clearly, unnecessary prolongation of therapy should be avoided because of unresolved concerns about possible deleterious effects of anticonvulsants on the immature nervous system (7).

Prognosis

The mortality rate for poorly controlled clinical seizures has decreased to approximately 15% in recent years. The incidence of neurologic sequelae, especially mental retardation and motor deficits (e.g., cerebral palsy), are reported to range from 35% to 55% (1).

Of course, the most important determinant of outcome is the underlying neurologic disease (Table 50-2). Additionally, seizures of early onset, frequent or prolonged seizures, and seizures that are refractory to multiple anticonvulsant treatment are often associated with poor prognosis. Clearly, these features reflect the severity of the underlying cerebral abnormality. Furthermore, in term newborns, normal, background activity on the EEG is rarely associated with neurological sequelae, whereas severe abnormality of background activity, e.g., burst suppression or marked voltage suppression is associated with abnormal outcome in over 90% of cases. However, in a significant proportion of newborns, the EEG is borderline,

P.1388

equivocal, or contains moderate background abnormalities that are associated with an intermediate or uncertain prognosis. Furthermore, the unique features of the neonatal EEG may lead to difficulties in interpretation which, in turn, limits its prognostic value. Also, the number of electrographic seizures and the rate of improvement of serial EEG's is also a useful prognostic factor (18).

HYPOXIC-ISCHEMIC CEREBRAL INJURY

Hypoxic-ischemic cerebral injury results from a combination of hypoxemia and ischemia, which often is associated with impaired cerebrovascular autoregulation and probably exacerbated by diminished cerebral glucose substrates, lactic acidosis, the accumulation of free radicals and excitotoxic amino acids (especially glutamate), and other metabolic derangements. The localization and extent of perinatal hypoxic-ischemic cerebral injury is determined principally by the maturity of the brain at the time of insult and the severity and duration of the insult (1).

Although the importance of antepartum and intrapartum factors have been recognized since 1862, when Little described a relationship between perinatal complications and cerebral palsy, data from large, epidemiologic studies, including the National Collaborative Perinatal Project and the Western Australia Cerebral Palsy Register, suggest that the etiologic role of antepartum factors may have been underestimated in the past (19,20,21). Review of these large populations of children with cerebral palsy indicate that the incidence of cerebral palsy related to intrapartum asphyxia do not exceed 20% when all factors are considered. Moreover, approximately one-third of these patients had at least one congenital anomaly unrelated to the CNS. This observation raises the possibility that an insult that originated much earlier during gestation may predispose some infants to subsequent hypoxic-ischemic insult at the time of delivery. Nevertheless, there are extensive experimental, clinical, and neuroimaging data that provide compelling evidence that acute, intrapartum hypoxic-ischemic insult is an important etiologic factor for neonatal brain injury (1,22).

Diagnosis

Clinical Features

Term newborns who sustain sufficient intrapartum insult to result in long-term sequelae invariably demonstrate clinical evidence of acute encephalopathy, i.e., altered brain function, during the first days of life (23). In contrast, infants who sustain hypoxic-ischemic cerebral injury earlier in gestation may be asymptomatic during the neonatal period. It is important to consider that the clinical features of hypoxic-ischemic encephalopathy are nonspecific, and similar clinical features may occur in the context of other causes of brain dysfunction, e.g., metabolic derangements, cerebral dysgenesis, and infection. Several aspects of labor and delivery may be used as clinical indicators of probable hypoxic-ischemic insult, e.g., prolonged fetal bradycardia or repetitive late decelerations of the fetal heart rate, low fetal scalp or cord pH, and low extended Apgar scores after 5 minutes of age. However, no single factor or combination of factors can predict accurately the severity or duration of the hypoxic-ischemic insult or the long-term sequelae (22). In the term newborn, the duration and severity of the encephalopathy, the type of EEG abnormality and the neuropathologic patterns of cerebral injury, which may be identified by neuroimaging, may permit determination of outcome with a reasonable degree of accuracy in many instances.

There is a complete spectrum of hypoxic-ischemic encephalopathy in the term newborn. However, classification of the severity of encephalopathy (Table 50-3) is useful for prognostic purposes (23,24,25,26,27). Thus, for example, according to the classification scheme developed by Sarnat and Sarnat (23), mild encephalopathy is characterized by hyperalertness, jitteriness, exaggerated tendon reflexes and Moro response that last only approximately 1 to 2 days. It is generally not associated with long-term neurologic sequelae. Moderate encephalopathy is comprised of lethargy, stupor, hypotonia, diminished spontaneous movements, suppressed tendon reflexes and, in some instances, seizures. Abnormal long-term outcome has been reported in 20% to 40% in this group. Severe encephalopathy is characterized by coma, seizures, brainstem and autonomic dysfunction,

P.1389

absent spontaneous movements, and, in some instances, elevated intracranial pressure (28,29,30). Infants with severe encephalopathy almost invariably die or develop major neurologic sequelae, e.g., microcephaly, spastic quadriplegia, seizures. In severe encephalopathy, the clinical features characteristically worsen during the first 3 days of life. Death occurs most commonly between 24 and 72 hours of life, which corresponds to the time of maximal cerebral edema (1,28). Autopsy studies of infants with increased intracranial pressure demonstrate extensive cerebral necrosis. Thus, increased intracranial pressure appears to be a consequence rather than a cause of extensive hypoxic-ischemic brain injury and interventions to reduce cerebral edema may reduce the intracranial pressure but do not appear to improve the ultimate neurologic outcome (28,31,32,33).

TABLE 50-3 SEVERITY AND OUTCOME OF HYPOXIC-ISCHEMIC ENCEPHALOPATHY IN THE FULL-TERM NEONATE

Severity	Level of Consciousness	Seizures	Primitive Reflexes	Brain Stem Dysfunction	Elevated Intracranial Pressure	Duration	Poor Outcome^a (%)
Mild	Increased irritability, hyperalertness	-, Jitteriness	Exaggerated	-	-	<24 h	0
Moderate	Lethargy	Variable	Suppressed	-	-	>24 h (variable)	20–40
Severe	Stupor or coma	+	Absent	+	Variable	>5 d	100

^a Poor outcome is defined as the presence of mental retardation, cerebral palsy, or seizures.
+, common; -, rare.

Seizures occur in approximately 50% of asphyxiated infants and are indicative of moderate or severe encephalopathy. Seizures, which most commonly are of the subtle and multifocal clonic type, usually begin during the first 24 hours of life. In severe cases, they often occur soon after delivery and are refractory to anticonvulsant therapy. Infants with hypoxic-ischemic encephalopathy who survive beyond 3 or 4 days of age generally demonstrate an improving level of consciousness and gradual resolution of seizures, although impairment of feeding, abnormal muscle tone, and delayed development may persist.

In addition to the neurologic dysfunction, there is often evidence of acute hypoxic-ischemic insult to organs other than brain, e.g., kidneys are particularly vulnerable, but myocardial, GI, hematologic, endocrine and lung complications may also occur (34,35,36). Such involvement of other organs is often transient and reversible, even in the context of severe encephalopathy, and the extent of systemic abnormalities appears to correlate with the severity of encephalopathy. However, in some instances, especially when intrapartum asphyxia is severe and of short duration, as in the context of uterine rupture or cord prolapse, there may be little or no evidence of injury to organs other than the brain on routine investigations (37,38).

Neuroimaging

In addition to the clinical examination, neuroimaging techniques are of major value for the identification of specific neuropathologic patterns and quantification of extent of cerebral injury (39).

Cranial Ultrasound

In term newborns with severe hypoxic-ischemic injury, abnormalities include diffuse increased echogenicity of parenchyma and effacement of cortical sulci by cerebral edema during the first day of life. Unfortunately, if abnormalities are diffuse, detection may be difficult. This accounts for the disappointing correlation between ultrasound imaging and neurologic outcome in term newborns (39,40).

In term infants who have sustained an hypoxic-ischemic insult, cranial ultrasonography before 24 hours of age has a role for the exclusion of other entities, e.g., hemorrhage or mass lesions, which may produce a clinical picture which may mimic hypoxic-ischemic encephalopathy.

Ultrasound has better predictive value in premature infants with hypoxic-ischemic brain injury, in whom the principal lesions during in the first days of life are increased periventricular echogenicity and intraventricular hemorrhage. The hyperechoic periventricular abnormalities evolve into cystic lesions (cavitations) during the ensuing 2 to 3 weeks in severe cases (41,42). These lesions are transient and if the phase of cyst formation is not documented by serial ultrasound examinations, a later sonogram may show only enlargement of the lateral ventricles with irregular margins.

Current recommendations in many centers are that routine screening with cranial ultrasonography should be performed on all infants of less than 30 weeks gestation at least once between 7 and 14 days of age and should be repeated optimally between 36 and 40 weeks postmenstrual age. Of course, additional scanning may be indicated on the basis of clinical events.

Computed Tomography

In the term newborn, scanning with computed tomography (CT) during the newborn period has excellent prognostic value and may demonstrate diffuse or focal cerebral injury. Optimal timing of CT scans to demonstrate the maximal extent of decreased tissue attenuation is approximately between 2 and 5 days of age, which corresponds to the time of occurrence of maximal extent of cerebral edema (Fig. 50-1A) (28). Accurate interpretation of tissue attenuation on CT requires careful attention to scanning technique to ensure appropriate window and level settings. Two major patterns of hypoxic-ischemic brain injury may be identified on CT. The first pattern in which there is predominantly hypodensity of cortex and subcortical white matter with relative sparing of the deep central grey matter (28), corresponds to a neuropathological pattern which has been documented in experimental animal models following a period of "prolonged, partial asphyxia" usually lasting more than one hour. A second pattern is characterized by low attenuation in thalami and basal ganglia with relative preservation of cortex and subcortical white matter. This pattern occurs in the context of what has been termed an "acute, total" hypoxic-ischemic insult which was identified initially in experimental studies using fetal monkeys. Of course, in the human newborn such an insult should be more correctly termed "acute, near-total" in that the artificially created acute, total insult in the experimental animal studies never occurs even with acute and severe events such as umbilical cord prolapse and uterine rupture (37,43). CT scans performed later in

childhood may demonstrate focal or generalized cerebral atrophy, often with multicystic encephalomalacia (Fig. 50-1B).

In contrast to the term newborn, CT is of more limited value for assessment of acute hypoxic-ischemic injury in premature newborns, because the normal high water

P.1390

content of the immature brain results in low tissue attenuation. However, CT scans performed at a later age may demonstrate the characteristic features of end-stage periventricular leukomalacia, which include (a) ventricular dilation with irregular margins of the body and trigone of the lateral ventricles, (b) decreased volume of periventricular white matter, and (c) deep sulci that abut directly on the lateral walls of the ventricles (44).

Figure 50-1 **A:** Computed tomographic scan of a full-term newborn (age 3 days) with severe, acute hypoxic-ischemic encephalopathy shows generalized, decreased tissue attenuation throughout both cerebral hemispheres. **B:** CT scan of the head performed at 4 months of age after hypoxic-ischemic cerebral injury at term demonstrates multicystic encephalomalacia and cerebral atrophy. **C:** Magnetic resonance imaging (T1 weighted image) performed at age 2 years after hypoxic-ischemic brain injury at term shows similar findings to CT, ie., multicystic encephalomalacia and cerebral atrophy.

P.1391

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has the capability to demonstrate specific patterns of injury in both preterm

and term newborns that may not be visualized by other imaging techniques (45,46,47,48,49,50,51). Thus, T2 prolongation resulting from edema (which may be transient or permanent) may appear as early as 12 to 18 hours after injury, and T1 shortening (high signal on T1-weighted images) appears in injured areas after approximately 3 days. Thus, if CT has been performed and is inconclusive, MRI should be performed between 2 and 10 days of age. Diffusion-weighted MRI appears to be even more sensitive than standard MRI during the first hours following hypoxic-ischemic injury (49,50). However, technical difficulties, e.g., the longer scanning time and difficulty with close monitoring of the sick newborn in the scanner, may limit the routine clinical application of MRI in the context of acute hypoxic-ischemic encephalopathy. At the present time, there are no large studies of CT or MRI to determine the role of MRI for the routine assessment of premature newborns with suspected hypoxic-ischemic brain injury.

Radionuclide Scanning

Radionuclide technetium scanning (52), positron emission tomography (53,54,55) and single photon emission CT (56), which utilize radionuclides that have the capability to cross the intact blood-brain barrier, can provide insights into regional abnormalities of cerebral perfusion. However, since advances in neuroimaging, especially MRI, have become widely available, these techniques are utilized less frequently in the routine clinical assessment of newborns with hypoxic-ischemic encephalopathy.

Magnetic Resonance Spectroscopy

In severely affected infants studied by phosphorus and proton MRS, a consistent observation has been the development of delayed derangements in cerebral energy metabolism between 12 and 48 hours after resuscitation, despite the maintenance of cardiovascular and respiratory homeostasis, which, in turn, correlates closely with poor neurologic outcome (57,58). However, because of the complexity and cost of the technique, MRS remains essentially a research technique available only on a limited basis at selected centers.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS), a noninvasive technique that may be used at the bedside, has the capability to provide information concerning cerebral oxygenation and cerebral blood flow in real time. However, the technical limitations of the equipment and complexity of the data analysis have limited its application in critically ill newborns in all but a few centers. In a small number of infants with hypoxic-ischemic encephalopathy, significant cerebral vasodilation and vasoparalysis have been documented using NIRS (59).

Electrodiagnostic Techniques

Electrodiagnostic techniques are used in the evaluation of hypoxic-ischemic cerebral injury, especially in term newborns. On EEG recordings, a discontinuous pattern with voltage suppression or rapid bursts of sharp and slow waves are associated with poor outcome. In contrast, rapid resolution of EEG abnormalities and a normal interictal EEG pattern are associated with a good outcome (23,60,61,62).

Serial evoked potentials, especially visual evoked responses (63,64,65), and somatosensory evoked responses (13,66) may provide valuable prognostic information. However, their routine clinical application, especially in premature infants (67,68) has been limited by technical difficulties.

Biochemical Markers

Several enzymes and metabolites (e.g., creatine kinase BB isozyme, hypoxanthine, lactate) in urine, blood, or CSF may be of value as indicators of hypoxic-ischemic cerebral injury (1). In this regard, the measurement of urinary lactate to creatinine ratios appears to be most promising (69). However, further study of the precise sensitivity and specificity of these metabolic parameters is required before they can be recommended for routine use. Furthermore, metabolic derangements that are considered secondary to the hypoxic injury, e.g., acidosis, hypoglycemia, and hyponatremia secondary to inappropriate secretion of antidiuretic hormone, and hyperammonemia may contribute to the cerebral injury.

Pathogenesis and Neuropathology

The pathogenetic mechanisms that determine the major neuropathologic patterns of injury may be explained by a combination of regional circulatory and metabolic factors of the affected brain, especially the regional distribution of excitatory amino acid synapses (e.g., glutamate receptors) and the severity and duration of the hypoxic-ischemic insult. The major neuropathologic patterns of hypoxic-ischemic cerebral injury are listed in Table 50-4.

Circulatory Factors

The initial circulatory response to perinatal asphyxia involves the redistribution of cardiac output with increased perfusion of vital organs, e.g., brain, heart, adrenals and with concomitant decreased blood flow to other organs, e.g., the lungs, kidneys, liver. Prolonged hypoxic-ischemic insult results in systemic hypotension. The significance of hypotension is potentiated by impairment of cerebrovascular autoregulation which may occur even after relatively moderate hypoxic-ischemic insult (70,71). Cerebrovascular autoregulation is the homeostatic mechanism that maintains relatively constant cerebral perfusion over a wide range of systemic arterial blood pressures by means of cerebral arteriolar constriction or dilation. As a consequence of

P.1392

the deficiency in the muscular lining of cerebral arterioles in the immature brain, the occurrence of hypercarbia or hypoxemia, or because the normal blood pressure of the newborn is close to the down slope of the normal autoregulatory curve, (or a combination of these factors), the protective mechanism of cerebrovascular autoregulation may be disrupted. This dysfunction of the cerebrovascular autoregulation mechanism results in a direct, linear correlation between cerebral perfusion and systemic blood pressure.

TABLE 50-4 MAJOR NEUROPATHOLOGIC PATTERNS

Pattern of Injury	Gestational Age		Anatomic Distribution
	Full Term	Premature	
Selective neuronal necrosis	+	+	Cerebral and cerebellar cortex, thalamus, brainstem, hippocampus
Parasagittal	+	-	Parasagittal cortex, subcortical white matter
Focal or multifocal necrosis	+	+	Unilateral or bilateral cerebral cortex
Periventricular leukomalacia	-	+	Periventricular white matter

+, common; -, rare.

Systemic hypotension, which results in moderate decreases in cerebral perfusion, may result in injury confined principally to the watershed zones of arterial supply. In the term newborn, the watershed zones between the anterior, middle, and posterior cerebral arteries are located in the parasagittal regions of the cerebral cortex. In the premature newborn, the most vulnerable watershed zone is located in the periventricular white matter (72).

Metabolic Factors

Regional differences in the rate of energy metabolism, lactate accumulation, calcium influx, and free-radical formation may explain the increased susceptibility of specific regions, e.g., thalamus, basal ganglia, and brainstem, to acute hypoxic-ischemic insult. Additionally, selective vulnerability may reflect the active myelination in specific locations during the newborn period.

A fundamental process believed to play a critical role in hypoxic-ischemic neuronal damage is excitotoxicity, a term which refers to cell death mediated by excessive stimulation of extracellular excitatory amino acid receptors (73). There is compelling experimental evidence that excitatory neurotransmitters, especially glutamate, play a critical role in the expression of hypoxic-ischemic neuronal injury. Clearly, evolving hypoxic-ischemic injury is accompanied by increased neuronal excitement, e.g., seizures. Furthermore, based on experimental animal models, drugs that block *N*-methyl-d-aspartate (NMDA) type glutamate channels may protect the brain from severe hypoxic-ischemic insults (74).

Additional processes that are receiving increased attention include mitochondrial failure and delayed programmed cell death or apoptosis (73).

MAJOR NEUROPATHOLOGIC PATTERNS OF INJURY

Selective Neuronal Necrosis

Selective neuronal necrosis of neurons involves specific regions of the cortex, e.g., the Sommer sector of the hippocampus, thalamus, brainstem, cerebellum, and anterior horn cells of the spinal cord. Major pathogenetic factors include circulatory factors and the severity and duration of the insult. Thus, in both experimental animal models (75,76) and human term newborns (28,77,78), "prolonged, partial" hypoxic-ischemic insult results in cerebral injury involving principally the cortex and subcortical white matter. In contrast, "acute, near total" asphyxia, which may occur in the context of events such as umbilical cord prolapse or uterine rupture, results in a pattern of injury affecting predominantly thalamic, basal ganglia, and brainstem with relative preservation of cortex and subcortical white matter (37,43). This regional vulnerability relates principally to the differing rates of metabolism and myelination of various locations within the affected brain, including the anatomic distribution of glutamatergic synapses (1,73,79).

The clinical manifestations in the newborn reflect to the specific sites of injury. For example, infants with extensive cortical/subcortical injury may have seizures and possibly raised intracranial pressure (28,78), whereas infants who have predominantly thalamic, basal ganglia and brainstem involvement have characteristic features of irritability, tonic posturing, and lower cranial nerve dysfunction e.g., tongue fasciculations, feeding problems (1,37,43). Although the injury is predominantly central, there is still some cortical injury, albeit less severe, that may result in seizures and other cortical signs.

The late neuropathologic sequelae of selective neuronal necrosis which involves predominantly the cortex and

P.1393

subcortical white matter include cerebral atrophy and, following severe injury, multicystic encephalomalacia (Fig. 50-1B, 50-1C). Clinical features in older children include spastic cerebral palsy, mental retardation, microcephaly, and seizures of varying severity. Injury to thalamus and basal ganglia which may have occurred in the context of an acute, near total type of hypoxic-ischemic insult may result in a striking, marbled appearance of these structures (Fig. 50-2B), and the evolution appears radiologically as shown in Fig. 50-2A,C, which has been termed as "status marmoratus." The characteristic clinical sequelae include choreoathetotic cerebral palsy and bulbar dysfunction (feeding difficulties) and there is relative preservation of function referable to cortex, e.g., cognitive function and absence of seizures.

Parasagittal Cerebral Injury

In the term newborn, the parasagittal cortex and subcortical white matter are located in the watershed zone of arterial supply between the anterior, middle, and posterior cerebral arteries, an area that is vulnerable to ischemic injury (1,77) (Fig. 50-3).

Clinical features of parasagittal injury during the newborn period include hypotonia and weakness, which are more prominent in the proximal upper extremities (shoulder girdle) than in the lower limbs.

Focal and Multifocal Cerebral Necrosis

Focal arterial occlusion by embolus or thrombus is well recognized in the newborn (Fig. 50-4). In premature newborns, such infarction is often multifocal. In the majority of cases, no specific cause can be identified. However, conditions that may predispose to focal ischemic necrosis include coagulation disturbances, e.g., polycythemia, disseminated intravascular coagulation, protein C or S deficiency, antithrombin deficiency, Factor V Leiden deficiency, maternal isoimmune thrombocytopenia, and intrauterine cocaine exposure, vascular maldevelopment, and emboli from punctured or catheterized vessels or involuting placental vessels (80,81,82,83).

Newborn infants who develop focal arterial infarction most commonly present with unilateral, focal motor seizures. Alternatively, infants may be asymptomatic or display asymmetric motor function. Long-term sequelae include cerebral palsy (often hemiparesis), seizures, and intellectual impairment (84,85).

Venous sinus thrombosis in the newborn has been diagnosed more frequently because MRI has become more readily available. Predisposing conditions include coagulation disturbances, dehydration, and sepsis (86,87). Clinical features in the newborn include lethargy and seizures that are not necessarily focal. The long-term

sequelae are not well defined. Approximately one-third of affected children are reported to have developmental delay.

Periventricular Leukomalacia

This lesion which affects primarily infants born prematurely, involves the arterial end zones within the periventricular white matter in the premature brain (1,72). Two principal components of injury have been recognized: focal and diffuse white matter injury. There is increasing evidence that the pathogenesis of periventricular leukomalacia relates to a variable combination of three major factors: the distribution of arterial vascular end zones within the cerebral white matter, maturation-dependent impairment in cerebrovascular auto-regulation of cerebral blood flow, intrinsic vulnerability of early differentiating oligodendroglial precursors to free radicals and, in some instances, exposure to endotoxemia (71,72,88). Secondary hemorrhage, albeit often of mild severity, has been reported in approximately 25% of autopsy studies in patients with periventricular leukomalacia (89) and in survivors (90).

The severity of white matter injury ranges from minor focal areas of gliosis or necrosis to diffuse involvement (Fig. 50-5). Severe focal lesions may be visualized in vivo by cranial ultrasonography as areas of increased echogenicity in periventricular white matter during the first days of life, which subsequently evolve into cystic lesions after approximately 2 to 3 weeks (41). MRI and diffusion MRI may also permit early visualization of these lesions, but the role of these techniques has not been defined fully (45).

Hemorrhagic periventricular leukomalacia must be distinguished from periventricular hemorrhagic infarction, which is usually unilateral (Fig. 50-6) or strikingly asymmetric (91). This lesion is associated with large GMH or IVH, and it is considered to represent venous infarction resulting from obstruction of the terminal vein by a large GMH (92,93).

The clinical features of periventricular leukomalacia in the premature newborn may be subtle and include weakness or altered muscle tone involving predominantly the lower extremities. Long-term sequelae include spastic diplegia or quadriplegia and, occasionally, visual and auditory impairment related to involvement of the optic and auditory radiations (1). Additionally, periventricular leukomalacia may have a role in the genesis of derangements of cerebral cortical organization because of injury to subplate neurons or interference with late migrating astrocytes, which, in turn, may insult in impaired cognitive function (94).

Management

Awareness of major risk factors during the intrauterine period has promoted prevention of hypoxic-ischemic insult by close monitoring of the high-risk fetus and consideration of urgent delivery in the event of persistent fetal distress. Furthermore, an asphyxiated newborn requires immediate and close surveillance to minimize additional postnatal injury. In this context, provision of adequate ventilation and perfusion, maintenance of normal blood pressure and normoglycemia, and control of seizures are of

P.1394

P.1395

critical importance. On the other hand it is important to avoid excessive oxygen delivery in that there is increasing concern about the potential deleterious effects of hyperoxia especially in premature newborns (95). There is a high incidence of dysfunction of other organ systems, e.g., heart, kidneys, and gastrointestinal (GI) tract, which must be monitored carefully.

Figure 50-2 Composite image demonstrating evolution of central hypoxic-ischemic brain injury (involving thalami and basal ganglia) in term newborn on neuroimaging. Upper right image shows CT at 3 days of age demonstrating decreased tissue attenuation in thalami. Upper left image shows coronal MRI (T1 weighted image) at age 10 days with abnormal signal in thalami, basal ganglia and motor strip of cortex bilaterally. Lower right image shows MRI at age 10 days with abnormal signal in thalami and basal ganglia. Lower left image shows MRI (T2 weighted image) at age 2 years with atrophy and low signal in thalami and basal ganglia.

Figure 50-3 Coronal MRI scan (T1-weighted image) of term newborn performed at 10 days of age demonstrates abnormal signal in parasagittal watershed zones and thalami bilaterally.

Adequate ventilation and the avoidance of postnatal hypoxemia may be difficult to achieve because of the cardiorespiratory problems associated with severe hyaline membrane disease in the premature newborn and persistent fetal circulation and pulmonary hypertension in the term newborn. Administration of surfactant and nitric oxide, extracorporeal membrane oxygenation and high-frequency ventilation are newer treatment modalities that are discussed in detail elsewhere. Because hypoxemic episodes in the premature newborn may be associated with events such as suctioning or spontaneous crying, minimal handling is recommended for these infants. On the other hand, there is increasing concern that hyperoxia should also be avoided (95).

Because impaired cerebrovascular autoregulation has been documented even in the context of moderate hypoxic-ischemic encephalopathy, maintenance of normal systemic arterial blood pressure and adequate cerebral perfusion are essential. This may require volume replacement and the use of inotropic agents (e.g., dopamine) especially if there is evidence of myocardial dysfunction. In the premature newborn, systemic hypotension may occur in the context of patent ductus arteriosus and recurrent apnea of prematurity. On the other hand, systemic hypertension must also be avoided, especially in the premature newborn, because it may predispose to GMH/IVH from rupture of the fragile vasculature of the germinal matrix.

Seizures that occur in the context of acute hypoxic-ischemic encephalopathy may be refractory to anticonvulsant therapy. Nevertheless, aggressive treatment is indicated to minimize associated apnea, hypertension, and metabolic derangements, such as depletion of brain glucose and high-energy phosphate compounds.

The optimal levels of blood glucose that should be maintained after hypoxic-ischemic insult have not been established. However, maintenance of normoglycemia is generally recommended. Inappropriate antidiuretic hormone secretion following major hypoxic-ischemic cerebral injury may result in hyponatremia and decreased osmolality, with a consequent risk of cerebral edema and seizures. Fluid overload should be avoided.

Data from human and experimental animal studies suggest that elevated intracranial pressure associated with hypoxic-ischemic encephalopathy in the term newborn reflects extensive cerebral necrosis, which represents a consequence rather than a cause of hypoxic-ischemic brain injury. Maximal elevations of intracranial pressure are observed between 36 and 96 hours after the initial insult and are associated with a poor outcome. Although it is possible to reduce elevated intracranial pressure by antiedema agents (e.g., mannitol and diuretics), there is no evidence that such intervention improves long-term neurologic outcome (28,33).

Potential neuroprotective strategies that are currently under investigation include NMDA receptor antagonists, inhibitors of free radical production, free radical scavengers, nerve growth factors and mild hypothermia. These interventions target either excessive excitotoxic glutamate release or the mitochondrial failure following severe hypoxic-ischemic insult which is associated with disruption of cell membranes and tissue necrosis, or the delayed process of programmed cell death, i.e., apoptosis (73,96,97).

There is increasing understanding of the fact that hypoxic-ischemic insult/reperfusion sets in motion a

deleterious cascade of events leading to neuronal death that evolves over many hours and days and which may be interrupted by interventions which are instituted after termination of the insult (96,97). Of the current interventions under consideration, there is extensive experimental evidence from animal studies and promising clinical data in human newborns for the use of mild hypothermia, either whole body hypothermia or head cooling only. Modest hypothermia 34.5°C or 35°C or slightly lower appears to postpone secondary energy failure and may potentially prolong the window for usefulness of other pharmacologic interventions. Observed physiologic changes and complications of hypothermia include fall in heart rate or abnormal cardiac rhythm and coagulation disturbances, none of which are considered to be life-threatening. Preliminary results on the value of hypothermia regarding extent of brain injury based on MRI evaluation and neurological outcome are encouraging. Randomized controlled trials are currently under way to confirm this experience and to establish clinical protocols for the use of hypothermia in human newborns (97,98 and 99).

Figure 50-4 Computed tomographic scan of a full term newborn with acute, focal infarction involving the territory of the left middle cerebral artery. **B:** CT scan of an infant at 18 months of age showing porencephalic cyst in location of earlier cerebral infarction. **C:** MRI of infant performed at age 2 years with abnormal signal in location of infarction.

Prognosis

In our experience in the term newborn, the severity and duration of the clinical hypoxic-ischemic encephalopathy and severity of the EEG background abnormality, combined with the extent of abnormality on acute neuroimaging, e.g., decreased tissue attenuation visualized on CT scans (performed between 2 and 5 days

after the original insult) or abnormal signal on MRI permit reasonably accurate prediction of outcome. The prediction of outcome in the asphyxiated premature newborn is more difficult.

INTRACRANIAL HEMORRHAGE

The incidence of GMH/IVH in premature newborns has declined in recent decades from approximately 40% to less than 20%. Although there has been a significant

P.1397

reduction in incidence during recent years, GMH/IVH remains a major concern, principally because of the improved survival rates of very-low-birth-weight infants who are at highest risk for the development of GMH/IVH. In the premature newborn, rupture of fragile vessels in the subependymal germinal matrix occurs relatively frequently (Fig. 50-7). In approximately 80% of cases, there is associated IVH, and in approximately 15% there is associated parenchymal hemorrhagic infarction. Serial cranial ultrasonography has demonstrated that 50% of cases of GMH/IVH originate during the first day of life and 90% occur before 4 days of age. In 20% to 40%, the hemorrhage may extend during the first week of life (1).

Figure 50-5 A: Computed tomography scan performed at 14 months of age in an infant born prematurely demonstrates periventricular leukomalacia with marked loss of volume of periventricular white matter, with cortex abutting directly onto the ventricles and secondary ventricular enlargement. **B:** MRI scan (T1 weighted image) of infant performed at 2 years of age demonstrating similar findings as CT.

Diagnosis

Neuroimaging

Cranial ultrasonography is considered the neuroimaging modality of choice for the diagnosis of GMH/IVH because of its portability, high resolution, and lack of ionizing radiation. Computed tomography and MRI remain superior for the diagnosis of other types of intracranial hemorrhage, including primary subarachnoid, convexity, and posterior fossa subdural or epidural hematomas and for differentiating between hemorrhagic and ischemic parenchymal infarction.

Because of the relatively high risk of GMH/IVH, in many centers cranial ultrasonography is recommended to be performed routinely at least once between 7 and 14 days of age in all infants of less than 30 weeks gestation (100). Ultrasonography should be performed earlier if there are specific clinical concerns. Ultrasound scans are recommended to be done after the first week of life to establish the maximal extent of the lesion. Subsequently, serial scans may be indicated every 1 to 2 weeks after major GMH/IVH for surveillance of ventricular size and possible development of posthemorrhagic hydrocephalus. This is particularly important because of the high degree of compliance of the premature brain and cranium which, together with the relatively large subarachnoid spaces permit considerable increase in ventricular size prior to the onset of excessive head growth.

Clinical Features

The diagnosis of GMH/IVH may be suspected on the basis of clinical signs alone in only approximately 50% of patients. The severity of clinical abnormalities ranges from an asymptomatic state through a saltatory neurologic deterioration over several days to a catastrophic presentation with coma, apnea, tonic extensor posturing, brainstem dysfunction, and flaccid quadriplegia. Associated systemic abnormalities may include hypotension, metabolic acidosis, bradycardia, and disturbances of serum glucose and

P.1398

electrolytes. Bloody or xanthochromic CSF supports a diagnosis of intracranial hemorrhage.

Figure 50-6 A: Coronal ultrasound scan of premature infant showing left periventricular hemorrhagic infarction with fan-shaped unilateral increased echoes in periventricular white matter. B: CT scan of infant showing unilateral fan-shaped periventricular hemorrhagic infarction. Note absence of intraventricular hemorrhage. C: Late CT scan of infant showing fan-shaped cyst in location of previous hemorrhagic infarction.

Pathogenesis

The pathogenesis of GMH/IVH is multifactorial and consists of a combination of intravascular, vascular, and extravascular factors (Table 50-5). The importance of individual factors may vary in different situations.

Consideration of these major pathogenetic mechanisms provides a framework for the selection of appropriate interventional strategies.

Intravascular factors involve principally the regulation of cerebral perfusion (e.g., cerebral blood flow and pressure) within the fragile vasculature of the germinal matrix, platelet-capillary interactions and coagulation disturbances. Vascular pathogenetic factors include the fragility of vessels

P.1399

in the germinal matrix and their vulnerability to hypoxic- ischemic insult. Extravascular factors relate to the characteristics of the supporting tissues, excessive fibrinolytic activity, and a possible decrease in tissue pressure postnatally.

Figure 50-7 A: Periventricular hemorrhage with large right subependymal hemorrhage. Blood fills both lateral ventricles. **B:** Hemorrhage can be seen in the lateral ventricles, the aqueduct of Sylvius, the fourth ventricle, and the subarachnoid space around the cerebellum and the base of the brain (courtesy of John Axley, MD).

Posthemorrhagic hydrocephalus and periventricular hemorrhagic infarction are the major complications of GMH/IVH. Other mechanisms of cerebral injury associated with GMH/IVH include concomitant or preceding hypoxic-ischemic cerebral injury (e.g., periventricular leukomalacia, neuronal necrosis of the brainstem), and destruction of the germinal matrix with its glial precursors.

Ventriculomegaly and hydrocephalus, i.e., progressive ventriculomegaly associated with disturbed CSF dynamics, occur commonly after major GMH/IVH (Table 50-6). Clearly, massive GMH/IVH may be associated with acute ventriculomegaly. More commonly, communicating hydrocephalus develops gradually over weeks, usually as a consequence of impaired CSF reabsorption secondary to an obliterative arachnoiditis in the posterior fossa. An additional potential mechanism involves the blockage of CSF resorption at the small arachnoid villi by particulate debris floating in CSF after GMH/IVH. Obstructive hydrocephalus may occur secondary to blockage of the flow of CSF especially at the level of the aqueduct of Sylvius by blood clot or other intraventricular debris (1,101).

The characteristic clinical signs of hydrocephalus (e.g., abnormally rapid increase in head circumference, bulging anterior fontanel, suture diastasis) may be delayed for days or weeks after the onset of progressive ventricular dilation is observed on serial ultrasound scans (1).

Figure 50-8 A: Ultrasonographic scan in the coronal plane of marked intraventricular hemorrhage delineates blood in the dilated frontal horns of the lateral ventricles and central clearing of the hematoma. **B:** Ultrasonographic scan in the coronal plane of marked intraventricular hemorrhage delineates blood in the dilated frontal horns of the lateral ventricles and intraparenchymal hematoma.

The delay in clinical manifestation of increased intracranial pressure is related to the high compliance of periventricular tissue in the immature brain, especially after hypoxic-ischemic injury, and the relatively generous subarachnoid space in the premature infant, which allow

P.1400

increase in ventricular size without expansion of head circumference.

TABLE 50-5 PATHOGENESIS OF GERMINAL MATRIX-INTRAVENTRICULAR HEMORRHAGE

Pathogenic Factor
Intravascular
Alterations in cerebral blood flow
Alterations in cerebral venous pressure
Coagulation disturbances
Vascular
Fragility of vessels in subependymal germinal matrix
Extravascular
Poor vascular support of germinal matrix
Decrease in tissue pressure (?)

Ventriculomegaly after GMH/IVH may become static or resolve spontaneously usually within four weeks of onset in approximately 65% of cases (1). In the remainder, amelioration of increased intracranial pressure by temporary or permanent drainage of CSF or by medical intervention to decrease CSF production is required. Recent data suggest that the natural history of posthemorrhagic ventriculomegaly may be evolving such that the course is more aggressive necessitating intervention in a greater percentage of affected infants (102). In approximately 5% of cases, progressive posthemorrhagic hydrocephalus may be delayed for many months, which necessitates ongoing surveillance of ventricular size by serial cranial ultrasonography during the first year of life (103).

Periventricular hemorrhagic infarction has been documented in approximately 15% of infants with major GMH/IVH. This predominantly unilateral parenchymal lesion is a major determinant of long-term neurologic sequelae (91). Neuropathologic studies indicate that such fan-shaped parenchymal hemorrhage results from venous infarction, usually with secondary hemorrhage related to obstruction of the medullary and terminal veins by large GMH (92,93). This pathogenesis differs from that of hemorrhagic periventricular leukomalacia, which is usually bilateral and represents an arterial ischemic lesion with secondary hemorrhage. Because periventricular hemorrhagic infarction and periventricular leukomalacia often occur concomitantly, distinction between the two conditions may be difficult.

Management

Clearly, the primary goal is prevention of GMH/IVH. Prevention of premature labor and delivery may be considered to be the optimal management strategy. Alternatively, interventions should address the major pathogenetic mechanisms as outlined previously (104,105).

Antenatal Interventions

Prevention of premature labor and delivery has been attempted with maternal tocolytic therapy, e.g., β -sympathomimetics, indomethacin, or magnesium sulfate. Unfortunately, these medications often succeed in delaying labor for only several days, although even such brief delay may be sufficient to permit administration of a course of antenatal steroids to induce fetal lung maturation, thereby reducing the likelihood of GMH/IVH. Unfortunately, tocolytic medications may have adverse hemodynamic effects in the fetus, which, in turn, may increase the risk of hemorrhagic and ischemic cerebral injury and outweigh potential benefits (106,107,108). A more encouraging approach to prevention of premature labor in selected women involves antimicrobial treatment (e.g., metronidazole, erythromycin) of bacterial vaginosis, a relatively common condition in which normal vaginal flora is replaced by anaerobic organisms. Such intervention has been shown to decrease the risk for premature rupture of membranes, chorioamnionitis and premature delivery (109,110).

TABLE 50-6 MAJOR COMPLICATIONS OF GERMINAL MATRIX-INTRAVENTRICULAR HEMORRHAGE

- Ventriculomegaly, posthemorrhagic hydrocephalus
- Periventricular hemorrhagic cerebral infarction
- Acute increased intracranial pressure with major intraventricular hemorrhage
- Destruction of germinal matrix glial precursors
- Focal ischemia (?)
- Concomitant hypoxic-ischemic cerebral injury (i.e., periventricular leukomalacia)

Antenatal corticosteroids which induce fetal lung maturation and lead to maturation and involution of the fragile germinal matrix vasculature, definitely reduce the overall incidence and severity of GMH/IVH. Because even an incomplete course of antenatal corticosteroid has some benefit, prompt treatment is indicated for most women who are at imminent risk for premature delivery (111,112,113). Additionally, transfer of the high-risk mother to a tertiary perinatal center prior to delivery is recommended.

Intrapartum Management

There is increasing evidence that vaginal delivery, duration of labor longer than 12 hours regardless of the mode of delivery, and a trial of labor before cesarian section are all associated with increased risk of GMH/IVH (111,114). Presumably, risks of labor and vaginal delivery relate principally to deformations of the compliant skull and associated transient increases in cerebral venous pressure. Although earlier studies had suggested that antenatal phenobarbital and Vitamin K may be associated with a reduced incidence of GMH-IVH, recent comprehensive review of combined data from all clinical trials for the Cochrane Database failed to demonstrate a benefit from either medication (115,116).

P.1401

Postnatal Management

Correction or prevention of major hemodynamic disturbances, including fluctuating cerebral blood flow, systemic hypotension and hypertension, and increases in cerebral venous pressure, may reduce the overall incidence and severity of GMH/IVH. Because of the impaired cerebrovascular autoregulation in the sick premature newborn, alterations in systemic blood pressure are reflected directly in changes in cerebral blood flow. Care must be taken to prevent systemic hypertension associated with excessive handling, suctioning, and rapid infusions of blood or colloid. Additionally, adequate ventilation must be maintained to avoid apnea, pneumothorax, and hypercapnia. Although not available routinely, the noninvasive technique of NIRS has the potential capability of identifying in real time the premature infants with pressure-passive circulation, who are at high risk for developing GMH/IVH (71,72).

Respiratory distress syndrome and its complications, e.g., pneumothorax, bronchopulmonary dysplasia, are associated with a high risk of hemodynamic disturbances and hence, GMH/IVH. Treatment with surfactant is the single most important advance in the management of lung immaturity. Collective data from the Cochrane Database suggests that intratracheal surfactant, either natural or synthetic, administered prophylactically in the delivery room is most efficacious (117). In ventilated infants whose respirations are asynchronous with the ventilator and who are at increased risk of GMH/IVH and pneumothorax, neuromuscular paralysis with pancuronium bromide is associated with significant reduction in GMH/IVH (1). However, at the present time, the routine use of pancuronium in ventilated newborns is not recommended as a result of concerns about long-term pulmonary and neurologic effects (118). Sedation with other agents, e.g., phenobarbital (119), midazolam (120) and the use of high frequency oscillating ventilation (121) have not been shown to be effective for reducing GMH/IVH and may, in fact have deleterious effects.

In addition to hemodynamic disturbances, abnormal coagulation, especially abnormal platelet function, is thought to play a role in the genesis of GMH/IVH in some instances. However, to date, the combined data from all randomized trials do not show a reduction of severe GMH/IVH or mortality with routine use of early volume expansion with normal saline, fresh frozen plasma, albumin or blood substitutes (122).

Indomethacin, which is used for treatment of symptomatic patent ductus arteriosus, appears to be associated with significantly reduced incidence of severe GMH/IVH without adverse long-term effects (123). In addition to altering the hemodynamic status and reduction of cerebral blood flow, indomethacin may have beneficial effects by inhibition of free radical synthesis and acceleration of maturation of the germinal matrix vasculature.

Posthemorrhagic Hydrocephalus

Ventriculomegaly, which has been reported to occur in approximately 25% to 35% of infants with GMH/IVH, may arrest or resolve spontaneously, usually within four weeks of onset. More recent studies suggest that the course of posthemorrhagic hydrocephalus may be evolving such that approximately two thirds of affected infants may require active intervention (102). A major obstacle to developing a rational strategy for the management of posthemorrhagic ventriculomegaly is an inability to diagnose precisely the onset of associated brain injury in premature newborns in whom multiple mechanisms are occurring simultaneously which may predispose to cerebral injury (101).

The situation is complicated further because clinical criteria for the diagnosis of increased intracranial pressure lack sensitivity in the newborn and are often delayed. Serial cranial ultrasonography may identify progressive ventricular dilation which precedes clinical signs. However, to date, there are no standardized measurements of ventricular size. Useful observations of progressive hydrocephalus on ultrasound scans include: rapid progression of ventricular dilation, prominent dilation of the temporal horns of the lateral ventricles, decrease in

ventricular size following CSF removal, a periventricular hyperechoic outline (as a result of transependymal CSF accumulation) and echogenicity (signifying subarachnoid hemorrhage) in basal cisterns, sylvian fissure and spinal subarachnoid space.

Temporizing interventions for progressive posthemorrhagic hydrocephalus during the first weeks of life usually involve mechanical removal of CSF by serial lumbar punctures, external ventricular drainage, subcutaneous ventricular access device or ventriculosubgaleal shunt in which fluid is drained from the ventricles into the subgaleal space. These techniques may be effective if it is technically possible to remove sufficient CSF, i.e., 10-15 ml/kg/day, for at least 2 to 3 weeks. The value of early "prophylactic" intervention prior to development of progressive ventriculomegaly with repeated lumbar punctures or ventricular puncture (124) or intraventricular fibrinolytic therapy with streptokinase (125) before the onset of ventriculomegaly to prevent hydrocephalus has revealed no benefit in terms of requirement for permanent shunt placement, death or severity of neurologic sequelae.

The nonsurgical approach to treatment of posthemorrhagic hydrocephalus involves either medications which decrease CSF production, e.g., acetazolamide, furosemide or osmotic agents, e.g., isosorbide, glycerol. Medical therapy is limited by complications which include metabolic acidosis, electrolyte disturbances, hypercalciuria, nephrocalcinosis, glial and myelin toxicity. Comprehensive analysis on medical therapy has concluded that acetazolamide and furosemide are neither effective nor safe for treatment of posthemorrhagic hydrocephalus (126).

The optimal timing for permanent ventriculoperitoneal shunt placement remains controversial. Earlier studies favored early shunt insertion but more recent studies found no correlation between timing of shunt insertion and outcome. In fact, it may be argued that shunt insertion when residual blood clot and debris are present, increases the risk for shunt obstruction and infection which correlate with poor outcome.

P.1402

Prognosis

The outcome of infants with GMH/IVH is related principally to the size of the hemorrhage, complications of posthemorrhagic hydrocephalus and associated hypoxic-ischemic cerebral injury, e.g., PVL. For infants with small GMH/IVH alone, survival without major neurologic sequelae is the rule. In infants who sustain severe GMH/IVH with ventriculomegaly or parenchymal involvement, the incidence of major neurologic sequelae increases to 30 to 40%. Of course, the most critical determinant of long-term outcome is the extent of parenchymal involvement. Major GMH/IVH occurs frequently in the context of hypoxic-ischemic cerebral insult, and long-term neurologic outcome depends in large part on concomitant or preceding hemorrhagic or nonhemorrhagic hypoxic-ischemic cerebral injury.

There is also a high risk of major neurologic sequelae in infants with posthemorrhagic hydrocephalus, especially those who had placement of a ventriculoperitoneal shunt. In one study, approximately 35% died and 50% had moderate or severe neurologic impairment at 5 years of age (127). In another multicenter, randomized controlled trial of 157 cases of posthemorrhagic hydrocephalus, 20% died and 76% had major motor impairment. Furthermore, early drainage of CSF did not improve outcome significantly compared with controls (128).

SUBDURAL HEMORRHAGE

Improvements in obstetric practice and a decrease in mechanical birth trauma have reduced considerably the incidence of severe subdural hemorrhage. This type of hemorrhage accounts for less than 5% to 10% of intracranial hemorrhage in the newborn (129). However, the data must be interpreted with the recognition that mild subdural hemorrhage which is not uncommon in the posterior fossa may have few associated clinical abnormalities and may remain undiagnosed.

Subdural hemorrhage occurs in premature and term infants and results from laceration of the major veins and sinuses, usually associated with a tear of the dura or dural reflections (e.g., falx, tentorium) overlying the cerebral hemispheres or cerebellum. Excessive molding of the head may play a role in the genesis of subdural hemorrhage. Clinical features include a decreased level of consciousness, seizures, or asymmetry of motor function. Clinical outcome is determined in large part by the extent of associated hypoxic-ischemic injury.

Diagnosis

CT or MRI are the techniques of choice for the identification of subdural hemorrhage. Differentiating subdural from intracerebellar hemorrhage may be difficult in infants who have evidence of hemorrhage in the posterior fossa on CT or MRI scans. Intracerebellar hemorrhage appears to be more common in premature infants (130), and posterior fossa subdural hemorrhage is more common in term newborns (1).

The diagnosis of posterior fossa hemorrhage and small lesions located over the cerebral convexities may be difficult using the traditional cranial ultrasonography approach through the anterior fontanelle. Imaging through the posterolateral fontanelle may improve visualization of the posterior fossa. Supratentorial lesions are usually demonstrated better by CT, whereas MRI is superior for evaluation of posterior fossa hemorrhage. Lumbar puncture is not indicated for diagnostic study in this setting because of the possibility of provoking herniation.

Occipital diastasis and skull fractures are demonstrated best by skull radiographs.

Management

Convexity subdural hemorrhage, particularly if associated with displacement of the midline, should be referred for a neurosurgical opinion for consideration of evacuation by subdural tap or craniotomy, especially if there is clinical deterioration with signs of transtentorial herniation. Massive subdural hemorrhage located in the posterior fossa may require surgical evacuation. Surgical intervention may not significantly improve the long-term outcome if there are no major neurologic signs (1).

Prognosis

The prognosis for infants with major lacerations of the tentorium or falx is poor. The mortality rate is approximately 45%, and survivors frequently develop hydrocephalus and other sequelae. More than 50% of survivors who sustain lesser degrees of hemorrhage are neurologically normal at follow-up. Concomitant hypoxic-ischemic cerebral injury is often the critical factor in determining outcome.

PRIMARY SUBARACHNOID HEMORRHAGE

Primary subarachnoid hemorrhage, which is located most prominently in the subarachnoid space over the cerebral convexities and in the posterior fossa, refers to hemorrhage within the subarachnoid space that is not secondary to extension of subdural hemorrhage, IVH, or cerebellar hemorrhage. Unlike the dramatic arterial hemorrhage in adults, subarachnoid hemorrhage in the newborn is usually self-limited and of venous origin, originating from small vessels in the leptomeningeal plexus or in bridging veins within the subarachnoid space (1). Trauma or hypoxic events may be important antecedents of major degrees of primary subarachnoid hemorrhage, although the pathogenesis usually is uncertain. Long-term sequelae are uncommon. Rarely, hydrocephalus may develop secondary to adhesions at the outflow of the fourth ventricle or over the cerebral convexities.

P.1403

Clinical Features

Definition of the clinical features related solely to primary subarachnoid hemorrhage has been made difficult by its association with trauma, hypoxic ischemic insult, and other forms of intracerebral hemorrhage that produce abnormal neurologic signs. Nevertheless, three syndromes of primary subarachnoid hemorrhage are generally recognized (1). The first syndrome of minimal or no clinical features is the most common. In the second syndrome, seizures occur most commonly on the second day of life, and the infant is usually well between seizures. The third syndrome, associated with massive subarachnoid hemorrhage, consists of rapid neurologic deterioration and is uncommon. The infant usually has also sustained severe hypoxic-ischemic cerebral injury, with or without trauma, or has a major vascular abnormality, e.g., arteriovenous malformation or aneurysm.

Diagnosis

The diagnosis of primary subarachnoid hemorrhage is based on the finding of uniformly blood-stained CSF on lumbar puncture in an infant in whom other forms of intracranial hemorrhage have been excluded by CT. With primary subarachnoid hemorrhage, CT usually demonstrates blood in the superior longitudinal fissure and in sulci.

Management

Seizures are treated with anticonvulsant medication. Hydrocephalus is managed as described previously in this chapter.

Prognosis

In the absence of preceding severe trauma, hypoxic-ischemic cerebral injury, or ruptured vascular lesion, the outcome is favorable. Outcome correlates well with the neonatal clinical syndrome. In infants with minimal or no clinical signs, the prognosis is excellent. In term infants with seizures, 90% are normal at follow-up. In the rare instance of massive subarachnoid hemorrhage with catastrophic deterioration, death and hydrocephalus are common.

INTRACEREBELLAR HEMORRHAGE

Postmortem studies suggest that primary hemorrhage into the cerebellum is a relatively common lesion, especially in infants born prematurely. The routine use of cranial ultrasonography through the posterolateral fontanelle in premature infants has confirmed that this lesion may have been under diagnosed previously in surviving infants (130).

Neuropathology

Causes of cerebellar hemorrhage include traumatic laceration of the cerebellum or sinuses, venous infarction, or extension of IVH or massive subarachnoid hemorrhage into the cerebellum. Pathogenetic factors include tenuous vascular integrity, skull deformation, occipital diastasis, impaired cerebrovascular autoregulation with hypoxic-ischemic insult, and bleeding from fragile vessels of the germinal external granule cell layer of the cerebellum.

Clinical Features

Most reports of intracerebellar hemorrhage in premature infants are based on autopsy studies. Clinical details are based on retrospective analyses. There is usually a history of hypoxic-ischemic insult or an association with severe respiratory distress syndrome. In most instances, there is a catastrophic deterioration with apnea, bradycardia, and a decrease in hematocrit. Clinical signs appear usually in the first 3 weeks of life, with most beginning within the first 2 days of life. In term infants, there is usually a history of difficult breech delivery, with subsequent development of neurologic signs referable to brainstem compression, e.g., stupor or coma, cranial nerve abnormalities, apnea, bradycardia, and opisthotonus.

Diagnosis

The lesion may be suspected on the basis of the history and physical features as described previously. Definitive diagnosis is made by CT or MRI. Traditional cranial ultrasonography through the anterior fontanelle is of limited value for visualizing intracerebellar hemorrhage (130).

Management

Early detection by CT, MRI, or ultrasound scans is essential. Decisions concerning surgical or conservative management are based on the size of the lesion and the clinical state of the infant. Recovery without surgical intervention has been reported. Fishman and colleagues (131) reported successful conservative management of six full-term infants with intracerebellar hemorrhage and recommend that, if the clinical picture is stable and there is no increase in intracranial pressure, supportive care and serial CT examinations may be all that is necessary. Our ongoing experience with nonsurgical management of selected cases supports this notion. The appropriate management of this lesion in the premature newborn is unclear, although it is unlikely that surgery plays a significant role.

Prognosis

Most reports of intracerebellar hemorrhage in the premature infant are based on autopsy studies. For the

premature infant with severe intracerebellar hemorrhage and especially when there are relevant clinical abnormalities, the prognosis is uniformly poor. The outcome of premature newborns with clinically silent presentation and term newborns may be more favorable for survival. However, the

majority develop significant long-term motor and cognitive impairment. Hydrocephalus requiring VP shunt insertion occurred in approximately 50% of both surgically treated and untreated infants.

INTRAVENTRICULAR HEMORRHAGE IN THE TERM NEWBORN

Intraventricular hemorrhage is considered to be a condition which occurs principally in premature newborns. However, it occurs also in a small percentage of term newborns, often in the context of prior hypoxic-ischemic or traumatic insults. The sites of origin of IVH in the term newborn are more variable and include residual germinal matrix, choroids plexus, vascular malformations, tumor or hemorrhagic venous infarction of the thalamus. This latter entity often presents somewhat later, after several days or weeks of age (1,132).

The diagnosis and management of IVH and its complications in the term newborn are similar to those described for premature newborns.

The prognosis for IVH in term newborns may be worse than in premature newborns. Approximately 70% of term newborns with IVH develop posthemorrhagic ventriculomegaly, of which only 20% arrest or resolve spontaneously and 50% require placement of a ventriculoperitoneal shunt (1). Long-term neurological sequelae of varying degrees of severity occur in more than 50% of affected children. These relate principally to the associated parenchymal damage, and the underlying etiology, especially trauma and hypoxic-ischemic insult.

BRAIN DEATH IN NEONATES

Current guidelines for the diagnosis of brain death in adults and children do not include preterm or term newborns who are less than 7 days of age because of the lack of sufficient data dealing with this age group (133,134). This topic has been reviewed in detail by Ashwal (125). Clearly, there are fundamental differences between the evolution of brain death in neonates compared to older individuals. In the newborn infant, factors such as the patent sutures and open fontanelle make it unlikely that increased intracranial pressure and consequent decreased cerebral perfusion will develop. Furthermore, brainstem reflexes, which are fundamental for brain-death determination, may be difficult to elicit or they are incomplete especially before 32 weeks' gestation. Apnea testing, which is considered critical for the objective diagnosis of brain death in older individuals, may be invalid especially in infants below 33 weeks of gestational age, who have diminished respiratory drive to CO₂ stimulation (135).

The role of confirmatory neurodiagnostic testing in the newborn, e.g., EEG, cerebral blood flow measurements and radioisotope studies also remains unclear because of the limited data available. Earlier studies of brain-dead neonates have shown significant lack of correlation between EEG and cerebral blood flow (CBF) studies, e.g., one third of neonates who had electrocerebral silence had evidence of CBF and 58% of those with absent CBF had evidence of EEG activity on an initial recording (135). Of the techniques that are currently available for the assessment of cerebral perfusion, four vessel angiography, positron emission tomography and xenon-CT are generally too cumbersome technically for routine use in neonates. Radioisotope flow studies appear to have greater sensitivity and specificity than Doppler CBF velocity measurements. However, this technique does not address the critical issue that blood flow is more likely to persist in brain dead newborns and the lower limits of blood flow required to support the immature brain or brainstem have not been established (136,137).

Although unresolved issues remain, current data suggests that brain death can be diagnosed in the term newborn, provided that there is an awareness of the limitations of the clinical examination and that laboratory investigations, e.g., EEG, CBF studies frequently do not demonstrate the typical confirmatory abnormalities. It is important to perform repeated examinations of infants in whom brain death is suspected to demonstrate the absence of brainstem reflexes more accurately and to perform formal apnea testing that documents loss of respiratory effort when arterial CO₂ tension is greater than 60 torr. An observation period of 48 hours has generally been recommended to establish the diagnosis. This period of time may be shortened to 24 hours if the EEG is isoelectric or if CBF studies demonstrate absence of flow. Although there are few preterm infants who meet these criteria for brain death, it is likely that a similar time frame would be applicable. Using these guidelines, based on the available data, the risk for misdiagnosis appears low. In the rare instances when minimal transient clinical or EEG improvements have been demonstrated, meaningful neurologic function has

not been attained and all infants have died after brief periods of time (135).

NEUROMUSCULAR DISORDERS

Neuromuscular disease implies dysfunction of the motor system at a level between the motor cortex and muscle. However, in conventional discussions, this term is often restricted to lower motor neuron and muscle diseases, i.e., disorders at a level between the anterior horn cell and muscle. The most critical task for the physician is to define the anatomic level of the underlying abnormality.

Diagnosis

Lower motor neuron disorders should be considered clinically whenever an alert newborn presents with hypotonia and weakness. However, in many instances, e.g., congenital

P.1405

muscular dystrophy, myotonic dystrophy, and mitochondrial cytopathies, there may be associated CNS involvement. Furthermore, infants with neuromuscular disease may sustain secondary hypoxic-ischemic brain injury related to respiratory muscle weakness or pulmonary hypoplasia.

Because most neuromuscular disorders are inherited and some, e.g., Duchenne muscular dystrophy, may be asymptomatic in the newborn period, a detailed family history is of critical importance. Specific complications of pregnancy, e.g., decreased fetal movements, polyhydramnios, and breech presentation, are a common occurrence. In addition to assessment of muscle bulk, tone, and power, examination for presence of muscle fasciculations, facial diplegia, or ptosis support a diagnosis of neonatal neuromuscular disease.

Laboratory investigations in older children with muscle disease often include elevation of serum creatine phosphokinase levels. Unfortunately, this screening test is of limited value in the newborn, because levels may be increased up to tenfold following normal vaginal delivery. Chest x-ray may demonstrate thin ribs related to decreased fetal respiratory efforts or cardiac enlargement suggestive of cardiomyopathy. Nerve conduction velocities and electromyography may establish the level of involvement of the motor system, but the technical performance and interpretation of data are difficult in the newborn age group (138). Although imaging techniques, e.g., ultrasonography, CT, and MRI, have some role in the investigation of muscle disease, there is limited experience in the newborn. Muscle biopsy, either by open, surgical, or needle biopsy technique, is technically feasible. However, problems with histologic interpretation may arise during the newborn period, as a result of nonspecific abnormalities that exist in the early stages of progressive muscular dystrophies (139).

Molecular genetic techniques have clearly revolutionized the diagnosis of neuromuscular disease and decreased the need for invasive investigations. However, clinical assessment must still direct these genetic investigations (140).

Major Neuromuscular Conditions

Anterior Horn Cell Disease

Anterior horn cell disorders, include type I spinal muscular atrophy (Werdnig-Hoffman disease), type II glycogen storage disease (Pompe's disease), neurogenic arthrogryposis multiplex congenita, and neonatal poliomyelitis. These disorders account for approximately 35% of all cases of neonatal hypotonia of neuromuscular origin. Characteristically, infants are alert but profoundly hypotonic and weak with absent tendon reflexes, paradoxical diaphragmatic respiratory movements, and a majority have prominent fasciculations of the tongue. Electrical studies and muscle biopsy demonstrate severe acute and chronic denervation. The genetic defect of autosomal recessive type I spinal muscular atrophy has been identified on chromosome 5q, which enables molecular diagnostic tests and prenatal testing (141). Although muscle strength may remain relatively static, overall deterioration and decreased survival result from repeated respiratory infections and aspiration, prolonged immobility, and hospitalization (142).

PERIPHERAL NERVE DISORDERS

Disorders of peripheral nerves rarely present in the newborn period. The clinical course is variable and may even be nonprogressive or reversible (1,143). Diagnosis may be confirmed by nerve conduction studies. Adjunctive investigations include measurement of CSF protein, lactate levels, and possibly sural nerve biopsy. Peripheral

neuropathy may be one presenting problem of metabolic disorders in the newborn, e.g., Krabbe's disease, mitochondrial disease.

DISORDERS OF THE NEUROMUSCULAR JUNCTION

These conditions present with fluctuating muscle weakness, variable ptosis, ophthalmoplegia, facial weakness, impaired feeding, hypoventilation, and autonomic disturbances. Disorders include myasthenia gravis (transient or congenital) and toxic-metabolic problems, e.g., hypermagnesemia, aminoglycoside toxicity, and infantile botulism.

Transient myasthenia gravis, which is related to circulating maternal antiacetylcholine receptor antibodies, occurs in approximately 20% of infants of mothers with myasthenia. There is no correlation between the disease severity in the mother and that observed in the infant and only poor correlation between maternal antibody titers and disease severity in the infant. The diagnosis may be confirmed by evaluating the infant's response to neostigmine. The advantage of neostigmine in neonates relates to its more prolonged duration of action (1-4 hours) which permits serial assessments. Neostigmine is usually administered intramuscularly or subcutaneously at a dose of 0.15 mg/kg with a maximum dose of 2 mg. The intravenous dose is one third the intramuscular dose and should be accompanied or preceded by atropine, as a result of risk of bronchorrhoea, asystole, bradycardia and hypotension.

Management of transient myasthenia gravis includes supportive treatment, anticholinesterase therapy, and possibly exchange transfusion and intravenous immunoglobulin (IVIG) (144) until symptoms resolve, often after several weeks. Congenital myasthenia relates to anatomic defects of the neuromuscular junction, which have variable response to pyridostigmine (139,145).

P.1406

Early diagnosis of disorders of neuromuscular transmission is critical because many of these conditions respond to treatment and timely intervention may prevent serious complications.

Primary Muscle Disorders

Generalized muscle disorders include the genetically determined progressive muscular dystrophies which have nonspecific histologic features of muscle necrosis, regeneration, fibrosis on muscle biopsy and nonprogressive congenital myopathies, which are characterized by distinctive histologic abnormalities (1,139).

The major muscular dystrophies that present in the newborn include congenital myotonic dystrophy and congenital muscular dystrophy. Congenital myotonic dystrophy is inherited exclusively from the mother. A family history may often not be recognized because the disease is often milder in the mother and may have been undiagnosed prior to the birth of a more severely affected infant. The diagnosis may be confirmed by molecular genetic studies in either the mother or the affected newborn, i.e., demonstration of an increase in trinucleotide repeats (CTG) at the myotonic dystrophy gene locus at chromosome 19q. During pregnancy, there are often decreased fetal movements and a history of polyhydramnios. Often there is failed labor and urgent cesarean section is required. Affected infants are often premature and present at birth with hypotonia, weakness, hypoventilation, impaired sucking and swallowing, facial diplegia, ptosis, and arthrogryposis. Additionally, there is usually significant cognitive impairment, which may be associated with abnormalities on neuroimaging, especially increased risk of intracerebral hemorrhage. Clinical signs of myotonia are absent in neonates but develop later in childhood. However, the EMG of affected newborns may demonstrate myotonic potentials, which are generally higher pitched, quieter and less sustained than those in adults. The mortality rate is high and the long-term clinical course is variable (146). Many affected newborns require ventilator support for respiratory insufficiency. Prognosis is poor for survival if ventilation is required for longer than four weeks. There is risk for recurrent aspiration and persistent feeding difficulties. Orthopedic interventions, e.g., splinting and surgery are required for management of talipes.

The term congenital muscular dystrophy (CMD) comprises several disorders that have an autosomal recessive inheritance pattern and may be classified according to whether there is isolated muscular dystrophy (merosin-positive CMD) or a combination of CNS and skeletal muscle involvement (merosin-deficient CMD). CNS involvement may include cerebral dysgenesis, cerebral white matter, and ocular abnormalities and may be suspected on the basis of seizures, glaucoma, optic nerve abnormalities, or cataracts. The clinical course of patients with a combination of CNS involvement and evidence of merosin deficiency on muscle biopsy is often progressive with decreased survival, whereas in infants who have myopathy alone, (merosin positive CMD)

muscle weakness is often static and affected individuals may even attain ambulation (139,147).

Investigations reveal normal or moderate elevation of creatine kinase levels (<1,000 IU) and dystrophic abnormalities on muscle biopsy. Results of neuroimaging studies may be abnormal. In cases with CNS abnormalities, immunocytochemical analysis of the muscle biopsy may reveal deficiency of merosin, an extracellular protein that is associated closely with the muscle membrane. The merosin protein is thought to play a significant role in the pathogenesis of congenital muscular dystrophy.

In addition to the muscular dystrophies, there are numerous congenital myopathies that are classified according to their specific histologic abnormalities. The pathologic process affects exclusively the striated or voluntary muscles. Rarely cardiac muscle may be involved. With the exception of nemaline myopathy and X-linked myotubular myopathy, which may present with respiratory failure in early infancy, hypotonia and weakness are often relatively mild and static.

Nemaline myopathy is the most common type of congenital myopathy, which may have either an autosomal dominant or recessive inheritance pattern. There is a severe neonatal variety which presents at birth with severe muscle weakness, respiratory insufficiency and difficulties with sucking and swallowing. Pregnancy complications with fetal akinesia may occur. Death as a result of respiratory complications is common during the first weeks or months of life, although some severely involved newborns have survived, with relatively little residual disability. There is a mild, congenital form of nemaline myopathy that presents with mild weakness, feeding difficulties and delayed motor milestones.

Metabolic Myopathies

With the availability of electron microscopy, muscle enzyme assays, and MRS, the diagnosis of muscle conditions in which there is primary derangement of energy metabolism, is being made with increasing frequency, e.g., mitochondrial cytopathies, carnitine deficiency, and disorders of lipid and glycogen. Clinical features in these disorders include hypotonia, weakness, failure to thrive, encephalopathy, hypoglycemia, and cardiomyopathy. Muscle histology and enzyme abnormalities usually are diagnostic. Detailed discussion of the biochemical aspects of metabolic myopathies is beyond the scope of this chapter.

Management

The management of neuromuscular disorders in the newborn is often associated with major genetic and ethical dilemmas, especially regarding a reasonable approach to the initiation and duration of mechanical ventilatory support. Unfortunately, few scientific guidelines exist. Other supportive management strategies include oxygen therapy, nasogastric feeding, and aggressive physiotherapy and orthopedic interventions to minimize joint contractures. Specific therapies exist for some conditions, e.g., pyridostigmine for myasthenia gravis.

P.1407

Clearly, the prognosis of neuromuscular conditions is variable and depends principally on the specific disorder involved.

Chapter 51

Neurosurgery of the Newborn

Joseph R. Madsen

David M. Frim

Anne R. Hansen

Treatment of structural and functional abnormalities of the neonatal central nervous system (CNS) provides unique challenges to both the neurosurgeon and neonatologist caring for the infant. Considerations of several interrelated pathophysiologic processes can provide an understanding of the nature of the abnormality and goal of treatment. This understanding forms the basis for a successful interdisciplinary team approach to the management of these infants.

THE PATHOPHYSIOLOGY OF NEONATAL NEUROSURGERY

Almost all neurosurgical interventions in the neonate can be discussed in terms of four categories of technical intervention: (a) drainage or diversion of fluids, (b) closure of openings (including neural tube defects), (c) removal of tissue (including neoplasms and anomalous masses), and (d) opening of fusions (such as craniosynostoses). In the management of many newborn patients, two or more of these inventions may be necessary. Some neonatal nervous system problems, such as vascular disorders, do not yet have a workable neurosurgical intervention.

When applying these inventions to neonatal care, their use must be guided by pathophysiologic mechanisms unique to the neonate, such as (a) the biomechanics of neonatal brain tissue and a distensible skull, (b) recognized and unrecognized congenital anomalies (microscopic and macroscopic), and (c) the plasticity of neonatal CNS tissue and its effects on response to injury. Recent advances in antenatal diagnosis allow unprecedented opportunity to manage these processes even before birth. Frequently, solutions to a neonatal neurosurgical problem must address combinations, or complex interactions, of these pathophysiologic mechanisms.

The biomechanic nature of neonatal brain tissue and a distensible skull accounts for one of the best-known cardinal signs of neurosurgical difficulty in the neonate, namely abnormal head growth. The prodigious ability of the skull to grow and sutures to widen can allow some of the most severe cases of hydrocephalus to result in relatively mild pressure effects, even with an obvious need for cerebrospinal fluid (CSF) shunting for long-term management. These same considerations in the type and nature of response of the tissues to abnormal fluid build-up can result in dramatic structural difficulties once the pressure is relieved. The certainty that the brain and skull biomechanics will change over time adds particular challenge to management of these problems.

Obvious congenital anomalies, especially those involving open neural-tube defects and exposed CNS tissue, may require urgent neurosurgical intervention. A complicating aspect is the potential occurrence of concurrent microscopic abnormalities, such as widespread synaptic miswiring. In many cases, neurologic deficits may be present in a patient with macroscopic structural abnormalities, but major neurologic disability may come from less obvious problems with tissue development, currently not treatable by neurosurgical means.

The details of the plasticity and vulnerability of the neonatal CNS is discussed in Chapter 50. It is well known that the ability to recover function after CNS injury is age dependent and seems to be better in younger individuals. Interaction between the age-dependent variables of CNS plasticity, recoverability, and vulnerability make the task of estimating prognosis after an injury or neurosurgical intervention extremely difficult.

Antenatal diagnosis has changed many aspects of neurosurgical conditions. Obstetric management may be altered, for example, site and mode of delivery in the setting of a known neural-tube defect. In addition, the psychologic issues around the time of neurosurgical therapy for the newborn are altered, as the child's family now has the opportunity to meet the neurosurgeon prenatally and fully discuss and decide upon any contemplated care

plan before birth. Antenatal surgery for some neurosurgical conditions (such as neural-tube defects and hydrocephalus) may one day be routine, but at this time these techniques are still available only in

experimental, randomized trials.

FLUID COLLECTIONS AND THEIR MANAGEMENT

Disorders of Cerebrospinal Fluid Accumulation

The most common neurosurgical consultation for newborn patients is to evaluate and treat enlargement of the ventricular system. The clinical signs of progressive enlargement of the ventricular system include excessive increase in the head circumference (HC), fullness in the anterior fontanelle (especially when the patient is upright, the venous and fontanelle pressures should be low), episodic apnea and bradycardia, general lethargy, and abnormalities of ocular movement, especially restricted upgaze. Many of these findings are nonspecific and can they be seen with hydrocephalus of any etiology. At a practical level, the most important distinction is between progressive and static abnormalities in ventricular volume. This is relatively easy to determine using serial cranial ultrasound examinations (Fig. 51-1). The recent addition of resistive index (RI) measurements adds a physiologic dimension to the anatomic images gathered by ultrasonography (1). In our experience, the presence of dramatic changes in the Doppler-measured flow signals in the anterior cerebral artery with gentle, brief compression of the anterior fontanelle correlates extremely well with the intracranial pressure by measurement and the probability of eventual need for a ventriculoperitoneal (VP) shunt (1).

The vast majority of hydrocephalus cases seen in neonates are associated with, and traditionally thought to result from, abnormal resorption of CSF. However, Egnor (2) has persuasively argued the contrasting view that abnormalities in the pulsatile dynamics of the CNS may play a role in the etiology of communicating hydrocephalus. In this view, the purpose of CSF and the ventricular system is to absorb the kinetic energy of the arterial pulsations and transfer this energy out of the skull, primarily via the venous system. After intraventricular hemorrhage (Fig. 51-1), traditional thinking is that partial occlusion of the normal resorptive pathways of CSF through the arachnoid villi causes hydrocephalus. Pulsatile theories suggest that breakdown of the resonance of pulsations could also play a role. Thus, relative blockade of bulk CSF absorption or blockade of absorption of the pulsations could raise the steady state to a relatively higher pressure. In the neonate with open sutures, this results in a larger intracranial volume. It also follows that there would be some cases of mild increase in resistance to absorption of fluid (or pulsations) that would not require specific treatment, whereas higher grades of failure to absorb fluid would cause substantial increases in pressure, leading to neurologic symptoms if not treated.

Figure 51-1 Cranial ultrasonography of intraventricular hemorrhage in the coronal plane. **A:** Head ultrasound performed within the first week of life depicts a clot in the left lateral ventricle with mildly dilated ventricles. **B:** Ultrasonography performed 1 month later shows no residual clot, but significant enlargement of the ventricular system, consistent with posthemorrhagic hydrocephalus.

Placement of a shunt in borderline cases may result in atrophy of physiologic resorption systems and, thereby, cause more permanent obstruction to resorption of CSF. This is conceptualized as atrophy of arachnoid granulations or failure to develop normal resorptive pathways, but the detailed pathology is not well known. A related paradox of shunt physiology, particularly applicable to neonates, is that, with currently available hardware, it is impossible to distinguish between a well-functioning shunt and nonfunctioning shunt in a patient who is no longer shunt dependent. Technologies that accurately measure the flow through the shunt, or through some physiologic pathway such as the aqueduct of Sylvius, or a ratio of these two numbers, could be a reliable

descriptor of shunt dependence. It is theoretically possible that such measurements could be made from dynamic magnetic resonance imaging (MRI) studies. So far, such a technique has not been applied reliably.

One of the problems with assessing the growth of ventricular size in the neonate is the possibility that the enlargement of the ventricles may at least partially reflect loss of tissue in the brain, rather than increase in pressure. This can become a very complicated situation, as prolonged hydrocephalus itself certainly can cause loss of tissue bulk (3), and the value of shunt placement may be more difficult to determine when the tissue loss is not obviously the result of high pressure. The specific loss of myelin or white matter, called periventricular leukomalacia, is discussed in Chapter 50. The relationship between periventricular leukomalacia and hydrocephalus is of particular concern in neurosurgical decision making. When a preterm infant, especially one who has sustained an intracranial hemorrhage, shows lateral ventricular enlargement, it is difficult to determine to what extent this is a result of impaired CSF flow or absorption versus diffuse white matter damage or inadequate density of axons. In general, the absence of macrocephaly is an indicator of the atrophy. More specific strategies to rescue white matter in such circumstances probably will evolve and may diminish the call for shunts in some of these patients (4).

Nevertheless, assessing for macrocephaly is complicated by the changing growth rate of the normal neonatal head (5). In general, an HC growth of less than 1 cm/week is acceptable, and an HC growth of more than 1.5 cm/week is considered excessive. Head growth must be interpreted in the context of overall somatic growth measured by weight and length. Babies can have preferential brain catch-up growth, but it is suspicious if the rate of HC increases at the high end of normal while the weight and length remain relatively unchanged. Because major intervention decisions are based on the intrinsically imprecise measurement of HC, any effort to improve its precision is worthwhile. Minimizing the number of care providers obtaining the measurement and overtly standardizing the measurement site and technique improves accuracy. The effect of interpreter variability can be dampened by comparing the HC to the previous day and also to 1 week earlier to calculate average daily growth by dividing by seven. Using a correct and accurate growth curve is also important (6,7).

Fluid in the subarachnoid space outside the brain, sometimes termed "benign external hydrocephalus," is probably a normal variant. The increased collection of extraaxial fluid is generally in the frontal regions. The diagnosis of subdural hygroma frequently has been applied to these cases; this diagnosis must be applied with great caution if it is intended to imply a pathologic collection benefiting from drainage (8).

Treatment of Neonatal Hydrocephalus

Due to the disadvantages and complications of VP shunting, the decision to place a shunt must be made only after all nonsurgical options have failed. The fact that the CSF resorption may change with time, and indeed may improve, provides a rationale for conservatism. As a patient grows and the dynamic relationship between CSF production and resorption changes, the need and indications for diversion of CSF may change over the child's lifetime.

Children born with hydrocephalus due to nonhemorrhagic causes, such as aqueductal stenosis, posterior fossa cysts, holoprosencephaly, or hydranencephaly, can be shunted within 1 to 2 days of birth, pending evaluation of general medical status. Although affected infants usually are born at or near term, a presurgical weight of approximately 1,500 to 2,000 grams is adequate size to support peritoneal drainage of ventricular CSF (9). There are ethical issues that should be raised before placing a VP shunt in a child suffering from hydrocephalus with significantly reduced brain function from either an *in utero* event or developmental anomaly. Frank discussion with the child's parents regarding prognosis is critical. Shunting for affected children without other life-threatening anomalies is certainly reasonable for the purposes of controlling head size in the growing infant. With maximal interventional therapy, most of these children are expected to live beyond a few weeks, and such day-to-day issues as whether the child's head will fit in an infant car seat need to be considered. Shunting at birth is a relatively low-risk method of preventing massive head enlargement and allowing other factors aside from congenital hydrocephalus to determine the child's outcome (10).

Nearly all acquired hydrocephalus in the premature infant is posthemorrhagic (Fig. 51-1). These infants have usually not achieved adequate weight for placement of permanent shunts, and the final determination of lifelong hydrocephalus has not been made. In this situation, medical management (11) is instituted to temporize until surgical management is both clearly indicated and feasible. The mainstays of medical management are serial lumbar punctures and diuretic therapy, though use of the latter is becoming increasingly controversial (12,13). The use of these maneuvers is discussed in Chapter 50. An additional approach that has been tried for

posthemorrhagic hydrocephalus (PHH) is the introduction of fibrinolytic therapy directly into the ventricular system. Enzymes such as streptokinase, urokinase, and tissue plasminogen activator all have been proposed and tested with variable success. Some centers have suggested that the risk of VP shunts can be reduced using this technique (14). Others have been unable to show a decrease in the need for VP shunting with this maneuver (15,16). It is possible that the trials which found no helpful effect from fibrinolytic therapy had less favorable results because of patient selection, with a trend toward enrolling the most severe and potentially intractable cases. Infants enrolled in a recent, small trial combining fibrinolytic therapy with continuous drainage and irrigation had a reduced rate of shunt requirement, disability, and mortality compared to historic controls (17). However, larger trials are needed to further delineate the risks and benefits of this high-risk, labor-intensive treatment. At this point, the underlying difficulty with

P.1413

fibrinolytic therapy is the lack of overlap of the safety and efficacy windows. This therapy cannot currently be considered standard therapy.

Another intervention that has been suggested is the use of ventriculoscopic removal of clot, however, based on little published experience, this has not been demonstrated to avert the need for VP shunts. A new technique for the treatment of hydrocephalus caused by obstruction of the aqueduct of Sylvius employs the fiberoptic ventriculoscope to place a fenestration in the floor of the third ventricle to allow the escape of CSF into the subarachnoid space. Indeed, even in such cases of aqueductal stenosis, where eventual therapy using the ventriculoscope works well in older children, most surgeons currently find that the defect in the floor of the third ventricle in the neonate tends to close at a very high rate (18).

The risk of PHH correlates with the severity of intraventricular hemorrhage. Although other grading systems have been described, we use the Papile four-level system of intracranial hemorrhage (19): grade I, subependymal hemorrhage only (no increased risk of PHH); grade II, intraventricular hemorrhage without ventriculomegaly (low risk of progressive PHH); grade III, intraventricular hemorrhage with ventriculomegaly (moderate risk of progressive PHH); and grade IV, intraventricular hemorrhage with intraparenchymal extension (generally at high risk of need for VP shunting, depending on degree of intraventricular component).

There are many published management protocols for children with PHH (9-11,19,20). Evaluation usually includes neurosurgical consultation, ultrasound of the head to assess the size of the ventricles, and lumbar puncture to measure CSF pressure. During a head ultrasound, it can be helpful to measure the RI defined as

$$\frac{\text{systolic} - \text{diastolic blood flow velocity}}{\text{systolic blood flow velocity}}$$

Concern regarding hemodynamic compromise is raised either by an RI above the normal value of 0.5 to 0.7 or a rise in RI with gentle compression of the anterior fontanelle.

Interventions are tailored to maintain the lumbar or ventricular CSF pressure at approximately 5 to 8 cm of water while evaluating the need for permanent shunt placement. The medical approaches to this problem have been described (11,21). The goal of medical management is to decrease CSF volume either by decreasing CSF production via diuretic therapy or removing CSF in bulk.

Mechanical CSF drainage by serial lumbar puncture or direct ventricular access is the mainstay of treatment of elevated intracranial pressure while awaiting the appropriate time for VP shunt insertion. The frequency of CSF drainage procedures is determined by measuring opening CSF pressures during lumbar taps with a goal of less than 10 cm of water (10). For example, if an every third day tapping schedule allows the CSF pressure to rise to greater than 10 cm of water, the frequency of CSF withdrawal should be increased to every other day. Fontanelle tenseness, HC, and ultrasonographic RIs also are acceptable indications of intracranial pressure (1). Approximately 10 to 15 mL/kg should be removed to leave the closing CSF pressure as low as is feasible, usually less than 3 cm of water. This approach is based on cerebral perfusion management rather than measures of HC or ultrasonographic documentation of ventricular size.

HC, ultrasonographic criteria, and other physical examination criteria provide additional data to guide CSF drainage therapy. Data interpretation and management decisions should be based on the overall goal of maximizing the potential for neuronal development in an environment of low intracranial pressure and minimal periventricular axonal stretch.

Although serial lumbar punctures may be useful in many cases, they often fail because of abnormalities within the spinal system that block CSF flow, particularly common after intraventricular hemorrhage. These have been documented with spinal ultrasound (22).

Acetazolamide and furosemide reduce CSF production. Though theoretically their effects are synergistic, this combination of diuretic therapy is now used with more caution because of concerning studies that found possibly worse neurologic outcome secondary to the use of these medications together (12,13). There are extremely limited data regarding acetazolamide alone. In a sample size of only five, short-term improvement was appreciated in the three patients who did not require the medication to be discontinued secondary to metabolic acidosis (23). Thus, its safety and efficacy as a single agent are essentially unknown. In certain circumstances when serial lumbar punctures are either not possible or not feasible, acetazolamide therapy may play a role. Furosemide should be added with great caution as it adds potential risk with no documented benefit.

Medical treatment with CSF drainage and/or diuretic therapy is continued to determine the natural history of the condition and allow for adequate growth of the infant to permit safe placement of a VP shunt, should that be necessary. During this period, the requirement for CSF drainage will accelerate, remain stable, or decrease. This is ascertained by continuing to measure CSF pressures. If there is no increase in pressure between taps, then it is likely that CSF is being reabsorbed internally. In this situation, the ultrasound image of the ventricles, as well as the HC measurements, is helpful in confirming that the reabsorptive surface is functioning adequately.

Implantation of devices that allow easier intermittent (Fig. 51-2), or continuous CSF drainage, should be considered when the need for drainage accelerates to the point when the neonatal intensivist or neurosurgeon is performing lumbar punctures daily or with such frequency as to endanger an infant's medical stability. Additionally, serial lumbar puncture can cause arachnoid scarring and lead to an inability to obtain adequate CSF drainage from a lumbar approach. In cases of noncommunicating PHH, CSF removal from the lumbar region is not an option. In all of these cases, direct approach to the ventricles either by percutaneous tap or implanted access device is required.

Figure 51-2 Ventricular access device with 30-mm catheter. Implantation allows easy percutaneous access to ventricular fluid.

P.1414

Though percutaneous ventricular tap in a neonate is a relatively simple procedure, it should only be performed by experienced practitioners. A 20-gauge intravenous catheter is introduced perpendicularly to a plane tangential to the scalp at the lateral edge of the anterior fontanelle. After penetrating the dura with the inner needle, the soft catheter is advanced over the needle into the ventricle. Drainage then proceeds as with a lumbar puncture.

Ventriculosubgaleal shunts are increasingly being used instead of ventricular access devices to temporize prior to placement of a VP shunt. The device, as well as the surgical implantation technique, is very similar to that of the ventricular access device (Fig. 51-3). The only differences are that the blind end of the catheter is cut off, and the open end is allowed to drain into a subgaleal (essentially subcutaneous) pocket in the infant's head. The major advantage is that the subgaleal pocket may allow some resorption of CSF and certainly can absorb fluid pulsations. Infants with ventriculosubgaleal shunts typically require far less frequent taps, and sometimes no taps at all (24). If necessary, the reservoir or subcutaneous fluid collection can be tapped, just like a ventricular access device. The cosmetic issue of a visible subcutaneous fluid-filled space can be concerning to parents and

care providers who are unfamiliar with this technique, but all can be reassured that this will resolve after placement of a VP shunt, which follows in the vast majority of cases. The indications for tapping ventriculosubgaleal shunt devices are the same as for ventricular access devices, and the follow-up assessment tests are identical, including HC, sonographic assessment of ventricular size, and RI.

Figure 51-3 1,770-g premature infant, with ventriculosubgaleal shunt (VSGS) and associated subgaleal fluid collection, photographed as positioned for replacement of the VSGS (sketched in the upper right panel) with a ventriculoperitoneal shunt, trajectory shown at left and in the lower right panel.

P.1415

Though largely replaced by the subgaleal shunt at many institutions, ventricular access devices (Fig. 51-2) are still occasionally placed. These devices allow direct percutaneous access to the ventricle via the subcutaneous reservoir. The protocol for CSF drainage is identical to that for lumbar puncture. Infection of these devices is rare despite frequent percutaneous access. Ventricular access devices can be set up for continuous drainage by placement of a Huber needle into the reservoir, which is connected to a ventricular drainage bag. This maneuver is performed when taps are required more than once a day. During periods of continuous drainage, infants should be treated with prophylactic intravenous antibiotics.

After long intervals between CSF removal, if the pressure is unchanged and the ventricles are not enlarging, it is reasonable to continue to follow ventricular size by ultrasound alone. At that point, any diuretic treatment is weaned and then discontinued if tolerated. If the need for CSF drainage remains unchanged or accelerates as the patient grows, then the diagnosis of uncompensated hydrocephalus is made and a VP shunt is inserted. A patient weight of 1,750 grams is usually sufficient to permit implantation of a permanent VP shunt with minimal complications.

The contraindications to implantation of a permanent VP shunt are similar to those found in older children: evidence of CSF infection, significantly elevated CSF protein, presence of a high CSF red blood cell count which may mechanically obstruct the shunt, peritoneal inflammation, or infection such as necrotizing enterocolitis. These problems necessitate a delay in implantation until the child is healthy. CSF glucose parameters are sometimes quite low (less than 20 mg/dL) in neonates with PHH in the absence of infection. The significance of this finding is unclear; however, there is not an increase in shunt infection in these patients. Similarly, patients with intraventricular hemorrhage, whether adult or neonatal, can manifest fever perhaps from the presence of blood in the CSF. The exact cause of this increased temperature in the neonate is unclear; without positive bacteriologic data, it is unlikely to be infection. Therefore, in the absence of positive culture data, shunt placement should not be delayed.

Complications of Ventriculoperitoneal Shunting

Many of the problems of CSF diversion can be managed with simple surgical techniques. For example, since shunts tend to clog with very high protein concentrations, an externally draining system or a ventricular catheter with a tapping reservoir is initially placed (Fig. 51-2). At a later time, it is revised into a VP shunt if the infant requires permanent diversion (10,25). Another potential problem is patients outgrowing their shunts. Initial placement of longer tubing eliminates the need to periodically lengthen the peritoneal catheter because of growth. Catheters up to 90 cm in length are well tolerated, even by neonates. Prospective studies have not shown any increase in complications, even with tubing up to 120 cm in length (26). Therefore, many centers now place a very long catheter into the peritoneum of even a small baby.

Shunt infection and malfunction are the most serious complications of VP shunting at any age. Neonates are at particularly high risk of these complications because of such factors as their relatively thin skin, nutritional difficulties causing delayed wound healing, and the tendency for CSF to be proteinaceous. Plastic hardware items such as shunts are particularly susceptible to infection, because a small pathogen inoculation, even with a relatively nonpathogenic bacterium, can avoid normal immune surveillance. In several series, the rate of infection correlated significantly with patient's age and often with little else (27).

Another complication of VP shunting sometimes seen in infants, although rarely seen in older individuals, is injury to bowel or other abdominal viscera (28). This is a result of the fragility of these tissues. In addition, migration of the catheter within the infant resulting in penetration into the pleural cavity (Fig. 51-4) has been seen. Migration of ventriculoatrial shunts further into the heart has also been documented (29).

Especially with very large ventricles, rapid decompression of the ventricular system can cause bleeding into the subdural space, ventricles, or parenchyma of the brain. For this reason, only moderate amounts of CSF are typically removed at the time of surgery, and patients are kept flat for the immediate postoperative period, with the elevation of the head titrated gradually based on assessment of the anterior fontanelle. The head can be raised as long as there is not extreme concavity or "ashtray deformity" of the fontanelle. Other authors have suggested the use of higher-pressure valves with very large ventricles (30).

An additional degree of freedom in management of hydrocephalus has come from the introduction of adjustable valves. These valves have a magnetic rotor that changes the tension on a tiny spring in the valve, thus changing the effective opening pressure of the valve. With such valves, clinicians can "try on" specific valve characteristics without having to surgically revise the valve. Drawbacks include a higher price to purchase the valves, and the possibility of the settings changing with exposure to the strong magnetic field of an MRI scanner. Each individual valve design has a different protocol for ensuring that the setting is as intended; these protocols are well documented in the package inserts from the manufacturers (31).

Ventricular asymmetry occurs with relative frequency. This can be minimized by deliberate placement of catheters across the midline, so that openings on either side of the septum can drain bilateral ventricles (32). Spontaneous resolution of ventricular asymmetry sometimes occurs and therefore, in the absence of an associated asymmetric physical examination, ventricular asymmetry can generally be tolerated with close observation.

P.1416

P.1417

Intracranial Cystic Spaces in the Neonate

Interhemispheric, temporal fossa, posterior fossa, and other arachnoid cysts can frequently complicate the treatment of hydrocephalus. There are a variety of techniques for dealing with these entities, including fenestration using either open technique or ventriculoscopy, direct shunting of the cyst, or combined shunting of the cyst and ventricle. Interhemispheric cysts can become quite large, and large arachnoid cysts generally require treatment. Fenestration of the cyst may be the best way to avoid the need for an additional catheter (33). Large interhemispheric cysts can be confused with lobar holoprosencephaly, a diagnosis that confers a considerably worse neurologic prognosis. Frequently, these require placement of a shunt catheter in the cyst, rather than in the ventricle (Fig. 51-5) (34). Dilation of the isolated fourth ventricle is a particularly difficult surgical problem, both because the posterior fossa is a somewhat more technically difficult area into which to place a catheter that will continue to work over a long period of time, and because the neurologic risks are quite high if the catheter draining such a cyst has even a transient failure. This can result in emergent brainstem symptoms, such as apnea and bradycardia. The risks of fourth ventricular cysts and specific placement of shunts into the cysts to drain them have been documented in several reports (35,36).

MANAGEMENT OF THE INFANT WITH AN OPEN DEFECT OF THE NEURAL AXIS

Abnormal developmental folding of the neural tube and anterior neuropore can result in a wide spectrum of abnormalities. The most benign presentation is spina bifida occulta, a bifid spinal arch seen in up to 30% of the general population with no neurologic sequelae. The most severe presentation is anencephaly or craniospinal raschisis, complete absence of neural-tube closure.

The general guideline is to defer urgent repair of these defects if they are small and truly skin covered, i.e., lipomyelomeningocele. Open defects, such as myelomeningocele, or defects that leak CSF or interfere with airway patency, such as large nasofrontal encephaloceles,

P.1418

require repair within a few days of birth. Infants with enlarging lesions such as occipital encephaloceles are often managed most safely with close observation until they achieve adequate weight to minimize surgical risks.

Figure 51-4 Example of an unusual infection-related shunt complication to placement at a very early age—erosion through the chest wall into the pleural cavity. **A, B:** This ventriculoperitoneal shunt was placed in a 1,300-g neonate after treatment of posthemorrhagic hydrocephalous with a ventricular access device and serial taps. Several months later, an umbilical hernia appeared to enlarge, and plain radiographs were obtained of the abdomen. The loops of shunt tubing, which had already migrated into the chest cavity, were not appreciated at that point. Panel **(C)** was obtained only 3 days prior to panel **(D)**. The patient was discharged and returned with a suddenly sunken anterior fontanelle and diminished breath sounds on the right. A plain x-ray demonstrated migration of the shunt tubing into the right pleural cavity **(D)**. The fluid in the chest proved to be purulent. A functioning shunt ultimately was replaced in the peritoneum after removal of hardware, external drainage, and treatment with antibiotics. Presumably a distal catheter infection, although the infant did not present with sepsis, resulted in fluid along the shunt, which erupted into the pleural space, allowing the tubing to retract and coil there with movement of the patient.

Neurosurgeons frequently are called upon to evaluate a variety of midline “lumps, bumps, and dimples” along the neural axis from nose to coccyx (Figs. 51-6, 51-7, and 51-8). These lesions often represent myelodysplasia that will require repair. However, in the stable newborn, evaluation and treatment can be deferred until after 3 months of age when surgical intervention is medically safer. Even MRI evaluation can be deferred until that time to obtain a technically superior study. Head and spine ultrasound are useful in the neonatal period for screening these lesions, but a high false-negative rate has been noted. The MRI scan remains the gold standard for preoperative planning of these occult lesions.

Myelomeningocele

Antenatal diagnosis has markedly changed the management of patients with myelomeningoceles. The vast majority of patients with this deformity are diagnosed prenatally on the basis of an elevated serum alpha-fetoprotein, generally followed by an ultrasound study and sometimes an antenatal MRI scan (37,38). Delivery of patients with myelomeningocele by cesarean section prior to labor may improve the functional outcome relative to the anatomic level of the myelomeningocele (39). Elective cesarean section for such patients is recommended as soon as the fetal lungs are known to be sufficiently mature. The technical considerations have been well outlined (40). Because of the associated type II Chiari malformation, as well as some potential obstruction to CSF flow around the incisura and subarachnoid space, more than 90% of these patients require placement of a VP shunt. Most commonly, the shunt does not have to be placed at the time of the initial closure. Placement of the VP shunt can be delayed for at least several days so that the CSF coming in contact with the shunt has not recently had access to the open defect. In some series, the patients with myelomeningocele manifested high incidences of shunt malfunction within the first year, some in excess of 40% (40). In general, the more severe the ventricular dilatation, the higher the incidence of complications, which also may be a measure of the degree of shunt dependence of individual patients.

Surgery for repair of a myelomeningocele has been well described (40,41). The goal of the surgery is to reconstruct the terminal end of the neuraxis and approximate the topologic relationships that would have occurred if closure of the neural tube had been complete. The neural placode itself is usually plainly visible beneath, or associated with, translucent abnormal tissue stretching from the edge of the skin defect inward to the small island of pinkish tissue, which represents the termination of the spinal cord. It is flat with a groove down the middle. With surgical dissection, it is found to have nerve roots projecting both ventrally through the remnants of the sacrum and lumbar bony elements, as well as some nerve roots projecting more aberrantly out into the soft tissue and skin. Because of the tendency of this placode tissue to dry out in the hours prior to closure, dressing with sterile gauze kept continuously moist with sterile saline is crucial. Antibiotics can be administered as prophylaxis against meningitis until the skin defect is closed.

Once in the operating room, the patient is handled and managed so as to avoid any further trauma to the placode. The patient is usually intubated in the lateral or supine position, with padding very carefully arranged to avoid any pressure on the meningocele sac or placode.

The dissection begins with a circumferential division of the abnormal, thinly epithelialized translucent tissue, which joins the placode to the surrounding skin. The surgeon must carefully remove from the space any remaining dermal elements that may end up inside the dura. Such elements later can cause dermoid tumors that require resection and chronic inflammatory conditions that make later spinal cord untethering difficult.

The tissue of the placode itself is trimmed. Magnification with operating loupes or operating microscope is extremely helpful in preserving all of the neural tissue but

removing any possible dermal remnant. The placode then can be rolled into a tubular structure if its shape permits, anchoring pia to pia using very fine sutures. It is important at this stage of the procedure to examine both above and below the placode for other intraspinal pathology, such as a fatty filum or diastematomyelia. Sometimes removal of one lumbar lamina above the area of exposure is necessary to permit full exploration.

Figure 51-5 Intracranial cysts in the neonate. **A:** Coronal ultrasonography of a suprasellar cyst in a newborn. **B, C:** An intrahemispheric cyst may mimic fluid collection in the posterior fossa, allowing it to be confused with Dandy-Walker malformations. This patient was born with a very severe craniomegaly and compression of brain tissue, and ultimately required a catheter in both the cystic space and residual ventricular system. With these two catheters, the brain configuration eventually returned much more to normal (**D**), and the patient has had normal developmental milestones subsequently.

Figure 51-6 Dermoid cyst. External view (A) and lateral topogram (B) of dermoid cyst arising from the anterior fontanelle. The lesion had eroded the bone around the fontanelle but was removed easily in its entirety.

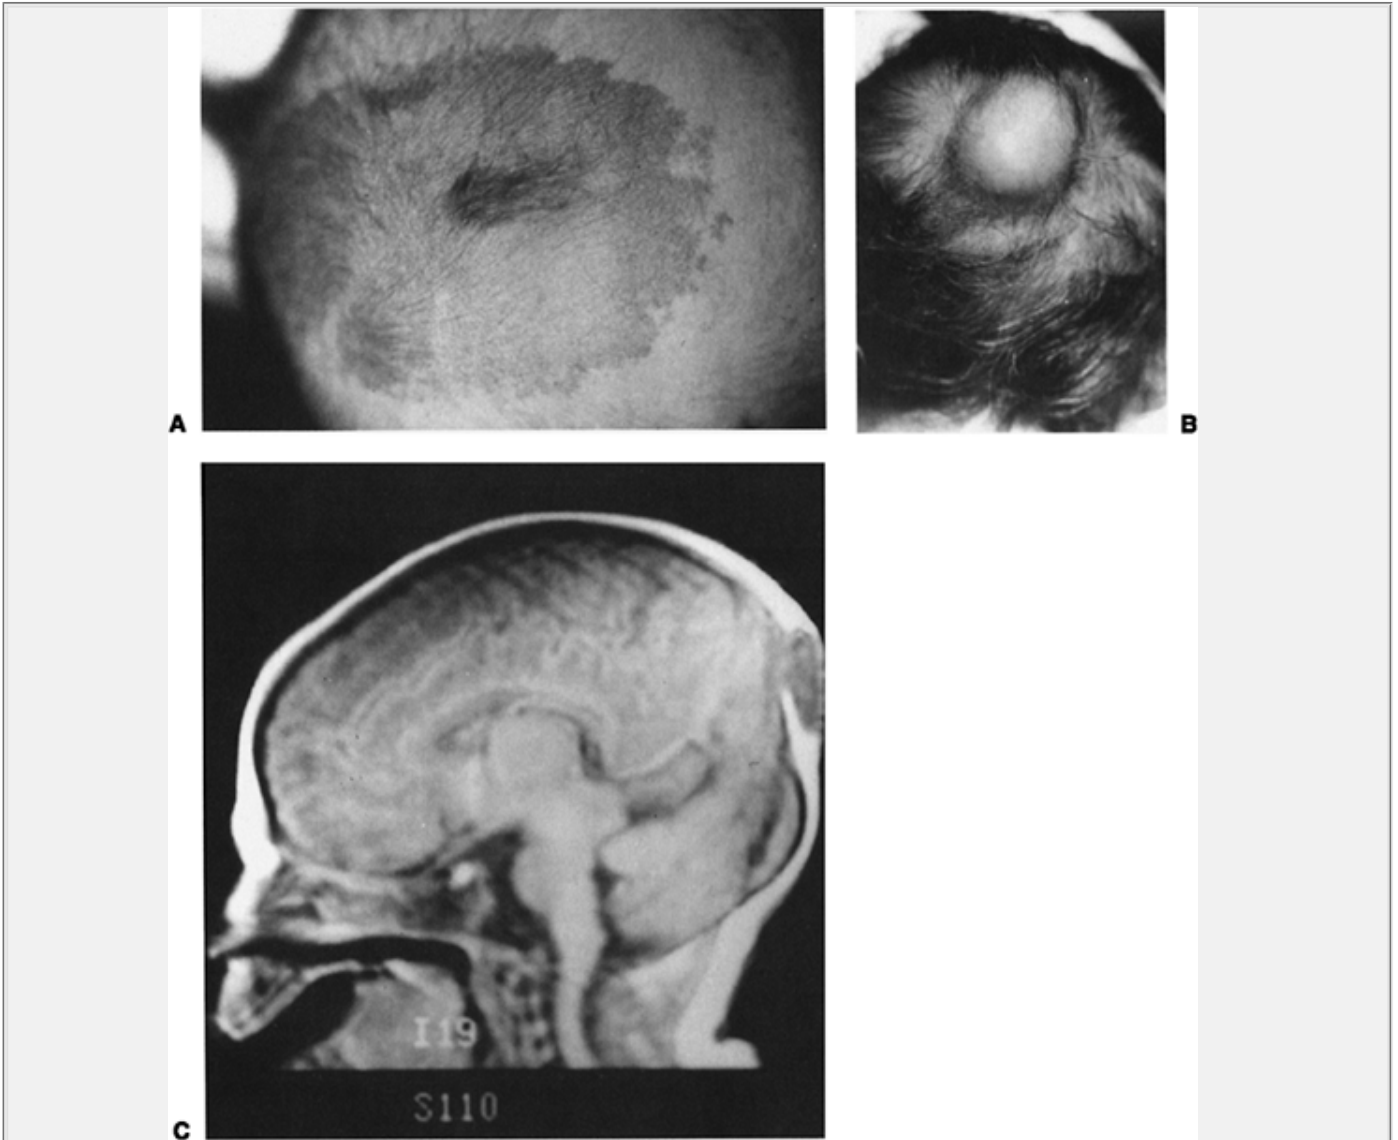

Figure 51-7 A: A small hairy patch with surrounding discolored skin noted at birth in the midline occipitally. On exploration, this lesion proved to be a small encephalocele. B: A larger occipital encephalocele without a hairy covering was detected easily at birth. C: Magnetic resonance scanning of the lesion seen in (B) demonstrates the brain tissue outside the confines of the skull as well as anomalous hindbrain anatomy.

Spinal Dysraphism Other Than Myelomeningocele

Although myelomeningocele is the easiest spinal cord defect to identify, the diagnosis of tethered cord syndrome, spinal lipomas, or other related closed malformations can be made in the newborn period. In general, patients who have hemangiomas, hairy patches, fatty lumps, or deep sinus tracts in the area of the lumbosacral spine deserve investigation within the first few months of life. Spinal ultrasound can be an excellent screening test for determining the level of the conus medullaris, as well as the respiratory excursions of the nerve roots. Ultrasound is also useful in cases of dimples without any other associated findings. As mentioned previously, in the absence of a truly open defect or draining sinus that increases the risk of meningitis or other infection, there is no urgent need to surgically correct these deformities. To diminish the risk of surgical complication, elective repair of tethered spinal cords is typically delayed until the patient is at least 3 months old. Urodynamic

P.1420

evaluation with electromyographic studies of sphincter function can be useful in comparing the preoperative to postoperative bladder functions in patients too young to be toilet trained. An MRI is extremely useful, preferably obtained at several months of age, shortly before surgery, when the characteristics of the tissue allow better anatomic definition of structures. It is now a generally recommended pediatric neurosurgical practice that all

tethered spinal cords be untethered at a relatively early age to prevent the neurologic deterioration that may occur later in life.

Figure 51-8 **A:** This small sacral dimple, with encircling reddened patch, was noted at birth. At surgery, it was found to be a dermal sinus tract into the spinal cord. The gluteal cleft is seen below. **B:** This skin-covered lesion noted at birth was found to be an anatomically identifiable myelomeningocele with intact placode and associated meningocele sac. The child had no neurologic deficits at birth. **C:** The skin tag being held up at the cervical area was noted at birth but not referred for evaluation until 3 months of life. Upon surgical exploration, a dermal sinus tract was identified and followed directly into the central canal of the spinal cord. The child had no pre- or postoperative neurologic deficits.

Encephaloceles

The cranial analogue of the open myelomeningocele is the encephalocele (Fig. 51-9). Clinically, these vary from small lesions that may cause relatively little disruption of brain structure to large lesions with massive amounts of brain tissue extruded through the cranial opening. Again, the availability of ultrasound and MRI scanning antenatally has allowed improvements in the planning and advice given to prospective parents of babies with these problems. As with open myelomeningocele defects, open cranial

defects require acute closure, generally within 24 hours of birth, to minimize the risk of meningitis. Closed

lesions can be managed in a variety of ways. If the lesion is large or enlarging, or could potentially cause airway obstruction, early repair is required. As with occult spinal dysraphic states, repair of small lesions can be deferred until radiologic imaging quality is maximized and surgical risks are minimized.

Figure 51-9 Encephaloceles, or open defects of the cranial end of the neuraxis, span a broad range of clinical presentations. A frontal encephalocele with a large extrusion of brain tissue frontally. This was demonstrated on an antenatal magnetic resonance imaging scan (**A**), which accurately predicted the appearance of the mass at birth (**B**). A smaller occipital encephalocele (**C**) had much less central nervous system tissue within it and was almost entirely cystic. This required a skull reconstruction to patch the cranial defect (**D, E**), which healed without any bony defects 1 year after surgery in a neurologically normal child.

P.1422

The surgical repair of an encephalocele is very much analogous to myelomeningocele repair. The encephalocele sac is entered and explored for nervous tissue. Generally, extracranial tissue is truncated and discarded because it is nonfunctional. The remainder of the repair is devoted to reconstructing a barrier between brain and subcutaneous tissue by repairing the dural lining and forming a reinforced barrier to CSF leakage through the skin.

The normal skin around the margin of the encephalocele is inspected and trimmed to yield a skin edge that eventually can be closed. There is typically a defect in the cranium as well as in the normal dura. As with myelomeningoceles, there is usually a gradual change from normal tissue to abnormal scar tissue around the edges of the lesion. If the encephalocele is quite large, it is often essentially pedunculated glial material, and it becomes necessary to amputate the excess neural tissue to allow any possibility of a closure. The edges of relatively normal dura are identified and then either closed primarily or with a patched graft, which can be taken

from pericranium in some cases, or commercially available dural substitute materials can be used. After a watertight seal is created, the scalp over the dural closure is approximated. In some cases, relaxing incisions or rotational flaps have to be made to allow for a satisfactory closure. Postoperatively, the patient must be carefully observed for the development of symptomatic hydrocephalus, which may have been masked by a gradual leakage of fluid out of the encephalocele. Some encephalocele patients require shunts, but the majority do not.

Children born with encephaloceles, either frontal or occipital, have variable outcomes. In general, frontal nasal encephaloceles that involve the frontal cortex or are purely fluid filled can be resected and repaired with good neurologic and cosmetic outcome. A high percentage of these children will go on to have normal cognitive function. Hydrocephalus is common but certainly not the rule in these children. Occipital encephaloceles, particularly those that involve a significant amount of herniated brain tissue, are predictive of a less robust cognitive outcome. These children have a very high rate of hydrocephalus and often will grow to have developmental delay and other cognitive difficulties.

REMOVAL OF EXCESS INTRACRANIAL MASS

An increase in the contents of the cranial vault can be due to sources other than CSF accumulation. Head trauma and congenital CNS tumors are pathophysiologic categories that cause an increase in intracranial contents that are amenable to neurosurgical intervention. Regardless of the etiology, excess intracranial mass may not present with neurologic symptoms because of the distensibility of the neonatal skull. The fontanelle provides the capacity for constant monitoring of intracranial pressure.

Head Trauma in the Neonate

Mechanical injury to the CNS or peripheral nervous system in the neonate generally is a result of conditions immediately surrounding birth itself. These injuries are dramatically less frequent than they were only a decade or two ago, largely because of improvements in monitoring and imaging that have improved the overall level of obstetric care. The true incidence of head trauma is unknown (42,43) because clinically insignificant injuries are rarely diagnosed. Among diagnosed cases of neonatal head trauma, one in twenty is fatal. Isolated spinal cord or brainstem injury has been observed in 3% to 10% of neonatal autopsies (44).

Extracranial injuries resulting in blood collections in the neonate can be important because of the low circulating blood volume and relatively large capacity for sequestration of blood in infants of this size. An important example is subgaleal hemorrhage, where dramatic blood loss can occur because blood collects below the galea and, therefore, is not bounded by suture lines. Occasionally, these require aspiration of nonclotted blood. Coagulopathies should be excluded.

Cephalohematoma is the collection of blood below the pericranium of the outer surface of the skull. It does not cross suture lines, is unilateral, and is almost always over parietal areas. These clots resolve spontaneously over time. Because these hemorrhages are generally self-limited, the clots are usually not aspirated to avoid the risk of introducing infection. Neurosurgical intervention is largely limited to the occasional cephalohematoma that calcifies and causes an obvious cosmetic deformity.

In the majority of cephalohematomas, there is probably an underlying skull fracture which is never formally diagnosed and reduces spontaneously. These minimally depressed, "ping pong" fractures generally involve the parietal bones. If they do not reduce spontaneously, they can either be elevated by a limited and careful digital manipulation or can be surgically reduced with a very simple procedure in which an instrument is passed through a small hole below the fracture to pop it back into place.

Leptomeningeal cysts, also called growing skull fractures, are usually the result of an underlying brain injury and failure of normal CSF reabsorption, with communication of the leptomeninges through the subarachnoid space. Most frequently, they communicate with the ventricular system through a porencephalic cyst and may be associated with hydrocephalus. In cases of more significant brain injury, it is important to identify these lesions to effect primary closure of the dura, or at least to follow these children closely to ensure that hydrocephalus does not develop.

Although they only rarely require surgical exploration or treatment, the full range of intracranial injuries can occur in the neonate: epidural, subdural, subarachnoid, and parenchymal hemorrhages. An important sign frequently seen on scans is the accumulation of blood within the leaves of the tentorium, which may mimic a tentorial subdural hematoma. It is important to identify this condition because

it may look quite dramatic on computed tomographic scan, but surgical exploration can lead to disastrous, uncontrolled bleeding, essentially from the communication of this intradural space with the sinuses. The distensibility of the head and the open sutures and fontanelle provides the neurosurgeon with unique, direct access to the intracranial space. The newborn's head allows for percutaneous aspiration of subdural hematoma or intraparenchymal clot, in a fashion impossible in older children. In many cases, percutaneous aspiration of subdural clot is the procedure of choice for the injured neonate (45).

Spinal Cord Injury

Ligaments are generally lax in the pediatric patient, and in the newborn particularly. However, it is possible to stretch the spinal cord beyond its elastic capacity to the point of injury. Though some patients recover with no observable abnormalities, others will suffer permanent nerve damage that can cause neurologic syndromes with pathophysiologic correlation with the involved nerves. High cervical injury will result in quadriplegia. An extensive lesion of the lower cervical cord would be expected to cause partial dysfunction in the upper extremities, impaired diaphragmatic movement, and paraplegia. The presence or absence of Horner syndrome (failure of sympathetic innervation to the pupil and face on one side) can be an important clue to the structural integrity of the roots emerging from the cervical spinal cord.

Congenital Tumors of the Central Nervous System

There are several types of congenital CNS tumors (Fig. 51-10), all of which are rare. These tumors demonstrate biologic behavior depending on their location and histology (46). Important types of tumors include choroid plexus papillomas (47), teratomas (48,49), and anaplastic lesions such as astrocytomas (50), glioblastomas (51), primary neuroblastomas (52), and astroblastomas (53). Even asymptomatic antenatal tumors have been noted, with one very large intracranial teratoma that caused maternal pain (54).

Although these tumors are extraordinarily rare, their diagnosis is generally rather straightforward because the masses themselves may show up on antenatal ultrasound or postnatal ultrasound obtained to evaluate macrocranium. The initial management of the tumor almost always is neurosurgical, requiring biopsy and generally decompression of tissue, to establish diagnosis and prognosis, as well as to initiate therapy.

OPENING PREMATURE FUSIONS IN THE NEONATE

Craniofacial Anomalies

With the exception of severe synostosis of all of the sutures (Fig. 51-11), treatment of craniosynostosis is aimed at allowing development of a more cosmetically acceptable spherically shaped skull. It has minimal or no effect on ultimate neurologic outcome. Generally, the earlier synostosis is treated, the less severe is the surgery. The most common isolated synostosis is sagittal synostosis (Fig. 51-2), which produces a long, narrow cranium, often with a ridge and characteristic lack of movement in the sagittal suture on physical examination. A variety of procedures have been proposed for this condition, but a wide sagittal craniectomy is favored, within the first few months of life. The rounding effect of brain growth is usually adequate for restoring excellent contours. For more complex deformities, particularly the syndromic categories of Crouzon, Apert, and Pfeiffer syndromes, all of which have associated abnormalities of the extremities and other congenital defects, treatment of the brachycephaly is usually deferred for several months beyond the neonatal period so that a more definitive and planned craniofacial approach can be taken, if necessary, with frontal advancement and orbital reshaping.

Figure 51-10 Congenital tumors are quite rare, and actual diagnosis during the neonatal period is particularly unusual. This patient proved to have a choroid plexus papilloma, which presented at 4 months of age with a large mass and growing head circumference, although it almost surely was present at birth.

Treatment of the kleeblattschädel, or cloverleaf deformity, when all sutures are congenitally closed, is the only craniosynostotic syndrome requiring treatment in the neonatal period. Such multisuture synostosis requires early craniectomy, which may involve almost complete removal of the cranial vault to allow early growth. It generally requires one or more frontal advancements, starting several months later, to achieve an acceptable cranial shape.

A

Figure 51-11 Closed sutures. Cranial synostosis is a condition that usually is managed several months after birth, but certain conditions, such as kleeblattschädel (**A, B**), require earlier decompression to diminish the risk of increased intracranial pressure.

P.1424

CEREBROVASCULAR ANOMALIES OF THE NEWBORN

Although adult-type aneurysms have been demonstrated in children and even newborns, the most common vascular lesions are arteriovenous malformations (55). The characteristic neonatal presentation of an arteriovenous malformation derives from its deep drainage into the vein of Galen system. It can cause a very large dilatation of the vein of Galen, called a vein of Galen aneurysm. Such lesions frequently present as high output cardiac failure in the neonate, due to the very high flow shunting that occurs. These lesions have an extremely high mortality regardless of interventional efforts. However, there are many lesions with less extensive flow that are amendable to postnatal interventional angiographic techniques to occlude a fistula. The arteriovenous malformations themselves may be identified and respond to resection. Some of these patients do quite well (56).

The angiographic diagnosis and interventional radiographic treatment of arteriovenous malformations, fistulas, and other associated lesions in the neonate have been extensively described (56). These lesions can be subgrouped according to the morphology of the channels comprised (e.g., venous vs. arteriovenous), flow characteristics (low vs. high), and location (galenic, parenchymal, pial, or dural). Antenatal diagnosis has significantly altered the thinking about some of these lesions (56). For high-flow lesions, the flow itself becomes the major symptom, with systemic signs of high-output cardiac state and, in severe cases, cardiac failure with multiple organ dysfunction. Smaller lesions with lower flow may present as macrocephaly and hydrocephalus related to the increased venous pressure and subsequent functional diminution in absorption of CSF. Furthermore, progressive cerebral atrophy may develop.

Vein of Galen aneurysms are believed to occur between 6 and 11 weeks of gestation as a result of arterial communications with the embryologic precursor of the vein of Galen. Circularly, the aneurysm itself becomes symptomatic of the venous hypertension, which results from the abnormal communication.

Transcatheter occlusion of galenic arteriovenous shunts can be accomplished by either a transarterial or transvenous route. Although the transarterial modality is preferred by many endovascular centers, a transvenous approach involving access to the venous drainage by transtorcular, transfemoral, or transjugular catheterization can result in subtotal occlusion of the venous drainage, thereby reducing the shunt volume and cardiac failure. Ultimate cure by thrombosis can potentially be seen in either type of therapy. In cases of severe cardiac failure, however, the cardiac prognosis is poor enough that the outcome is guarded. If possible, these patients should be managed in centers where interventional radiology is available. Antenatal diagnosis makes such postnatal evaluation considerably more feasible.

The management of other arteriovenous malformations and fistulas independent of the vein of Galen also can be undertaken with endovascular or open surgical treatment.

PROGNOSIS AND LONG-TERM OUTLOOK FOR THE NEUROSURGICAL NEONATE

An understanding of the long-term prognosis after any particular type of abnormality is crucial for planning and evaluating therapeutic strategies and for counseling the parents.

P.1425

Unfortunately, these weighty decisions must be based on general guidelines that are often not predictive for an individual baby. du Plessis and Volpe (57) have outlined a rational sequence of considerations to use when discussing prognosis in these cases. They emphasize the importance of establishing the etiology of a disease process as the most important predictor. Thus, a particular degree of ventriculomegaly may be associated with a significantly worse cognitive prognosis in Dandy-Walker malformation or aqueductal stenosis than in myelomeningocele or communicating PHH. Such differences can be understood on the basis of major

contributions from associated cerebral dysgenesis, earlier called the microanatomic malformations or “wiring” abnormalities. In addition, hydrocephalus resulting from infection will depend, to a very large degree, on the nature of the infection at the cellular level. This will be more predictive of developmental outcome than the degree of secondary ventriculomegaly. From the neurosurgical point of view, it is important to separate the portion of projected disability that is based on hydrodynamic or other neurosurgically solvable problems from that which is intrinsic to the neurons themselves and not remediable by the neurosurgeon. In counseling parents, this distinction should be made quite explicitly, and it should be stated that the disease process involves at least two types of processes: those that can be treated with neurosurgical intervention such as a shunt and those that the intervention will not alter. This enables the neurosurgeon to say, for example, that a shunt may be absolutely necessary to treat a particular infant's condition, but that it may not be sufficient to correct the overall neurologic problem. In effect, this defers part of the issue of prognosis back to the medical and neurologic teams, while enforcing the importance of the proposed neurosurgical intervention. Nevertheless, the general implications of recent literature on the outcome of patients with common neurosurgical conditions should be well understood by neurosurgeons and other clinicians involved at the time of this family counseling.

Figure 51-12 Sagittal synostosis, a far more common type of craniosynostosis, can be detected in the nursery and referred for neurosurgical intervention. Definitive treatment may be delayed for several months.

The outcome for infants with PHH is difficult to ascertain for several reasons. First, long term outcome data lags behind advances in neonatal, neurologic, and neurosurgical care such that the data quickly becomes obsolete. Next, this is a rare condition, making it best suited to multicenter analysis; however, there is also a fairly wide range of practice styles rendering these comparisons of limited value. Finally, these infants often have multiple comorbid complications of prematurity that have a more than additive impact on neurodevelopmental deficits. This makes the exact role of PHH and details of its treatment difficult to tease out.

That said, parents and physicians alike are anxious to understand the prognostic implications of PHH. Though prognosis varies widely by patient population, the majority (from 62% [58] to 88% [59]) of patients who require a temporary ventricular access device progress to need a permanent VP shunt. Direct complications of the temporary ventricular access device and VP shunt include infection (5% to 8%) (57,58,59) and occlusion (10% to 45%) (58,59), with overall shunt revision rates of approximately 1.5 per patient (60). Long-term neurodevelopment is determined less by shunt mechanics (60) than preexisting parenchymal injuries (58). Expectedly, “grade IV hemorrhage” (parenchymal bleeding), periventricular leukomalacia, shunt infection, and the need for multiple shunt revisions all predict a worse neurodevelopmental outcome (61). A recent study confirmed highly significant predictors for mortality and neurologic outcome on the factors that intuitively are consistent with clinical experience (62). Mortality was best predicted in this study by the extent of intracranial hemorrhage, number of shunt revisions, and birth weight, in that order, with a very high degree of statistic correlation. The grade of hemorrhage, birth weight, and presence of seizure activity were the most important determinants of motor outcome. The grade of hemorrhage itself proved to be the most important variable determining cognitive outcome, motor function, and seizure activity. Because appreciating the long-term outcome of these vulnerable patients is critical to therapeutic improvement, every effort must be made to obtain and interpret outcome data, despite the above difficulties. Clear communication between neurosurgeons and neonatologists will remain a cornerstone of treatment for these small patients.

Chapter 52

Orthopedics

William W. Robertson Jr.

The orthopedic or musculoskeletal examination is a significant part of the neonate evaluation. Normal variations in contour, size, relationships, and range of motion of joints are influenced by genetic factors and by position *in utero*. These normal variations must be distinguished from congenital anomalies and traumatic lesions. The basic principle, that the earlier appropriate treatment is started, the better the correction, makes it incumbent on those caring for the neonate to make an early diagnosis and obtain appropriate consultation promptly.

In current practice, musculoskeletal abnormalities may be detected in the prenatal examination of the fetus. Using ultrasound, conditions such as skeletal dysplasia, spinal malformations, limb length discrepancy, and clubfoot deformities can be detected with some accuracy (1,2,3,4). The neonatal examination is vital to the confirmation of such anomalies and to the completion of any prenatal counseling rendered for such problems.

PHYSICAL EXAMINATION

The clinician examines the musculoskeletal system first by inspection, looking for abnormalities in contour, size, and position and observing the spontaneous and reflex movements of the infant, and second by palpation and manipulation to determine whether there are abnormalities of passive motion. This is followed by stimulation, where indicated, so that active motion can be noted. All observations include comparisons between opposite extremities. A routine for examining a newborn should be developed so that each examination will be complete. This routine may vary among physicians, but each part of the musculoskeletal system should be examined systematically.

Head and Neck

The neck is examined passively for rotation, lateral flexion, anterior flexion, and extension. Rotation of 80 degrees and lateral flexion of 40 degrees should be present in a full-term infant. Both these motions are normally symmetric to the right and left. Extension and flexion are difficult to measure, but in flexion the chin should touch or nearly touch the chest wall. Extension should be at least 45 degrees from neutral. When rotation or lateral flexion is asymmetric or when motion is limited, radiographs of the neck should be made.

Upper Extremities

The clavicle and shoulder girdle, including the scapula and proximal humerus, elbow, forearm, and hand, are inspected and palpated, with any anomalies in contour, size, and postural attitudes noted. Range of motion of the shoulder girdle is evaluated. Normal flexion and abduction of the shoulder are 175 to 180 degrees. Extension, internal rotation, and external rotation of the shoulder should be at least 25 degrees, 80 degrees, and 45 degrees, respectively.

The elbow is inspected next, and its motion is evaluated. Normally the newborn's elbow lacks 10 to 15 degrees from going to full extension and flexes 145 degrees. The forearm should pronate and supinate at least 80 degrees. Limitation of these two motions can be missed easily. Supination and pronation are tested by holding the humerus at the side of the trunk with the elbow held flexed 90 degrees with one hand while checking supination and pronation with the other. The wrist flexes 75 to 80 degrees and extends 65 to 75 degrees. The normally clenched fist of the newborn should have full passive extension of the thumb and all fingers. Active finger extension may be elicited, if necessary, by a pinprick to the palm. Extension should be to 0 degrees at the metacarpophalangeal joint, but active extension of the interphalangeal joint usually lacks 5 to 15 degrees from going to 0.

Spine

In the newborn, congenital anomalies of the spine are not readily detectable on physical examination; however, gross anomalies frequently can be recognized by inspection of the spine. Passive flexion and extension and

lateral bending of the spine should show smooth contours. Lateral flexion may be slightly asymmetric, secondary to position *in utero*. A hairy tuft, cutaneous vascular pattern, or lipomatous mass may signal underlying axial anomalies.

Lower Extremities

The lower extremities are observed for symmetry and variations in contour, position, and size. The hips of a newborn should flex 145 degrees and generally have flexion contractures, as shown by the Thomas test. This test is performed by fully flexing the infant's hips, and then extending the hip being tested while holding the opposite hip in flexion to lock the pelvis. The number of degrees that the extended thigh lacks from going to 0-degree extension is the degree of flexion contracture present in that hip. It is normal for the term newborn to have a 25- to 30-degree flexion contracture. The hip flexion contracture gradually diminishes during the first 12 weeks after birth, but occasionally will be present longer than 3 months. When hip extension is asymmetric, the more extended hip may be unstable. The stability of the hip always must be evaluated by an Ortolani test (Fig. 52-1A) or the oppositely directed provocative Barlow test (Fig. 52-1B). When there is a difference in the extension of the hips or a positive Ortolani or Barlow test, additional evaluation of the hip by radiography or, preferably, sonography is indicated. The timing of this imaging is discussed later in this chapter.

Internal and external rotation of the newborn's hip should range between 40 and 80 degrees, abduction is between 45 and 75 degrees, and normal abduction is between 10 and 20 degrees. Any asymmetry of motion should be investigated to determine the cause.

Infants who were not in a frank breech fetal position generally will have a knee flexion contracture of 10 to 25 degrees, with additional ability to flex to 120 to 145 degrees. In those positioned in frank breech, the knees usually will hyperextend 10 to 15 degrees and have limitation of flexion.

Examination of the ankles and feet includes observation of resting positions and range of active motion, stimulated by stroking the sole and dorsal, medial, and lateral sides of the foot. The range of passive motion of the ankle in both dorsiflexion and plantarflexion varies depending on the fetal position. Dorsiflexion to above neutral should always be present. Plantarflexion of less than 10 degrees below neutral generally is abnormal. Abduction and adduction of the forefoot is at least 10 to 15 degrees, and the hindfoot has 5 to 10 degrees or more of motion in both varus and valgus.

MUSCULOSKELETAL ANOMALIES

It is not within the scope of this text to discuss all the congenital and acquired abnormalities of the musculoskeletal system seen in the neonate; this chapter does, however, cover most of the more common abnormalities.

Neck

Klippel-Feil syndrome is a defect in segmentation of the cervical vertebrae (5). There is both a decrease in the number of vertebrae and a fusion of two or more vertebrae. The neck appears shorter than normal, and motion is limited in all directions. The limitation of motion depends on the number of fused segments and frequently is asymmetric in both rotation and lateral flexion. The asymmetric motion may simulate muscular torticollis, but radiographic examination of the neck can confirm the presence of the Klippel-Feil deformity. Treatment started early, done several times a day, and consisting of passive stretching of the neck to improve rotation, lateral bending, and flexion-extension, may improve the range of motion of the neck.

Torticollis of the neonate may be one of several types. The typical muscular torticollis (Fig. 52-2A) involves a mass from an intramuscular hematoma that appears in the sternocleidomastoideus at 2 weeks of age and gradually disappears during the next 8 to 10 weeks. This mass may go unnoticed, and the torticollis unrecognized until there is facial asymmetry and limited motion of the neck. The physical findings of muscular torticollis are limited rotation of the neck toward the side of the lesion (Figs. 52-2B,C) and limited lateral flexion away from the lesion. In well-established, persistent torticollis, there is flattening of the maxillary and frontal bones on the side of the lesion and of the occiput on the opposite side. The asymmetry is not present in the newborn, but may become apparent as early as 2 or 3 weeks and is progressive until

the tightness is corrected. Torticollis associated with intrauterine deformation may be apparent at birth.

Figure 52-1 A Ortolani sign. The fingers are on the trochanter and the thumbs grip the femurs as shown. The femurs are lifted forward as the thighs are abducted. If the head is dislocated, it can be felt to reduce. **B:** Barlow maneuver. The thighs are adducted. If the head dislocates, it will be both felt and seen as it suddenly jerks over the acetabulum.

Figure 52-2 **A:** Congenital muscular torticollis. There is a fibrous mass in the right sternocleido-mastoideus muscle. **B:** Rotation toward the right is limited by the tightness in the right sternocleidomas- toideus muscle. **C:** Rotation toward the left is normal.

Initial treatment of muscular torticollis is by passive exercise and appropriate positioning of the infant in bed (6). The neck should be gently but firmly stretched four or five times each day toward the direction of limited

rotation and lateral flexion. Sandbags or some similar objects may be used to position the baby's head to prevent it from assuming the position that the tight muscle encourages.

There is a type of congenital torticollis that is associated with neither a mass in the sternocleidomastoideus nor cervical spine abnormalities. In these infants, there is a myostatic contracture of the sternocleidomastoideus, probably secondary to *in utero* position or compression. This type of torticollis often is associated with scoliosis and abductor contracture of one hip and adductor tightness of the opposite hip. The adducted hip may show acetabular dysplasia (Fig. 52-3). The abductor contracture may not be detectable until the normally present tightness of hip flexors has spontaneously diminished enough that the hip can be extended. Whereas this type of torticollis corrects with little or no treatment, the associated hip contractions require stretching. The tight hip abductor needs particular attention, with passive stretching and abduction devices such as multiple diaper layers. Rarely, the associated acetabular dysplasia progresses to dislocation.

Spine

Scoliosis

Congenital scoliosis is difficult to recognize at birth unless there is asymmetric movement, a cutaneous lesion (such as aplasia, dimple, dermal sinus tract, flat hemangioma, or hairy tuft), or a lipomatous mass. In the newborn infant, scoliosis is caused by an isolated defect in vertebral body

P.1431

formation or by failure of segmentation. There is little evidence that it is an inherited anomaly, except when it occurs as part of a genetically transmitted syndrome. Because of the cartilaginous nature of much of the spine at birth, only significant anomalies, such as hemivertebrae, can be diagnosed by plain x-ray. Ultrasound is a good alternative for evaluation of suspected cases when magnetic resonance imaging (MRI) is not indicated in the newborn (7,8). For the older infant with significant abnormalities, MRI evaluation is certainly indicated for determination of occult intraspinal pathology, including syringomyelia, diastematomyelia, and tethered cord (9). Because spinal orthoses seldom are of benefit, congenital scoliosis initially is followed only by observation. If a curve is progressive, spinal fusion will be needed and should be done before the curve becomes cosmetically or functionally significant (10). Fusion of a short segment, with or without excision of markedly abnormal bone segments, may be done as early as necessary. Congenital scoliosis is associated with a high incidence of cardiac and related genitourinary anomalies; therefore, the function and anatomy of the cardiovascular and genitourinary systems should be evaluated by MRI and ultrasonic techniques (11).

A

B

Figure 52-3 A: A 6-month-old infant with left torticollis, left scoliosis, right abductor contracture, and left adductor tightness. **B:** The right abductor and left adductor are tight.

Congenital kyphosis is a rarer condition that carries a higher risk of progression and the development of neurologic compromise (12). Certain types of deformity require surgical treatment before the age of 5 years (13).

Myelomeningocele

Diagnosis of a myelomeningocele generally poses little problem when there is a skin defect. Because the skin over myelomeningoceles is not always defective, any soft mass in or off the midline must be examined closely to determine its composition. Lipomata always have good skin coverage and tend to be off the midline.

The care of an infant born with myelomeningocele is complex and requires input from several specialties (see Chapter 51). It is important to determine immediately after birth the level of involvement by inspection of the back, careful examination of the muscle function of the lower extremities, and radiographic examination before surgical closure.

The most common abnormalities of the lower extremities associated with myelomeningocele are deformations of the feet, indicating lack of normal fetal muscle activity.

P.1432

Initial treatment of the deformed foot is with plaster cast correction, followed, if necessary, by surgical releases and transfer of muscle insertions to maintain the correction. These surgeries may be done at almost any age.

Gentle passive exercising and progressive splinting treat flexion or extension deformities of the knee. New splints need to be made frequently as the deformity improves.

Treatment of a dislocated hip in the patient with myelo-meningocele is controversial. There is general agreement that in those children with intact hip musculature, the dislocated hip, as in an otherwise normal newborn, reduces easily in flexion and abduction. For those lesions below L-2, hip abduction therapy helps in developing a more stable hip. The flexed, abducted, and externally rotated position achieved in a Pavlik harness should not be used when the lesion is above L-2 because this position may lead to development of contractures that prevent the hip from extending and adducting.

Infants with high lumbar or low thoracic myelomeningoceles have very high mortality and morbidity. The degree of disability correlates well with the level of defect, presence and degree of hydrocephalus, and presence of a bony kyphosis. A lesion above L-1 associated with hydrocephalus and kyphosis indicates, almost without exception, significant mental and motor disability.

Upper Extremities

Duplication and Reduction

Supernumerary parts, absence or reduction anomalies of the extremities, and segmentation defects of the limb should offer no problem in diagnosis. These orthopedic anomalies seldom need immediate attention, but they should be seen early by the orthopedist to plan appropriate therapy and discuss prognosis with the family. This is true for anomalies of both the upper and lower extremities.

Syndactylism, or fusion of any portion of two or more digits, is a common anomaly that is transmitted through an autosomal-dominant gene with varying expressivity. Surgical treatment should be within the first year, with timing dependent on the completeness of the syndactyly and the fingers involved. The thumb and index finger should be separated at 6 months of age, and the little and ring finger separated at 1 year. It is important to determine by radiography if there is a synostosis between fingers because this should be divided by 1 year of age. A delay in surgical separation in synostosis will result in a bowing of the longer finger due to differential

growth.

Polydactyly is correctable by surgery, with timing dependent on the extent of duplication. When the duplication does not contain bone or cartilage, it should be removed in infancy. When there is a question about function, surgical correction should be delayed until the degree of function present in each of the duplicated digits can be ascertained.

Absence of the radius, commonly called radial clubhand, is easily recognized (Fig. 52-4). The wrist and hand are deviated 90 degrees or more. Absence of the radius may be bilateral or unilateral, and the thumb may be present, absent, or hypoplastic. The clubhand is caused by damage to the apical ectoderm or deeper mesenchymal tissue of the limb bud (14). It is not genetically transmitted in the otherwise normal child, but it is associated with several genetically transmitted syndromes and frequently is accompanied by aplastic anemia. Early treatment by corrective splints may be sufficient to correct the radial deviation and prepare the extremity for surgery at a later date.

Figure 52-4 Congenital absence of the radius.

Congenital absence of the thumb occurs as an isolated anomaly or may be associated with a radial clubhand. When unilateral, little or no treatment is needed, but when the absence is bilateral, pollicization of the index finger of the dominant hand will improve function. When the thumb is rudimentary and nonfunctional, treatment is controversial.

In the extremities, congenital constriction band (Streeter) syndrome is diagnosed at birth by the presence of defects in the soft tissue underlying the skin (that is usually intact). This entity, possibly more accurately called early amnion rupture sequence, has been proposed as an etiologic factor in extremity, truncal, and facial abnormalities, including cleft lip/palate (15). In either the upper or lower extremity, a circumferential band can lead to vascular compromise of the distal part of the extremity (Fig. 52-5). The presentation is one of a visible constriction or, in more extreme cases, cyanosis or extreme edema in the portion of the extremity distal to the band. Surgical treatment to release the band or amputation in severely compromised extremities may be indicated at a relatively early age (16).

Shoulder Girdle

The Sprengel deformity of congenital elevated scapula is one of the more common congenital anomalies of the

P.1433

shoulder girdle. The deformity may be bilateral or unilateral, and usually it is associated with other abnormalities, such as Klippel-Feil syndrome, congenital anomalies of the upper thoracic vertebrae, or anomalies of the ribs. Asymmetry of the shoulders in unilateral involvement makes recognition easier. On palpation, the affected scapula is high and rotated outward and downward so that its vertebral border lies superiorly and more horizontally than normal. Shoulder abduction and flexion usually, but not always, are limited. The early, conservative treatment is passive range of motion. Surgical correction, at 3 to 4 years or up to 16 years of age, generally improves appearance and function, with the overall improvement from surgery better in the younger child.

Figure 52-5 Constricting band secondary to amniotic band disruption sequence.

Two congenital malformations of the clavicle are congenital pseudoarthrosis and congenital (partial or complete) absence of the clavicle. The physical signs on palpation of congenital pseudoarthrosis are angulation of the clavicle and a painless, bulbar mass in the midclavicular area (Fig. 52-6). The shoulder girdle is hypermobile, with motion in the clavicle at the pseudoarthrosis. Early treatment is not needed before surgical grafting of the defect at 3 to 4 years of age. Because the need for any intervention is controversial, therapy should be individualized. Congenital pseudoarthrosis of the clavicle can be differentiated from perinatal fracture of the clavicle by abundant callus formation in the healing fracture within 2 to 3 weeks after birth.

Partial or complete absence of the clavicle may be recognized by palpation and the presence of excessive scapulothoracic motion (Fig. 52-7). The completely absent clavicle usually is associated with cranial dysostosis or a widened pubic symphysis. There are no symptoms, and no treatment is needed in complete absence. With partial absence, the end of the clavicle may irritate the brachial plexus, necessitating excision of the fragment. Whereas congenital pseudoarthrosis tends to be an isolated anomaly, partial absence of the clavicle almost always accompanies an axial or appendageal skeletal anomaly.

Figure 52-6 A 2-year-old child with pseudoarthrosis of the right clavicle.

Defects of Limb Segmentation

limb segmentation. Elbow synostosis is easily recognized by the lack of motion and significantly smaller size of the affected extremity. Synostosis of the radius and ulna seldom is diagnosed in the nursery and commonly not diagnosed for several years. This is particularly true if the defect is bilateral because the child himself will not appreciate a difference in his arms. Supinating and pronating the forearm in the initial examination of the newborn should demonstrate this anomaly by lack of range of motion.

Figure 52-7 Partial absence of the right clavicle.

Lower Extremities

Feet

Metatarsus adductus (Fig. 52-8) may be either a positional deformity with no bony abnormality or a structural defect, and it is not always easy to distinguish between the two. The distinction becomes easier with time because a positional metatarsus adductus corrects fairly rapidly by passive exercises or even without treatment. A structural deformity does not spontaneously correct completely, becoming more rigid with time.

The differentiation between postural and structural metatarsus adductus is made primarily by physical examination. In structural metatarsus adductus (Fig. 52-8A), the base of the fifth metatarsus and cuboid are prominent, creating an impressive, well-defined skin crease on the medial side of the foot at the first metatarsal-cuneiform joint. In a positional metatarsus adductus, the lateral and medial borders of the foot are curved more gently than in the structural deformity. The most significant physical finding, however, is the presence or absence of rigidity of the forefoot, as determined by its resistance to abduction. In structural deformity, the forefoot usually cannot be abducted beyond the midline (Fig. 52-8B), whereas in positional deformity, the forefoot is more flexible and can be abducted (Fig. 52-8C). The heel of the structural metatarsus adductus foot usually is in valgus, and in positional deformity, it is likely to be in varus or at neutral. The valgus position of the hindfoot can be seen on clinical evaluation and, if necessary, confirmed by radiographic studies.

Treatment of the flexible positional deformity is either observation for spontaneous resolution, or passive stretching of the forefoot into abduction with the foot held as shown in Fig. 52-8B. Structural metatarsus adductus generally needs treatment with repeated cast changes. Surgical treatment may be necessary in the case of more severe structural abnormalities, such as a skew foot.

Talipes calcaneovalgus is not a structural deformity, but rather a reflection of the foot's position *in utero* (Fig. 52-9). The sole lies against the uterine wall, and the foot is dorsiflexed so that its dorsal skin lies against the anterior surface of the tibia. The fibula is prominent and appears to be dislocated posteriorly, being pushed backward by the excessive dorsiflexion. There is a depression over the sinus tarsi. The calcaneovalgus foot is flexible and passively plantarflexes

at least to neutral and, in most instances, to 5 to 10 degrees beyond neutral.

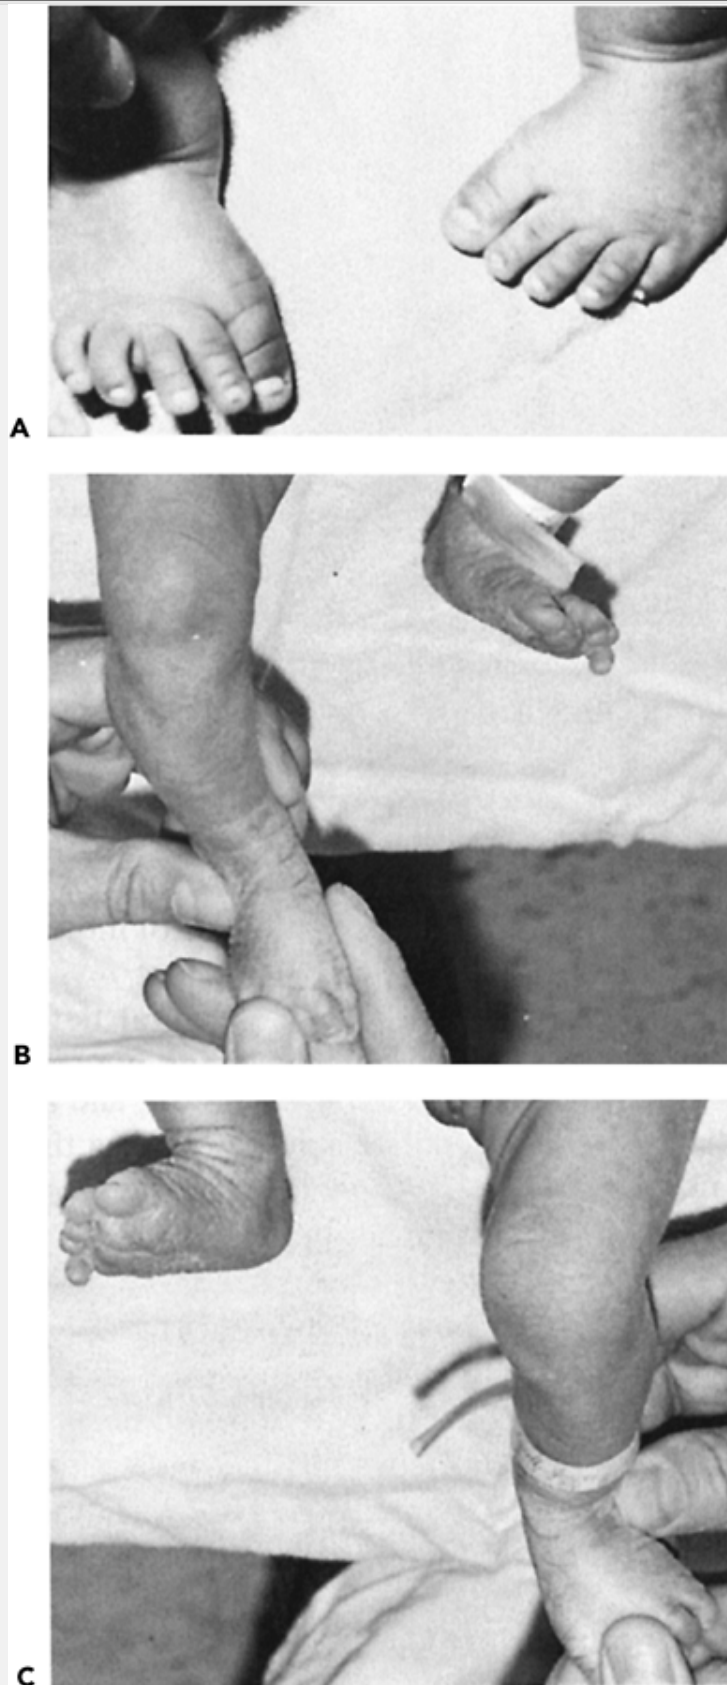

Figure 52-8 A: Structural metatarsus adductus. **B:** Structural metatarsus adductus. The forefoot does not abduct beyond neutral. **C:** Positional metatarsus. The forefoot abducts beyond the midline.

Figure 52-9 Talipes calcaneovalgus.

Treatment of the calcaneovalgus foot is by either passive exercises or corrective plaster cast, depending on the severity of the deformity. Mild cases are treated with exercises that stretch the foot into equinus and varus 15 to 20 times at four to five sessions daily.

The more severely resistant deformities, those that flex only to neutral plantarflexion, are treated by repeated applications of plaster casts for 8 weeks. Casts are changed as needed with growth, and, at each change, the foot is placed in equinus and varus with a mold placed in the arch to relax the plantar ligaments and posterior tibialis muscle. The goal of treatment is to obtain a plantarflexed varus position to allow the plantar ligaments and posterior tibialis tendon that have been stretched *in utero* to shorten.

It is important that the positional calcaneovalgus foot not be confused with congenital vertical talus, a rare but serious anomaly. In congenital vertical talus, the forefoot is dorsiflexed, and the hindfoot is in equinus (Fig. 52-10A). The talus is rigidly fixed in plantarflexion; if the examiner places one thumb on the talus and dorsiflexes and plantarflexes the foot with the other hand, the talus will remain almost stationary as the forefoot moves around it. The forefoot cannot be plantarflexed as much as the calcaneovalgus foot, and seldom can it be plantarflexed more than 5 degrees beyond neutral. A lateral radiographic examination of the foot (Fig. 52-10B) demonstrates the hindfoot equinus and forefoot dorsiflexion. With further dorsiflexion of the forefoot, the lateral radiographic examination (Fig. 52-10C) shows continued equinus of the calcaneus and talus. Serial casting rarely results in correction of this deformity. Although treatment will not create a normal foot, the results are far better when started in the first year of life.

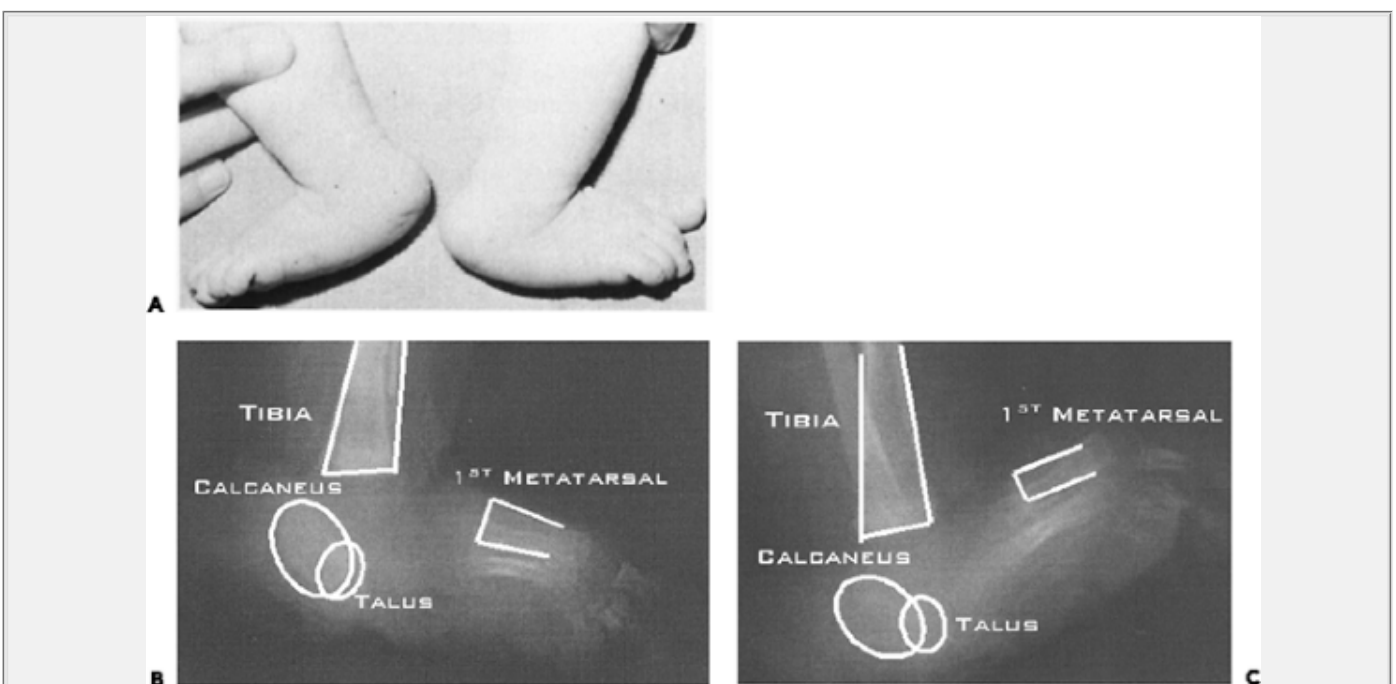

Figure 52-10 A: Flat foot secondary to congenital vertical talus. **B:** Lateral radiograph demonstrating equinus position of calcaneus and talus with dorsal subluxation of the forefoot. **C:** Lateral radio-graph with forefoot dorsiflexion demonstrating persistent equinus position of calcaneus and talus.

Figure 52-11 Talipes equinovarus foot (i.e., clubfoot).

P.1436

The classic clubfoot is a developmental anomaly of the entire foot (Fig. 52-11). There is varus of the hindfoot, varus and adduction of the forefoot, and equinus that is not apparent until the varus and adduction are corrected to neutral. This is a structural deformity and resists correction; it is easily recognized by its rigidity. There is a positional equinovarus foot that may resemble the true clubfoot, but it is flexible and can be corrected beyond neutral with little difficulty. Treatment of the structural clubfoot is by repeated manipulation and strapping or by manipulation and application of a cast (17). Although early treatment usually is instituted, no studies have demonstrated clearly the advantage of casting newborn as opposed to infants. When conservative measures are unsuccessful in correcting the foot, surgical correction is necessary (18).

Figure 52-12 Anterior bowed tibia.

Tibia and Fibula

Significant deformities of the tibia and fibula occur infrequently and are not difficult to detect. Congenital

absence of the tibia or fibula, congenital amputation, and congenital bowing all are easily recognized. When the tibia is absent, the foot is in varus; when the fibula is absent, the foot has an equinovalgus deformity. These deformities should be seen early by the orthopedist because conservative and supervised treatment of the foot deformities is indicated in some of these children, whereas early amputation is the treatment of choice in others. With newer techniques and knowledge of the biology of bone elongation, more of these limbs are being salvaged.

Anterior bowing of the tibia is a serious deformity (Fig. 52-12). The bone of the tibia is of poor quality, and in most cases, it either is sclerotic with partial or complete obliteration of the intermedullary space or has cystic areas that contain material similar to that in fibrous dysplasia. Pseudoarthrosis may be present at birth; it is always present following a fracture, which is likely within the first 2 years of life. Protection of the tibia by casts and braces is important and may be sufficient to prevent a fracture. Although the case shown in Fig. 52-12 is mild, there is a narrow intramedullary canal, and the bone needs protection for it is unlikely to heal should it fracture. There is no tendency for these cases of anterior bowing to improve spontaneously.

Conversely, a tibia that is posteriorly and medially bowed corrects spontaneously. The posterior-medial bowed tibia needs only to be observed, and any foot deformity treated with manipulation and splinting. There can be subsequent leg length discrepancy as a residual of this deformity (Fig. 52-13).

Most neonates have an inward or medial torsion of the leg distal to the knee and outward rotation above the knee. The medial torsion below the knee may occur in the knee, tibia, ankle, or combination of these, and, except in extreme cases, no treatment is necessary because alignment will improve progressively. The exception to this may be in relatively immobile, premature infants who lie in the same position most of the time.

Knee

Significant deformities of the knee are very rare. Genu recurvatum, a relatively frequent bilateral positional deformity associated with a frank breech position, is not serious and will respond to gentle exercising. The spectrum of knee recurvatum to subluxation or dislocation may reflect congenital hypotonia or Ehlers-Danlos syndrome in the newborn. Recurvatum must be differentiated from the more serious subluxation or dislocation of the knee. When there is doubt as to whether or not a recurvatum represents a subluxation or dislocation, a radiograph should be made. In subluxation, the tibia is forward on the femur but is not completely dislocated, whereas in dislocation, the tibia is completely anterior to the femur. In congenital dislocation, the knee can be hyperextended but not flexed beyond

P.1437

neutral, and the tibia is anteriorly displaced on palpation. Both subluxation and dislocation of the knee can be treated with early serial casting. Care must be taken to follow the reduction of the articular surfaces with imaging studies. The subluxed knee reduces with casting, but a dislocated knee may require open reduction.

Figure 52-13 A: Posterior-medial bowed tibia at 20 days of age. **B:** Marked spontaneous remodeling of posterior-medial bowed tibia at 4 months of age.

Unilateral, or more rarely bilateral, congenital fibrosis of part of the quadriceps is an anomaly that prevents knee flexion, causing a more extended posture than normal in neonates. Active and passive flexion is limited and seldom is more than 40 degrees. Treatment is by surgical excision of the fibrous mass.

Hip

Developmental Dysplasia of the Hip

The most common of the neonatal hip abnormalities is developmental dysplasia. This hip is embryologically normal, but as a result of mechanical forces *in utero* and maternal hormones that relax tissues in preparation for parturition, it is dislocated or dislocatable in the perinatal period. The less common type is a teratogenic hip that probably dislocates in the embryologic period of gestation and is associated with malformation of the pelvis and femur.

Developmental dysplasia of the hips occurs more frequently in female infants who present in breech position at term gestation and who have a positive family history. The dysplasia more often is unilateral with the left hip more frequently affected, but it may be bilateral.

In the newborn, the typical dislocated hip may not have the classically described signs of dislocation, such as asymmetric skin folds, limited abduction, and shorter-appearing femur (i.e., Galeazzi sign). These signs are secondary and may not develop until the end of 6 weeks of life as the dislocated hip migrates laterally and superiorly. The clinician diagnoses this condition in the newborn by demonstrating that the femoral head can be lifted into the acetabulum as the thigh is abducted in flexion (i.e., Ortolani maneuver; Fig. 52-1A) and that it dislocates as the hip is flexed, adducted, and pushed posteriorly (i.e., Barlow maneuver; Fig. 52-1B). The Ortolani test is positive in the dislocated hip until 6 to 8 weeks of age, and sometimes longer. In addition to feeling the dislocation as the thigh is adducted, the examiner should reduce the hip by abduction in flexion and, while maintaining the same degree of abduction, extend the thigh to dislocate the hip. In each instance, whether dislocation is obtained by adducting or extending the thigh, the examiner not only can feel the hip dislocate and relocate but also can see the sudden jerk that occurs as the femoral head rides in and out of the acetabulum.

Hip dislocation usually can be recognized clinically in the first few days of life. However, a large number of hips that are unstable at birth may become stable once the intrauterine environment, both positional and hormonal, is eliminated (19). Unstable hips most at risk for development of dysplasia are those with evidence of uterine packing problems (e.g., first born, breech presentation, torticollis, or metatarsus adductus), female gender, and a positive family history of hip dysplasia. The widespread use of hip ultrasound to evaluate and confirm hip dysplasia makes the quantification of the problem much easier. The question arises as to when to treat an abnormal hip. Some authors advocate the initiation of treatment as soon as any abnormality is discovered (20,21). Other authors feel that this approach may cause overtreatment of as many as one in three hips that would stabilize within 2 to 4 weeks after birth without treatment (22,23,24,25). Early treatment is easier on the family and child, with results that are far better than when treatment is started several months or years later.

Hip displacement almost always is reduced in flexion and abduction. The hip is usually, but not always, stable if held flexed 90 degrees or more and then abducted. In the newborn, radiographs of the hip are not necessarily diagnostic, although in some, the hip appears laterally displaced in the anteroposterior projection (Fig. 52-14).
Sonography,

P.1438

if well done, is the method of choice in the neonate, both to confirm the diagnosis of hip dysplasia and to follow the progress of acetabular development during treatment (26). The greatest advantage of the hip ultrasound is the ability to view the hip when it is stressed in a Barlow-like maneuver.

Figure 52-14 Bilateral congenital dislocation of the hip. The metaphyseal-acetabulum distance is wide.

When sonograms are not available, hip radiographs in both the anteroposterior and horizontal planes should be taken, with the infant in the splint to determine that the hip is held reduced. Rarely, the hip dislocates posteriorly in the splint but appears to be reduced in the anteroposterior view; only the horizontal view will show the dislocation in this instance.

The Pavlik harness is the splint of choice from birth to 6 months of age, but it must be applied properly. Excessive abduction from tight posterior straps can cause avascular necrosis (27).

All infants should have follow-up hip examinations at well-baby checks in the first 3 months. The Ortolani test may be positive for 6 to 12 weeks, but, more commonly, the late physical signs of dislocation are the following:

Asymmetric folds in unilateral dislocation

An apparent discrepancy of leg length caused by pelvic obliquity and a high-riding femoral head

High trochanter

Limited abduction

A palpable defect in the anterior groin where the femoral head normally lies

A piston or telescoping motion

These signs are sufficient to make the diagnosis, but sonography or radiography confirms it. After the development of the ossific nucleus of the femoral head (at 3 to 6 months), the ultrasound no longer is useful, so plain radiographic views are indicated to demonstrate hip displacement.

Developmental hip dislocation is probably the most important condition in the musculoskeletal system in which a delay in diagnosis and treatment has a profound effect on the outcome. The results of treatment in the neonate are far superior to those at any other time, so that special care in diagnosing this condition is warranted.

Teratologic Hip Dislocation

Teratogenic hip dislocation presents with different findings. The hip, which has dislocated early in fetal life, typically will not reduce by flexion and abduction because the femoral head is displaced proximally. Therefore, the Ortolani sign is not present in the teratogenic dislocation. If the dislocation is unilateral, there is asymmetry of abduction of the hips. The dislocated hip will have more extension than the opposite hip and may have limited rotation. When the dislocation is bilateral, the diagnosis is more difficult because there is no asymmetry. Abduction of both hips is limited, the thighs appear short in relation to the lower legs, and the perineum appears wider than normal. Although the diagnosis can be confirmed by ultrasound, plain radiographic examination is always abnormal in teratogenic hip dislocation.

Proximal Femoral Focal Deficiency

Proximal femoral focal deficiency is an anomaly of serious magnitude that may be either unilateral or bilateral. The degree of deficiency is variable and ranges from absence of the diaphysis, upper metaphysis, and femoral head to a very short femur, with coxa vara of the neck and head. It is not uncommon for the fibula to be absent and the foot deformed in the more severely affected infant with proximal femoral focal deficiency. The shortness of the femur is obvious on inspection. Motion of the hip may be limited. Early referral to the orthopedist, who will provide the definitive treatment, is important. Initial treatment may include stretching exercises, traction, or both for correction of contractures about the hip, although these have proven to be of limited value. Definitive surgical management depends on the potential for function in the extremity, and ranges from measures to correct leg length discrepancy to fusion of the knee and amputation of the foot to create a stump for an above-knee prosthesis.

P.1439

GENERALIZED MUSCULOSKELETAL ANOMALIES

The generalized musculoskeletal disorders/malformations are a diverse group of metabolic diseases and genetic syndromes, including more than 100 recognized forms of skeletal dysplasia (28). In the last 10 years, the classification of these disorders has moved from descriptions of physical and radiographic appearance to genetic etiologies (29). There is little to be done orthopedically for most of these syndromes, but when there is a correctable deformity, treatment should be initiated early.

Some of these entities, such as achondroplasia, chondroectodermal dysplasia (Ellis van Creveld disease), and epiphyseal dysostosis (diastrophic dwarfism), are recognizable at birth and are associated with dwarfism. Infants affected by many skeletal dysplasias or metabolic skeletal abnormalities, however, appear normal at birth, with the skeletal anomalies appearing later in infancy and childhood.

One generalized condition that may require orthopedic evaluation and intervention in the neonatal period is osteogenesis imperfecta. This spectrum of genetic syndromes is manifested by soft, fragile bone. If severe, it is very obvious at birth, but it may be mild enough to go undiagnosed until the child is several years old. Osteogenesis imperfecta involves primarily the skeleton but also affects the skin, ligaments, tendons, sclera, nose, ear, platelet function, and probably other systems (30).

The diagnosis of osteogenesis imperfecta is not difficult when there are multiple fractures, a very soft skull, paradoxical respirations indicating rib fractures, and bluish-gray sclera. For those who survive delivery, gentle handling to prevent additional injuries and skin traction to align the extremities are important considerations. Whether treated with traction, splinting, or observation, the fractures heal rapidly. An important key to the treatment of fractures of osteogenesis imperfecta is to avoid increasing bone fragility with prolonged immobilization.

Arthrogryposis multiplex congenita (Fig. 52-15) is an uncommon but easily recognizable syndrome of the musculoskeletal system. All four extremities and the trunk may be affected, or the abnormalities may be limited to the arms or legs. The hallmark of this entity is the lack of active and passive motion in the affected extremities.

The microscopic picture of the muscle in arthrogryposis shows changes of denervation and fibrofatty replacement. Secondary to the muscle weakness and dysfunction, there is distortion of the joints, as well as limitation of motion. Frequently, these infants have dislocation of the hips, knees, or radial heads, or combinations of the three. In addition, they may have either clubfeet or vertical talus, both of which are more resistant to treatment than those not associated with arthrogryposis. Treatment should begin in the nursery and is directed at increasing the motion of all affected joints by passive exercises done six to eight times each day. Joint dislocation and the hand and foot deformities should be treated early with appropriate plaster splints or casts, or with traction.

Figure 52-15 Arthrogyrosis multiplex congenita.

BIRTH FRACTURES

Long, difficult labor—particularly with a breech position, large infant, or fetal distress requiring rapid extraction—makes birth injuries in otherwise normal infants more likely. Birth fractures almost always involve clavicle, humerus, or femur. It is rare for birth fractures in a normal infant to occur below the elbow or below the knee. The fracture is more likely to be through either the diaphysis or epiphyseal plate, so that the epiphysis and epiphyseal plate are separated from the metaphysis. At times, the fractures are not noted because pain may be minimal and a deformity may not be apparent. Diagnosis in such cases is made incidental to a radiograph taken for unrelated indications.

P.1440

In other infants, the fracture is painful and is a cause of pseudoparalysis, with the limb lying limp and not moving on stimulation.

Diaphyseal Fractures

The obstetrician, who hears and feels the snap when the humerus breaks as the baby is being extracted, generally diagnoses fractures of the diaphysis of the humerus. The same can be said about fractures of the femoral shaft and clavicle. A radiograph confirms the fracture.

Fracture of the shaft of the humerus is treated by immobilization of the arm by the side. Soft padding is placed between the arm and chest, and the elbow is held at 90 degrees flexion.

Fractures of the femoral shaft can be held with a posterior splint that extends from below the knee to the waist and is held in place with an elastic bandage for 10 to 14 days.

Fractures of the clavicle may be asymptomatic if undisplaced and need no treatment except care in handling the infant. If the fracture is displaced, it usually is painful. The fracture can be treated either by strapping the arms to the chest, with padding placed in the axilla and the elbow flexed 90 degrees, or by using a figure-of-eight

bandage made of stockinette to immobilize the fracture. In 8 to 10 days, the callus is sufficient for immobilization to be discontinued.

Epiphyseal Injuries

An epiphyseal separation or fracture occurs through the hypertrophied layer of cartilage cells in the epiphysis. A fracture through the proximal epiphyseal plate of the humerus is one of the more common skeletal injuries associated with a difficult delivery. The diagnosis has to be based primarily on the clinical findings of swelling about the shoulder and crepitus and pain when the shoulder is moved. Motion is painful, and the arm lies limply. The proximal humeral epiphysis is not ossified at birth and, therefore, is not visible on radiograph. This makes diagnosis by radiography very difficult. If there is complete or almost complete separation of the epiphysis, the metaphysis appears displaced in relation to the glenoid of the scapula, but usually the separation is minimal and there are no radiographic changes noted except soft tissue swelling. After 8 to 10 days, callus appears and is visible on radiographs. Ultrasonic evaluation of suspected epiphyseal injuries is gaining popularity because nonossified epiphyses and hematomas, as well as bony structures, are visible (31).

Treatment for a fracture of the proximal epiphysis of the humerus is immobilization of the arm by the side, with soft padding in the axilla for 8 to 10 days. Healing is rapid, and remodeling is such that even a striking angulation will improve progressively to a point where the bone contour appears normal. If a complete separation is present, reduction by gentle traction probably should be attempted before immobilization.

A fracture separation of the distal humeral epiphysis is very rare. It is difficult to diagnose radiographically because this epiphysis, like the proximal epiphysis, is completely cartilaginous. When an injury is present, there will be swelling about the elbow with pain and crepitus on passive motion. If the epiphysis is displaced, the anteroposterior radiograph will show that the olecranon is displaced medially or laterally in its relationship with the long axis of the humerus. A fracture of the distal epiphysis is more likely to have a significant residual deformity than is a fracture of the proximal humeral epiphysis. Skin traction on the forearm for 9 to 10 days is an option to treat this injury.

Fracture of the proximal femoral epiphysis is an uncommon problem but one that can be confused with a congenital dislocation or with acute pyarthrosis. The epiphyseal plate of the proximal femur is a crescent-shaped line extending from the greater to lesser trochanter and includes the cartilaginous epiphysis of the trochanter, neck, and femoral head. Swelling about the hip is difficult to appreciate, and suspicion of the presence of this injury should be aroused when the baby does not move the extremity on stimulation. Abnormality is confirmed by the presence of pain and crepitus when the hip is moved passively. The radiograph of the hip will show the upper end of the femoral metaphysis to be displaced laterally, and if the separation is complete, the metaphysis is likely to be displaced above the center of the acetabulum as well as displaced laterally. Ultrasonic evaluation will confirm the position of the cartilaginous femoral head in relation to the acetabulum and femoral metaphysis. After several days of incomplete separation, the hip will no longer be painful; most of these fractures will be recognized only after callus formation is seen on an incidental radiograph or after a large callus presents as a firm mass in the groin or upper thigh (Fig. 52-16). If the diagnosis is recognized before healing is underway, the hip should be manipulated gently and immobilized in flexion and abduction for 10 to 14 days.

If ultrasound is not available, aspiration of the joint will help to differentiate a fracture from congenital dislocation and acute pyarthrosis. If a fracture is present, blood should be found in the joint.

Diagnosis of a fracture separation of the distal femoral epiphysis can be made by radiographic studies. Ossification of the distal femoral epiphysis is present at birth, and even slight displacement and angulation can be recognized. If there is swelling around the knee and pain on passive motion, a radiograph will confirm the diagnosis. Treatment is by immobilization in plaster for 10 to 14 days, if displacement is not severe. When displacement or angulation is excessive, reduction by manipulation should be performed and the extremity immobilized in plaster for 14 days.

OBSTETRIC PALSY

Traumatic neuropathy of the brachial plexus is one of the more common birth injuries. It is caused most frequently by traction and lateral flexion of the neck.

In vertex presentations, the stretch results in traction, and lateral flexion is applied to deliver the shoulder in large babies, and in breech presentations from traction and lateral flexion to deliver the head.

Figure 52-16 A 3-week-old infant with a birth fracture of the proximal epiphysis of the femur.

The clinical picture is easily recognized by the absence of active motion of the involved extremity in the Moro reflex. There may be supraclavicular swelling and an associated fractured clavicle.

There are three types of obstetric palsy, and the clinical findings are different in each. The upper plexus type is called Erb-Duchenne (Fig. 52-17), in which the C-5 and C-6 nerve roots are affected, and C-7 roots are less involved. In the lower plexus type, known as Klumpke palsy, the C-8 and T-1 roots are involved. The third type is a total involvement of all roots that make up the plexus. If the C-5 and C-6 roots are affected, the shoulder is held internally rotated with the forearm supinated and the elbow extended and wrist and fingers flexed. A grasp may be present, whereas traction will be absent. When the lower roots, C-8 and T-1, are involved, the hand is flaccid with little or no control. When the entire plexus is affected, the total extremity is flaccid.

The early treatment of obstetric palsy is conservative. Myelography and surgical exploration have little to offer initially in the management of this problem. Recovery of function depends on the degree of injury. When the injury is a neurapraxia, complete recovery usually takes place over several weeks. When there is a neurotmesis or complete avulsion, no recovery takes place. Loss of sensory function suggests a more severe involvement. Because it is not possible to be certain regarding the severity of injury, all additional injury to the plexus should be prevented in newborns by gentle handling. The arm needs protection for the first 4 to 5 days, until swelling has subsided. After this period, the joints of the arm may be carried through a passive range of motion several times each day for maintenance of flexibility. The paralyzed muscles should be supported in a position of relaxation for part of each day, with care being taken that a contraction of the protected muscles does not occur. Denervated muscles undergo fibrosis; the fibrous tissue can become contracted, producing a fixed deformity. Most obstetric plexus palsy patients recover within 3 months (32). The return of function of the deltoid and biceps are the best clinical parameters of recovery; if these have not shown some recovery by 3 months, return of function is unlikely. When the lesion is limited to the C-5 and C-6 nerve roots without recovery at 3 months, surgical intervention should be considered (33).

In those patients with residual paralysis, passive exercises and progressive active exercises should be continued for months and years, as long as there is some progressive improvement. At 3 to 5 years, certain residual deformities can be improved surgically. Brachial plexus injuries are discussed further in Chapter 50.

BONE AND JOINT INFECTIONS

Osteomyelitis and acute septic arthritis occur in the neonate, although not as frequently as in older infants. Infants with altered immune function or the presence of indwelling vascular lines remain at particular risk for these unusual infections. The priorities of treatment are different in osteomyelitis and septic arthritis, and the differences are of paramount importance.

Osteomyelitis almost always occurs by hematogenous spread, from either a cutaneous or nasopharyngeal lesion, or from other sources such as omphalitis or an indwelling arterial line. *Staphylococcus* (including *Staphylococcus epidermidis* in very premature neonates) and *Streptococcus* species are the most frequent causative organisms, with group B β -hemolytic *Streptococcus* and gram-negative organisms increasing in frequency more recently.

Osteomyelitis begins in the metaphyses of long bones. Bacteria reach the metaphysis through the nutrient artery, which terminates in the sinusoids adjacent to the epiphyseal plate. The rate of blood flow in the sinusoid is slowed, creating an ideal situation for bacterial stasis and multiplication. Edema, vascular engorgement, and cellulitis are followed by thrombosis and abscess formation, with destruction and absorption of trabeculae. The purulent exudate in the metaphysis spreads by way of Volkmann canals to the periosteal space and elevates the loosely attached periosteum, which responds by laying down new

P.1442

bone over the original cortex. The new bone is the involucrum. In infants, unlike in older children, the exudate perforates the cortex of the metaphysis early and does not spread down the diaphysis, sparing the endosteal and haversian vessels and, therefore, does not cause massive sequestrum in infants as readily as in older children.

In children beyond infancy, the epiphyseal plate acts as a barrier against spread to the epiphysis. Blood vessels cross the infant's epiphyseal plate so that infection of the metaphysis may spread to the epiphysis and cause irreparable damage to the secondary center of the ossification and epiphyseal plate. For this reason, early diagnosis and treatment are very important to prevent destruction of the metaphysis and epiphysis (34).

The neonate with hematogenous osteomyelitis presents with varied complaints and findings. Movement of the affected part may provoke crying. There may be loss of active motion of the affected extremity (i.e., pseudoparalysis), or the baby may have unexplained fever or hypothermia. Palpable swelling of the extremity appears early after the onset of bone infection and is visible in a soft-tissue radiograph. In the newborn, this swelling may be massive, including the entire extremity, before visual changes in the bone are apparent on radiographic evaluation. In a newborn with extensive swelling of an extremity, osteo-myelitis must be strongly considered as the diagnosis, until proven otherwise. The infant may be so overwhelmed by infection that he or she responds very little to stimulation. In any infant who is seriously ill or failing to thrive, careful examination of the extremities should be performed, with observation for any evidence of tenderness, pain, and swelling that may indicate the presence of osteomyelitis.

The symptoms of osteomyelitis due to group B β -hemolytic *Streptococcus* are unusual (35). There may be minimal systemic response and little or no local swelling, with a pseudoparalysis or pain on motion as the only symptom of osteomyelitis. When the proximal humerus is involved, the infant holds the affected arm in the same position, as does the infant with an obstetric palsy. Three-phase bone scan has become the diagnostic imaging modality of choice for neonatal osteomyelitis, with a 90% sensitivity in detecting single or multiple lesions (36).

Figure 52-17 An Erb-Duchenne type of brachial plexus injury.

Early treatment with appropriate antibiotics and immobilization usually will control the osteomyelitis. If treatment is started too late, abscesses may form which will require surgical drainage.

Acute septic arthritis has even greater urgency for treatment than osteomyelitis in the neonate, although delayed therapy in either may cause irreparable damage to the secondary centers of ossification. Joint infection is primarily by hematogenous spread, although the hip may be infected by needle inoculation during attempted femoral vein puncture.

The neonate with septic arthritis generally is very ill, but may be so overwhelmed that there are few specific signs. Failure to thrive, as in osteomyelitis, may be the reason for admission. Pseudoparalysis, pain on passive motion, swelling, and increased local warmth are the usual physical findings. Diagnosis is difficult when the hip is affected because visible swelling and palpable warmth are minimal except when there is osteomyelitis associated with the arthritis. Radiographic examination will show a joint effusion and distention, with widening of the joint space. Ultrasound studies may be of significant help in making the diagnosis.

An infected hip joint frequently will be subluxated, and if diagnosis is delayed several days, the intraarticular pressure will cause dislocation of the hip. When dislocation occurs secondary to pyarthrosis, the joint usually is severely and permanently damaged.

P.1443

Treatment of an infected joint in an infant should be by joint cleaning to remove debris as soon as the diagnosis is confirmed. If the hip is infected, there is no acceptable alternative to arthrotomy for decompression and debridement. A delay in surgical decompression may cause the hip to become dislocated by the increasing accumulation of joint fluid. The blood supply to the femoral head is vulnerable both to the increased pressure and products of the infection, and delay in adequate debridement may cause occlusion of the vessels, which will result in further deterioration of the femoral head. Both these complications can be prevented by early diagnosis, treatment with appropriate antibiotics, and surgical decompression. In other joints, repeated needle aspiration and irrigation may sufficiently debride, but the clinician never knows whether there is pannus covering the joint surface that must be removed to prevent further destruction of the articular cartilage. Because of this risk, open surgical decompression with debridement is a more reliable treatment than needle aspiration.

Chapter 53

Neoplasia

Robert J. Arceci

Howard J. Weinstein

Although neoplasia in infancy is quite rare, it presents important and unique biologic, diagnostic, and therapeutic problems. Such neoplasms often show peculiarities that distinguish them from those occurring later in life. Many tumors in early life are composed of persistent embryonal or fetal tissues, suggesting a failure of proper maturation or cytodifferentiation during intrauterine or early postnatal life. The failure of proper maturation of fetal tissue may be sometimes difficult to distinguish from neoplasia. Additionally, an unexpectedly large number of neoplasms of early life are associated with growth disturbances and congenital anomalies. Spontaneous regression and cytodifferentiation also occur most frequently in tumors of early life.

The unique physiology of the developing neonate provides the clinician with special problems in terms of therapeutic interventions and their long-term sequelae. The neonatal period is also one in which different types of treatment and exposures may affect the long-term risk of secondary malignancies.

EPIDEMIOLOGY

From the data in The Third National Cancer Survey (1969 to 1971), Bader and Miller (1) reported that, in the United States, the annual incidence of malignant neoplasms in infants younger than 1 year of age was 183.4 per 1 million live births and within the first 28 days of life was 36.5 per 1 million live births. They further estimated that approximately 653 infants per year in the United States are diagnosed with cancer and that about 130 (20%) of these patients are neonates. In a later study from Denmark, the incidence of neonatal cancer was calculated to be between 1.88 to 2.98 cases per 100,000 births (2). Approximately one-half of the neonatal malignancies are noted on the first day of life (3). The incidence of childhood cancers also has been observed to show regional differences over time and, over the past 20 years, an absolute increase in childhood cancer has been reported (4,5).

When incidence for all malignancies is compared with mortality as determined from death certificates, the incidence in patients younger than 1 year is 3.5 times greater than mortality, whereas the incidence in patients younger than 29 days old is 4.8 times greater than mortality (1,6). These figures offer an interesting comparison to those reported in children up to 15 years of age, among whom the

incidence of malignancy is only about 1.3 to 1.8 times greater than mortality. When individual diseases are considered, there are marked differences in incidence vs. mortality. For example, in neonates, the incidence of neuroblastoma is 10 times greater than the mortality, whereas the incidence of leukemia is only 1.8 times the mortality. The distribution of the types of malignancies found in infants younger than 1 year of age differs from that found in later childhood. In infants younger than 1 year of age, neuroblastoma is the most common malignancy and accounts for about 50% of malignancies in the neonatal period; it is followed by leukemia, renal tumors, sarcomas, central nervous system (CNS) tumors, and hepatic malignancy (2,3,7,8). However, when one considers the total spectrum of neoplastic disorders of infancy, teratoma is usually reported as the most frequently encountered neoplasm, followed by hemangiomas, lymphangiomas, and small nevi lesions (9,10,11,12). In older children younger than 15 years of age, leukemia is the most common malignancy (about 30%), followed by CNS tumors, lymphoma, neuroblastoma, sarcoma, and renal tumors. Thus, the incidence and types of neoplastic disorders of infancy contrast greatly compared to later childhood and define the neonatal period as epidemiologically distinct in terms of these disorders.

DEVELOPMENTAL GROWTH DISTURBANCES, GENETIC ABERRATIONS, AND CANCER PATHOGENESIS

Primary, inherited, cytogenetic syndromes usually occur as a result of chromosomal aneuploidy, deletions, translocations, increased fragility or altered epigenetic imprinting, which in turn represent the end result of germline chromosomal defects. An example of aneuploidy is Down syndrome (trisomy 21), in which the frequency of acute leukemia is approximately 15 times the normal. Additionally, an increased incidence of solid tumors has been reported for persons with trisomy 8, 9, 13, and 18 (13). Deletion of part

P.1445

of the long arm of chromosome 13 is associated with psychomotor retardation, microcephaly, cardiac and skeletal defects, and the early development of retinoblastoma. The deletion of the short arm of chromosome 11 results in mental retardation, microcephaly, aniridia, ear and genital anomalies, and an increased incidence of Wilms tumor (WAGR syndrome). These syndromes provided support for the assignment of a retinoblastoma locus to chromosome 13q14 and a Wilms tumor locus (WT1) to 11p13. These mutant genes are heterozygous in constitutional cells and homozygous in retinoblastoma and Wilms tumor cells. WAGR syndrome results from loss of several genes from the 11p13 region. Deletion of one copy of PAX 6 is responsible for aniridia, and loss of one WT1 allele results in genitourinary anomalies. Deletion of the WT1 gene in patients with

WAGR syndrome is thought to be the first “genetic hit” in the genesis of a Wilms tumor. The function of WT1 is not clear, but it is an important transcription factor that contributes to the regulation of cell proliferation and differentiation. Homozygosity at the “Wilms tumor locus” on chromosome 11 has also been found in embryonal rhabdomyosarcomas (RMS) and hepatoblastomas, suggesting a common pathogenesis for these embryonal tumors (14). The specific loss of constitutional heterozygosity and its relationship to oncogenesis has been confirmed in studies of transgenic mice that lack a functional tumor suppressor gene, p53. This phenotype, termed Li-Fraumeni Syndrome in humans, is characterized by a higher incidence of embryopathy, and an increased incidence of malignancies developing early in life (15).

A number of inherited syndromes, including Bloom syndrome, Fanconi Anemia, ataxia-telangiectasia, xeroderma pigmentosum, and Werner's syndrome, are characterized by developmental abnormalities and increased incidence of various types of cancer (16,17). These syndromes also demonstrate increased defects in DNA recombination, increased sensitivity to genotoxic agents, increased chromosomal fragility, and abnormal DNA repair (18). Of particular interest is that these syndromes now are known to be caused by defects in genes encoding several novel proteins involved in deoxyribonucleic acid (DNA)/ribonucleic acid (RNA) recombination and repair, such as the DEAD-box helicase of Bloom syndrome or excision repair enzymes associated with some of the complementation groups of xeroderma pigmentosum (18,19,20). It is intriguing that when these defective genes are inherited through the germline, patients show both developmental abnormalities and an increased incidence of cancer. It will be important to determine whether somatic cell mutations of such genes will increase the chances of a cell becoming malignant, thus showing how the identification of altered genes leading to developmental defects can also increase our understanding of cancer in older individuals.

Malformations (21) and malformation syndromes without obvious cytogenetic abnormalities include hemihypertrophy and Beckwith-Wiedemann syndrome (BWS), which consists of mental retardation, gigantism, macroglossia, omphalocele, and organomegaly; both of these disorders are associated with the development of Wilms tumor, hepatoblastoma, and adrenocortical carcinoma. BWS, which occurs in approximately 1 in 13,000 births, usually is sporadic, although an autosomal dominant inheritance pattern with incomplete penetrance also has been proposed. Patients with BWS have an approximately 7.5% to 10% risk of developing a tumor (22). Sacrococcygeal teratomas and teratocarcinomas are associated with anomalies of the lower spine and urogenital region.

Hamartomas are benign proliferations of cells in their normal anatomic location. Hamartomas in which malignant neoplasms arise include congenital melanotic nevi, which can progress to melanoma, and familial polyposis, which may evolve into colonic carcinoma. Examples of malignancies developing from persistent fetal

rests include craniopharyngioma arising from tissue derived embryologically from the Rathke pouch, and persistent neuroblastic cellularity leading to adrenal neuroblastoma.

Naturally occurring DNA sequences homologous to transforming viral oncogenes exist in normal, untransformed cells of all metazoa. Such DNA sequences are called cellular oncogenes and are used in normal cells during growth, development, and differentiation in precise temporal and tissue-specific patterns (23,24). Some of their products function as potent cell growth and death (apoptosis) regulators. The protein products of some cellular oncogenes are quite similar to the products from the homologous viral oncogenes. Because of their expression and critical role during normal development, inherited or acquired mutations affecting cellular oncogene expression can lead to a variety of developmental abnormalities and congenital defects, such as hemihypertrophy syndromes and hamartomas. Additionally, the persistent expression beyond birth of certain growth-related oncogenes may play a role in such proliferative states as the transient myeloproliferative disorder associated with Down syndrome and stage IV-S neuroblastoma found in infants, which both are characterized by subsequent, spontaneous regression.

These predisposing conditions share at least one common element: an inherited or developmental disturbance of cellular growth and/or cell survival, which may be linked to the molecular pathways regulating these genetically determined cellular responses. The finding of these different classes of genes helps to define the molecular links between conditions of abnormal development (i.e., teratogenesis) and neoplastic transformation (25,26).

EXPOSURE TO MATERNAL MALIGNANCY

In addition to the susceptibility of the fetus to adverse effects of chemotherapy during pregnancy, there also is the possibility that the maternal cancer will metastasize to the placenta and fetus. Although many anecdotal reports have documented such involvement, it occurs only very rarely. The types of tumors shown to be transmitted from the

P.1446

mother to the placenta or fetus are quite varied, with melanoma most commonly cited. Although lymphoma and leukemia may involve the placenta, they have usually not been found to be transmitted to the fetus (27,28,29,30,31). The evaluation of infants born to mothers with cancer has not been clearly established, in part because of the rarity of such events. However, recommendations would suggest the utility of close follow-up during the first year of life including physical exams, blood studies such as complete blood count (CBC) and liver function tests, and scans only when indicated. Careful examination of the placenta is an important component of this evaluation.

PRENATAL EXPOSURE TO MATERNAL GENOTOXINS

There are relatively few reports and/or studies of outcome in infants born to mothers undergoing chemotherapy and/or radiation therapy for cancer. Nevertheless, several important lessons can be learned from the available reports. The risk of developmental problems increases with decreased gestational age at the time of maternal treatment (32,33,34). For example, a recommendation to terminate a pregnancy is often reasonable when significant numbers and doses of anticancer drugs are used during the first trimester because of the increased risk of major birth defects and spontaneous abortions. Outcomes for infants whose mothers are treated during the second and third trimesters are significantly better, although there has been reported some risk of low birth weight, intrauterine growth retardation and stillbirths (32,33,34). Last, other prenatal drug exposures may lead to increased risk of cancer in offspring. For example, prenatal exposure to diethyl stilbesterol has been closely linked to the development of clear cell adenocarcinoma of the vagina (35,36), dilantin exposure with neuroblastoma (37,38), nitrosourea compounds with central nervous system tumors (39) and topoisomeras II inhibitors (epipodophyllotoxins, flavonoids, catechins, caffeine) with leukemia associated with mixed lineage leukemia (MLL) gene rearrangements (40,41,42,43). Significant use of alcohol and tobacco/marijuana and exposure to pesticides has been reported to be associated with an increased risk of congenital leukemia (44,45,46). Radiation therapy or significant exposures to radiation through diagnostic testing such as computed tomography (CT) scanning is usually avoided whenever possible in pregnant mothers because of concerns of potential morbidity to the developing fetus (47,48,49,50).

TUMORS OF NEUROEPITHELIAL ORIGIN

Neuroectodermal cells of the neural tube differentiate to neuroblasts, which become nervous system tissue and melanocytes; free spongioblasts, which become either astrocytes or oligodendroglia cells; and ependymal spongioblasts, which become ependymal cells. These primitive neuroectodermal cells may be the target for neoplasia, giving rise to a group of morphologically similar tumors involving central and peripheral sites of the nervous system. Neonatal tumors originating from neuroectodermal cells include neuroblastoma, retinoblastoma, peripheral nerve tumors (i.e., neuroepithelioma), medulloblastoma, choroid plexus papilloma, ependymblastoma, and melanotic neuroectodermal tumors. These tumors show varying degrees of cellular differentiation, have similar histologic features (e.g., small, primitive cells with rosettes or pseudorosettes), and tend to spread along cerebrospinal fluid pathways.

Neuroblastoma

Neuroblastoma is the most common malignant tumor in neonates. It originates from neural crest cells that normally give rise to the adrenal medulla and sympathetic ganglia. Its reported occurrence in siblings and other family members suggests that some cases are hereditary (51,52). In such cases, the tumors usually are diagnosed at an earlier age and often are characterized by having multifocal primary tumors (53,54). An interesting syndrome has been reported in several women who delivered infants diagnosed as having neuroblastoma during the first few months of life (55). The mothers had sweating, pallor, headaches, palpitations, hypertension, and tingling in their hands and feet during the last trimester of pregnancy. These symptoms were relieved after the birth of the affected infants. The authors of that study postulated that this symptom complex is caused by the introduction of fetal tumor catecholamines into the maternal circulation. Although at least half of infants present with an abdominal mass from tumors arising in the adrenal medulla or retroperitoneal sympathetic ganglia, neuroblastoma may arise anywhere along the sympathetic nervous system and present with disseminated disease. An abdominal sonogram or CT scan demonstrates displacement of the kidney without distortion of the calyceal system. The neoplasm also may originate in the posterior mediastinum, neck, or pelvis. Cervical sympathetic ganglion involvement in the neck may result in Horner's syndrome; posterior mediastinal tumors may cause respiratory distress; paravertebral tumors tend to grow through the intervertebral foramina and cause symptoms of spinal cord compression; and presacral neuroblastomas may mimic presacral teratomas. Neuroblastoma also has been detected prenatally by ultrasonography, showing a solid and sometimes cystic suprarenal mass (56,57,58). Two unusual presentations of neuroblastoma are intractable diarrhea secondary to release of vasoactive intestinal peptide, and the syndrome of opsoclonus, myoclonus, and truncal ataxia (59,60), the etiology of which remains uncertain. The diarrhea secondary to vasoactive intestinal peptide abates after removal of the neuroblastoma. In contrast is the unpredictable improvement after the removal or treatment of neuroblastoma associated with opsoclonus-myoclonus. Nevertheless, survival for children with this syndrome is excellent.

P.1447

Metastatic lesions are common presenting findings of neuroblastoma, especially in the neonate (60). The primary tumor often cannot be found in infants younger than 6 months of age. These infants present with bluish subcutaneous nodules and extensive hepatomegaly. The liver may be studded with tumor nodules and be so large that it causes respiratory distress secondary to abdominal distention. Clumps of tumor cells often are found in the bone marrow aspirates. Metastases to bones, skull, and orbit, which present as periorbital ecchymoses, are rare in the neonate. The unique metastatic pattern to liver, bone marrow, and skin in infants is classified as stage IV-S neuroblastoma (61,62,63,64,65).

The differential diagnosis for neuroblastoma is limited. The subcutaneous nodules

appear similar to those found in congenital leukemia cutis and several congenital infections. The leukoerythroblastosis secondary to bone marrow metastases from neuroblastoma also is observed with congenital infection, severe hemolytic disease, and leukemia. More than 90% of children with neuroblastoma will have elevated urinary excretion of catecholamine metabolites, vanillylmandelic acid or homovanillic acid, or both (66). The diagnosis of neuroblastoma is made by biopsy of the primary tumor or metastatic lesions. The most histologically primitive lesion is neuroblastoma without differentiation and is composed of small, round cells with scant cytoplasm. The ganglioneuroma, its benign counterpart, is composed of large, mature ganglion cells. Ganglioneuroblastoma is intermediate in its degree of cellular differentiation. In the absence of a tissue specimen, the findings of elevated urinary catecholamines and tumor pseudorosettes in a bone marrow specimen usually are sufficient to make a definitive diagnosis.

The prognosis for children with neuroblastoma is inversely correlated to the age of the child at diagnosis and the extent of disease. The infant with stage IV-S disease has a better chance of survival than does the older child with less advanced disease. Evans and associates (61) proposed a clinical staging system for children with neuroblastoma that was prognostically useful (67,68). This system has evolved into an International Staging System, which takes into account many of these basic concepts (63,64,65).

Infants with stage IV-S have had spontaneous regression of disease, and in other patients malignant neuroblastomas apparently have undergone maturation into mature ganglioneuromas (68). The incidence of spontaneous regression of neuroblastoma may be more common than is clinically evident. Primitive sympathetic neuroblasts, which are derived from neural crest ectoderm, migrate in early embryonic life into the adrenal primordium, in which they arrange themselves in nodules before differentiation into adrenomedullary tissue. These nodules are present in all fetal adrenal glands at 14 to 18 weeks of gestation (69). Beckwith and Perrin (70) detected the presence of microscopic clusters of neuroblastoma cells (i.e., neuroblastoma in situ) in the adrenal glands in a number of autopsies from infants younger than age 3 months who had no clinical evidence of tumor. They estimated that neuroblastoma in situ occurs in 1 of 250 stillborn infants and infants younger than 3 months of age. Clinically detectable neuroblastoma is noted in only 1 of 10,000 live births. Also pertinent to these data are the observations of the catecholamine screening programs (71,72,73,74,75). These programs demonstrated that this type of screening resulted in an increased incidence of early stage neuroblastoma that, most likely, would not have presented as clinically detectable disease (76,77,78,79,80,81).

These observations raise the interesting question regarding whether stage IV-S neuroblastoma is not a true malignancy. If stage IV-S neuroblastoma is a classic malignant neoplasm, it should be clonally derived. One such example of clonality in stage IV-S neuroblastoma tumor specimens has been demonstrated by

cytogenetic analysis. Although no consistent and specific chromosomal alteration has been found in all stage IV-S specimens, there are increasing numbers of examples of cytogenetic clonality. Additionally, stage IV-S neuroblastoma is often characterized by being hyperdiploid and having variable expression of 1p deletions and N-myc amplification (82,83,84,85,86). The reason(s) for spontaneous regression of stage IV-S disease remains a mystery.

The extent of treatment for neuroblastoma depends on the stage of the disease and biological factors such as histology, N-myc amplification, and DNA ploidy. The infant with stage IV-S disease should be observed for a period of weeks to months before treatment is initiated because of the reasonable likelihood of spontaneous regression (67,79,87,88). Respiratory difficulties, blood vessel (usually vena cava) obstruction, and gastrointestinal compression secondary to rapid tumor expansion can develop and should be considered a medical emergency, with more than 50% mortality in some reports (89). Hsu and associates (90) have described a monitoring and scoring system to follow these patients and predict when, and if, therapeutic interventions should be initiated. This scoring system is based on the presence of the severity of several clinical symptoms, including respiratory compromise, renal insufficiency, extent of lower extremity edema, disseminated intravascular coagulopathy, and the rate of increasing abdominal girth (90). Although both chemotherapy (often single-agent cyclophosphamide) or radiation therapy have been used to effect symptomatic relief for such patients, some reports suggest that 200 to 600 cGy delivered tangentially to the liver to avoid other organs, such as kidneys and gonads, provides for a rapid response and possibly an improved outcome (90,91). Embolization approaches have also been reported to be successful (92).

Complete surgical removal of neuroblastoma is usually accomplished in infants with stage I or II disease. Postoperative treatment generally is not indicated for these patients, and their long-term survival is excellent (93,94,95). For infants with stage III disease in whom gross residual tumor remains after surgery, postoperative chemotherapy, radiotherapy, or both may be indicated (96). Chemotherapy is the treatment of choice for infants with stage IV disease. The active chemotherapeutic agents against neuroblastoma

P.1448

include alkylating compounds (e.g., cisplatin, cyclophosphamide, dacarbazine, nitrogen mustard), vincristine, and doxorubicin. Combinations of several of these agents administered for 6 months to 1 year have resulted in greater than 50% long-term survival for children younger than 1 year of age with stage IV neuroblastoma and, in some subgroups up to 90% cure rates (97). This is in contrast to the dismal prognosis for similarly staged children who are older than 1 year.

Retinoblastoma

Retinoblastoma is a congenital malignant tumor arising from the nuclear layer of the retina. Although an extremely rare tumor, it is the most common ocular tumor of childhood. The median age at presentation is 18 months, or 14 months for bilateral cases, but a small percentage of infants are diagnosed during the first few months of life (98). Prenatal diagnosis by sonography of retinoblastoma has been reported (99). Approximately 10% of children with retinoblastoma have a family history of the disease. Approximately 30% with bilateral or multifocal unilateral tumors have a negative family history (100,101). These two groups are capable of transmitting the disease to their offspring in an autosomal dominant fashion. This hereditary tendency is governed by a genetic locus on the long arm of chromosome 13 (i.e., band 13q14), which includes the retinoblastoma (rb) tumor suppressor gene. Retinoblastoma has also been associated with chromosomal 13 deletion mosaicism (102). Preimplantation diagnosis of retinoblastoma has been reported (103). If there is a family history of retinoblastoma, an experienced ophthalmologist should examine the eyes of unaffected siblings regularly although they are under general anesthesia to detect cases early (104). Moll and associates have proposed such screening until age 4 years (105).

The most common initial signs of retinoblastoma include an abnormal white pupil (i.e., leukocoria), known as a cat's-eye reflex and a squint or strabismus. A clinical picture resembling retinoblastoma may result from granulomatous uveitis, congenital defects, and severe retrolental fibroplasia. Once the diagnosis of retinoblastoma is suspected, both eyes should be examined with the infant under general anesthesia. A bone marrow aspiration and spinal tap for malignant cells should be performed for staging. A staging system for retinoblastoma is based on the size, location, number of tumors in each eye, and distant hematogenous metastases. Vitreous seeding, tumors extending anteriorly to the ora serrata, tumors invading over one-half of the retina, residual orbital disease, and optic nerve or distant metastases are adverse prognostic features.

Retinoblastoma usually is curable when diagnosed early; vision often need not be sacrificed even when bilateral disease is present (106). More recent treatment approaches using cryosurgery in combination with chemotherapy and/or radiation therapy are being developed with the hope of preserving vision and reducing the risk of subsequent in-field radiation-induced secondary malignancies (106,107,108,109,110). Additionally, stereotactic and proton beam radiation methods are being tested to reduce the amount of normal tissue irradiated and the risk of radiation-induced secondary malignancies (106,111,112,113,114,115,116). Patients with adverse prognosis features often require enucleation. Children with very advanced and metastatic disease require aggressive chemotherapy regimens.

Brain Tumors and Other Neuroectodermal

Tumors

Intracranial tumors presenting in the first year of life are uncommon. In a review from the Hospital for Sick Children in London, 107 of 1,296 children with brain tumors had symptoms before the age of 1 year; 17 were symptomatic within 2 months of birth (117,118). Brain tumors in children in this age group tend to be supratentorial, in contrast to those in older children, which tend to be infratentorial. In infants, the most common presenting symptom is macrocrania, with a bulging fontanelle secondary either to hydrocephalus or tumor volume. Seizures, vomiting, failure to thrive, abnormal eye movement, and irritability also are frequent. The histologic diagnoses of the neuroectodermal tumors are similar to those of tumors in later childhood, with gliomas accounting for most. Of particular interest, a majority of intracranial tumors in neonates have been reported to be teratomas (12,118,119,120,121). There is also a high frequency of choroid plexus papillomas in this age group (122). An association of choroid plexus papillomas and the presence of SV40 viral DNA has been reported (123).

Desmoplastic infantile gangliogliomas are rare, but massive, cystic tumors that usually occur supratentorially in the neonatal period (124). They present most commonly with signs of increased intracranial pressure, including seizures. Therapy has included surgery and chemotherapy, but without radiation therapy. For patients who have a complete surgical resection, additional therapy may not be required (125). Prognosis may be better than that observed with other tumors, such as high-grade astrocytoma. In contrast, pineoblastomas are malignant tumors with an extremely poor outcome, even when treated with surgery, chemotherapy, and radiation therapy. Part of the reason for the poor outcome in these infants may be the propensity of pineoblastoma to involve the leptomeninges and extraneural spread (125).

Treatment of infants with brain tumors historically included surgical removal or biopsy followed by radiotherapy (126,127,128). Operative mortality has been high, and few infants survived for longer than 1 year. In these few, brain radiotherapy resulted in severe intellectual and psychomotor retardation. In attempts to avoid the adverse effects of radiotherapy on the developing brain, more recent therapeutic approaches have evaluated surgery followed by preradiation chemotherapy (119,127,128,129,130,131).

Atypical teratoid/rhabdoid tumors (AT/RT) of the central nervous system, although rare, are usually large, aggressive

P.1449

and have historically had very poor outcomes with the use of conventional therapies used in children with brain tumors (132,133,134). More aggressive, multidisciplinary approaches have started to show some improvement in patients with this type of brain tumor, although median survival is still estimated to be less than 2 years (134,135). Of particular note is the etiologic role of mutations in the

SNF5/INI1 gene in these tumors which encodes for a chromatin remodeling factor (136,137).

Primitive neuroectodermal tumors of peripheral nerve represent a group of soft tissue tumors known as neuroepitheliomas, medulloepitheliomas, and peripheral neuroblastomas (138,139). They are associated with major branches of peripheral nerves (i.e., tumor of the chest wall arising from intercostal nerve). These are extremely rare tumors, quite aggressive in their biologic behavior, with frequently occurring distant metastases, including to the CNS. Treatment approaches include wide excision, if possible, and chemotherapy modeled after either neuroblastoma or brain tumor protocols.

The melanotic neuroectodermal tumor of infancy has its origin in the neural crest population. Most of these tumors are diagnosed between 1 and 8 months of age and occur in the maxilla, although extremely rare cases have been reported in other sites such as the epididymis (140). They are considered a benign neoplasm, with a local recurrence rate of about 15%. These tumors originate from pluripotential neural crest cells that give rise to both melanoblasts and neuroblasts. The rate of malignancy for this tumor is reported to be approximately 5%. Recommended treatment is wide local excision.

CONGENITAL LEUKEMIA

Leukemia in the newborn is extremely rare with approximately 5 cases reported per million live births (141,142,143). It has been customary to categorize leukemia as congenital when it is diagnosed within a few days after birth and as neonatal when it manifests itself during the first 4 to 6 weeks of life (144). The kinetics of leukemic cell growth and the estimated leukemic cell burden at the time of diagnosis make it reasonable to assume that clinically detectable leukemia during the first 4 weeks of life originated in utero (145). Molecular studies indicate a prenatal initiation of acute lymphoblastic leukemia (ALL) and some acute myeloid leukemias, in children diagnosed in infancy or even later in life (146,147,148,149,150,151,152,153). In the following discussion, congenital leukemia is considered as leukemia diagnosed from birth to 4 weeks of age.

The etiology and pathogenesis of congenital leukemia, and other leukemias, are unknown. The strongest evidence for a genetic predisposition to acute leukemia is its occurrence in identical twins in which there is a very high concordance (154). If leukemia develops in one of a set of identical twins before 6 years of age, the risk of disease in the other twin is 20%. Leukemia usually develops in the other twin within weeks to months of the first case. In some of these cases, intrauterine exchange of leukemic cells from one twin to the other has been strongly suggested by the identity of molecular and genetic changes observed postnatally in the leukemias from each twin. For fraternal twins and siblings, the risk of development of leukemia is two and four times higher than in the general

population. Congenital leukemia has been associated with trisomy 9, trisomy 13, Turner syndrome, and Down syndrome and rearrangements of the MLL gene (147, 155,156,157,158). More than 95% of the childhood leukemias, including congenital leukemia, are classified as acute, because they are characterized by a predominance of immature lymphoid or myeloid precursors. In children, the proportion of cases of ALL to acute myelogenous leukemia (AML) is approximately 4 to 1, but this ratio is reversed in the congenital leukemias (141,142). Whereas lymphoblasts from most children with ALL express the common acute lymphoblastic leukemia antigen (CALLA or CD10) on the cell surface and express markers of early B-cell differentiation (e.g., cytoplasmic immunoglobulin or Ig gene rearrangement), the lymphoblasts of congenital and infant ALL are often pre-B, but CD10-negative (159,160). These infants have a higher incidence of CNS leukemia at diagnosis, a higher leukocyte count, increased frequency of hepatosplenomegaly, and a poorer prognosis than older children with ALL. A translocation of the long arms of chromosomes 4 and 11, t(4;11), involving the MLL gene at chromosome 11q23, is commonly observed in infant leukemia. This translocation is associated with greater than 80% of ALL in infancy and carries a poor prognosis (161,162,163,164,165,166).

The most common subtype of AML in the neonate is acute monocytic leukemia, which accounts for only 20% of AML in older children (167). It is associated with a high incidence of extramedullary leukemia, especially in the CNS. Translocations involving chromosome 11q23 with MLL gene rearrangements are associated with this subtype of AML (167).

Cutaneous manifestations are the most frequent clinical findings noted at birth. In addition to petechiae and purpura, leukemic skin nodules (i.e., leukemia cutis) have been observed in approximately 50% of cases (168,169,170). These skin nodules may vary in size from a few millimeters to a few centimeters, are bluish to slate gray in color, may appear in all sites, and are palpated as firm tumors of the deep skin (Fig. 53-1). Neonatal leukemia cutis may undergo a spontaneous, temporary regression, but tends to recur in a more generalized form within a few weeks to months.

Hepatosplenomegaly is common, but lymphadenopathy is not. Respiratory distress, secondary to leukostasis within the pulmonary vasculature, may complicate the clinical course. Other nonspecific symptoms of neonatal leukemia include lethargy, pallor, poor feeding, and umbilical, gastrointestinal, or genitourinary bleeding.

In the report of congenital leukemia by Pierce (141), the mean hemoglobin concentration at birth was normal, with a wide range of values (7 to 20 g/dL); the mean leukocyte counts were 150,000 per mm³ (range 2,000-850,000); and mean platelet counts were 70,000 per mm³ (range

6,000-300,000). The diagnosis of leukemia is confirmed by examination of a bone marrow aspirate obtained from the posterior iliac crest.

Figure 53-1 Congenital acute monocytic leukemia with skin nodules. (See color plate)

A variety of disorders in the newborn imitate leukemia. The newborn bone marrow response to infection, hypoxemia, or severe hemolysis commonly is a leukemoid reaction and an increase in circulating nucleated erythrocytes. These conditions can easily be confused with congenital leukemia.

An enigmatic myeloproliferative disorder described as transient acute leukemia or transient myeloproliferative syndrome occurs primarily in infants with Down syndrome (171,172,173). This syndrome, noted during the first few days of life, mimics AML. Peripheral leukocyte counts can range from 25,000 to several hundred thousand; bone marrow aspirates reveal 30% to 70% blasts. Hepatosplenomegaly and thrombocytopenia are also common findings. The hematologic status of these neonates usually returns to normal in 1 to 4 months, with only supportive therapy. Several of these children who subsequently died of cardiac or pulmonary disease years after the resolution of their transient myeloproliferative syndrome showed no evidence of leukemia at autopsy. This syndrome has been

observed in neonates with stigmata of Down syndrome and in phenotypically normal infants who have trisomy 21 mosaicism in their hematopoietic cells or skin fibroblasts (174). Molecular studies have identified the presence of truncated GATA1 mutations in essentially all cases of transient myeloproliferative syndrome and the acute mega-karyoblastic leukemia associated with Down Syndrome (175,176,177,178,179,180). GATA1, a critical transcription factor that regulates megakaryopoiesis and erythropoiesis, has thus been etiologically linked in these two hematologic disorders and in the increased drug sensitivity of leukemic megakaryoblasts from children with Down Syndrome (181). There have also been reports of spontaneous remissions of congenital leukemia, even in those children without Down Syndrome (182,183), suggesting that some cases can be initially conservatively managed with observation and/or supportive care (144,184).

In approximately 20 to 30% of these infants, acute leukemia requiring systemic chemotherapy will develop within the first 4 years of life. This leukemia is nearly always acute megakaryoblastic leukemia (M7 subtype). In the setting of constitutional trisomy 21, acute megakaryoblastic leukemia usually has an excellent prognosis, even with less intense therapy than observed for non-Down syndrome children with the same subtype of leukemia (185,186,187,188). Although time is still the most definitive indicator of transiency, serial cytogenetic studies may be of value. If there is a chromosome marker in addition to trisomy 21 in spontaneously dividing bone marrow cells, a more aggressive leukemic clone is likely to be present.

Congenital ALL is fatal if untreated and should be managed with systemic chemotherapy. Several national trials are ongoing to improve the outcome of these infants with this poor prognosis leukemia. Age has been an important prognostic variable in childhood ALL, with the most favorable prognosis for patients between 2 and 9 years of age. Prognosis for young infants with ALL remains poor (162, 189,190,191,192). Because untreated congenital AML also is fatal, aggressive combination chemotherapy in an institution with maximal supportive services is mandatory. One report has described the successful treatment of several neonates with acute monocytic leukemia with either VP-16 or VM-26, but this experience has not been confirmed (193). Aggressive AML treatment regimens have met with considerable success in achieving long-term disease-free survival in neonates with AML (194,195,196,197,198,199).

NEOPLASMS OF THE KIDNEY

Mesoblastic Nephroma

Most abdominal masses presenting in infancy are renal in origin, and most can be accounted for by cystic disease of the kidney and congenital malformations of the urinary tract leading to hydronephrosis. Although neoplasms of the kidney are

rare in infancy, they do occur and have important prognostic implications, making it mandatory that they be included in the evaluation of abdominal masses.

The most common renal tumor found in infants is mesoblastic nephroma, which accounts for nearly 80% of renal tumors in the neonatal period. It also has been called fetal renal hamartoma, mesenchymal hamartoma of infancy, and leiomyomatous hamartoma (200). Mesoblastic nephroma commonly presents as an asymptomatic, enlarging abdominal mass during the first few months of life (201). It is not associated with congenital anomalies and has no race predilection. Of note is the more frequent occurrence of polyhydramnios and premature labor in women whose infants have mesoblastic nephroma (202). The differential diagnosis includes renal cystic disease, congenital malformations of the urinary tract resulting in hydronephrosis, and Wilms tumor. Molecular studies have demonstrated that mesoblastic nephroma shares with most Wilms tumors the expression of insulin-like growth factor II (IGF-II), but, unlike Wilms tumor, does not express the WT1 gene and shows no loss of heterozygosity at 11p13 or 11p15 (203). The bi-allelic expression of the IGF-II has shown that there is a relaxation of the normal epigenetic imprinting pattern of this gene (i.e., the paternal allele is normally expressed with the maternal allele silent) (204). An intriguing finding has been the identification of a chromosomal translocation resulting in a fusion protein, ETV6-NTRK3, in both mesoblastic nephroma and infantile fibrosarcoma (205,206). Of further interest is the requirement of IGF-1 signaling for the transformation potential of the ETV6-NTRK3 to be realized (207).

Most patients with mesoblastic nephroma are cured by surgical excision without adjuvant chemotherapy or radiotherapy (208,209,210). The addition of chemotherapy has resulted in increased morbidity and, in some instances, fatal complications. In rare cases, such as older infants presenting with metastatic disease or when there is tumor rupture and spillage, chemotherapeutic intervention with regimens containing actinomycin D, vincristine, cyclophosphamide, and doxorubicin have been used effectively. Similar regimens have been used in the rare recurrences (209, 211,212,213). Radiotherapy also has shown efficacy in patients for recurrences, which are relatively uncommon (210,214,215).

Persistent Renal Blastema, Nephroblastomatosis, and Wilms Tumor

The adult or metanephric kidney arises from a complex, inductive interaction between the evaginating uterine bud and its bifurcations with the metanephric, mesodermally derived blastema. By 36 weeks of gestation, normal nephrogenesis is complete, with no residual metanephric blastema. When these metanephric blastemal elements persist, they usually are characterized by microscopic clusters of primitive blastema and occasionally some tubular differentiation (i.e., persistent

metanephric blastema). If these fetal rests proliferate, they may develop along several different histologic pathways, each of which has particular relevance to the evolution of Wilms tumor (216,217,218,219). Nephroblastomatosis represents the persistence and cellular expansion of metanephric blastema beyond the cessation of nephrogenesis. The proliferation may occur in characteristic patterns, either multifocal or diffuse.

Multifocal nephroblastomatosis refers to the widespread proliferation of blastemal cells, most prominently in the subcapsular cortex and along the penetrating columns of Bertin. Nephromegaly is not always evident. Unlike mesoblastic nephroma, multifocal nephroblastomatosis is associated with congenital malformation syndromes and chromosomal abnormalities. Within the category of multifocal nephroblastomatosis, there are several characteristic lesions. When persistent blastema proliferate in small 100- to 300-mm foci separated by normal renal parenchyma, they are referred to as nodular renal blastema. Nodular renal blastema may regress or evolve into what has been called sclerosing metanephric hamartoma and into Wilms tumorlets, which are 0.3 to 3.5 cm in diameter, noninfiltrating, often multiple, neoplastic tumors separated by normal renal parenchyma. They usually consist of blastema with a monomorphous epithelial pattern of differentiation. Although they resemble true Wilms tumor, they are distinguishable by their smaller size and their noninfiltrating behavior.

A second type of nephroblastomatosis, which is quite rare but found more commonly in infants and young children, is diffuse nephroblastomatosis. The blastemal proliferation may be pan-nephric or superficial, with the latter lesion encasing a normal cortex and medulla. Diffuse nephroblastomatosis presents as bilateral, palpable nephromegaly in association with congenital malformations. Radiographic examination by intravenous pyelogram reveals distortion and elongation of the calyceal system without obstruction (220). On gross inspection, there is an exaggerated pattern of fetal lobulation of the enlarged kidneys.

That these various histologic lesions are related to one another and to the evolution of frank Wilms tumor has been strongly suggested by case studies and by epidemiologic and pathologic correlations (221,222,223). In about one-third of cases of Wilms tumor, there is suggestive pathologic evidence for the association of nodular renal blastema, nephroblastomatosis, Wilms tumorlets, and Wilms tumor; in bilateral Wilms tumor, this association is nearly always present (224,225,226).

Management of nephroblastomatosis involves surgery and sometimes chemotherapy, depending on the extent of disease (227,228). Radiation therapy is not very effective. If only one kidney is involved, surgical resection is sufficient, but exploration and biopsy of the contralateral kidney are critical. When both kidneys are extensively involved, nephroblastomatosis usually will respond to the combination chemotherapy used in Wilms tumor (i.e., vincristine and actinomycin). The goal of such treatment is to cause regression of the

nephroblastomatosis or cause its development into an end-stage hamartoma. The duration of treatment is based on clinical response. Close follow-up with both radiographic and second-look operations is important in that patients may still progress to the development of true Wilms tumor despite therapy.

P.1452

True Wilms tumor rarely is seen in the neonatal period (201). It generally presents as an asymptomatic abdominal mass that does not cross the midline but, occasionally, the mass is large enough to cause dystocia at the time of delivery. It is rarely associated with gross hematuria, hypertension, or polycythemia secondary to increased erythropoietin levels. The most common congenital abnormalities associated with Wilms tumor are genitourinary and musculoskeletal anomalies, hemihypertrophy, aniridia, and hamartomas (e.g., hemangiomas, nevi, cafe-au-lait spots). Additionally, there is the Wilms tumor-aniridia syndrome, associated with a deletion of part of the short arm of chromosome 11. CT scan and particularly magnetic resonance imaging (MRI), along with renal ultrasonography, can help define the extent of the tumor.

Pathologically, classic Wilms tumor consists of neoplastic blastemal elements with epithelial and stromal components. In the neonate, Wilms tumor is predominantly epithelial and localized, displaying little invasiveness or metastatic potential. The primary prognostic variables include histology, extent of disease, and age (209,211, 229,230,231).

The management of a patient with Wilms tumor depends primarily on staging. In the neonate, most patients will be classified as stage I, in that the tumors usually are relatively small (i.e., less than 550 g), localized, noninvasive, and completely resectable. Neonatal Wilms tumor commonly shows favorable histology and appears to metastasize infrequently. At the time of surgery, a frozen section diagnosis is important in ascertaining whether or not nephroblastomatosis is also present. If nephroblastomatosis is present, wedge biopsy of the contralateral kidney is indicated, even if it is grossly normal. The management of bilateral Wilms tumor must often be individualized, with the intent of trying to spare as much normal renal parenchyma as possible (232,233). Careful follow-up in such cases is critical.

For patients with stage I disease, the National Wilms Tumor Study group has recommended 6 months of combination chemotherapy with vincristine and actinomycin; radiation therapy is not given. Disease-free, long-term survival is greater than 90%. Other studies have shown that in infants with localized, noninvasive, nonmetastatic, histologically favorable tumors weighing less than 550 g, are likely to do well with reduced courses of chemotherapy or even no further therapy apart from radical nephrectomy (209,230,234). For advanced stages and for tumors with unfavorable histology, more aggressive therapy, including radiation and intensive chemotherapy, is used (230,235).

Renal Neoplasms Not Associated with Wilms

Tumor

Malignant rhabdoid tumor of the kidney, which represents about 2% of primary renal malignancies during childhood and for which the mean age at diagnosis is 13 months, was first described as a rhabdomyosarcomatoid variant of Wilms tumor. Subsequent studies suggested that this tumor is neuroepithelial in origin, possibly from neural crest, and therefore is unrelated to Wilms tumor (236,237,238). Malignant rhabdoid tumor may also primarily arise in the liver, chest wall, or paravertebral area. There is an association with posterior fossa brain tumors and a predilection for metastasizing to the brain (239). Additionally, the presence of dermal neurovascular hamartomas has been associated with rhabdoid tumors. (240). Despite aggressive therapy, this tumor is associated with a very poor prognosis.

Clear cell sarcoma of the kidney, also originally described as a Wilms tumor variant, is considered a separate entity (241,242,243). It represents about 2% to 5% of all childhood malignant tumors of the kidney. Age at presentation is similar to that in Wilms tumor. Clear cell renal sarcoma demonstrates a predilection to metastasize to bone and carries a poor prognosis when metastatic but recent studies have demonstrated improved survival for advanced stage III and IV disease (244,245,246,247).

TUMORS OF GERM CELL ORIGIN

Germ cell tumors are derived from the stem cells of the embryo that ultimately are determined to differentiate into spermatocytes or ova. Such cells are totipotent and, therefore, are capable of giving rise to tumors containing any fetal, embryonal, or adult tissue. Additionally, their spatial distribution and migration pattern during embryogenesis help explain the various anatomic sites in which such tumors may develop. For example, human primordial germ cells can be recognized first in the 4-week embryo as large cells embedded in a restricted area of the yolk sac. During the fifth week of gestation, the germ cells migrate from the yolk sac to the hindgut wall and along the mesentery to the gonadal ridge, in which they encounter the gonadal anlage. From there they descend into the pelvis or scrotal sac. During their migration from the yolk sac to the definitive gonad, germ cells may be left behind or they may migrate too far along the dorsal wall of the embryo near the midline. Thus, aside from the gonads, germ cell-derived tumors quite commonly arise in locations at or near the midline, anywhere from the sacrum to the head. Depending on their viability, embryonic stage, and anatomic location, they may differentiate along a variety of different cell lineages.

For example, germinomas arise from primitive but developmentally restricted germ cells. When they occur in the testis, they are referred to as seminomas;

when they are found in the ovary, they are called dysgerminomas. These neoplasms also may be found outside the gonads, particularly in the mediastinal and pineal regions, and in such cases are referred to as extragonadal germinomas. Germinomas occur only rarely during infancy and develop almost exclusively in older children and adults.

Embryonal carcinoma, which occurs most commonly in individuals from 4 to 28 years of age (median age 15 years), represents a highly malignant tumor of the multipotential germ cells that has the capacity to differentiate

P.1453

further into either extraembryonal or embryonal tissue lineages. Because of this capacity, embryonal carcinoma is considered to arise in the stem cells that can give rise to endodermal sinus (i.e., yolk sac) tumor or choriocarcinoma, both of which are extraembryonal in origin, and to teratomas, which are embryonal in origin.

ENDODERMAL SINUS OR YOLK SAC TUMORS

The endodermal sinus, or yolk sac, tumor represents the most common testicular malignancy occurring in children under the age of 4 years. This tumor also has been called embryonal adenocarcinoma, mesoblastoma, orchioblastoma, and choroid teratoma. At times, it has been confused with embryonal carcinoma. These tumors characteristically form a histologic picture reminiscent of the yolk sac. They may metastasize to the retroperitoneal lymph nodes, which constitute the drainage pathway from the testis, to the liver, to the lung, and to bone, although metastatic disease in the infant is unusual (248,249,250). Biochemically, yolk sac tumors usually are associated with elevated levels of alpha-fetoprotein, which serves as a useful marker in diagnosis, assessment of treatment response, or of relapse.

The assessment of a patient with the possibility of a germ cell tumor of the testis should include the determination of both alpha-fetoprotein and human chorionic gonadotropin levels; the latter, if positive, suggests a mixed tumor with choriocarcinomatous elements (251). Radio-graphic workup should include a chest radiograph, chest CT scan, and abdominal CT scan or MRI. A radionuclide scan may be helpful in detecting spread to bone.

After the workup, the operation of choice is a radical orchiectomy with high ligation of the spermatic cord at the level of the internal inguinal ring. A trans-scrotal approach is contraindicated because of the risk of seeding the scrotal sac with tumor cells. Whether or not all children with testicular yolk sac tumors should undergo retroperitoneal dissection as part of further staging remains controversial. Some studies suggest that in infants younger than 12 months of age, only orchiectomy is needed, with close follow-up including radiographic studies, monitoring of α -fetoprotein levels, and physical examination (249,252).

In other studies, however, approximately 40% of children younger than age 2 years treated only with orchiectomy die from metastatic disease, compared to only 12% treated with retroperitoneal node dissection and radiation therapy with or without chemotherapy (253,254,255). These reports suggest that management should include orchiectomy, lymph node dissection, combination chemotherapy, and radiation therapy for those patients with retroperitoneal nodes positive for metastatic disease. Endodermal sinus tumors also may arise in the ovary, usually at a median age of 19 years, and in extragonadal sites such as the pineal body, mediastinum, sacrococcyx, and vagina.

The extraembryonal cell lineage pathway also may lead to a trophoblastic-derived tumor called choriocarcinoma. Although this neoplasm is extremely rare, when it occurs in infants younger than 12 months of age, it usually is a result of transmission of a placental choriocarcinoma. Patients usually present with pallor, hepatomegaly, and a history of gastrointestinal bleeding with hemoptysis or hematuria. There may be endocrinologic manifestations, with breast enlargement and pubic hair. Chest radiographs may reveal pulmonary metastases; human chorionic gonadotropin levels most often are elevated. Such gestational-related choriocarcinomas are particularly responsive to treatment with methotrexate (256,257).

Teratomas

When germ cell tumors arise from the embryonal compartment, they form teratomas. These are neoplasms that contain cellular or tissue derivatives of more than one of the three primary embryonal germ layers and that are foreign to the anatomic region in which they arise. The name teratoma is derived from the Greek *teras*, which literally means monster, plus the ending “-oma,” which is used to denote a neoplasm. This name derived from cases in which these tumors contained tissue elements so well organized regarding resemble a deformed fetus.

In early childhood, teratomas primarily occur as extragonadal masses located along the midline axis; about 40% to 50% occur in the sacrococcygeal region, with head and neck, brain, mediastinum, retroperitoneum, abdomen, spinal cord, and other soft tissue locations accounting for 1% to 5% each (258,259). Gonadal teratomas occur more frequently after puberty, particularly in the ovary. About 80% to 90% of early childhood teratomas are benign; malignant teratomas usually are characterized histologically by areas containing embryonal carcinoma or endodermal sinus tumor. Such malignant lesions most often arise in the sacrococcygeal region.

Sacrococcygeal teratoma is the most common teratoma in infancy, with about 67% diagnosed by the age of 1 year. These tumors occur at a rate of 1 in 25,000 to 1 in 40,000 live births and display a significant gender predilection, with girls being affected more than 75% of the time (260,261).

Clinically, these tumors present as a mass protruding between the coccyx and the rectum (Fig. 53-2). They nearly always arise from the tip of the coccyx and vary greatly in the amount of their internal versus external tissue extensions (261). Some lesions can be diagnosed only by rectal examination; however, this examination should be done with extreme care in the neonate to avoid any traumatic damage. The differential diagnosis of a sacrococcygeal teratoma includes meningomyelocele, rectal abscess, pilonidal cyst, bladder neck obstruction, rectal prolapse, duplications of the rectum, imperforate anus, dermoid cyst, angioma, lymphangioma, lipoma, neurogenic tumors of the pelvis and perineum, giant cell tumor of the sacrum, and soft tissue sarcoma.

Benign teratomas usually will produce no functional problems other than obstruction, whereas the presence of

P.1454

bowel or bladder dysfunction suggests a malignant lesion. Evidence for venous or lymphatic obstruction or lower leg paralysis is found more commonly in malignant tumors. Approximately 15% of patients with sacrococcygeal teratomas have associated congenital anomalies, including imperforate anus, sacral bone defects, genitourinary abnormalities such as duplication of the uterus or vagina, and occasionally spina bifida and meningomyelocele (262). Radiographic evaluation of the spine can be informative in that meningomyeloceles are associated with characteristic vertebral abnormalities. Abdominal and pelvic ultrasonography along with CT or MRI scanning are useful in assessing the internal extension of the mass. Barium enema may distinguish between a bowel duplication and displacement caused by a tumor mass. Chest radiographs and liver- spleen scans may indicate evidence of metastatic disease. Serum α -fetoprotein and human chorionic gonadotropin levels may be elevated in those teratomas with mixed cellular elements.

Figure 53-2 Large sacrococcygeal teratoma in a newborn infant.

The prognosis for a patient with a sacrococcygeal teratoma depends primarily on whether the lesion is benign or malignant (263). For benign lesions, disease-free survival is greater than 90%, whereas for those tumors with malignant components, such as anaplasia or yolk sac histology, associated mortality secondary to tumor may be greater than 90%. The age of the patient at diagnosis appears to be extremely important in determining the likelihood of malignancy. For example, the incidence of malignancy is only 7% to 10% for tumors diagnosed at younger than 2 months of age, whereas this figure increases to about 37% at age 1 year and to 50% by age 2 years. Additionally, there is a significantly higher incidence of malignancy in lesions that show mostly internal tissue extension (261).

The management of a patient with a benign sacrococcygeal teratoma is primarily surgical and includes removal of the coccyx, the site in which the tumor arises. Leaving the coccyx is associated with a 30% to 40% incidence of recurrence, many of which are malignant. Patients with malignant teratomas are managed after surgery with irradiation, if residual disease is present, and always with combination chemotherapy. Some regimens include vincristine, actinomycin D, and cyclophosphamide; others use vinblastine, bleomycin, and cis-platinum (264,265,266,267,268). Regardless of intensive therapy, the prognosis in such patients is poor. The average interval between diagnosis and death usually is less than 10 months, with metastatic disease occurring in lungs, bone, liver, lymph nodes, and peritoneum (269,270). Not surprisingly, survival is poor among patients who develop metastatic disease.

PRIMARY HEPATIC NEOPLASMS

The differential diagnosis of a right upper quadrant mass with hepatomegaly in infants is extensive and includes nonneoplastic lesions and a variety of benign and malignant tumors (271,272,273). Hemangioendothelioma is the most common tumor found in neonates. Hepatomegaly associated with malignant disease in the infant is secondary much more commonly to leukemia or disseminated neuroblastoma than to a primary hepatic cancer.

Hepatocellular carcinoma, often associated with chronic underlying liver disease, rarely occurs in infancy. This tumor usually is massive, multifocal, and rapid growing, all contributing factors to its frequent unresectability. Despite aggressive combined modality treatment, such patients have a poor prognosis, with up to 90% mortality (274,275,276).

Hepatoblastoma occurs primarily but not exclusively in children younger than age 3 years, with a mean age of 18 months; it also has been reported in neonates (277,278,279). There have been anecdotal reports of patients with

hepatoblastoma associated with the maternal use of oral contraceptives or with the fetal alcohol syndrome (280,281). Low birth weight also has been associated with the development of hepatoblastoma (282,283,284,285,286,287). Familial cases of hepatoblastoma have been documented, suggesting an environmental or genetic contribution in some instances (288,289,290,291,292). Hepatoblastoma also has been associated with a variety of congenital anomalies, most notably hemihypertrophy and renal abnormalities, but also with macroglossia, Meckel's diverticulum, tetralogy of Fallot, diaphragmatic hernia, talipes equinovarus, and digital clubbing (293). Wilms tumor and adrenal cortical neoplasms also have been found in patients with hepatoblastoma (294).

Hepatoblastoma presents in most cases with abdominal enlargement and hepatomegaly. In approximately 25% of patients, there also will be associated anorexia, weight loss, pallor, and pain. Less common are vomiting and jaundice. Diarrhea, fever, and precocious puberty are rare. Laboratory studies reveal a mild anemia, a thrombocytosis with bone marrow megakaryocytosis, and, occasionally, thrombocytopenia secondary to platelet trapping (295,296). Increased levels of liver enzyme transaminases and alkaline phosphatase are variable, but mild elevation of bilirubin may be present in up to 15% of cases with hepatoblastoma. A-fetoprotein is elevated many fold in nearly 70% of

P.1455

patients with hepatoblastoma (297). Although not specific for hepatoblastoma, this protein marker, with a half-life of 4 to 6 days, is useful in the assessment of the response to therapy and of tumor recurrence. It should be noted, however, that not all recurring metastatic lesions are positive for alpha-fetoprotein, even though the primary tumor was positive. All values for alpha-fetoprotein should be compared to age-matched values, because levels normally are elevated in the neonatal period and may normalize to adult values for up to 9 months (298,299).

Abdominal radiographs show enlargement of the liver, with right lobe involvement more common. Areas of calcification occur in up to 20% of cases. Chest radiographs may reveal pulmonary metastases, present in about 10% of cases at diagnosis. Abdominal CT or MRI scanning and hepatic angiography are useful in determining tumor size and surgical resectability. Radioisotopic liver scans demonstrate the tumor by its decreased ability to take up the isotope; it appears as a cold lesion when compared with the surrounding, normal hepatic tissue.

The prognosis for patients with hepatoblastoma appears to depend primarily on the lesion's surgical resectability and on histology. Complete surgical excision is possible in 40% to 75% of patients, although perioperative mortality has been reported as high as 10% to 25%. Local and metastatic recurrences after surgical resection usually appear within 36 months, although there have been recurrences as late as 8 years after surgery (277,300).

The histopathology of hepatoblastoma can be viewed as occurring in two major

patterns. The first is the pure fetal epithelial type. Several studies have strongly suggested that this type of tumor is associated with a better outcome (301,302). The second type, composed of both epithelial and mesenchymal elements, usually is referred to as a mixed hepatoblastoma and has been associated with a poorer prognosis. Additionally, some hepatoblastomas may have anaplastic or sarcomatous elements that portend a poor prognosis.

Although some reports have demonstrated that approximately 30% to 60% of patients can be cured with complete surgical resection alone, others have shown that adjuvant chemotherapy after tumor resection significantly reduces the risk of development of distant metastases. Chemotherapy should begin about 4 weeks after resection to allow for the adequate regeneration of normal hepatic tissue. For those children with unresectable primary tumors, preoperative embolization or combination chemotherapy may reduce tumor size to allow resection (303,304,305,306,307,308,309,310). Radiation therapy has a limited role, in part because normal liver has a relatively low tolerance to irradiation. The response of both the primary tumor and metastatic disease to chemotherapeutic agents has been best when such agents have been used in combination; they include vincristine, actinomycin D, cyclophosphamide, 5-fluorouracil, doxorubicin, cisplatin, and methotrexate (311,312). Chemotherapy not only has caused regression of primary tumors, but it also has been associated with a few long-term remissions in patients with pulmonary metastases. For situations in which the tumor cannot be resected, even after cytoreductive therapy, liver transplantation has been used (313,314,315).

SOFT TISSUE SARCOMAS

Soft tissue tumors represent a diverse group of neoplasms, all of which share a common cellular origin from mesenchymal elements. In the infant, the spectrum of soft tissue tumor types includes fibrosarcomas, rhabdomyosarcoma (RMS), non-RMS soft tissue sarcomas and fibrous proliferative neoplasms and the rhabdoid tumor (see section on neoplasms of the kidney) (316,317,318,319).

RMS accounts for about one-half of soft tissue sarcomas, but is extraordinarily rare in the neonate (320). It may present as an orbital, nasopharyngeal, or sinus tumor; as a truncal or extremity lesion; as a genitourinary tract tumor, usually arising from bladder, prostate, or vagina; or as a paratesticular mass. At the time of diagnosis, about 20% to 40% of patients have evident metastatic disease, usually to lung, lymph nodes, liver, bone marrow, bone, and brain (321,322).

After appropriate assessment of the primary tumor and possible metastatic sites, complete surgical resection with clean margins should be attempted if this can be accomplished with acceptable morbidity. Adjuvant chemotherapy with vincristine, actinomycin D, and cyclophosphamide significantly prolongs disease-free survival. If there is residual microscopic disease as evidenced by involved surgical margins,

irradiation usually is used in older children, but should be modified for the neonate or infant because of long-term toxicities (323).

The prognosis for patients with RMS depends on the stage at presentation and histology. In children with the embryonal subtype and early stage tumors, disease-free survival is greater than 80%, whereas in those with more extensive disease or alveolar histology, prognosis remains poor (319,324,325,326,327,328,329,330).

Fibrosarcoma represents about 10% of soft tissue sarcomas in patients younger than age 15 years, and more than one-half occur in children younger than age 5 years, with about one-third of these appearing at or shortly after birth (331,332,333). Congenital infantile fibrosarcoma is a cellular, mitotically active neoplasm with a paradoxically limited biologic potential in most children in contrast to fibrosarcomas in older children (334,335). Molecular studies have linked them to mesoblastic neoplasms in that both neoplasias are characterized by a translocation resulting in a ETV6-NTRK3 fusion protein (205,206). Fibrosarcoma most commonly arises in the extremities, with the remaining cases involving the back, retroperitoneum, sacrococcyx, and the head and neck, and occurring as an intracardiac lesion (334,336,337,338,339).

For extremity lesions, complete surgical resection is curative in more than 90% of cases, even though local recurrences are common, appearing about 20% to 40% of the time. Occasionally, amputation may be required. Metastatic

P.1456

disease occurs only rarely. For tumors that are not amenable to surgical resection because of size or location, or both, there is some evidence that combination chemotherapy may be quite effective (340,341). Overall survival for infants with fibrosarcoma, RMS, or non-RMS neoplasms has been estimated to be about 60% (316).

Possibly related to fibrosarcoma, but nevertheless distinguishable pathologically, is a group of fibroblastic proliferative disorders that may be seen in the infant and newborn. The digital fibroma is usually found as a soft tissue mass on the medial side of digits, with the exclusion of the thumbs and great toes. As with fibrosarcoma, surgical resection is curative, although recurrence rates may be as high as 75% to 90%. Congenital (i.e., infantile) fibromatosis may occur as solitary or multiple soft tissue lesions (342,343,344,345,346). The solitary lesions occur nearly anywhere on the body. The lesions can involve a wide variety of skeletal sites, and be the cause of significant bone pain in the neonate (347,348,349,350,351,352). When present as multiple lesions, they involve subcutaneous tissue, muscle, and bones; in some cases, the lesions may become more generalized, producing significant morbidity and mortality from visceral organ involvement (353). These tumors are pathologically benign in appearance. The solitary and multiple lesions are histologically similar, and it has been

proposed that they are related to congenital fibrosarcoma and congenital hemangiopericytoma (354).

Treatment of solitary lesions is surgical and curative. There have been several reports of patients with multiple congenital fibromatosis in which spontaneous regression has occurred. After a diagnosis is made, treatment has been primarily supportive, with an excellent prognosis for multiple lesions involving subcutaneous tissue, muscle, and bone, and a poor prognosis when visceral organ involvement is extensive, and especially when involving the central nervous system (355,356,357). There is little proven benefit from the use of chemotherapy in cases of fibromatosis, although reports of using chemotherapy, including vincristine, actinomycin D, cyclophosphamide and other agents in infants with unresectable fibromatosis have shown some good responses (354,358,359,360). There are some reports of extensive involvement undergoing spontaneous regression (361).

VASCULAR NEOPLASMS AND MALFORMATIONS

Hemangiomas are the most common tumors found in infancy and childhood and include several different types based on histology, protein expression markers and clinical course (362,363,364,365). Most commonly they appear during late fetal or early neonatal life and affect girls more commonly than boys. Skin is the most frequent site of involvement, although they may arise in any organ and often occur in multiple locations. They are soft, compressible, bright red to blue lesions found on a level with, or slightly above, the surface of the skin. They range in size from a few millimeters to quite massive, occupying large areas of the skin or internal organs.

Their natural course is characterized by rapid growth for the first 4 to 6 months of life, followed by stabilization, then gradual involution over several years. They may be considered true neoplasms in that, during the proliferative phase, they show greatly increased endothelial cell proliferation. They should be distinguished from vascular malformations such as arteriovenous fistulas, which represent anomalous vascular development and do not demonstrate endothelial cell proliferation. Such lesions nearly always are present at birth and increase in size along with the patient, without the usual phase of involution. Lymphatic lesions, such as lymphangioma, are best considered malformations rather than neoplastic growths (366,367,368,369).

The clinical complications that arise from hemangiomas are secondary to their size, site of origin, and physiology. They may compromise vision by encroaching on the eye; cause respiratory distress by impinging on the trachea; cause severe and even fatal congestive heart failure when they are very large, as in some liver lesions; cause gastrointestinal or CNS hemorrhage; or cause a consumptive coagulopathy from platelet and fibrinogen trapping, as in Kasabach-Merritt

syndrome. Lesions responsible for Kasabach-Merritt syndrome may be a mixture of a proliferative endothelial neoplasm and a malformation sometimes involving lymphatic channels (370).

The first principle of treatment should be to do no harm, because most of these lesions eventually will regress on their own. Nevertheless, when they are the cause of significant morbidity, intervention may be necessary. Corticosteroids can be effective treatment and may accelerate regression (371,372,373,374).

Radiotherapy may cause undesirable side effects, such as cutaneous scarring, dermatitis, growth disturbances, and possible second tumors (375). Surgery may be difficult for large lesions and may result in unsightly scarring (376). For large lesions of the liver, hepatic artery ligation or embolization occasionally has been successful in controlling high-output cardiac failure, but liver necrosis, renal failure, and other embolic complications may result (377,378,379,380,381,382,383). In cases of Kasabach-Merritt syndrome, heparin or aspirin plus dipyridamole, pentoxifylline, and steroids plus epsilon-aminocaproic acid have proven to be useful in treating the associated consumptive coagulopathy (384,385,386,387,388). Laser therapy also has been used effectively (389,390,391,392,393). Subglottic hemangiomas may be life threatening secondary to airway compromise; their treatment has involved laser therapy and surgery, and steroids and alpha-interferon (394,395,396,397,398,399). The use of α -interferon has demonstrated promising results in cases resistant to corticosteroids (400,401). MRI can be an effective tool for imaging hemangiomas and assessing their response to therapy (402).

Malignant tumors arising from vascular endothelium, such as hemangioendothelioma, hemangiopericytoma, and angiosarcoma, are extremely rare but have been

P.1457

reported in infants (403,404). More information on vascular neoplasms and malformations is given in Chapter 55.

HISTIOCYTOSSES

The histiocytoses of childhood represent a heterogeneous group of disorders primarily involving bone marrow derived antigen-presenting cells (405,406,407,408). In the late 1980s, the histiocytoses were classified into three separate classes, in part based on the type of histiocyte believed to be pathologically involved (409). This classification schema separated these disorders into: class I—Langerhans cell histiocytosis (LCH); class II—non-LCH; and class III—malignant histiocytosis. Although this classification system has proven useful in delineating these complex disorders, particularly for treatment study purposes, improved understanding of the biology of these diseases is continuing to change the manner in which they are defined, grouped, and treated (405,410,411).

Class I, or the Langerhans cell histiocytoses, includes disorders historically referred to as eosinophilic granuloma, Hand-Christian-Schuller disease, and Letterer-Siwe disease. The diagnosis of the class I histiocytoses is made by biopsy showing characteristic pathologic changes, which include a histologically mixed, reactive infiltrate of cells including eosinophils, neutrophils, lymphocytes, multinucleated giant cells, and proliferation of Langerhans cell histiocytes. Langerhans cell histiocytes are identified by their expression of S-100 and CD1a surface antigens and/or the presence of cytoplasmic Birbeck granules, identifiable by electron microscopy. Birbeck granules most probably represent internalized membrane components and have a characteristic racquet appearance under the electron microscope. Several studies have demonstrated that LCH is a clonal neoplastic disorder (412,413,414,415,416,417).

Eosinophilic granuloma is found predominantly in older children, teenagers, and young adults, usually presenting as solitary or multiple lytic lesions of bone. Surgical curettage alone is usually curative. The prognosis is excellent. Local recurrences rarely need additional surgery and often can be treated with local injection of steroids if in an easily accessible site (418,419), local radiation therapy with doses in the 400- to 800-cGy range, or even oral, nonsteroidal antiinflammatory agents such as indomethacin (418,420).

Hand-Schuller-Christian disease occurs in younger children from ages 2 to 5 years and often presents with multifocal, lytic bone lesions, particularly of the skull; exophthalmia; oral soft tissue involvement; eczematoid rash; and, sometimes, diabetes insipidus secondary to hypothalamic infiltration. The clinical course is chronic, with multiple recurrences over several years. Therapeutic interventions are indicated for disease that is symptomatic, potentially disfiguring, or likely to result in loss of function, such as loss of vision with proptosis, loss of hearing with extensive mastoid involvement, or paralysis secondary to cord compression (405,406,421). For localized lesions, surgical curettage, lesional injection of steroids, or low-dose radiation therapy is effective. When there are multifocal bone lesions or multisystem disease, chemotherapy is indicated (422,423,424,425,426,427,428,429). Vinblastine or steroids alone or in combination has been shown to be quite effective (423,424,425,426,427,428,429,430,431). An international randomized trial compared vinblastine plus steroid with etoposide plus steroid and demonstrated no difference in efficacy of one regimen over the other (432). More intensive, combination chemotherapy is being studied for patients with extensive disease in an attempt to reduce the incidence of recurring disease and long-term sequelae as a result of the disease (429).

Letterer-Siwe disease is the most severe and life-threatening form of LCH (407). It most commonly presents within the first year of life and occasionally in neonates. Cases have been reported among siblings and in twins (433,434,435). Infants present with scaly, seborrheic, eczematoid, and sometimes maculopapular

rashes involving the scalp, face, ear canals, abdomen, and intertriginous areas. Hepatosplenomegaly is common, and there may be signs of hepatic dysfunction with hypoproteinemia and coagulopathy. Draining ears, lymphadenopathy, cough, and tachypnea are common. These infants are commonly irritable and fail to thrive, secondary either to chronic disease and liver dysfunction, or to malabsorption as a result of gastrointestinal infiltration. Lytic bone lesions often are present.

The prognosis for severe Letterer-Siwe disease or systemic involvement with liver, lung, or hematopoietic organ dysfunction is poor despite intensive combination chemotherapy, especially for those patients who show a poor response to initial therapy (425). Hematologic studies reveal anemia, a variable leukocytosis, and thrombocytopenia, with the latter result frequently predicting a fatal outcome. As in the case of Hand-Schuller-Christian disease, vinblastine with prednisone has been shown to be a relatively effective combination, although a more intensive combination chemotherapy regimen is being tested in an international trial (405,429,432,436,437). Small numbers of patients treated with cyclosporine A have been reported (438,439,440,441). In refractory cases, allogeneic bone marrow transplantation has been effective in some patients, but the overall results have been disappointing (442,443,444,445,446,447). Low-dose hemi-body or whole-body radiation therapy has been used, but without prolonged efficacy (448). New agents such as nucleoside inhibitors and more potent immunosuppressive agents are being tested (449,450,451,452).

Class II represents the non-Langerhans cell histiocytoses and primarily includes the hemophagocytic lymphohistiocytic (HLH) disorders, some of which are primary (inherited) such as familial erythrophagocytic lymphohistiocytosis (FEL) and or acquired, such as infection-associated hemophagocytic syndrome (453). Primary HLH, which usually presents in early infancy, is inherited as an autosomal recessive condition (454,455,456,457). Several gene defects have been shown to be responsible for this disorder and involve pathways in lymphocyte cytolytic granule formation and/or function. Established mutations have been

P.1458

determined in perforin and MUNC-13.4 genes, the former a cytolytic granule and the latter involved in the exocytotic movement of cytolytic granules (458,459,460,461,462,463,464,465,466). Infants present with failure to thrive, anorexia, fever, and irritability. Seizures and spastic weakness of the limbs may occur secondary to CNS involvement (456). Hepatosplenomegaly usually is prominent. Skin, bones, and lymph nodes, although often affected, are less involved than in Letterer-Siwe disease. Laboratory data characteristically show a hypofibrinogenemia and a distinctive hyperlipidemia, with increased triglycerides and decreased high-density lipoproteins (453,467). Pancytopenia develops, and bleeding often becomes a major concern. These patients usually have very low to absent natural killer lymphocyte function, confirming that these disorders are as a

result of an underlying immune defect (468,469,470,471,472). Of interest is the observation that otherwise normal parents or siblings of these patients also may show severely depressed natural killer lymphocyte function (468,473).

Pathologically, there is extensive lymphohistiocytic infiltration associated with erythrophagocytosis in the visceral organs and leptomeninges, with ultimate depletion of lymphoid tissue.

Prognosis is poor, and most infants will die within weeks of diagnosis from sepsis or hemorrhage, or both unless early treatment is initiated. Plasmapheresis, repeated blood exchange, and high-dose intravenous immunoglobulin have been reported to produce temporary remissions (474). Treatment with the epipodophyllotoxin, VP-16, along with high-dose steroids and intrathecal methotrexate, is an effective regimen that can achieve a temporary remission of disease (475,476,477). Following the induction of a remission, however, allogeneic stem cell transplantation is the only known curative therapy for primary HLH (476,477,478,479).

Congenital self-healing histiocytosis, or self-healing reticulohistiocytosis is characterized by a rash that shows hard, red to dark blue nodules, which occasionally may crust over and often undergo spontaneous resolution. This condition is part of a spectrum of disorders known as juvenile xanthogranulomatous disease (480,481,482). In some instances, lesions can become quite extensive with involvement of visceral organs, including the central nervous system, requiring systemic chemotherapy.

Class III includes malignant disorders of the histiocyte, such as malignant histiocytosis and histiocytic sarcoma, neither of which occurs in the neonatal period (405,430). Additionally, it is now appreciated that most cases described as malignant histiocytosis are really anaplastic large cell lymphomas, which rarely, if ever, appear in infants (483,484).

THERAPEUTIC ISSUES AND LATE EFFECTS OF THERAPY

The issues surrounding the treatment of cancer in infants and young children are unique. Because of their very young age, the balance between therapy and long-term side effects becomes especially important. A close collaboration and coordination by subspecialists and primary care physicians is critical.

Surgical management must consider the distinctive aspects of neonatal biology (485). Some tumors, such as hemangiomas and stage IV-S neuroblastoma, frequently involute or regress on their own, obviating surgical intervention. With other tumors, such as localized neuroblastomas, a complete resection may be unnecessary, whereas in cases of hepatoblastoma, a complete resection is critical for survival.

The detrimental effects of irradiation to infants are profoundly demonstrated in the treatment of patients with brain tumors, resulting in a high incidence and degree of physical and neurocognitive deficits. Skeletal growth also may be severely affected, with deformities of limbs and scoliosis. Liver, lung, and kidney are major organs whose short- and long-term function can be compromised (215). Additionally, the late appearance of second tumors may be significantly increased as a result of the mutagenic effects of irradiation (215,486).

For many solid tumors, chemotherapy has been effective in the treatment of micrometastatic disease and residual disease after incomplete resection. In cases of disease that is disseminated at the time of diagnosis, such as in leukemia or advanced neuroblastoma, systemic chemotherapy is imperative. The use of chemotherapy in the newborn is complicated by unique differences in absorption, distribution, metabolism, and excretion of such drugs (487, 488). Additionally, these characteristics are constantly changing, as the infant undergoes rapid developmental changes. Dose adjustments are required for certain chemotherapeutic drugs to avoid untoward complications in situations in which decreased drug metabolism occurs, and in cases of increased drug metabolism to achieve effective antitumor drug levels (489,490,491). Some of the signs and symptoms of drug toxicity may be subtle and must be related to the behavioral repertoire of the infant. Survivors of the successful treatment of malignancy in infancy should be followed closely for long-term sequelae (323,492,493).
